We dedicate this edition to the memory of Gerald B. Merenstein, MD—our friend, colleague, and mentor who was also a wonderful husband, father, and grandfather. As the inspiration for this text, Gerry contributed to the fields of neonatal and pediatric care through his dedication to nurses, nurse practitioners, child health associates, interns, residents, fellows, neonates, and their families. We miss him every day and know that his empathy, knowledge, teaching, and compassion influences all of us, as well as the newborns, children, and families that he and we serve.

SLG BSC MEH SN

In memory of Stephanie Marie Gardner, whose three days of life did have a purpose. To Muffy Roo, Millie Moo, and Mollie Mittens, my sweet rescue dogs, for their eminent patience for the last 3 years!

SLG

To my family: Angel, Sean, Yvonne, Rebecca, and Jacquelyn; my mentors and colleagues; and all of the children and families who have allowed me to share with them both joyous and difficult times in their lives.

BSC

To my family: James, Jennifer, Sean, Finnoula, Steve, and Sarah for their enduring source of love, confidence, and encouragement and to all the families who have informed my practice and knowledge about caring for fragile infants.

MEH

To all of the babies, families, and dedicated caregivers who have been my constant teachers; my mentor Jacinto Hernandez, who opened my horizons to a larger world; and my husband John for his unfailing love and support.

PREFACE

The concept of the team approach is important in neonatal intensive care. Each health care professional must not only perform the duties of his or her own role but must also understand the roles of other involved professionals. Nurses, physicians, other health care providers, and parents must work together in a coordinated and efficient manner to achieve optimal results for patients in the neonatal intensive care unit (NICU).

Because this team approach is so important in the field of neonatal intensive care, we believe it is necessary that this book contain input from major fields of health care—nursing and medicine. Both nurses and physicians have edited and co-authored every chapter.

The book is divided into six units, all of which have been reviewed, revised, and updated for the ninth edition. Unit One presents evidence-based practice and the need to scientifically evaluate neonatal therapies, emphasizing randomized controlled trials as the ideal approach. Units Two to Five are the clinical sections, which have been fully updated for this edition. The chapters within these sections include highlighted clinical directions for quick reference, Parent Teaching boxes to aid in discharge instructions, Critical Findings boxes to prioritize assessment data, and medication tables.

The combination of physiology and pathophysiology and separate emphasis on clinical application in this text is designed for neonatal intensive care nurses, nursing students, medical students, and pediatric, surgical, and family practice housestaff. This text is comprehensive enough for nurses and physicians, yet basic enough to be useful to families and all ancillary personnel.

Unit Six presents the psychosocial aspects of neonatal care. The medical, psychological, and social aspects of providing care for the ill neonate and family are discussed in this section. This section in particular will benefit social workers and clergy, who often deal with family members of neonates in the NICU.

In this handbook we present physiologic principles and practical applications and point out areas as yet unresolved. **Material that is clinically applicable is set in bold type so that it can be easily identified.**

INTRODUCTION

In 1974 as the Perinatal Outreach Educator at the Children's Hospital in Denver, Colorado, I took a folder to Gerry Merenstein, MD, at Fitzsimmons Army Medical Center to discuss his lectures for the first outreach education program in La Junta, Colorado. When we finished, he removed from his desk drawer a 1-inch-thick compilation of the neonatal data, graphs, nomograms, and diagrams he had created for the medical housestaff during his fellowship. Giving the document to me, he asked that I review it and let him know what I thought. Several weeks later, I told him it was good *except* there was no nursing care or input, which is essential in every NICU. So Gerry asked, "Want to write a book?"—and the idea for the *Handbook* was born!

With this ninth edition in 2020, we celebrate 35 years of publication of the *Handbook of Neonatal Intensive Care*. Gerry and I co-edited this book for 21 years until his death in December 2007. To fulfill my promise that Gerry's name would always be on the book, the seventh and all subsequent editions are now known as *Merenstein & Gardner's Handbook of Neonatal Intensive Care*. Instead of editing this edition alone or with another physician, I decided to convene an editorial team consisting of myself, a nurse colleague, and two neonatologists. Together we bring 180 years of clinical practice, research, teaching, writing, and consulting in neonatal, pediatric, and family care to this ninth edition.

In the eighth edition, we have the distinction of translation to Korean and Portuguese. We are still working on a Spanish translation because this was an ongoing wish of Gerry Merenstein. In addition, the *Handbook* is available on multiple e-platforms to facilitate use at the bedside. Multiple editions of the *Handbook* (first in 1985; fifth in 2002; seventh in 2011; and eighth in 2016) have won the *American Journal of Nursing* Book of the Year Award. The eighth edition of the *Handbook* placed first in the Critical Care/Emergency Nursing category.

For our new audience and for our continuing loyal readers, this is my opportunity to introduce myself and all members of the editing team.

I am currently the Director of Professional Outreach Consultation (www.professionaloutreach-consultation.org), a national and international consulting firm established in 1980. I plan, develop, teach, and coordinate educational workshops on perinatal/neonatal/pediatric topics. I graduated from a hospital school of nursing in 1967 with a diploma, obtained my BSN at Spalding College in 1973 (magna cum laude), and completed my MS at the University of Colorado School of Nursing in 1975 and my PNP in 1978. I have worked in perinatal/neonatal/pediatric care since 1967 as a clinician (37 years in direct bedside care), practitioner, teacher, author, and consultant. In 1974, I was the first Perinatal Outreach Educator in the United States funded by the March of Dimes. In this role, I taught nurses and physicians in Colorado and the seven surrounding states how to recognize and stabilize at-risk pregnancies and sick neonates. I also consulted with numerous March of Dimes grantees to help them establish perinatal outreach programs. In 1978, I was awarded the Gerald Hencmann Award from the March of Dimes for "outstanding service in the improvement of care to mothers and babies in Colorado." I am a founding member of the Colorado Perinatal Care Council (now the Colorado Perinatal Care Quality Collaborative). I am an active member of the Colorado Nurses Association/American Nurses Association, the Academy of Neonatal Nurses, and the National Association of Neonatal Nurses.

Mary Enzman-Hines, PhD, APRN, CNS, CPNP, APHN-BC, is currently Professor Emeritus at Beth-El College of Nursing at the University of Colorado

in Colorado Springs and co-owner and certified Pediatric Nurse Practitioner at Integrative Pediatric Health Care in Englewood, Colorado (www.ip-hcdenver.com). This is the first nurse practitioner owned and operated practice in Colorado. Early in her nursing career, Mary worked in the NICU and PICU as a staff nurse, charge nurse, and nurse manager. After completing her PNP/CNS program and her master's degree at the University of Colorado, Mary became the Neonatal and Pediatric Clinical Nurse Specialist at Denver Health and Hospital, where she created a beginning, intermediate, and advanced orientation for nurses in the NICU and PICU. At the University of Colorado, Mary accepted the practitioner/teacher role in maternal-child services, providing clinical care and mentorship in the NICU and pediatric units where nursing students were placed from the CU nursing program. When University Hospital and The Children's Hospital combined their pediatric services, Mary became the Clinical Nurse Specialist in Research and Education and consulted in the NICU, PICU, and pediatric medical-surgical areas. In this role, she was a founding member of the interdisciplinary Pain Management Team and provided consultation throughout The Children's Hospital for pain management issues. In 1996, Mary became a nursing faculty member at Beth-El College of Nursing and Health Sciences, where she created a student health center at the University of Colorado Colorado Springs and a school-based clinic for schoolchildren in Fountain, Colorado, while maintaining an active pediatric practice at Colorado Springs Health Partners. Currently Mary provides pediatric care at her own practice and continues to teach courses to DNP students at the University of Northern Colorado as an adjunct faculty. Mary is well published in the areas of pediatric, neonatal, and family health care, as well as in legal issues in maternal-child nursing. Mary is also a nurse researcher in the areas of pain, chronic illness, caring/healing praxis, pediatric pain, holistic nursing, and technology in health care.

Brian S. Carter, MD, FAAP, is a graduate of David Lipscomb College in Nashville, Tennessee, and of the University of Tennessee's College of Medicine in Memphis, Tennessee. Brian completed his residency in pediatrics at Fitzsimmons Army Medical Center in Aurora, Colorado. He completed his fellowship in neonatal-perinatal medicine at the University of Colorado Health Sciences Center in Denver. During the "Baby Doe" era, Brian trained in bioethics, and, in addition to clinical neonatology and neonatal follow-up, he has dedicated most of his academic career to the advancement of clinical ethics in neonatology and pediatric palliative care. Brian has been recognized nationally for his efforts in both of these fields. Currently he is William T. and Marjorie Sirridge Professor of Medical Humanities and Bioethics and Professor of Pediatrics at the University of Missouri–Kansas City School of Medicine. He also practices in the NICU/Follow-Up clinics and antenatal counseling at the Children's Mercy Hospital in Kansas City, where he works in the Bioethics Center, serves on the Ethics Committee, and mentors students, residents, and fellows in the areas of clinical ethics, neonatology, pain management, and palliative care. Brian has previously co-edited the book *Palliative Care for Infants, Children, and Adolescents: A Practical Handbook,* whose second edition was published in 2011 by Johns Hopkins University Press. He has a forthcoming book on perinatal palliative care, co-edited with Rana Limbo, PhD, RN, and Charlotte Wool PhD, RN.

Susan Niermeyer, MD, MPH, FAAP, is Professor of Pediatrics at the University of Colorado School of Medicine and Colorado School of Public Health. She also serves as Senior Medical Advisor for newborn health to the United States Agency for International Development. Susan graduated from Vanderbilt University School of Medicine and completed training in pediatrics and neonatal-perinatal medicine at the University of Colorado and Children's Hospital Colorado. She earned an MS in Public Health in 2010 at the Colorado School of Public Health. Susan practices and teaches at Children's Hospital Colorado and the University of Colorado Hospital as well as community hospital nurseries in the Denver area. She has served as co-chair of the American Academy of Pediatrics (AAP) Neonatal Resuscitation Program Steering Committee and editor of the International Liaison Committee on Resuscitation (ILCOR) neonatal resuscitation guidelines. She is editor of *Helping Babies Breathe,* the AAP educational program for neonatal resuscitation in resource-limited settings and a member of the Helping Babies Survive Planning Group. Susan's research interests center on adaptation in the neonatal period, with a focus on delayed umbilical cord clamping and cardiopulmonary adaptation at high altitude. She has been honored as a Career Teaching Scholar at the University

of Colorado and received the Avroy Fanaroff Neonatal Education Award from the AAP.

Borrowing from the words of Brian Carter in the introduction to the sixth edition of the *Handbook:*

> *The goals of care should be patient- and family-centered. It is the patient we treat, but it is the family, of whatever construct, with whom the baby will go home. Indeed, it is the family who must live with the long-term consequences of our daily decisions in caring for their baby.*

These goals include the provision of skilled professional care. An effective neonatal intensive care team consists of educated professionals of many disciplines—none of us can do it alone.

It has been my honor and privilege to work with these co-editors, who are all patient- and family-centered, and with the amazing editing team of Laura Klein, Lee Henderson, and Carol O'Connell for this ninth edition.

1 EVIDENCE-BASED CLINICAL PRACTICE

ALFONSO F. PANTOJA AND MARY ENZMAN-HINES

Globally, health care systems are experiencing challenges when evaluating therapies, quality of care, and the risk of adverse events in clinical practice. Over the past several decades, health care disciplines have made major strides to ensure that clinical decisions and actions are based on sound scientific evidence. Expert practice decisions and actions are embedded in a complex web that reflects all forms of knowing and understanding. Each element of knowing has a similar but distinct foundation of reliability and validity. Health care scholars/researchers who provide direct patient care, administrators, and educators have joined in the effort to identify the most reliable and sound scientific evidence available to inform and guide practice.[20]

Often health care systems fail to optimally use evidence. This failure is either from underuse, overuse, or misuse of evidence-based therapies and/or system failures.[92,93] **Evidence-based practice (EBP) requires the integration of the best research evidence with our clinical expertise and each patient's unique values and circumstances.**[92,93] EBP approaches in all fields of health care could prevent therapeutic disasters resulting from the informal "let's-try-it-and-see" methods of testing new therapies that are not recognized as risky. The epidemic of retinopathy attributable to the indiscriminate use of supplemental oxygen; gray baby syndrome attributable to the administration of chloramphenicol; kernicterus attributable to the introduction of sulfonamides[82]; and death due to liver toxicity of 40 premature newborns attributable to the administration of a parenteral form of vitamin E (E-Ferol)[89] are examples of these therapeutic misadventures in the field of neonatal care. Silverman described how painfully slow health care providers were to embrace a culture of skepticism and emphasizes, "We must insist on the highest standards of evidence in studies involving the youngest human beings; and, since there is no short route to this goal, we must prepare to be patient."[82] The use of experimentation and the scientific method has ultimately led to our present views of how to ask and answer clinical questions.[71]

Mistakes have also occurred at the other extreme, resulting in a failure to adopt therapies that are of proven benefit or an assumption that the risks associated with changing practice justify complacency about current treatments. The significant delay in the adoption of antenatal corticosteroids by the obstetric community to promote fetal lung maturation[23,86] is a good example of failure to use the available evidence. **One of the most important benefits of EBP is the constant questioning: "Have our current clinical practices been studied in appropriately selected populations of sufficient size to accurately predict their efficacy, benefit, safety, side effects, and cost?"**

EBP is a systematic way to integrate the best patient-centered, clinically relevant research with our clinical expertise and with the unique preferences, concerns, and expectations that each patient brings to a clinical encounter.[92] Furthermore, EBP presents an opportunity to enhance patient health and illness outcomes, increase staff satisfaction, and reduce health care expenses. **There is great interest in identifying barriers and facilitators that could help in closing the knowledge-to-practice gap that is inherent to the acceptance and adoption of EBP by all providers.**[96]

BLUE type highlights content that is particularly applicable to clinical settings.

FINDING HIGH-QUALITY EVIDENCE

As new therapies are integrated into neonatal care, health care providers must continue to increase existing knowledge of the health and health problems of newborns. **Providers need to formulate well-designed questions about the specific clinical encounter and learn how to evaluate the quality of evidence regarding risks and benefits of new practices.** Most clinical questions arise through daily practice and often involve knowledge gaps in background (general knowledge) and foreground (specific knowledge to inform clinical decisions or actions). The knowledge needs will vary according to the experience of the clinician.[92]

It is not the purpose of this chapter to provide a detailed review of the various research designs that permit reliable scientific inference. Rather, **our purpose is to promote the propositions that (1) challenge clinical observations and wisdom by finding the current best evidence and (2) carefully assess and critique research that supports or challenges the use of new and established clinical practices.**

Clinical observations, although valuable in shaping research questions, are limited by selective perception—a desire to see a strategy work or fail to work. At times, a single case or case study may prompt us to question whether we should consider changing current practice. In some situations, much can be learned from carefully maintained databases. Such knowledge is gained only when we have formed databases with clear intentions and have collected the necessary data.

Sinclair and Bracken[85] described **four levels of clinical research used to evaluate safety and efficacy of therapies,** based on their ability to provide an unbiased answer. **In ascending order, these are (1) single case or case series reports without controls, (2) nonrandomized studies with historical controls, (3) nonrandomized studies with concurrent controls, and (4) randomized controlled trials (RCTs). RCTs test hypotheses by using randomly assigned treatment and control groups of adequate size to examine the efficacy and safety of a new therapy.** In theory, random assignment of the treatment balances unknown or unmeasured factors that might otherwise bias the outcome of the trial. **A *meta-analysis* is a systematic review of the current literature that uses statistical methods to combine the results of individual studies and summarizes the results (**http://neonatal.cochrane.org**).**[22] Tyson[97] has suggested criteria for identifying proven therapies in current literature (Box 1.1). **Ideally, therapeutic recommendations are supported by evidence from systematic reviews of RCTs; however, such evidence is not always available.** It is then important to have a system to grade the strength of the quality of the evidence found. **An international collaboration developed GRADE (Grading of Recommendations Assessment, Development and Evaluation) to provide an explicit strategy for grading evidence and the strength of recommendations.[44] GRADE classifies the evidence into one of four levels: high, moderate, low, and very low (Table 1.1).** The strength of the recommendation is graded as strong or weak. Factors

BOX 1.1 PROVEN THERAPIES

Reported to be beneficial in a well-performed meta-analysis of all trials
or
Beneficial in at least one multicenter trial or two single-center trials

Modified from Tyson JE. Use of unproven therapies in clinical practice and research: how can we better serve our patients and their families? *Semin Perinatol.* 1995;19:98.

TABLE 1.1 LEVELS OF EVIDENCE

LEVEL OF EVIDENCE	THERAPY/PREVENTION/ETIOLOGY/HARM
1a	Systematic reviews of RCTs
1b	Individual RCT with narrow confidence interval
1c	All or none
2a	Systematic review of cohort studies
2b	Individual cohort study (including low-quality RCT [less than 80% follow-up])
3a	Systematic review of case-control study
3b	Individual case-control study
4	Case-control studies
5	Expert opinion without critical appraisal

RCT, Randomized controlled trial.

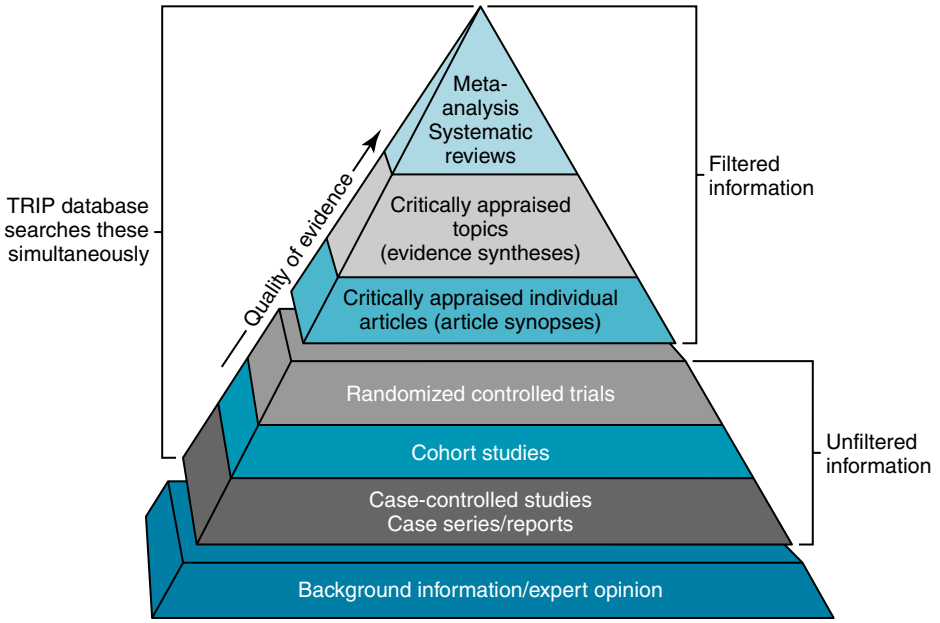

FIGURE 1.1 **Evidence appraisal.** (Modified from DiCenso A, Bayley L, Haynes RB: Accessing pre-appraised evidence: fine-tuning the 5S model into the 6S model. *Evid Based Nurs.* 2009;12(4):99.)

that influence the strength of the recommendation include desirable or undesirable effects, values, preferences, and economic implications (Fig. 1.1).

Although conclusions drawn from quantitative studies (RCTs, meta-analysis of RCTs) are regarded as the strongest level of evidence, evidence from descriptive and qualitative studies should be factored into clinical decisions. **Qualitative research provides guidance in deciding whether the findings of quantitative studies could be replicated in various patient populations. Qualitative research can also facilitate an understanding of the experience and values of patients, parents, and health care providers.** The validity, importance, and applicability of qualitative studies need to be evaluated in a similar way as quantitative studies.

PRESSURES TO INTERVENE

RCTs of appropriate size are cited as providing the best evidence for guiding clinical decisions; however, many take years to complete and publish. Providers find it difficult to delay the introduction of promising therapies. Bryce and Enkin[15] discussed myths about RCTs and rationales for not conducting them. **One myth is that randomization is unethical.** This might be true in rare instances when an intervention is dramatically effective and lifesaving. The more common situation is one in which there is limited evidence for a current or alternative strategy.

Pressure to intervene is, however, often overpowering. Believing that an infant is in trouble, interventions occur through a cascade of interventions, one leading to the next and each carrying risk. One of the most frequently cited examples is the epidemic of blindness associated with the unrestricted use of oxygen in newborns.[81,82] Oxygen, used since the early 1900s for resuscitation and treatment of cyanotic episodes, was noted in the 1940s to "correct" periodic breathing in premature infants. After World War II and the introduction of new gas-tight incubators, an epidemic of blindness occurred, resulting from retrolental fibroplasia (RLF). Silverman[81] pointed out that although many causes were suspected, it was not until 1954 that a multicenter, controlled trial confirmed the association between high oxygen concentrations and RLF. Frequently forgotten, however, is that in subsequent years, mortality was increased in infants cared for with an equally experimental regimen of strict restriction of oxygen administration, and many survivors had spastic diplegia. In the 1960s, the introduction of micro techniques for measuring

arterial oxygen tension permitted better monitoring of oxygen therapy, with a reduction in mortality, spastic diplegia, and RLF, now called *retinopathy of prematurity* (ROP). Severe ROP is currently limited to extremely-low-birth-weight (ELBW) infants.[81] Research continues to explore causes, preventive measures, and treatments (see Chapter 31).

Large multinational, pragmatic RCTs to resolve the uncertainty surrounding the most appropriate levels of oxygen saturation in premature infants have been recently conducted and the results published.[78,94,95] The publication of the results of the SUPPORT trial[94] brought about a significant debate about the ethical aspects of comparative effectiveness research and parental informed consent when one of the elements of the composite outcome was death before discharge.[81] The practice of allowing very-low-birth-weight (VLBW) infants to maintain lower oxygen saturations during the first weeks of life had been widely disseminated throughout the United States and the world due to anecdotal reports of a significant decrease in the severity of ROP and blindness with this approach.[21] A recent report of five multicenter studies (NEOPROM) with similar allocations and outcome measures that were prospectively organized with the aim to answer whether extremely premature infants kept at a low or a high oxygen saturation target had different outcomes. These studies are the SUPPORT trial (Surfactant, Positive Pressure and Pulse Oximetry Randomized Trial), the three BOOST II trials from the United Kingdom, Australia, and New Zealand, and the Canadian Oxygen Trial (COT). Low saturation targets (85% to 89%) until 36 weeks postmenstrual age (PMA) are associated with more deaths and more necrotizing enterocolitis (NEC). Higher saturation targets (91% to 95%) are associated with more ROP.[76] Results from all five trials were systematically reviewed and a final meta-analysis (the NeOProM) performed to determine optimal oxygen saturation targets for preterm infants (mean gestational age of 26 weeks; mean birth weights of 820 to 850 g).[7] At 18 to 24 months corrected age, no significant difference was found between the lower and higher saturation groups in mortality or major disability.[7] Secondary analysis of the data found that the *lower* saturation group had significantly higher death rates prior to 36 weeks PMA, before discharge from the neonatal intensive care unit (NICU), and before reaching 18 to 24 months' corrected age, a significantly higher risk of severe NEC and a significantly higher risk of PDA requiring ligation. Preterm infants randomized to the *higher* saturation group had a significantly higher risk of bronchopulmonary dysplasia (BPD) and ROP requiring treatment but no increase in blindness[7] (see Chapter 23).

The desire to see an intervention "work" encourages practitioners and investigators to seek early signs of benefit. Long-term effects are frequently overlooked. One reason is that they may not be foreseen. Consider the example of diethylstilbestrol (DES). DES administration to pregnant women was introduced in 1947 without clinical trials to prevent miscarriage, fetal death, and preterm delivery.[15,37] It was thought to be effective after uncontrolled studies despite controlled trials summarized in an overview (meta-analysis) by Goldstein et al.[41] (Table 1.2) that showed the opposite. Clearly, DES was not effective, but it continued to be used until the 1970s, when the Food and Drug Administration (FDA) finally disapproved its use. The unforeseen result was that female children born to mothers who were given DES had structural abnormalities of the genital tract, pregnancy complications, decreased fertility, and an increased risk for vaginal adenocarcinoma in young women. Male children had epididymal cysts. This is not the only example of physicians continuing to use therapies that have been shown in RCTs to be of no benefit.[18]

TABLE 1.2 EFFECTS OF DIETHYLSTILBESTROL ON PREGNANCY OUTCOMES

	TYPICAL ODDS RATIO[A]	95% CONFIDENCE LIMITS
Miscarriage	1.20	0.89–1.62
Stillbirth	0.95	0.50–1.83
Neonatal death	1.31	0.74–2.34
All three	1.38	0.99–1.92
Prematurity	1.47	1.08–2.00

[A]An odds ratio is an estimate of the likelihood (or odds) of being affected by an exposure (e.g., a drug or treatment) compared with the odds of having that outcome without having been exposed. Women receiving diethylstilbestrol did not have fewer stillbirths, premature births, or miscarriages than women who were untreated.

Data from Goldstein PA, Sacks HS, Chalmers TC. Hormone administration for the maintenance of pregnancy. In Chalmers I, Enkin M, Keirse M, eds. *Effective Care in Pregnancy and Childbirth.* New York, NY: Oxford University Press; 1989.

The costs of long-term studies and follow-up surveillance are numerous. However, when effects are measured later in life (e.g., psychological problems, ability to function in school), the cost cannot determine study design. Even when randomized trials are conclusive, unanswered questions remain: Will a technology or treatment have the same effect in all settings? Has an "appropriate" target population been selected? Are there long-term unforeseeable consequences?

EVALUATION OF THERAPIES

The major cause of death in premature infants is respiratory failure from respiratory distress syndrome (RDS) (see Chapter 23). Previously called *hyaline membrane disease,* this syndrome of expiratory grunting, nasal flaring, chest wall retractions, and cyanosis unresponsive to high oxygen concentrations was a mystery until the 1950s.[82]

The evaluation of various therapies for RDS contrasts the value of controlled and uncontrolled trials. Sinclair[84] noted that uncontrolled studies were more likely to show benefit than controlled trials. In 19 uncontrolled studies, 17 popular therapies showed "benefit." In 18 controlled studies, only 9 demonstrated benefit. An untrained reviewer of the research might base clinical practice on faulty conclusions of uncontrolled trials.

Surfactant Therapy

In contrast to many proposed treatments, surfactant therapy in premature infants has been well studied in RCTs.[4,5,46,48] Studies have evaluated the use of surfactant in treatment of RDS, including the optimal source and composition of surfactant and prophylactic versus rescue treatment. Morbidity (including pneumothorax, periventricular or intraventricular hemorrhage, BPD, and patent ductus arteriosus) and mortality rates in treatment and control groups have been compared. Systematic reviews of surfactant therapy confirm the effect of surfactant therapy in reducing the risk of morbidity and mortality.[85,90] **Although RCTs involving thousands of newborns have clearly demonstrated the benefits of surfactant therapy, unanswered questions remain.** One of these questions is if prophylactic administration of surfactant to an infant judged to be at risk of developing RDS was better than early selective use of surfactant to infants with established RDS. Early trials demonstrated a decreased risk of air leak and mortality with the prophylactic approach. However, recent RCTs that reflect current practice (i.e., greater utilization of maternal steroids and routine postdelivery stabilization on continuous positive airway pressure [CPAP]) do not support these differences and actually demonstrate less risk of chronic lung disease (CLD) or death when using early stabilization on CPAP with selective surfactant administration to infants requiring intubation[75,94] (Fig. 1.2).

Corticosteroid Therapy

Misuse of corticosteroids in perinatal medicine illustrates the consequences of failure to practice evidence-based care. Many practitioners initially declined to use antenatal steroids to promote maturation of the immature fetal lung and to prevent RDS despite strong supportive evidence, demonstrating a failure to use a proven therapy.

ANTENATAL CORTICOSTEROID THERAPY: SINGLE COURSE

Antenatal administration of corticosteroids to pregnant women who threatened to deliver prematurely was first shown in 1972 to decrease the neonatal mortality rate and the incidence of RDS and intraventricular hemorrhage (IVH) in premature infants.[57] In 1990, Crowley et al.[25] used meta-analysis to evaluate 12 RCTs of maternal corticosteroid administration involving more than 3000 women. The data showed that maternal corticosteroid treatment significantly reduced the risk for neonatal mortality, RDS, and IVH. Sinclair,[86] using a "cumulative meta-analysis" approach of randomized trials, clearly demonstrated that the aggregate evidence that was sufficient to show that this treatment reduces the incidence of RDS and neonatal death was available for almost 20 years before the use of antenatal corticosteroids was widely accepted by the medical community.

This led to the National Institutes of Health (NIH) consensus development conference statement on "Effects of Corticosteroids for Fetal Maturation on Perinatal Outcomes."[63] Antenatal corticosteroid treatment of women at risk for preterm delivery between 24 and 34 weeks of gestation has been shown to be effective and safe in enhancing fetal lung maturity and reducing neonatal mortality. Yet adoption by caretakers was inexplicably slow.[53]

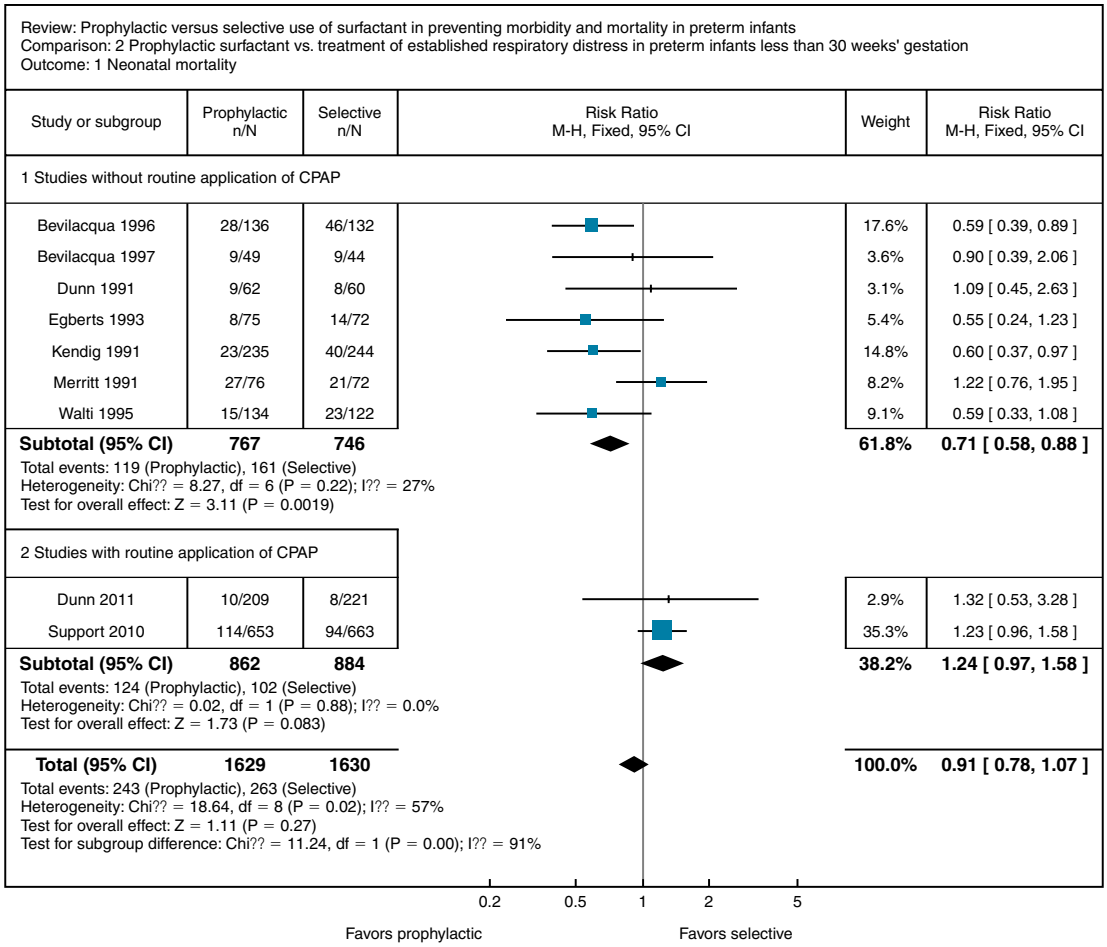

FIGURE 1.2 Table showing effect of prophylactic versus selective surfactant administration on morbidity and mortality rates in preterm infants. (From Rojas-Reyes X, Morley C, Soll R. Prophylactic versus selective use of surfactant in preventing morbidity and mortality in preterm infants. *Cochrane Database Syst Rev.* 2012;3:CD000510.)

ANTENATAL CORTICOSTEROID THERAPY: REPEATED COURSES

At the same time, **other practitioners administered repeated doses despite lack of evidence of additional benefit and questions about safety, representing unproven use of a proven therapy.** Repeated courses of antenatal corticosteroids have been shown in humans and animals to improve lung function and the quantity of pulmonary surfactant.[26,43] They may also have adverse effects on lung structure, fetal somatic growth, and neonatal adrenocortical function, as well as poorly understood effects on blood pressure, carbohydrate homeostasis, and psychomotor development.[25,61] A 2000 NIH Consensus Development Conference found limited high-quality studies on the use of repeated courses of antenatal steroids.[64] **The consensus statement discouraged routine use of repeated courses of antenatal corticosteroids.** Published preliminary reports of infants exposed to multiple doses of antenatal steroids reaching school age are emerging.[9] A recent meta-analysis of infants who were exposed to more than one course of antenatal corticosteroids concluded that "although the short-term neonatal benefits of repeated courses of antenatal corticosteroids support their use, long-term benefits have not been demonstrated, and long-term adverse effects have not been ruled

out. The adverse effect of repeated doses of antenatal corticosteroids on birth weight and weight at early childhood follow-up is a concern. Caution should therefore be exercised to ensure that only those women who are at particularly high risk of very early preterm birth are offered treatment with repeated courses of antenatal corticosteroids."[27] **The American College of Obstetricians and Gynecologists (ACOG) recommends a repeat course of antenatal steroids if the fetus is less than 34 weeks of gestation and the previous course of antenatal steroids was administered more than 14 days earlier.[6]**

POSTNATAL STEROID THERAPY

Postnatal glucocorticoids, administered to the infant after birth, have been widely used despite weak evidence of long-term benefit and suggestions of possible harm, illustrating use of an uncertain therapy.[53] Despite early calls for caution in the use of postnatal corticosteroids to decrease the risk for CLD and limit ventilator time, they were used liberally in the 1990s.[88,91] **A number of years passed before RCTs of postnatal corticosteroid administration included long-term follow-up.** Taken together, these studies showed positive short-term effects on the lungs. Studies also showed increased blood pressure and blood glucose concentrations in the short term; increased incidence of septicemia and gastrointestinal perforation in the intermediate term; and with dexamethasone administered soon after birth, abnormal neurodevelopmental outcome, including cerebral palsy, in the long term.[3,31,46,54,91] An increased risk for septicemia should have been anticipated, because it was first identified in an RCT by Reese et al.[74] over 50 years earlier.

In 2002, the American Academy of Pediatrics (Committee on Fetus and Newborn) and the Canadian Paediatric Society (Fetus and Newborn Committee) advised against the use of systemic dexamethasone and suggested that "outside the context of a RCT that include assessment of long-term development, the use of corticosteroids should be limited to exceptional clinical circumstances (e.g., an infant on maximal ventilator support and oxygen requirement)."[2] A 2005 reanalysis of many of the same data by Doyle et al.[31] suggests that relative risks and benefits of postnatal corticosteroids vary with level of risk for BPD. When the risk for BPD or death is high, the risk for developmental impairment from postnatal corticosteroids might be outweighed by benefit.[33, 36] Watterberg et al.[100] suggested that hydrocortisone might have the benefits of dexamethasone on the lungs without adverse neurologic effects. Following these statements, the exposure of at-risk premature infants decreased dramatically.[99,100] After reviewing the short-term and long-term effects of systemic and inhaled corticosteroid use for the prevention and treatment of CLD/BPD in the VLBW infant, both the AAP and the Canadian Pediatric Society issued and reaffirmed position statements regarding the use of postnatal steroids.[14,15,52]

QUALITATIVE RESEARCH EVALUATING EXPERIENCES IN THE NEONATAL INTENSIVE CARE UNIT

The contribution of qualitative research to EBP is evident when "best evidence from RCTs" may or may not work within the context of specific NICU environments. The context can be quite variable and influenced by practitioners, staff, the unit leadership, and family influence within the unit. **The implementation of family-centered care in the NICU has shown promising outcomes, including minimizing parental stress related to the technology and complex care of a tiny, fragile preterm infant.[59] An environment of family-centered care has also contributed in a positive way to the success of the implementation of clinical practice guidelines and evaluating outcomes.[32]** An additional area garnering focus in recent qualitative research is discharge planning for VLBW infants and how teams have implemented EBP projects to address the issues identified as key to parental success once the infant is discharged to home.[62,66,73,77] Findings suggest that discharge planning must include early integration of parents into the care team, CPR readiness of parents, how to deal with emergencies facing parents at home, and supportive infant care of the fragile infant for successful transition to home.

Qualitative studies are useful when limited information exists about a phenomenon or a deficiency is evident in the quality, depth, or detail of research in a specific area of clinical practice. **Qualitative research contributes to EBP in several**

areas: (1) describing patient needs and experiences; (2) providing the groundwork for instrument development and evaluation; and (3) elaborating on concepts relative to theory development.[60]

Systematic reviews and meta-analyses are emerging in qualitative literature researching parental experiences in the NICU.[40,65] In neonatology, qualitative studies provide in-depth views of parental and provider experiences within the NICU setting to humanize the health care of fragile infants. **Parents of infants who require NICU care begin an experience of parenthood in an unfamiliar and intimidating environment that results in delayed attachment**[47,79,80]**; high levels of stress, including anxiety, depression, trauma symptoms, and isolation (both physical and emotional) from their infant**[16,38]**; lack of disclosure of their infant's condition; and a lack of control.**[19] Mothers often experience feelings of ambivalence, shame, guilt, and failure because the infant is in the NICU.[79] Parents also experience the tension between exclusion and participation in their infant's care.[101,102,103] In contrast, **parents describe factors that contribute to parental satisfaction in the NICU, including assurance, caring communication, provision of consistent information, education,**[24] **environmental follow-up care, appropriate pain management,**[38] **parental participation in care, and emotional, physical, and spiritual support.**[24] Conversely, health care professionals' experiences of parental presence and participation in the NICU revealed similar findings to those described by parents: the need to develop a caring environment for parents to be present and take care of their child by guiding parents and giving parents permission to care for their child and the need for personnel training in the art of dealing with parents in crisis, identifying a balance between closeness and distance, and dealing with parental worry.[102,103]

Quality care is a major issue currently evaluating the delivery of health care services, yet little research has been conducted on what parents of premature infants perceive as quality nursing care. Price[72] used **a qualitative approach to reveal the meaning of quality nursing care from parents' perspectives and identified concepts inherent in the process of receiving quality nursing care. Four stages were identified: (1) maneuvering, (2) a process of knowing, (3) building relationships, and (4) quality care. For parents, nontechnical aspects of care, such as comforting infants after painful procedures, were as important as the technical aspects of care.** Another qualitative study revealed seven categories that influence changes in practice: (1) staffing issues, (2) consistency in practice, (3) the approval process for change, (4) a multidisciplinary approach to care, (5) frequency and consistency of communication, (6) rationale for change, and (7) the feedback process. Three categories further delineate quality care: human resources, organizational structure, and communications.[103] Conversely, nurse descriptions of quality care included five core measure sets for evidence-based developmental care: (1) protected sleep, (2) pain and stress assessment and management, (3) developmental activities of daily living, (4) family-centered care, and (5) providing a healing environment.[28] Nurses also revealed their experiences in developmental care as "walking the line between the possible and ideal" illuminated through the five aspects of care: (1) being attentive to the infant-mother dyad, (2) developing parent and provider relationships (the body tells it all), (3) timing is everything, (4) working in the quiet and caring, crowded and distressing space, (5) teamwork—demanding, smooth and helpful.[45] Introducing developmental care in the NICU requires an understanding of expectations, timing, and relationships.

Another aspect currently investigated is the integration of parents as members of the care team in the NICU (Family Integrated Care [FIC]). A recent multicenter, multinational, cluster randomized controlled trial that included 26 tertiary NICUs from Canada, Australia, and New Zealand demonstrated that infants assigned to FIC had improved infant weight gain, decreased parent stress and anxiety, and increased high frequency of exclusive breastmilk feeding at discharge[66] (see Chapter 29).

SYSTEMATIC REVIEW IN PERINATAL CARE AND EVIDENCE-BASED PRACTICE

Evidence-based practice is the integration of the best possible research evidence with clinical expertise and patient needs.[71,92] Examples from the literature, such as those cited in the preceding sections, illustrate how the application of the principles of EBP offer a strong argument countering those who

assert that EBP is nothing more than "typical practice using good clinical judgment." **Proponents of EBP argue that the principal four steps of evidence-based practice—formulating a clinical question, retrieving relevant information, critically appraising the relevant information, and applying the evidence to patient care—provide a foundation for practice that leads to improved newborn outcomes and avoidance of repeating medical disasters.**

Believing that the results of perinatal controlled trials had to be summarized in a manner useful to practitioners, Chalmers[17] and other perinatal professionals from various countries developed a registry of RCTs. They reviewed a vast amount of literature from published trials, sought out unpublished trials, and encouraged those who had begun, but not completed, studies to make them known to the registry. Once gathered, the studies' findings were summarized in "overviews."

A *meta-analysis* is a systematic review of the current literature that uses statistical methods to combine the results of individual studies (preferably well-conducted RCTs with similar characteristics of the participants and the treatments) and summarizes the results.[92] These results produce unbiased estimates of the effect of an intervention on clinical outcomes and are distinguished from nonsystematic reviews in which author opinions often are reported along with the evidence. Table 1.1 and Fig. 1.2 were developed after pooling the results of different studies.

From these systematic reviews, practitioners can learn the strengths or weakness of clinical trials and evaluate the claims of benefit for implementing a strategy. The result of the efforts of Chalmers et al. was the 1989 publication of a remarkably useful book, *Effective Care in Pregnancy and Childbirth*.[18] and an updated edition in 1993.[35] At the end of the book, the authors reported their own views of the reviewed treatments based on conclusions formed in the preceding articles. They found that although some strategies and forms of care were useful, others were questionable. Some interventions believed to be useful were not useful, of little benefit, or, in fact, harmful. In 1992 a companion publication, *Effective Care of the Newborn Infant,*[85] compiled and reviewed neonatal RCTs.

Multiple networks have been developed to perform multicenter RCTs. This is particularly useful, providing an opportunity to see whether treatments have similar effects in different practice settings. It is also useful in that practitioners in individual settings may not always see enough cases to reach robust conclusions. **Rare conditions and rare outcomes are better understood when trials are replicated or findings are pooled.** Systematic reviews provide the opportunity to understand these findings in the context of clinical practice.

About the same time the Chalmers et al. book was published, the **Cochrane Collaboration was established, again largely through the efforts of Ian Chalmers (**www.cochrane.org/index.htm**). The Cochrane Collaboration is a worldwide group with more than 50 Collaborative Review Groups whose members prepare, maintain, and disseminate systematic reviews based primarily on the results of RCTs.** These reviews are published electronically in the Cochrane Library, which contains the Cochrane Database of Systematic Reviews (CDSR: www.cochranelibrary.com/cdsr/about-cdsr), along with editorial comments on these reviews. **Comments come from an international group of individuals and institutions dedicated to summarizing RCTs relevant to health care.** In addition to the Collaborative Review Groups, there are now 14 Cochrane Centers in the world. These centers provide support for the review groups. The Neonatal Group is based at the University of Vermont.[64] **Cochrane Neonatal Reviews are available at www.neonatal.cochrane.org.[63]**

Additional sources of high-grade integrative literature are available to the practicing clinician. Critical appraisal of published research takes considerable time, and several groups assemble high-grade literature using a uniform methodology that is typically described to readers as a supplementary article.[12,13] Reading this article once can inform the practitioner if the method used to assemble a review or guideline is sufficiently rigorous. Also, a number of sites do not produce integrative literature but collect it from a number of sources. Some of these sites discuss the quality of the information presented. If we cannot appraise the method used to collect this information, we should always proceed with caution. Additional reliable sites include the following:

- The Database of Abstracts of Reviews of Effectiveness (DARE) (www.crd.york.ac.uk/CRDWeb), a collection of international reviews including those from the Cochrane Collaboration. Reviewers at the National Health Service Centre for Reviews and

Dissemination at the University of York, England, provide quality oversight, including detailed structured abstracts that describe the methodology, results, and conclusions of the reviews. The quality of the reviews is discussed along with implications for health care.

- The National Guidelines Clearinghouse (www.guideline.gov), maintained by the U.S. Department of Health and Human Services, Agency for Healthcare Research and Quality (AHRQ), that was originally created in partnership with the American Medical Association (AMA) and the American Association of Health Plans (AAHP). This site provides a wide range of clinical practice guidelines from institutions and organizations. Structured abstracts facilitate critical appraisal, and abstracts on the same topic can be compared on a side-by-side table, allowing comparisons of relevance, generalizability, and rigor of research findings. Links also are provided to the full text of each guideline, when available.

Conducting systematic reviews is time-consuming; thus not many are available. Often, the power of RCTs, especially in neonatology, is low. The evidence in published studies does not always apply to our specific patient. In addition, locating relevant evidence is time-consuming and may require access to online resources and a higher level of information-seeking skills than are available. Finally, although recognizing that medical expertise and scientific knowledge are crucial components of neonatal care, these rigorous, objective, scientific evaluations create the potential to overlook valuable experiential knowledge of the NICU provided by practitioners and parents.

Reasons to use an evidence-based approach have been well documented. According to Asztalos,[8] there are basically **two reasons to try to keep up with the literature: (1) to maintain clinical competence, and (2) to solve specific clinical problems.** Phillips and Glasziou[71] suggest that clinicians seek information "just in time" (as a clinician seeing patients) and "just in case" (an almost impossible task to keep up with information pertinent to a particular clinical specialty). The former can be achieved by actively searching for information in filtered, summarized clinical point-of-care resources. FirstConsult (www.firstconsultet.com), DynaMed (https://dynamed.ebscohost.com), and UpToDate (www.uptodate.com/home) fall into this category. The latter, "just in case" learning, also called *surveillance of the literature,* is best achieved by using technology tools to survey the current original literature. These tools include Evidence-Updates from the BMJ (http://group.bmj.com/products/evidence-centre/evidence-updates), auto-alerts, and RSS feeds in PubMed or online databases and journals. Learning about these ever-changing resources is a challenge. **Many hospitals and clinics are beginning to include a clinical librarian or informationist as part of the health care team.**[10,11,12,58,87,98]

Newer and practical resources to support evidence-based health care decisions are rapidly evolving. Large multicenter RCTs answer important clinical questions and provide more robust evidence synthesis and synopsis services that are currently integrated into electronic medical records. DiCenso et al.[30] propose a hierarchic organization of pre-appraised evidence linking evidence-based recommendations with individual patients. This 6S model describes the levels of evidence building from *original single studies* at the foundation, and building up from *syntheses* (systematic reviews, such as Cochrane reviews); *synopses* (succinct descriptions of selected individual studies or systematic reviews, such as those found in the evidence-based journals); *summaries,* which integrate the best available evidence from the lower layers to develop practice guidelines based on a full range of evidence (e.g., Clinical Evidence, National Guidelines Clearinghouse); to the peak of the model, *systematic reviews,* where the individual patient's characteristics are automatically linked to the current best evidence that matches specific circumstances. **Practitioners should start by looking at the highest-level resources available for the problem that prompts research.** These resources have gone through a filtering process to generate evidence that is rigorous and exhibited over multiple studies. **Evidence-based clinical information systems integrate and concisely summarize all relevant and important research evidence about a clinical problem, are updated as new research evidence becomes available, and automatically link (through an electronic medical record) specific patient circumstances to the relevant information.** Fig. 1.1 depicts elements of the 6S model.

At the end of this chapter is a list of additional evidence-based practice resources. To use these resources effectively, individuals must

become familiar with the principles and value of evidence-based patient care.

TRANSLATING EVIDENCE INTO PRACTICE

Literature demonstrates that EBP interventions can produce changes in clinicians' knowledge and skills. Even when it is difficult to demonstrate, EBP may induce changes in health care provider behaviors and attitudes.[92] Changes in clinical outcomes are more difficult to demonstrate. In neonatology, the extent to which Cochrane reviews are used and are in agreement with clinical practice guidelines have been found to be disappointingly low.[14] A quality chasm of evidence exists in NICUs.[34] Enormous variations in the use of established therapies exist, so it is not surprising that multiple neonatal networks throughout the world have demonstrated an unexplained center-to-center variability in outcomes.[39,49,50] There are reports of how EBP can be practiced successfully at the single NICU level.[67] However, the **implementations of "bundles" of EBPs by multiple NICUs using collaborative quality improvement efforts have reported meaningful results.[68,69,70]** Nosocomial infection rates seem to be the outcome most amenable to reduction using quality improvement methods.[29] However, other outcomes, such as chronic lung disease and necrotizing enterocolitis, decrease with similar approaches.[56,69]

In a recent multinational study in NICUs located in 19 European regions (Effective Perinatal Intensive Care in Europe), units were encouraged to implement four high-level evidence practices for infants between 24 and 28 weeks of gestation: delivery in a maternity unit with appropriate neonatal care services, any administration of antenatal corticosteroids before delivery, effective prevention of hypothermia, and surfactant use within 2 hours after birth or early nasal continuous positive airway pressure. While only 58.3% of very preterm infants received all of the four evidence-based practices for which they were eligible, those infants who received all four evidence-based practices had higher risk-adjusted survival without severe morbidity.[104]

Recently the formation of State Collaboratives to implement bundles of EBPs[42] using the Plan-Do-Study-Act (PDSA) model for improvement[55] has resulted in significant advancement in important outcomes of neonatal care such as decreasing nosocomial infections, increasing use of human milk for premature infants, antibiotic stewardship, and better obstetric care (antenatal use of progesterone for prevention of premature deliveries,[51] antenatal use of steroids, and decreasing the rate of primary cesarean sections).

CLINICAL PRACTICE GUIDELINES

Clinical practice guidelines are systematically defined statements that assist providers and patients with decisions about appropriate health care for specific clinical circumstances.[92] Valid clinical guidelines create components from evidence derived from systematic reviews and all relevant literature. **Essential components that should be considered when implementing the use of selected guidelines are: validity, meaning to be based in the highest level of evidence available; early participation and engagement of the different disciplines that will be affected by the guideline;[1] and detailed instructions for its application.** In addition, "killer *B*s" affect the instructions for application (Box 1.2). Detailed guides for assessing the validity of clinical guidelines have been developed. **The AGREE Collaboration has developed an instrument for assessing the**

BOX 1.2 THE KILLER Bs

Burden: Is the burden of illness (frequency in our community, or our patient's pretest probability or expected event rate [PEER]) too low to warrant implementation?

Beliefs: Are the beliefs of individual patients or communities about the value of the interventions or their consequences incompatible with the guideline?

Bargain: Would the opportunity cost of implementing this guideline constitute a bad bargain in the use of our energy or our community's resources?

Barriers: Are the barriers (geographic, organizational, traditional, authoritarian, legal, or behavioral) so high that it is not worth trying to overcome them?

From Straus SE, Richardson WS, Haynes RB. *Evidence-Based Medicine: How to Practice and Teach It.* 4th ed. London: Harcourt; 2011.

validity of the clinical guidelines, including items focusing on six domains: (1) scope and purpose, (2) stakeholder involvement, (3) rigor of development, (4) clarity of presentation, (5) applicability, and (6) editorial independence (www.agreetrust.org). As stated by Silverman[83]

> *Since ours is the only species on the planet that has achieved rates of newborn survival which exceed 90 percent, it seems to me we must demand the highest order of evidence possible before undertaking widespread actions that may affect the full lifetimes of individuals in the present, as well as in future generations. Here a strong case can be made for a slow and measured pace of medical innovation.*

EVIDENCE-BASED PRACTICE RESOURCES

DATABASES OF EVIDENCE AND SEARCH ENGINES

ACP Journal Club (http://annals.org/journalclub.aspx): Evidence-based evaluative summaries of articles taken from 100 clinical journals, written by MDs and others, with comments from MDs.

Campbell Collaboration (www.campbellcollaboration.org): An independent, international, nonprofit organization that aims to help people make well-informed decisions about the effects of interventions in the social, behavioral, and educational arenas. The vision of the Campbell Collaboration is to bring about positive social change and to improve the quality of public and private services across the world by preparing, maintaining, and disseminating systematic reviews of existing social science evidence. The Campbell Collaboration's substantive priorities include, but are not confined to, education, social welfare, and crime and justice.

Cochrane Library (www.thecochranelibrary.com): Premier evidence-based medicine resource composed of the following:

- Database of Systematic Reviews containing systematic reviews and meta-analyses conducted by Cochrane Study Groups.
- Database of Reviews of Effects including systematic reviews and meta-analyses from non-Cochrane sources, many with structured abstracts with comments on the reviews.
- Center Register of Controlled Trials: Indexes many trials not included in MEDLINE.

ClinicalTrials.gov (http://clinicaltrials.gov/ct/gui): Provides regularly updated information about federally and privately supported clinical research in human volunteers. Gives information about a trial's purpose, who may participate, locations, and phone numbers for more details.

Current Controlled Trials (www.controlled-trials.com): Allows users to search, register, and share information about randomized controlled trials.

Health Services/Technology Assessment Texts (HSTAT) (http://nlm.nih.gov): A free, Web-based resource of full-text documents that provide health information and support health care decision making. HSTAT's audience includes health care providers, health service researchers, policy makers, payers, consumers, and the information professionals who serve these groups.

Health Technology Assessment (HTA) and National Health Service (NHS) Economic Evaluation Database (EED) (www.crd.york.ac.uk/CRDWeb/SearchPage.asp): This is the HTA Web-based site that features the NHS EED focused on the economic evaluation of health care interventions and technical literature in the United Kingdom.

National National Health Service Centre for Reviews and Dissemination (www.york.ac.uk/inst/crd): Resource for systematic reviews of health economics and technology assessment. Also maintains the DARE, Health Technology Assessment, and NHS Economic Evaluation Databases included in Cochrane.

Turning Research into Practice (TRIP) database (www.tripdatabase.com): Locates high-quality, evidence-based medical literature using this metasearch engine. Some resources in the results list may require subscription.

World Health Organization Clinical Trial Search Portal (www.who.int/trialsearch): Enables researchers, health practitioners, consumers, journal editors, and reporters to search more easily and quickly for information on clinical trials.

DATABASES OF GUIDELINES

Agency for Healthcare Research and Quality. Canadian Medical Association (CMA) Infobase, Membrane Resources tab and then Clinical Practice Guidelines (www.cma.ca): Click on Clinical Resources tab; requires membership. Excellent access to guidelines and other point-of-care resources.

Guidelines International Network (G-I-N) (www.g-i-n.net): Guidelines organized by health topic. Links to worldwide sources of guidelines.

National Guideline Clearinghouse (www.guideline.gov): Use "Detailed Search" link on left for more specific searches. A U.S. resource for evidence-based clinical practice guidelines. A display tool allows side-by-side comparison of guidelines.

National Health Service National Institute for Clinical Excellence (NICE) (www.nice.org.uk): Evidence-based guidance on technology use, clinical care, and interventional procedures.

U.S. Preventive Services Task Force (USPSTF) (www.ahrq.gov-/clinic/uspstfix.htm): A collection of materials related to the work of an independent panel of experts in primary care and prevention that systematically reviews the evidence of effectiveness and develops recommendations for clinical preventive services.

EVIDENCE-BASED PRACTICE RESOURCES

Centre for Evidence-Based Medicine (Oxford, United Kingdom) (www.cebm.net): Major website for learning about, practicing, and teaching EBM. The Toolbox provides valuable resources for learning and practice.

Centre for Evidence-Based Medicine (Toronto, Canada) (www.cebm.utoronto.ca): In addition to learning resources, this site provides links only.

Centre for Health Evidence (www.cche.net): Based in Alberta, Canada, this center provides resources and support for evidence-based practice.

Cochrane Collaboration (www.cochrane.org): This international nonprofit and independent organization is dedicated to making up-to-date, accurate information about the effects of health care readily available worldwide through systematic reviews of medical research.

Evidence Based Medicine Toolkit (www.ebm.med.ualberta.ca): A collection of tools for identifying, assessing, and applying relevant evidence for better health care decision making.

JAMAevidence (www.JAMAevidence.com): Excellent self-paced learning modules based on the JAMA Users' Guides series, featuring interactive activities designed to reinforce learning.

Pediatric Critical Care Evidence-Based Medicine Resources (http://www.pedsccm.org/clinical-resources.php): An online collection of resources and training tools for the pediatric professional.

Understanding Evidence-Based Healthcare: A Foundation for Action (https://training.cochrane.org/resource/understanding-evidence-based-healthcare-foundation-action): A Web course created by the U.S. Cochrane Center that is designed to help the user understand the fundamentals of evidence-based health care concepts and skills.

Perinatal Quality Care Collaboratives (www.cdc.gov/reproductive-health/maternalinfanthealth/pqc-states.html): State quality improvement collaboratives whose websites contain free information about their initiatives, toolkits, resources, and projects.

2 PRENATAL ENVIRONMENT: EFFECT ON NEONATAL OUTCOME

JENNIFER WOO, SUZANNE M. CARRINGTON, AND ANNE AMBIA

The human fetus develops within a complex maternal environment. Structurally defined by the intrauterine/intraamniotic compartment, the character of the prenatal environment is determined largely by maternal variables. The fetus totally depends on the maternal host for respiratory and nutritive support and is significantly influenced by maternal metabolic, cardiovascular, and environmental factors. In addition, the fetus is limited in its ability to adapt to stress or modify its surroundings. **This creates a situation in which the prenatal environment exerts a tremendous influence on fetal development and well-being.** This influence lasts well beyond the period of gestation, often affecting the newborn in ways that have profound significance for both immediate and long-term outcome.

There is great utility in identifying maternal factors that adversely affect the condition of the fetus. Providers of obstetric care have long used this information to identify the "at-risk" population and design interventions that prevent or reduce the occurrence of fetal and neonatal complications. **It is equally important that neonatal care providers obtain a clear picture of the prenatal environment and use this information before birth to anticipate the newborn's immediate needs and make appropriate preparations for resuscitation and initial nursery care.** After birth, an awareness of the likely sequelae of environmental compromise helps focus ongoing assessment and aids in clinical decision making.

The purpose of this chapter is to help neonatal care providers evaluate maternal influences on the prenatal environment, identify significant environmental risk factors, and anticipate the associated neonatal problems. **Maternal factors and environmental influences are important determinants in neonatal outcome.**

PHYSIOLOGY

Two variables have a critical influence on fetal well-being throughout gestation: uteroplacental functioning and inherent maternal resources. The interplay of these factors is a major determinant of fetal oxygenation, metabolism, and growth. Alterations in the development and function of the placenta also influence fetal growth and development. The fetus may be affected to the point that survival is threatened. Likewise, extrauterine well-being may be compromised.

The placenta has a dual role in providing nutrients and metabolic fuels to the fetus. First, placental secretion of endocrine hormones, chiefly human chorionic somatomammotropin, increases throughout pregnancy, causing progressive changes in maternal metabolism. The net effect of these changes is an increase in maternal glucose and amino acids available to the fetus, especially in the second half of pregnancy.[46,121] Second, the placenta is instrumental in the transfer of these (and other) essential nutrients from the maternal to the fetal circulation and, conversely, of metabolic wastes from the fetal to the maternal system. Adequate maternal and fetal blood flow through the placenta is essential throughout the entire pregnancy.

BLUE type highlights content that is particularly applicable to clinical settings.

Fetal respiration also depends on adequate placental function. Respiratory gases (oxygen and carbon dioxide) readily cross the placental membrane by simple diffusion, with the rate of diffusion determined by the P_{O_2} (or P_{CO_2}) differential between maternal and fetal blood.[51]

Although the placenta mediates the transport of respiratory gases, carbohydrates, lipids, vitamins, minerals, and amino acids, the maternal reservoir is their source. Maternal-fetal transfer depends on the characteristics and absolute content of substances within the maternal circulation, the relative efficiency of the maternal cardiovascular system in perfusing the placenta, and the function of the placenta itself. The fetal environment can be disrupted by inappropriate types or amounts of substances (e.g., ethanol) in the maternal circulation, decreases or interruptions in placental blood flow (e.g., placental abruption), or abnormalities in placental function (e.g., small placenta). Maternal nutrition, exercise, and disease can impair placental uptake and transfer of substances across the placenta to the fetus.

COMPROMISED FETAL ENVIRONMENT

Maternal Disease

DIABETES

The prevalence of diabetes mellitus and gestational diabetes mellitus (GDM) is increasing worldwide. **Diabetes is the most common endocrine disorder affecting pregnancy,** having doubled in the past decade with approximately 4% to 10% of pregnant women in the United States diagnosed with GDM annually with a prevalence of 9.2% annually.[56] This increase is likely fueled by the obesity epidemic and the older age of pregnant women[46] Despite major reductions in mortality rates over the past several decades, the infant of a diabetic mother (IDM) continues to have a considerable perinatal disadvantage. The physiologic changes in maternal glucose use that accompany pregnancy, coupled with either a preexisting hyperglycemia (as found in types 1 and 2 diabetes) or an inability to mount an appropriate insulin response (as seen in patients with GDM), result in a significantly abnormal fetal environment. This is because of the increased level of maternal glucose, often in concert with episodic hypoglycemia, as well as high levels of triglycerides and free fatty acids. Early in pregnancy, this environment may have a teratogenic effect on the embryo, accounting for the dramatic increase in spontaneous abortions and congenital malformations in the offspring of diabetic women with poor metabolic control.[18,51] During the second and third trimesters, the mechanics of placental transport dictate that fetal glucose levels depend on, but are slightly less than, maternal levels.[25] Assuming adequate placental function and perfusion, elevations in maternal glucose lead to fetal hyperglycemia and increased fetal insulin production. Repeated or continued elevations in blood glucose result in fetal hyperinsulinism, alterations in the use of glucose and other nutrients, and altered patterns of growth and development.[18,25,32]

There is increasing evidence that maternal hyperglycemia with impaired glucose tolerance, in the absence of diabetes, increases the risk of neonatal morbidity.[70] Compared with women with normal glucose tolerance, those **with elevated blood sugar have an increased risk of having infants with a birth weight greater than the 90th percentile, increased cord blood C-peptide levels, and increased neonatal hypoglycemia.[76]**

Fetal macrosomia (greater than the 90th percentile for weight) occurs in 25% to 42% of diabetic pregnancies because of hyperinsulinemia. These macrosomic infants suffer increased morbidity and mortality rates from unexplained death in utero, birth trauma, hypertrophic cardiomyopathy, vascular thrombosis, neonatal hypoglycemia, hyperbilirubinemia, erythrocytosis, and respiratory distress.[98,126] Although intrauterine fetal death (IUFD) is an increased risk for pregnant women with preexisting or overt diabetes, the most contemporary literature does not support an increased risk for IUFD for those with true GDM.[98,126] However, there is a **fourfold increased incidence of fetal anomalies in those with fasting hyperglycemia with GDM.**[51,76] Macrosomic infants have an increased risk for shoulder dystocia during vaginal birth, as well as brachial plexus injury, facial nerve palsy, dysfunctional labor patterns, and operative vaginal birth.[51]

In addition to the basic metabolic disturbances, diabetes predisposes the pregnant woman to several other complications, including gestational hypertension, preeclampsia, renal disease, and vascular disease. As a consequence, the fetus may be compromised further by chronic hypoxia and other insults, which can lead to intrauterine demise, prematurity, growth restriction, cardiovascular problems, respiratory

distress syndrome (RDS), and long-term neurologic problems.[18] In terms of predicting perinatal morbidity and mortality, the **prognostically bad signs of pregnancy include diabetic ketoacidosis, hypertension, and maternal noncompliance, though risk of adverse neonatal outcome occurs on a continuum with no clear threshold.[18,51]**

For the woman with GDM, the standard therapy remains subcutaneous insulin, because multiple studies have documented its safety. For women using an oral agent, several medications have been studied for use during pregnancy. Metformin does not cause any short-term adverse effects, but long-term effects on the fetus are unknown because of lack of long-term neonatal follow-up.[11] If metformin is used, it is discontinued after the first trimester because metformin crosses the placenta. Oral glyburide has been studied for women who cannot or will not use subcutaneous insulin. When glyburide was compared to insulin for prevention of perinatal complications (i.e., macrosomia, neonatal hypoglycemia, neonatal hyperbilirubinemia), there was no clear evidence that the use of glyburide resulted in significantly fewer perinatal complications.[144] Therefore, these researchers concluded that the use of glyburide as a first-line treatment is not justified.

In preparing for the delivery of an IDM, the neonatal team should consider the classification of maternal diabetes (type 1 or 2, or gestational). In addition, the quality of metabolic control throughout the pregnancy and labor, maternal complications, and the duration of the pregnancy should be considered, along with indicators of fetal growth and well-being.[70] In cases in which oral hypoglycemic agents have been used, there should be careful assessment of the neonate because sulfonylurea (i.e., glyburide) may cause neonatal jaundice. Glyburide crosses the placenta, as does metformin, with the potential to affect neonatal physiology.[26] Both of these medications are thought to be safe for the neonate during lactation (see Chapter 18**).**

THYROID DISEASE

Thyroid disorders during pregnancy are relatively common. The thyroid hormones *triiodothyronine (T_3)* and *thyroxine (T_4)* cross the placenta in small amounts, though the significance of the transfer has not been well elucidated. The fetus depends on maternal T_4 in the first trimester of pregnancy. Maternal T_4 is transferred to the fetus throughout pregnancy.[13] At 8 to 10 weeks of gestation, the fetal thyroid begins to concentrate iodine and produce T_4. At approximately 24 weeks, thyroid-stimulating immunoglobulins (TSIs) or thyroid-stimulating hormone receptor antibodies (TRAbs), which are classes of immunoglobulin G (IgG), cross the placenta and stimulate fetal thyroid. Iodine is readily transferred from the mother to the fetus. **The fetal thyroid gland concentrates iodine and synthesizes its own hormones as early as 10 to 12 weeks of gestation; this is independent of maternal thyroid function.** Maternal T_4 contribution continues to remain important throughout gestation.[113] Maternal thyroid hormones are believed to be important for fetal neurologic development in the first trimester, and untreated hypothyroidism has been associated with a decrease in the intelligence quotient (IQ) of offspring.[2,51,92]

In analyzing thyroid function tests during pregnancy, reference ranges for normal function are different. Thyroid-stimulating hormone (TSH) is the best test of thyroid function in pregnancy. However, both the lower and upper limits of normal for pregnant women are lower than for nonpregnant women.[2]

Subclinical hypothyroidism is defined as an elevated TSH with a normal free T_4 level. In patients with subclinical hypothyroidism, thyroid peroxidase antibody (TPO-Ab) levels should be measured. If the pregnant woman has subclinical hypothyroidism and is TPO-Ab positive, treatment with levothyroxine is indicated because of the increased risk of pregnancy loss, preterm delivery, and neonatal hospitalization.[2,113] Pregnant woman who are TPO-Ab negative do not need treatment. Pregnant women with overt hypothyroidism, defined as an elevated TSH with low free T_4 levels, should be treated with levothyroxine[53] Lack of treatment during pregnancy is associated with increased neurodevelopmental delay in offspring, pregnancy loss, prematurity, preeclampsia, low birth weight, and placental abruption.[2] Treatment with replacement hormone during pregnancy is well tolerated by the fetus and reduces these risks.[53] However, a recent study showed that children of women treated for subclinical hypothyroidism did not have significantly better cognitive outcomes through 5 years of age than children whose mothers were not treated.[39]

Maternal hyperthyroidism presents a different situation. Thyroid-stimulating antibodies, commonly found in patients with Graves' disease, as well as many of the drugs used to treat hyperthyroidism, cross the placenta and can have a significant effect

on the fetus. Antibodies, including long-acting thyroid stimulant and TSIs, can increase fetal thyroid hormone production. High levels are associated with fetal and neonatal hyperthyroidism. Untreated Graves disease with maternal thyrotoxicosis has been linked to preterm delivery, intrauterine growth restriction (IUGR), low birth weight, and stillbirth.[128] **In rare cases, the offspring of women with Graves' disease may themselves have this condition. In fetuses and newborns, this is evidenced by elevations in heart rate, growth restriction, prematurity, goiter, and congestive heart failure.[53]** Administration of antithyroid medication to the mother can decrease thyroid hormone production in both the mother and the fetus but may result in fetal hypothyroidism and goiter.[53] In the first trimester, propylthiouracil (PTU) is the safest therapy, since methimazole has been associated with increased rate of congenital malformations.[53] In the second and third trimester, either propylthiouracil or methimazole are equally safe.[2]

Another maternal antibody, TSH-binding inhibitor immunoglobulin, also crosses the placenta and can prevent the expected fetal thyroid response to TSH. The result is a transient fetal and neonatal hypothyroidism. Iodine deficiency in the mother is another cause of fetal and neonatal hypothyroidism and, in its severe form, leads to cretinism because of the fetus's dependence on maternal iodine reserves.[53]

PHENYLKETONURIA

Phenylketonuria (PKU) is an inherited disorder in which an enzymatic defect precludes conversion of the essential amino acid *phenylalanine* to *tyrosine.* **This metabolic derangement is evidenced by an accumulation of excessive amounts of phenylalanine and alternative pathway byproducts in the blood, and these are toxic to the central nervous system (CNS).** Historically, PKU resulted in virtually certain mental retardation; affected individuals often were institutionalized and rarely reproduced. With the advent of universal neonatal screening in the United States since the 1960s and effective dietary treatment to prevent hyperphenylalaninemia during infancy and early childhood, genetically affected persons may avoid the devastating effects of this disease, have relatively normal development, and become pregnant. For women who do conceive, PKU poses a significant environmental risk for their developing fetus. The care of these women and their infants presents a unique perinatal challenge.

An estimated 3000 healthy young women of childbearing age with successfully treated PKU are in the United States.[105] However, most discontinued their special diet in childhood because, at the time, most doctors believed it was safe to do so. Unfortunately, their blood phenylalanine levels are very high when they become pregnant if they are eating a normal diet. In up to 90% of such cases, the offspring will be microcephalic, and/or have severe developmental delay. These babies also have an increased incidence of low birth weight, congenital heart defects, and characteristic facial features regardless of whether they are themselves affected with PKU, as well as preterm birth and intrauterine fetal death.[129,161] They cannot be helped by the PKU diet, or they suffer from brain damage caused entirely by their mothers' high phenylalanine levels during pregnancy. To prevent such damage, these women should resume their PKU diets, consuming specific types of protein low or free of phenylalanine, during preconception and pregnancy.[8,148,161] Studies have identified improved long-term outcomes when desirable phenylalanine levels (2 to 8 mg/dL) are achieved at least 3 months before pregnancy and maintained throughout gestation.[83] **Phenylalanine levels drop quickly once dietary restrictions are instituted, and there is a strong correlation between maternal blood levels and neonatal outcome.[103,129,148,161,162]**

PKU is an inborn error of metabolism, and approximately 1 baby in 14,000 inherits PKU when both parents have the *PKU* gene and both pass it on to their baby. **Neonatal blood screening will identify these PKU babies. If this screening is performed within the first 24 hours of life, the American Academy of Pediatrics recommends rescreening at 1 to 2 weeks of age to avoid missed cases of PKU.** Once identified, infants with PKU are fed a combination of special formula and breastfeeding with close monitoring of blood and urine levels of phenylalanine (see Chapter 18). When mothers of PKU babies are invested in breastfeeding, they need support to be successful.[23] When treatment is discontinued too soon, risks include blindness, learning disabilities, behavioral disturbances, and a decrease in IQ. When no treatment is instituted at all, phenylalanine accumulates in the bloodstream and causes brain damage and severe developmental delay.[25,29]

RENAL DISEASE

Maternal adaptation to pregnancy involves major changes in renal function and structure. Renal hemodynamic changes begin early in pregnancy and before significant expansion of plasma volume. Renal blood flow increases in the first trimester by 35% to 60% and then decreases from the second trimester to term. Additional changes include an increase in the glomerular filtration rate and effective renal plasma flow, a decrease in renal vascular resistance, an activation of the renin-angiotensin-aldosterone system, and increased retention of sodium and water.[51] These changes place unique demands on the renal system. Women with preexisting renal disease may have a successful pregnancy outcome with proper prenatal care; however, some women experience fetal loss and deterioration in renal function. Furthermore, moderate or severe renal dysfunction complicates pregnancy and increases maternal and fetal risks and adverse outcomes.[73]

Renal disease in pregnancy may occur as a result of urinary tract infections, nephrolithiasis, glomerular disease, or severe hypertension or as a complication of systemic diseases, including diabetes and systemic lupus erythematosus. Regardless of the underlying etiologic factors, pregnancy outcome relates most closely to these factors: the presence of hypertension and the degree of renal insufficiency before and during pregnancy.[73] Many women with renal disorders are hypertensive before pregnancy, and they often develop a superimposed pregnancy-induced hypertension leading to preeclampsia.[152] Even those with previously normal blood pressures run an increased risk for developing hypertension during pregnancy. **The presence of hypertension in these pregnancies represents a significant risk to the fetus and is strongly associated with IUGR, preterm delivery, and perinatal loss.**

Drug therapy to control chronic hypertension has been shown to have a beneficial effect on fetal outcome and generally is continued throughout pregnancy. Renal insufficiency, as measured by creatinine clearance or serum creatinine level, also has implications for fetal outcome. Mild to moderate renal insufficiency (serum creatinine <1.5 mg/dL) is associated with a generally favorable outcome, whereas severe insufficiency (serum creatinine >1.6 mg/dL) often carries an increased risk for perinatal death. Persistent proteinuria also may increase fetal loss, and a urinary protein excretion rate higher than 0.5 g per 24 hours may be an independent predictor of fetal outcome. As a rule, the number of preterm deliveries and growth-restricted infants increases with increasing blood pressure and decreasing renal function.[73]

Bacteriuria occurs in 2% to 7% of pregnancies. If untreated, asymptomatic bacteriuria may lead to pyelonephritis or acute cystitis. **Risks for the fetus are preterm birth and IUGR.** Fetal death is an additional risk with pyelonephritis. Prophylactic antibiotics (suppressive therapy) should be given to women with persistent or frequent recurrence of bacteriuria or a history of pyelonephritis in pregnancy.[170]

Two special circumstances in chronic renal disease are dialysis during pregnancy and pregnancy after renal transplant. Previously, it was felt that women with end-stage renal disease undergoing dialysis rarely become pregnant, and if pregnancy did occur, it was associated with significant perinatal morbidity and mortality risks, with spontaneous abortions reaching 50%. However, more recently, studies show that intensive hemodialysis improves fertility, although the rate of pregnancy is still lower, and can improve pregnancy outcomes.[124] Pregnancy after transplantation is more common and has a more favorable prognosis than pregnancy managed by dialysis.[165] Where maternal serum creatinine remains less than 1.5 mg/dL and the woman is on a stable immunosuppressive regimen, outcomes can be expected to be positive.[73,165] Neonatal outcomes are typically favorable unless there is maternal hypertension with impaired kidney functioning, in which case rates of preterm birth, small-for-gestational-age (SGA) infants, and neonatal mortality increase.[73,165]

NEUROLOGIC DISORDERS

The risks that accompany pregnancies complicated by maternal neurologic disorders vary according to the individual disease entity and pertain to both the course of the mother's disease and the pregnancy outcome. The physiologic and hormonal changes of pregnancy can influence the course of chronic neuromuscular disorders, such as epilepsy, multiple sclerosis, and myasthenia gravis. The medications used to control these disorders can be particularly problematic for the fetus.

The prevalence of *maternal seizure disorders* is about 4 in 1000 pregnancies, and most are treated with antiepileptic drugs (AEDs). The

disorders and/or the AEDs have been associated with increased fetal and neonatal risks, including spontaneous abortion, prematurity, low birth weight, SGA infants, congenital defects, intrauterine demise, neonatal depression, and hemorrhage.[160] In women with preexisting seizure disorders, prepregnancy planning is essential to minimize the risk of congenital malformations. Women anticipating pregnancy should begin daily folic acid supplementation. Maternal folic acid supplementation improves pregnancy outcomes for women taking AEDs and decreases the risk of spontaneous abortion, lower verbal IQ, and birth defects.[77] Women who are anticipating pregnancy should have the dose of their AED changed to the lowest effective dose, and valproic acid should be discontinued.[68] European recommendations include avoiding the use of valproate in women of childbearing age unless there are situations in which pregnancy is highly unlikely.[156]

Significant numbers of epileptic women experience an increase in seizure activity during pregnancy. This may be caused by decreased compliance with medication regimens, physiologic changes associated with pregnancy, and gestational changes in plasma levels of anticonvulsant drugs.[66,94] There is evidence that maternal seizures may compromise fetal oxygenation, possibly because of diminished placental blood flow or maternal hypoxemia resulting from postseizure apnea. For these reasons, control of maternal seizure activity with anticonvulsants is one of the primary goals of prenatal care.

Placental transport of anticonvulsants does occur, resulting in fetal levels that approximate or, in some cases, exceed maternal levels.[77] Although the majority of infants born to women with epilepsy are normal, these infants are at increased risk for poor outcomes.[156] **There is an increased risk of congenital malformations and adverse cognitive outcomes in offspring of epileptic women treated with some types of anticonvulsants.[77,156]** The risks of congenital malformations are highest with the use of valproic acid, and there is some increased risk with topiramate.[68] There is also a higher risk with polypharmacy than for those women on a single agent.[159] The AEDs with the greatest safety profile for use during pregnancy are levetiracetam and lamotrigine, and these medications are recommended if an AED is necessary.[114] Phenytoin, phenobarbital, and carbamazepine are intermediate-risk medications, being much safer than valproic acid and topiramate, but with a lower safety profile than levetiracetam and lamotrigine. **The most common major congenital malformations associated with AEDs are neural tube defects (e.g., spina bifida), orofacial defects (e.g., cleft lip, cleft palate), heart malformations (e.g., ventricular septal defect), urogenital defects (e.g., hypospadias), and skeletal abnormalities (e.g., radial ray defects, phalangeal hypoplasias).[66]** The influence of the seizure disorder itself, as well as genetic makeup, cannot be ignored. **Infants born to mothers treated with anticonvulsants, especially barbiturates, may exhibit signs of generalized depression, including decreased respiratory effort, poor muscle tone, and feeding difficulties. They also may have symptoms indicative of drug withdrawal (see Chapter 11). These symptoms are usually present in the first week of life and include tremors, restlessness, hypertonia, and hyperventilation.[35]** **In addition, abnormal clotting and hemorrhage in the offspring of women treated with phenytoin, phenobarbital, and primidone have been reported. This appears to be caused by a decrease in vitamin K–dependent clotting factors. Hemorrhage usually starts within the first 24 hours, is often severe, and may result in death. Infants born to these mothers should have cord blood clotting studies done, vitamin K prophylaxis soon after birth, and close observation. Breastfeeding should be encouraged, though adverse effects may occur if the mother is taking phenobarbital[77] (see Chapter 18).**

Multiple sclerosis (MS) frequently strikes women during their reproductive years. The onset of MS usually is insidious; the course is marked by a seemingly capricious cycle of exacerbation and remission. A wide range of sensory, motor, and functional changes is associated with this disease; the type and severity of symptoms vary dramatically from one individual to another and in any one patient over time. The disease is a T-cell–mediated autoimmune disease of the CNS triggered by unknown exogenous agents in individuals with specific genetics.[50] Pregnancy usually is well tolerated and may be associated with MS stability or improvement. The reported effects of the disease on pregnancy outcomes, including risk for malformations, cesarean section rates, newborn birth weight, and rate of preterm delivery, are inconsistent. Some groups report no increase in adverse pregnancy outcomes,

whereas others report a higher cesarean and infection rate and a greater number of preterm births in mothers with MS.[102] Alterations in neural function, fatigue, and general weakness may play a role in pregnancy outcomes. However, in women with MS, the disease process itself is not a threat to fetal or neonatal well-being.[50] **The priority for neonatal care providers is to determine the extent of the mother's disability, including her level of fatigue and her ability to care for her infant. The availability of appropriate support systems, both personal and professional, should be assessed, and the required follow-up and referrals should be made.**

Even though the prognosis for these infants is excellent, some factors associated with MS are potentially problematic. Bladder dysfunction, common in women with MS, often results in urinary tract infections during pregnancy. Associated fetal and neonatal problems include preterm delivery and sepsis. Early identification and prompt treatment with appropriate antibiotics should minimize these risks. Despite the fact that many women do have improvement or remission during pregnancy, 17% of women do experience a relapse of their MS, which is more likely in the late second and third trimesters.[5]

An additional area of concern is the variety of drugs administered to MS patients. Immunosuppressants are frequently used during severe exacerbations. The placental transport and fetal risk vary with the individual agent used. It is generally recommended that pregnant women with MS discontinue their disease-modifying drugs (DMDs) prior to conception. If they have to continue their medication because of the risk for relapse, then it is recommended to avoid mitoxantrone, fingelimod, and terflunomide.[82] Conversely, glatiramer acetate, interferon B, and steroids are considered safe.[50,82] A final consideration is the long-term one: The incidence of MS in offspring of a parent with the disease is about 2.5%, compared with 0.13% in the general population; the risk is even greater when a sibling has MS.[50]

Myasthenia gravis (MG) is a chronic autoimmune disease that causes neuromuscular dysfunction and is encountered rarely in pregnancy; only 1 in 20,000 pregnancies is complicated by MG.[90] Cells of the immune system make proteins called *antibodies* that block nerve impulses to the muscles. Antibodies to acetylcholine receptor (AchR) have been found in most affected persons. Distinguishing features include generalized weakness and muscle fatigue with activity. Pregnant women with MG also may experience respiratory compromise resulting from muscle weakness compounded by pressure of the fetus against the diaphragm,[109] as well as difficulty swallowing.[90] The course of MG during pregnancy is unpredictable and may vary in different pregnancies in the same woman.[64] Unmasking or exacerbations of MG occur in approximately 40% of pregnancies and remission in 30%, with the remaining 30% experiencing no change. During the first trimester and the first month postpartum, exacerbations are more likely.[90] Corticosteroids can be used to maintain the remissions of MG and should be continued on the lowest possible doses throughout the pregnancy and postpartum period. Certain immunosuppressive agents, such as methotrexate, cyclophosphamide, mycophenolate mofetil, and rituximab are contraindicated in pregnancy. If a patient is already on azathioprine or cyclosporine A, it may be continued, but these drugs should not be started in pregnancy.[74] Plasmapheresis and intravenous immunoglobulins are the safest modalities to use for an exacerbation and can be effective in the treatment of myasthenic crises during pregnancy.[67] Though uterine smooth muscle is not compromised during labor because it is not affected by AchR, patients with MG may become exhausted during the second stage of labor necessitating instrumental delivery.[90,109]

Infants born to myasthenic mothers may be affected by the drug therapy and the underlying immunologic dysfunction. Increased rates of premature rupture of membranes (PROM), preterm delivery, and cesarean birth have been reported, although a nationwide study found no increased risk in prematurity, LBW, SGA infants, or cesarean delivery.[59,64,167] **An additional risk stems from transplacentally acquired anti–acetylcholine receptor antibodies, which cause approximately 12% to 13% of these newborns to experience a transient, self-limited course of neonatal myasthenia gravis.[59]** It is difficult to predict which pregnancies will result in an affected infant, although infants born to women with very high AchR antibody titers may be at highest risk.[90] **Affected infants usually present within the first 48 hours of life with transient neonatal MG, demonstrating generalized weakness, a feeble cry, diminished**

suck and swallow, and a decreased respiratory effort that may require mechanical support.[64] Therefore, plans should be made in advance for delivery of the mother with MG, and intensive care facilities for the newborn should be available immediately. Neonatal MG generally subsides within 3 to 4 weeks after birth and does not recur.[64]

MG is not a contraindication to pregnancy and can usually be managed well with relatively safe and effective therapies, including maternal rest. Standard therapies for some obstetric complications, such as preeclampsia and preterm labor, may need to be altered in women with MG.[51] Vaginal delivery is recommended if possible.[51] Breastfeeding is not contraindicated but depends on maternal medications and on infant and maternal health postpartum (see Chapter 18).

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is an autoimmune disease that presents primarily in women of childbearing age. The pathogenesis involves the production of autoantibodies and immune complexes. The clinical effects of lupus range from mild or subclinical disease to serious illness affecting multiple organ systems. The leading causes of death are infections and renal failure. In pregnancy, SLE is associated with an increased incidence of preeclampsia, thromboembolic events, spontaneous abortion, preterm delivery, IUGR, congenital defects, and the need for neonatal intensive care.[36,123] Outcome is most favorable when infections, renal disease, and hypertension do not complicate pregnancy and when pregnancy occurs with prolonged disease remission.[57,106,139] One study suggests that 4 months of disease quiescence before pregnancy is enough to ensure a safe pregnancy.[122] The presence of lupus nephritis is the highest risk factor for perinatal complications.[91,122] Lupus nephritis is associated with an increased rate of hypertension, preeclampsia, and preterm delivery.[91] Additionally, it can cause a disease flare, with worsening of renal function.[91] Overall reported frequency of SLE flares in pregnancy is 15% to 60%.[1] When necessary, treatments used with pregnancies complicated by SLE include antiinflammatory, antimalarial, immunosuppressive, and biologic drugs and/or anticoagulants.[57,106]

The neonatal manifestations of SLE are rare and are attributed to the placental transfer of maternal antibodies to the fetus. Usual findings of neonatal lupus include a transient lupuslike rash (erythematous lesions of the face, scalp, and upper thorax), thrombocytopenia, and hemolysis.[1] These findings generally are transient and clear within a few months. A strong association has been established between maternal antibodies to the anti–Ro/SS-A and anti–La/SS-B antigens and congenital heart block, a rare manifestation of neonatal lupus syndrome.[1,122] The fetal heart block may be detected with antenatal testing; some authors believe that antenatal fetal surveillance with nonstress tests (NSTs) should begin at 28 weeks of gestation. Infants are treated with cardiac pacemakers (64% of neonates) after delivery; however, about one-third of affected infants die within 3 years.[106,122]

HEART DISEASE

Significant changes in cardiovascular function accompany normal pregnancy. Plasma and red blood cell volumes rise, heart rate and cardiac output increase, and peripheral vascular resistance falls. These changes facilitate increased uterine blood flow, placental perfusion, and fetal oxygenation and growth. They also increase maternal oxygen consumption and cardiovascular workload and can further compromise the cardiovascular status of women with preexisting serious heart disease. Approximately 2% to 4% of childbearing-age women have concomitant heart disease, which may be congenital (the most common type in the United States) or acquired (which includes valvular disease, cardiomyopathy, and pulmonary hypertension).[101,140,164] In the United States from 2003 to 2012, the incidence of pregnant women with heart disease increased by 24.7%.[101] Pregnancy creates a risk for maternal cardiovascular complications, but especially for those with underlying heart disease, and includes an increased incidence of arrhythmias, heart failure, thromboembolism, and sudden death.[69,115,164] In the United States, cardiac disease during pregnancy is the leading cause of maternal morbidity and mortality.[107] In some cases, such as Eisenmenger's syndrome and primary pulmonary hypertension, the risk to maternal survival is so great that pregnancy is contraindicated.[164] Pulmonary hypertension is associated with an increased risk for major adverse cardiac events during the hospitalization for delivery, especially when there is concomitant cardiomyopathy.[101,154] In general, how well the woman with heart disease

tolerates pregnancy depends on the specific disease process and the degree to which her cardiac status is compromised.

Maternal heart disease also affects the fetus. Fetal risks are the result of genetic factors, alterations in placental perfusion and exchange, and the effect of maternally administered drugs. **The genetic risk is demonstrated by the increased incidence of congenital heart defects that occur in the offspring of parents who have such a defect.** The exact risk depends on the specific parental lesion, mode of inheritance, and exposure to environmental triggers.[115,140]

Alterations in placental perfusion and gas exchange occur when the mother's condition involves chronic hypoxemia or a significant decrease in cardiac output. These factors increase the threat to the fetus, with fetal risk increasing as maternal cardiac status declines. Chronic maternal hypoxemia results in a decrease in oxygen available to the fetus and is associated with fetal loss, prematurity, and IUGR. Significant reductions in maternal cardiac output create decreased uterine blood flow and diminished placental perfusion with a resulting impairment in the exchange of nutrients, oxygen, and metabolic wastes. **Possible fetal and neonatal consequences include spontaneous abortion; IUGR; neonatal asphyxia; CNS damage; need for preterm delivery; and intrauterine, intrapartum, or neonatal death.**[115,140,164]

A wide variety of drugs are used in the management of maternal cardiovascular disease. Although sometimes it is difficult to differentiate drug effects from the effects of the underlying disease, some associations between drug administration and fetal outcomes can be made. Anticoagulants are used to decrease the risk for thromboembolism, especially in women with artificial valves, a history of thrombophlebitis, or rheumatic heart disease. **Oral anticoagulants, specifically warfarin sodium (Coumadin), have been associated with fetal malformations, including nasal hypoplasia and epiphyseal stippling, when administered during the first trimester. They also have been associated with eye and CNS abnormalities when administered later in pregnancy. The incidence of warfarin embryopathy is estimated to be 15% to 25%.** Warfarin also is associated with maternal and fetal hemorrhage. Because of these risks, warfarin is contraindicated in pregnancy except in special circumstances, such as pregnancy in women with prosthetic heart valves. Heparin is considered the preferred agent for anticoagulation therapy during pregnancy. **Heparin does not cross the placenta; therefore it does not result in fetal anticoagulation or neonatal hemorrhage (although maternal hemorrhage still may occur), nor has it been associated with congenital defects. Low-molecular-weight heparin is another alternative for anticoagulation during pregnancy.**[115,140] In general, patients being treated with low-molecular-weight heparin during pregnancy are converted to unfractionated heparin during the final weeks of pregnancy because of the ease of rapid reversal of anticoagulation for labor and delivery. Some studies, however, did not demonstrate any difference in bleeding complications for gravidas continued on low-molecular-weight heparin versus those who were converted to unfractionated heparin.[115]

Antiarrhythmic medications and cardiac glycosides used during pregnancy cross the placenta to varying degrees. They have not been implicated in fetal malformations and, although several have been associated with minor complications, generally are considered safe for use in pregnancy.[115] Reported complications include uterine contractions (quinidine, disopyramide), decreased birth weight (digoxin, disopyramide), and maternal hypotension with a sudden decrease in placental perfusion (verapamil).

Antihypertensives and diuretics also have been used in the treatment of cardiovascular disease during pregnancy. Labetalol and methyldopa are commonly used in pregnant women with chronic hypertension. These medications have been studied in prospective trials that revealed no adverse fetal or maternal outcomes, though methyldopa is not recommended postpartum because it is associated with increased incidence of depression.[115] Their use in the first trimester has also demonstrated safety. Atenolol has been associated with fetal IUGR and abnormal placental growth.[115,140] Calcium channel blockers, such as nifedipine, are also safely used during pregnancy without an increase in major birth defects or adverse neonatal outcomes.[115,140] Diuretic use in pregnancy remains an area of some controversy. **Fetal and neonatal compromise can result from diuretic-induced electrolyte and glucose imbalance and decreased placental perfusion caused by maternal hypovolemia. The use of thiazide diuretics has been linked to neonatal liver damage and thrombocytopenia.** In general,

diuretic use is restricted to women with pulmonary edema or acute cardiac or renal failure.[115]

Although a great number of complications are possible, remember that, with few exceptions, most of the drugs used in the treatment of maternal heart disease can be used in pregnancy if the maternal condition warrants it. **Angiotensin-converting enzyme inhibitors are contraindicated in pregnancy because of an association with fetal injury (renal dysfunction, fetal oliguria, oligohydramnios, fetal skull hypoplasia) and fetal death.**

RESPIRATORY DISEASE

Respiratory function is altered even in normal pregnancy. Changes include a decrease in lung volume and increases in oxygen consumption, tidal volume, and minute ventilation.[79] Significant decreases in maternal respiratory function and oxygenation can result in fetal growth restriction and fetal hypoxia with negative outcomes, but careful management of respiratory disease during pregnancy generally results in a favorable outcome.

Asthma is the most common respiratory disease in pregnancy, occurring in 4% to 12% of women, and the prevalence among pregnant women is rising.[4] For about two-thirds of pregnant women, the course of asthma worsens.[4] **Infants born to women whose asthma is well controlled usually do well;** unstable or worsening disease, especially status asthmaticus, increases fetal risk. Commonly used asthma medications (e.g., long-acting beta agonists, inhaled corticosteroids, oral corticosteroids, other bronchodilators, and cromones) are generally considered safe for use in pregnancy.[111] Although children of women with asthma are 10% more likely to have malformations than those of nonasthmatic mothers, large controlled studies have concluded that most asthma medications had no impact on the overall risk for malformations.[108] The exception is cromone exposure, which slightly increases the risk of fetal musculoskeletal malformation.[108] Additional research is needed to determine whether a real risk exists and to guide asthma treatment during pregnancy. Presently, clinical evidence supports pharmacologic asthma control because the fetus is at greater risk from inadequate control of asthma than from asthma medications.[108]

Fetal risks related to maternal asthma depend on the severity of the condition. Controlled asthma carries few risks for the fetus. However, severe or uncontrolled asthma increases the risk for infant death and the incidence of low birth weight, IUGR, preterm birth (possibly influenced by steroid use), and the need for cesarean delivery.[108] Risks are higher in poorly controlled asthma patients.[20] Noncompliance with treatment, respiratory tract infections, allergens and irritants, smoking, gastroesophageal reflux, and exercise can lead to asthma exacerbations.[111]

Cystic fibrosis (CF) was once considered a lethal childhood disease, but the life expectancy of a person with CF has increased, and one study reports that those who had CF in 2000 will have a life expectancy of over 40 years.[62] With careful planning and appropriate medical care, women with CF of childbearing age may conceive and have successful pregnancies with favorable neonatal outcomes, especially if their nutritional state and lung function remain good.[61,132,155] Women with severe disease may be cautioned to avoid conception because there is a risk for significant deterioration during gestation. Women who are positive for *Burkholderia cepacia* in sputum also have a poorer prognosis.[155] Pregnancy in women with CF is likely to be associated with increased health care utilization and more antibiotic use compared with that of nonpregnant women with CF; a high rate of GDM (14%) compared with non-CF pregnancies; and aggressive interventions to ensure weight gain, including the use of total parenteral nutrition for some.[155] Although pregnancy with CF does not increase maternal mortality risk, women with CF have a shorter life span, and therefore their days as a parent may be limited. Twenty percent of mothers with CF will not live to see their child's tenth birthday and for those with severe CF, 40% will have died.

Fetal risks related to CF include prematurity, IUGR, and perinatal death, caused primarily by maternal hypoxemia and infection. Because all infants born to mothers with CF will be heterozygous carriers for CF (at least), genetic counseling and carrier testing of the father are important components of preconceptual care and early prenatal care.[7,155]

Maternal Behavior

Maternal health behavior is an important component of neonatal and childhood health and may even be the single most important factor for the overall health of a child.[117, 136] Health

behaviors evaluated here are smoking, substance abuse, and nutrition, but other maternal behaviors also influence pregnancy outcomes, such as sleep patterns and exercise. Appropriate preconceptual and prenatal counseling regarding maternal health behaviors can help optimize neonatal health.[117,135]

SMOKING

According to the latest Pregnancy Risk Assessment and Monitoring System (PRAMS) data, 10% of women in the United States smoked during the last 3 months of pregnancy.[22,39,98] Of women who smoked 3 months before pregnancy, 55% quit during pregnancy, and 40% of those who quit during pregnancy resumed smoking within 6 months after delivery.[39] Smoking during pregnancy is an even bigger problem globally.[99] **Maternal smoking during pregnancy is a risk factor for stillbirth, IUGR, placental abruption, placenta previa, PROM, and preterm labor.[22,43]** Mothers with pregestational diabetes who also smoke have an increased risk of congenital anomalies and preterm birth.[32] **Long-term effects include childhood obstructive airway disease, sudden infant death syndrome (SIDS), neurodevelopmental abnormalities (i.e., movement, eating, developmental disorders, and attention-deficit/hyperactivity disorder), early puberty in both boys and girls, and childhood cancer,[22,33,43,72] and concerns about exposure to secondhand smoke continue to escalate.** The exact mechanism by which fetal growth is restricted or fetal health is compromised is not entirely clear; reduced uterine artery blood flow, reduced placental blood flow resulting from vasoconstriction of smaller fetal capillaries in the placental capillary bed, elevated nicotine and carbon monoxide levels, and chronic fetal hypoxia all may play a role. Fetal risk increases with the number of cigarettes smoked, maternal anemia, and poor nutrition.[120] Complications of fetal growth are the most common issues of infants born to smoking mothers. These neonates are at increased risk for low-birthweight birth (<2500 g) and preterm birth, which is both dose-dependent and time-specific.[22] **The babies of smokers may undergo withdrawal-like symptoms manifested by jittery movements, and may be more difficult to soothe.[120]**

Eliminating or reducing smoking, especially by the end of the first trimester, can improve fetal growth and health. Smoking cessation programs consistently implemented during prenatal visits have been shown to significantly improve smoking cessation rates.[34] Smoking cessation during pregnancy must be a major priority in counseling women preconceptually and prenatally because these are times when women may be most receptive to quitting because of a strong desire for a healthy pregnancy and baby.[34] A recent systematic review of digital interventions for smoking cessation during pregnancy found that text messaging and computer-based interventions were the most effective platforms.[71] Nicotine replacement therapy (NRT) may increase smoking cessation rates, but a systematic review cites evidence that when potentially-biased and non-placebo randomized controlled trials (RCTs) are excluded, NRT is no more effective than placebo.[46] Only one trial followed infants after birth and found that NRT promotes healthy developmental outcomes.[47]

SUBSTANCE ABUSE

Prenatal substance abuse rates vary greatly; however, it is estimated that about 11% of childbearing women have used illegal substances.[120] There is a strong association between maternal smoking during pregnancy and use of other substances including cannabis, opioids, cocaine, amphetamines, tricyclic antidepressants, and benzodiazepines.[118] **Use of drugs and alcohol by the mother places the fetus and newborn at risk for a plethora of structural, functional, and developmental problems.** Perinatal morbidity is related to the direct effects of the abused substance on the developing fetus, its sudden withdrawal, the interactions of multiple abused substances, the nutritional effects of addiction on the mother, and the social and health care implications of substance abuse.[80,120]

Alcohol is one of the most commonly abused substances during pregnancy. Although known to be a teratogen since the 1970s, about 40% of women in the United States drink some alcohol during pregnancy, and about 1% to 5% drink heavily throughout pregnancy.[88] Alcohol in the maternal circulation crosses the placenta, resulting in direct fetal exposure to alcohol and its metabolites.[88] **There may be a wide range of effects on the exposed fetus; these include developmental and behavioral abnormalities, spontaneous abortion, stillbirth, craniofacial malformations, growth restriction, preterm birth, CNS dysfunction, and organ or joint abnormalities.[83,89]** The mechanism of fetal injury is not entirely clear but is likely related to

three main factors: a teratogenic effect, hypoxia as a result of increased oxygen consumption, and a diminished ability to use amino acids in protein synthesis.[37] The expression of fetal alcohol effects ranges from subtle to extreme and depends on the timing of exposure, the dose, and the genetic response of the mother and fetus to the effects of alcohol. Secondary factors, such as maternal age, nutritional status, general health, and the effects of other abused substances also may influence outcome.[75,117]

When the more severe effects are exhibited, the condition is known as ***fetal alcohol syndrome (FAS).*** **FAS is characterized by growth restriction; physical dysmorphic features, including facial anomalies (small palpebral fissures, low nasal bridge, indistinct philtrum, thin upper lip, shortened lower jaw); and neurologic dysfunction, including mental retardation and neurodevelopmental deficits.[83] Other physical abnormalities involve the heart, skeletal system, and ears. *Fetal alcohol spectrum disorders (FASD)* is an umbrella term for FAS and other less physically noticeable yet long-term effects of alcohol exposure on the fetus.[37] Infants with FASD also may exhibit problems with suck, tremors, irritability, and hypertonus related to alcohol withdrawal.** Continued abnormalities in motor, behavioral, and intellectual development often persist into childhood. Safe levels of alcohol intake have not been established; therefore women should be advised to avoid alcohol intake during pregnancy.

Chemical dependency in pregnancy is a complex problem and creates a high-risk patient. The mother's reporting of drug use often is unreliable; frequently, more than one substance is involved, and there may be a cycle of drug use and periodic abstinence during pregnancy. In addition, a host of medical and social problems are associated with maternal drug abuse. Substance abusers generally have poor health; infectious diseases, such as pneumonia, sexually transmitted diseases (including human immunodeficiency virus [HIV] infection and acquired immunodeficiency syndrome [AIDS]), urinary tract infections, and hepatitis are common.[24,80,120] Nutrition and prenatal care often are inadequate; anemia frequently is seen. These factors contribute to a poor pregnancy outcome and make it difficult to isolate the effects of any one drug on the fetus. However, several generalizations can be made. The majority of drugs used by the mother, including opiates (e.g., methadone, heroin), barbiturates, and sedative-hypnotic drugs, cross the placenta and affect the fetus. **Fetal risks include growth restriction, malformations, intrauterine demise, prematurity, asphyxia, CNS dysfunction, and neurobehavioral abnormalities. Fetal drug dependence does occur and is associated with neonatal abstinence syndrome (NAS), which is manifested by CNS irritability and vasomotor, metabolic, respiratory, and gastrointestinal dysfunction[120] (see Chapter 11).**

Marijuana (cannabis) is the most commonly used illicit drug during pregnancy.[34] With legalization of marijuana in many states in the United States, about 1 in 20 pregnant women report using marijuana.[151] Perinatal effects of marijuana use on the fetus/newborn include low birth weight and preterm delivery, which is attributable to concomitant tobacco and other substance use,[41,48] altered neurobehavior/sleep, and minimal alteration on motor development.[163] Long-term effects include altered attention/executive function, academic achievement, and behavior.[163] Recommendations are to cease marijuana use during pregnancy and lactation.[17,131]

Cocaine use by the mother merits special attention. Cocaine is a CNS stimulant that produces vasoconstriction, tachycardia, and hypertension in both the mother and the fetus. **Its use during pregnancy has been linked to IUGR, smaller head circumference, genitourinary tract anomalies, placental abruption, stillbirth, RDS, congenital infection, NAS, and cerebral infarcts, as well as impaired performance as measured with the Brazelton behavioral assessment tool.[38]**

All prenatal care providers should thoroughly assess pregnant women for alcohol and substance abuse at each prenatal visit, and treatment interventions should be initiated when abuse is identified. Toxicology screening of maternal blood or urine can verify suspicions of abuse; however, universal screening is not currently recommended. **Neonatal urine or meconium screening can provide an accurate indication of exposure when there are clinical indications of drug effect.** Laws in some states consider prenatal drug exposure to be a form of child abuse; thus the practitioner may be required to report positive drug tests in pregnant women or their newborns (see Chapter 11 for a complete discussion of complications in drug-exposed neonates).

MATERNAL NUTRITION, MALNUTRITION, AND OBESITY

Maternal nutritional status and placental function during pregnancy can significantly influence the growth, development, and health of the fetus and newborn. Nutritional problems that interfere with fetal cell division (increases in cell number) can have permanent consequences. If the fetus is at a stage in which cells are only enlarging (increases in cell size), nutritional deficits may be reversed if a healthy maternal dietary intake is resumed soon enough in the pregnancy. All women presenting for prenatal care should be questioned about their usual dietary intake and should have their weight and height assessed so that body mass index (BMI) can be determined and appropriate nutrition counseling initiated.[138] BMI can be calculated by dividing a woman's prepregnancy weight in kilograms by her height in meters squared; it is the most frequently used single tool in determining obesity. If a woman's prepregnancy weight is unknown, the value obtained at the first prenatal visit should be used. Although the BMI values for classification vary, the Institute of Medicine (IOM) employs the relative weight classification and prepregnancy BMI values as follows[86]:

- Underweight: less than 18.5
- Healthy weight: 18.5 to 24.9
- Overweight: 25 to 29.9
- Obese: greater than or equal to 30

Optimal ranges for weight gain in singleton pregnancies are also based on the IOM recommendations. As a general rule, weight gain should be as follows: underweight women should gain 28 to 40 lb; normal-weight women, 25 to 35 lb; overweight women, 15 to 25 lb; obese women, 11 to 20 lb. The optimal weight gain for women carrying twins is 35 to 45 lb.[86] The IOM guidelines are continually being evaluated, but at least one study confirms that following these guidelines can improve pregnancy outcomes. However, fewer than one-half of women gain the recommended weight during pregnancy, with 43.3% of women gaining above the IOM guidelines.[147] Excessive weight gain in obese women is highly associated with an increased risk of emergency cesarean delivery.[96] A recent study found that the strongest predictor of pregnancy outcome was the amount of gestational weight gain rather than the presence of GDM.[27] Excessive gestational weight gain is an independent factor for fetal macrosomia and birth at less than 37 weeks.

Prenatal nutrition involves more than appropriate weight gain; a variety of healthy foods should be consumed, providing essential nutrients.[169] The dietary reference intakes increase for most nutrients during pregnancy. Protein, iron, vitamin A, and iodine requirements nearly double, yet some nutrient requirements do not change much.[157] Other maternal factors that should be considered when counseling women on nutrition include age, parity, preconceptual nutritional status, preexisting medical conditions, current medical conditions complicating the pregnancy, food likes and dislikes, and cultural influences. Each woman's counseling should be individualized, and referral to a nutrition specialist and other medical specialists may be indicated.

Malnourished and underweight mothers have more perinatal losses and preterm births, and their newborns have lower Apgar scores and more frequently are of low birth weight (<2500 g). This is especially true of significantly underweight women (low BMI) and women with eating disorders, such as anorexia and bulimia, who fail to gain adequate weight during pregnancy.[119,166] SGA newborns, defined as below the 10th percentile birth weight for gestational age, have higher mortality rates in the perinatal period and are at risk for later problems, such as insulin resistance and poor school performance.[166] However, it may be difficult to draw direct correlations between inadequate maternal diet and fetal growth unless the nutritional disturbances are severe. Many fetuses grow well despite suboptimal maternal nutrition, in part because of the complexities of placental transport and the ability of the fetus to be preferentially supplied with some nutrients.

Although reduced birth weight is associated with inadequate carbohydrate, protein, and total caloric intake, inappropriate amounts of other nutrients may also affect the fetus. Vitamin and mineral deficiencies have been linked to miscarriage and stillbirth, congestive heart failure (thiamine), megaloblastic anemia (folic acid, vitamin B_{12}), congenital anomalies, including neural tube defects (folic acid, zinc, copper), and skeletal abnormalities (vitamin D, calcium).[49,65,158]

Recently, a plethora of evidence has been published about the impact of maternal vitamin D deficiency and an association with poor pregnancy outcomes such as preterm birth, preeclampsia, GDM, perinatal depression, SGA infants, and asthma symptoms in

offspring.[138] However, RCTs of vitamin D supplementation to improve perinatal outcomes has resulted in conflicting evidence because of a lack of consistency with dosing regimens and differing gestational ages when supplementation was initiated. One important result of the multiple meta-analyses that have been published about vitamin D supplementation in pregnancy is that there were no incidences of vitamin D toxicity despite using doses as high as 200,000 units intramuscular injection.[138]

Women who become pregnant after surgery are at increased risk for nutritional deficiencies and require close monitoring.[97,149] The current guidelines from the American College of Obstetricians and Gynecologists (ACOG),[9] the American Society of Metabolic and Bariatric Surgery, the Obesity Society, and the American Association of Clinical Endocrinology[110] recommend delaying pregnancy for at a minimum of 12 to 18 months after bariatric surgery.[97] Recent meta-analysis shows a decreased risk of GDM, large-for-gestational-age (LGA) infants, gestational hypertension, all hypertensive disorders, postpartum hemorrhage, and cesarean delivery rates in pregnant women after bariatric surgery.[97] However, there is an increased risk of SGA infants, IUGR, and preterm birth after bariatric surgery.

Obesity is not only an epidemic in the United States and other developed countries, but is a major problem globally.[21,171] Public health officials now cite obesity as the leading health problem confronting women today. Obesity is a complex problem resulting from a combination of genetic, cultural, behavioral, socioeconomic, and environmental influences. Obesity affects all organ systems and contributes to a multitude of physiologic complications, such as cardiovascular disease, GDM, infections, preeclampsia, and other adverse perinatal outcomes.[116,171]

Approximately 30% of pregnant women are obese (BMI ≥30) and at risk for perinatal complications.[116] Overweight, obese, and morbidly obese women (BMI >40) are at risk for chorioamnionitis, preeclampsia, stillbirth, cesarean delivery, instrumental delivery, postpartum hemorrhage, perineal lacerations, and prolonged hospital stay.[21,171] **Their offspring may suffer macrosomia, shoulder dystocia, meconium aspiration, fetal distress, preterm birth, early neonatal death, abnormal labor, complications from cesarean birth, birth defects, and higher risk of admission to the NICU.**[116,171] A 1% decrease in the number of obese pregnant women in the United States would result in 16,000 fewer cesarean births per year.[44]

In addition, obese women may be struggling with associated psychosocial problems, such as poor self-esteem, guilt about weight, depression, and ridicule from family and others. Some may not seek prenatal care until pregnancy is well into the second or third trimester. Thus obese women should be considered at high risk for childbearing complications, and these women and their fetus/newborn should be monitored closely throughout gestation and the perinatal period. Preconception or early pregnancy dietary counseling, taking into account the increased risk of GDM for women with obesity, and promoting routine exercise and sleep hygiene can improve maternal health and pregnancy outcomes. Women with obesity are less likely to stay within the gestational weight gain recommendations, yet staying within weight gain guidelines promotes normal birth weight (appropriate for gestational age) and improves perinatal outcomes.[116]

In conclusion, maternal health behavior, including smoking, problems with nutrition, and drug use, before and during pregnancy is associated with adverse outcomes for the newborn and also long-term health risks of the newborn well into adulthood. Supportive, informed prenatal care for pregnant women at risk is essential to improved newborn health.

Obstetric Complications

ANTEPARTUM BLEEDING

Maternal cardiovascular support is crucial to fetal well-being. Chronic blood loss can lead to maternal anemia and a related decrease in oxygen-carrying capacity. Uncompensated acute bleeding results in diminished blood volume, decreased systolic pressure, decreased cardiac output, and ultimately decreased placental perfusion. The net effect on the fetus is decreased oxygenation and impaired nutrient delivery.

Gestational bleeding in the first or second trimester of pregnancy has been linked to increased risk of preterm labor, preterm birth, PROM, and low birth weight.[42] The most common causes of hemorrhage late in pregnancy include placental abruption and placenta previa. The incidence of placental abruption is approximately 1%,[19] and it is more common in older pregnant

women.[46] In an abruption, a normally implanted placenta separates from the uterine wall before the time of delivery, resulting in maternal bleeding and a functional decrease in uteroplacental size. A relationship between hypertensive disorders, cocaine use, and cigarette smoking and an increased incidence of abruptions has been reported.[51] In those with preterm rupture of membranes, the incidence of placental abruption is 2% to 5%.[14] In the presence of an intrauterine infection, the relative risk increases ninefold. The separation may be partial or complete, involving peripheral and/or central portions of the placenta. **Fetal compromise relates to the extent of the separation and to the frequent need for preterm delivery.** When the abruption is small and bleeding is minimal, the pregnancy may continue without significant fetal compromise; however, remember that the decrease in uteroplacental surface area is irreversible and reduces the absolute placental capability. As the fetus grows or experiences additional stressors, its ability to tolerate the abruption may change. Extensive abruptions are poorly tolerated by both the fetus and mother; the resulting maternal hemorrhage and decreased placental function lead to fetal asphyxia and, without immediate intervention, to intrauterine demise.

A ***placenta previa*** exists when the placenta lies abnormally low in the uterus and to some extent covers or encroaches on the internal cervical os. In the latter part of pregnancy, the normal elongation of the lower uterine segment and changes in the cervix disrupt the attachment of the overlying placenta. This generally presents as episodic, painless maternal bleeding, often accompanied by preterm labor. To avoid active labor with resulting maternal hemorrhage, fetal lung maturity is assessed at 36 to 37 weeks.[28] If the lungs are sufficiently mature, a cesarean delivery is scheduled before the onset of labor. Multiparity, maternal age, prior intrauterine operations (≥3), and cigarette smoking are risk factors for placental previa.[46,63,133] **Fetal compromise relates to the extent of the previa, severity of maternal hemorrhage, degree of the resulting fetal hypoxia, degree of impaired fetal growth, and gestational age at delivery.[51,130]**

Other placental abnormalities leading to antepartum bleeding include velamentous insertion and vasa previa. A ***vasa previa*** occurs when naked fetal vessels traverse the cervical os below the level of the fetal presenting part; it is associated with a high perinatal mortality rate. A ***velamentous insertion*** is defined as the insertion of the umbilical cord into the chorioamnionic membranes rather than the mass of the placenta. These unprotected cord vessels have a higher rate of rupture. Rupture requires emergency cesarean delivery to prevent fetal demise and maternal hemorrhage. Antenatal diagnosis of vasa previa and velamentous insertion with ultrasonography enables hospitalization in the third trimester with planned delivery before the onset of labor.[31]

HYPERTENSIVE DISORDERS OF PREGNANCY

Chronic hypertension in pregnancy, defined as hypertension diagnosed before pregnancy or before 20 weeks of gestation, complicates 1% to 6% of births in the United States each year. **Chronic hypertension is associated with IUGR, preterm birth, placental abruption, and stillbirth.[51]** The degree of fetal compromise is related to the duration, degree, and control of maternal hypertension.[51] Women with chronic hypertension have a 25% risk for developing superimposed preeclampsia.[51,135]

Gestational hypertension was defined by the Working Group on Research on Hypertension in Pregnancy as hypertension arising after 20 weeks in the absence of proteinuria.[135]

Preeclampsia, a type of pregnancy-induced hypertension, is a condition in which hypertension, accompanied by proteinuria and edema, develops during the second half of pregnancy in women with or without preexisting hypertensive disease. It is most common in primigravidae, obese women, and women with multiple gestations and molar pregnancies, family history of preeclampsia, and history of pregestational diabetes mellitus.[51] As a perinatal complication, preeclampsia is significant because of its high toll in terms of both maternal and fetal well-being.

Pregnancy is normally associated with vasodilation and decreased peripheral vascular resistance. The net effect is that, even though there is a significant increase in blood volume, maternal blood pressure does not increase during pregnancy. In contrast, pregnancy-induced hypertension is associated with vasoconstriction and an increase in peripheral vascular resistance and arterial pressure. The result is a reduction in blood flow to the vital organs, including the kidney, liver, brain, and uterus; reduced maternal blood volume; and a host of maternal hepatic, CNS, and coagulation

abnormalities. **Associated fetal and neonatal risks include IUGR, prematurity with all of its attendant problems, perinatal asphyxia, and perinatal death.** The risk to the infant increases with earlier onset and increasingly severe maternal disease, such as chronic hypertension with superimposed preeclampsia. **Maternal seizures (eclampsia) further compromise the fetus by promoting hypoxemia and acidosis, which can result in intrauterine demise.**

HELLP syndrome, a severe form of pregnancy-induced hypertension manifested by hemolysis, elevated liver enzymes, low platelets, and renal function abnormalities, carries a high risk for fetal and maternal death. In many cases of HELLP syndrome, immediate delivery is indicated regardless of the gestational age of the fetus.[51] The use of steroids in HELLP syndrome has been shown to improve maternal oliguria, mean arterial pressure, mean increase in platelet count, mean increase in urinary output, and liver enzyme elevations. However, no evidence suggests an improvement in maternal and perinatal mortality or morbidity rates with the use of maternal corticosteroids except with regard to improvement in fetal lung maturity.[51]

Drugs commonly used to treat pregnancy-induced hypertension include magnesium sulfate, hydralazine, labetalol, nifedipine, and other antihypertensive agents. Magnesium sulfate is the most commonly used agent in the United States for the prevention of maternal seizures and has been shown to be more effective than other regimens.[51]

Hypotonia and CNS depression have been reported as neonatal side effects, but magnesium therapy appears to be safe for the fetus.[150] Hypotonia and CNS depression are more likely the result of coexisting complications, such as prematurity and asphyxia. Hydralazine and other antihypertensives are used in the treatment of severe maternal hypertension; actions include relaxation of the arterial bed, decreased vascular resistance, and decreased blood pressure. Maternal response to antihypertensives must be monitored carefully, because precipitous decreases in blood pressure reduce placental perfusion and further compromise the fetus.

INFECTION

Group B streptococcus (GBS) is a major cause of sepsis, meningitis, and death among newborn infants. It is estimated that 10% to 30% of all pregnant women are colonized with GBS in the vagina or rectum. The ACOG Committee on Obstetric Practice now recommends "vaginal or rectal group B streptococci screening cultures at 35 to 37 weeks of gestation for all pregnant women." Treatment for women with a positive culture, GBS bacteriuria in the current pregnancy, or a previously GBS-infected infant is usually penicillin.[6]

PRETERM LABOR

Preterm birth, **defined as any birth before 37 weeks of gestation, poses an unparalleled threat to neonatal survival and well-being. In the United States, 12% of all births are preterm, and prematurity accounts for 70% of all neonatal deaths.[15]** Its cost, both human and economic, is staggering, and its prevention is a primary focus of modern obstetric care. Prevention is best accomplished through an aggressive effort to identify women at risk and close follow-up to achieve early recognition and appropriate intervention should preterm labor occur. Unfortunately, many women continue to receive inadequate prenatal care or no care at all. Even women who obtain early and ongoing care often fail to recognize the signs of preterm labor and delay reporting symptoms until intervention becomes difficult if not impossible.[51]

Risk assessment markers in clinical use today include an extensive review of obstetric, social, and medical history.[51] Measurements of cervical length remain controversial. There are proponents of universal cervical length screening in those women with no history of prior preterm birth. Applying universal screening of cervical length presents the difficulties of patient access and the potential for unnecessary intervention. While the choice of universal screening in a low-risk population is left up to the discretion of the prenatal provider, if an incidentally short cervix is noted at the time of the second-trimester ultrasound examination, subsequent evaluation is necessary.[12]

Fetal fibronectin is a glycoprotein secreted by fetal membranes. Its presence in cervical-vaginal secretions between 22 and 35 weeks of gestation has been associated with an increased risk for preterm labor and delivery. Its absence (high negative predictive value) can be used to identify patients who are at low risk for preterm delivery. ***Cervical length*** is assessed by three consecutive measurements using transvaginal ultrasonography. The average length of the cervix varies with gestational change but

is approximately 4 cm in length from 26 weeks. Length of cervix has been inversely correlated with risk for preterm birth. Thus a combination of fetal fibronectin and cervical length may be used to assess the risk for preterm delivery for a given patient.[52]

Depending on onset of short cervix in pregnancy, cervical cerclage, intramuscular progesterone (17-hydroxyprogesterone caproate), and vaginal progesterone have been used to prevent preterm labor with encouraging success.[29,142] A recent systematic review and meta-analysis of RCTs of vaginal versus intramuscular progesterone found that daily vaginal progesterone, begun at 16 weeks of gestation, is a reasonable, if not better alternative for the prevention of recurrent spontaneous preterm, singleton birth.[142] However, the quality of the research data was evaluated as low or very low *grade,* indicating that the true effect may be different from the estimate of effect in the three RCTs included in the meta-analysis.[142] More recent studies found differing outcomes based on the types of progesterone used[95,145] and that vaginal progesterone was not associated with an increase in GDM risk.[172] The Ohio Perinatal Quality Collaborative launched a statewide initiative to reduce premature births by 10% by promoting progesterone prophylaxis and achieved a 13% reduction in births before 32 weeks in women with prior preterm birth.[85]

Even though there has been some conflicting evidence showing efficacy of intramuscular progesterone, it is still recommended for use in women with risk factors for preterm birth.[95] Evidence supports the use of vaginal progesterone for women with short cervix and no prior history of preterm delivery and early cerclage with short cervix and history of preterm delivery.

Although in many specific instances a definitive cause cannot be identified, it is possible to identify several factors that generally are associated with preterm labor and delivery.[12] **When preterm labor cannot be halted, it culminates in the delivery of a physiologically immature infant. The result is a host of neonatal problems that relate largely to the degree of immaturity** and also to compounding problems, such as infant anomalies or maternal disease, and to the events that led to the preterm delivery (e.g., asphyxia resulting from a bleeding placenta previa). **Problems commonly encountered in preterm infants include respiratory distress, asphyxia, hyperbilirubinemia, metabolic disturbances, fluid and electrolyte imbalances, neurologic and behavioral problems, infection, nutritional deficits and feeding problems, ineffective thermoregulation, cardiovascular disturbances, chronic respiratory disease, and hematologic disturbances.**

Beta-sympathomimetic agents are sometimes used to prolong pregnancy in women having uterine contractions but no sign of infection. Mothers may experience tachycardia and dysrhythmias, hyperglycemia, hypokalemia, anxiety, nausea, and vomiting. Myocardial ischemia and pulmonary edema are rare but serious maternal side effects. The fetus also may develop tachycardia and hyperglycemia. **Neonates born after beta-sympathomimetic therapy may develop a rebound hypoglycemia in response to in utero hyperglycemia and overproduction of insulin. Beta-sympathomimetic tocolytic agents increase fetal aortic blood flow and fetal cardiac output that might increase fetal systolic pressure and cerebral blood flow, which can lead to an increased incidence of intracranial bleeding in immature fetal brains.** More recent studies show lower risk of side effects and improved prolongation of pregnancy from nifedipine compared with beta-sympathomimetic tocolytics (see paragraph on calcium channel blockers later).[87]

Magnesium sulfate has also been employed as a tocolytic. Magnesium sulfate decreases muscle contractility, thereby inhibiting uterine activity and effectively interrupting preterm labor. **Neonatal consequences of maternal magnesium administration include decreased muscle tone and drowsiness, as well as decreases in serum calcium level.[92]** Serious maternal complications can occur with concomitant usage of beta-adrenergic receptor agonists or calcium channel blockers.[12] Antenatal administration of magnesium sulfate for neuroprotection of the preterm fetus, especially related to gross motor function, is well established.[55,58,146]

Prostaglandins play an important role in the onset of labor. *Prostaglandin synthetase inhibitors,* such as indomethacin, are a class of pharmacologic agents that interfere with the body's synthesis of prostaglandin, thereby inhibiting prostaglandin-mediated uterine contractions. These drugs have been used to treat preterm labor. They can cause in utero constriction, or closure, of the ductus arteriosus with resulting development of fetal pulmonary hypertension and congestive heart

failure. They also may lead to **oligohydramnios and must be used with caution, especially late in the third trimester. Other neonatal risks include decreased platelet activity and gastrointestinal irritation.**[92] Use of cyclooxygenase (COX-2) inhibitors in preterm labor treatment is being investigated.[100]

Calcium channel blockers, such as nifedipine, also have a demonstrated ability to interfere with the labor process. Uterine contractility is directly related to the presence of free calcium. Increased calcium concentration enhances muscle contractility, whereas decreased calcium levels inhibit contractility. Calcium antagonists block the entry of calcium into cells and inhibit uterine muscle contraction. In animal studies, these drugs have been associated with fetal acidosis. **However, lower umbilical artery pH values or lower Apgar scores have not been associated with nifedipine.**[92]

Corticosteroid treatment of pregnant women who are at sufficient risk to deliver prematurely was first introduced in 1972 to enhance fetal lung maturity. Human studies suggested possible benefits in reduction of the incidence and severity of RDS and the incidence of patent ductus arteriosus. **Little or no evidence supported a reduction in mortality rate or in the incidence of intraventricular hemorrhage, chronic lung disease, sepsis, necrotizing enterocolitis, or retinopathy of prematurity with repeated antenatal corticosteroid therapy. Some of the suggested fetal risks of repeated antenatal corticosteroid therapy include decreased somatic and brain growth, adrenal suppression, neonatal sepsis, chronic lung disease, and death.** All pregnant women between 24 and 34 weeks of gestation who are at risk for preterm delivery within 7 days should be considered candidates for antenatal treatment with a single course, such as 2 × 12 mg of betamethasone administered intramuscularly, within 24 hours. Recent data have also shown that administration of betamethasone in the late preterm period between 34 and 38 weeks of gestation is associated with decreased neonatal respiratory complications.[12] **The evidence to date is clearly against the routine administration of multiple antenatal steroid courses.**[16,134] **The latest ACOG** practice **bulletin recommends a single repeat course of antenatal corticosteroids for women: (1) who are less than** $^{36}/_{7}$ **weeks of gestation, (2) who are at risk of preterm delivery within 7 days, and (3) whose prior course of antenatal steroids was more than 14 days previously.**[16]

ENVIRONMENTAL EFFECTS OF LABOR ON THE FETUS

Effects of Contractions

During labor, the dynamics of uterine contractions alter the intrauterine environment and influence the fetus. **A "healthy" fetus is equipped to withstand the challenge of labor, but when the fetus is compromised or the labor is dysfunctional, the fetus can be taxed beyond its capacity, placing it at risk for further compromise, asphyxia, or intrauterine death.**

Strong uterine contractions are characterized by decreased blood flow through the intervillous spaces in the placenta. As blood flow decreases, a corresponding decline in placental gas exchange occurs and the fetus must depend on its existing reserves to maintain oxygenation until placental blood flow is reestablished. The net effect is that fetal Pao_2 decreases as the consequence of uterine contraction. In the fetus with adequate reserves, the fall in Pao_2 is not drastic; the fetus remains adequately oxygenated and so can tolerate the stress of labor.

Fetal Reserve

The factors that influence fetal reserves fall into two general categories: those that diminish reserves and those that exhaust reserves. When fetal oxygen reserves are diminished, the fetus has less-than-optimal oxygenation at the onset of a contraction. This may occur as a consequence of any condition that decreases placental exchange, including reduced placental surface area caused by abruption, placenta previa, an abnormally small placenta, decreased placental perfusion caused by maternal hypotension or hypertension, or maternal hypoxemia. Oxygen reserves can be diminished also as a result of a reduction in fetal oxygen-carrying capacity, as in severe anemia or acute fetal hemorrhage.[88]

A fetal reserve that is adequate at the onset of labor can be exhausted by factors that place unusual demands on the fetus. Exhaustion of

reserves occurs with contractions that last for a prolonged period, are of extremely high intensity, or occur with increased frequency and without an adequate recovery period between individual contractions.[88] This is often a consequence of the use of oxytocic agents to induce or augment labor.

Determination of cord gases at delivery provides objective evidence of the fetal metabolic state at the time of birth.[51] A base excess of less than or equal to 12 mmol/L generally is defined as the threshold that may be associated with hypoxic injury.[124,137] Fetal pulse oximetry may also be used. Decreased fetal pulse oximetry values, especially prolonged and recurrent recordings less than 30%, are correlated with abnormal fetal heart rate patterns, indicating an association with fetal compromise and metabolic acidosis.[153] However, a systematic review found that the addition of fetal pulse oximetry does not reduce and may increase the caesarean delivery rate and that a better method to assess fetal well-being in labor is needed.[60]

Fetal Response to Contraction-Induced Hypoxia

When the fetal oxygen reserve is diminished or exhausted, uterine contractions can precipitate a significant fall in Pa_{O_2}. The fetus is quite limited in its ability to compensate for this hypoxemia. The adult mechanism, which involves increasing total cardiac output by increasing heart rate, does not play a major role in the fetal response. **Instead, the fetus responds with a redistribution of cardiac output as a means of maintaining critical function; blood flow to the brain and heart increases, whereas perfusion of less critical organs is reduced.[10]** This mechanism enables the fetus to survive brief episodes of hypoxia, but severe and prolonged hypoxic episodes are poorly tolerated.

Acute hypoxemia leads to the development of acidosis and also produces a reflex bradycardia as a result of vagal stimulation, both of which further compromise fetal oxygenation. In addition, myocardial hypoxia has a direct bradycardic effect.[10] These mechanisms give rise to one of the classic signs of fetal distress, the late deceleration, in which the peak of uterine pressure, which also represents the nadir of intervillous blood flow and the onset of fetal hypoxemia, is followed by a decline in fetal heart rate. Late decelerations are significant in that they help identify the fetus who cannot tolerate labor because of inadequate oxygen reserves and they allow for the implementation of measures to enhance fetal reserve, improve placental perfusion, or interrupt labor.[168]

***Late decelerations* are particularly ominous when accompanied by loss of fetal heart rate variability and/or fetal baseline tachycardia, because these findings are indicative of fetal acidosis.** In the preterm infant, the findings of decreased variability and tachycardia, with or without late decelerations, correlate highly with acidosis, depression, and low Apgar scores.[168]

Other Factors That Evoke a Fetal Response During Labor

HEAD COMPRESSION

Pressure on the fetal head during labor, especially with pushing efforts in the second stage, also produces a vagal response and a reflex slowing of the fetal heart rate. In general, this does not indicate hypoxia or fetal compromise and often is seen in a healthy fetus. The deceleration that accompanies head compression, also called an *early deceleration,* is differentiated from the late deceleration of fetal asphyxia by its timing in relation to a contraction. **In early deceleration, the heart rate begins to fall as a contraction builds, reaching its lowest point as the contraction peaks. As the contraction subsides, the heart rate returns to baseline. The result is a uniformly shaped dip that mirrors the shape of the contraction.** In comparison, **a late deceleration also has a uniform shape but lags behind the contraction, with the fall in heart rate beginning at or slightly after the contraction peak and continuing to fall as the contraction subsides. With a late deceleration, the heart rate does not return to baseline until well after the contraction has ended.**

CORD COMPRESSION

Compression of the umbilical cord occurs when the cord is looped around fetal body parts, when it is knotted or prolapses, or when amniotic fluid is low (oligohydramnios). During labor, cord

compression may be exacerbated by contractions and descent of the fetus, resulting in varying degrees of occlusion of the umbilical vessels and diminution of blood flow. Partial venous occlusion may be manifested by fetal heart rate acceleration, whereas significant occlusion precipitates a rapid fall in heart rate, caused at least in part by vagal reflex. ***Variable decelerations* can be spontaneous, occurring at any time, or periodic, occurring with contractions. They typically have an abrupt descent in heart rate and may be *V*-, *U*-, or *W*-shaped—hence the term *variable deceleration*.** Periodic variable decelerations are identified by a decline in heart rate that generally begins before the contraction peaks but, unlike early decelerations, falls rapidly and does not mirror the shape of the contraction. **Typically, recovery of the heart rate also is rapid. However, when the occlusion is severe or of long duration or if the fetus has diminished oxygen reserves, recovery may be slow, indicating fetal hypoxia and, in essence, incorporating a component of late deceleration within the variable deceleration.**[168]

When variable decelerations are persistent and worsening during labor in the presence of oligohydramnios, intrapartum amnioinfusions have significantly decreased fetal heart rate abnormalities, acidemia at birth, and rates of cesarean delivery.[81] An *amnioinfusion* involves infusion of fluid into the uterine cavity via an intrauterine pressure catheter. This fluid provides cushioning of the umbilical cord, which may reduce the frequency and severity of the cord compression. However, amnioinfusion is no longer standard practice when moderate or thick meconium is present.[18,81]

MATERNAL PAIN MEDICATION

Maternal anesthesia and/or analgesia has the potential to affect the infant, either during labor and delivery or in the newborn period. The risk is increased if the fetus is preterm or is otherwise compromised. This is not to say that there is no place for these drugs in obstetric care—only that they must be used judiciously and with a clear understanding of the risks and benefits involved. Table 2.1 **summarizes the effects of commonly used analgesic and anesthetic agents on the fetus and newborn.**[18,127]

TABLE 2.1 FETAL AND NEONATAL EFFECTS OF MATERNAL ANALGESIA AND ANESTHESIA DURING LABOR

DRUG	POSSIBLE FETAL AND NEONATAL SIDE EFFECTS
Narcotics	Fetal and neonatal effects are related to the dose, route, and timing of maternal administration and may be reversed by the administration of a narcotic antagonist (naloxone): • CNS depression • Fetal bradycardia • Depressed respiratory effort • Decreased muscle tone and reflexes • Decreased responsiveness
Paracervical block	Fetal bradycardia and asphyxia related to decreased uterine blood flow and direct fetal myocardial depression
Epidural and spinal block	Fetal bradycardia and asphyxia related to maternal hypotension Fetal/neonatal toxicity Neonatal respiratory depression after epidural containing fentanyl
General (inhalation) anesthesia	Fetal and newborn effects related to the duration and depth of maternal anesthesia include the following: • CNS depression • Respiratory depression • Decreased responsiveness

CNS, Central nervous system.

ASSESSMENT OF FETAL WELL-BEING

Over the past 30 years, the capability to assess fetal well-being has advanced from simple auscultation of the fetal heart to direct physiologic and biochemical measurement of fetal status. With these advances, an appreciation of the similarities between the fetus and newborn, as well as a more complete understanding of the unique features of fetal life, has been gained. This knowledge reinforces the importance of viewing fetal physiology as a precursor of neonatal function and especially as a significant influence on the success with which the fetus will complete the adaptations required by the birth process.

The goal of antepartum fetal surveillance is to answer the following questions: What is the safest

environment for a fetus at the gestational age at which the testing is taking place? Is the fetus more likely to survive in utero for the week after testing, or does the fetus have a significant risk for in utero death based on the degree of environmental or intrinsic intolerance demonstrated through testing? In the case of preterm infants, this may mean delivery at a gestational age at which there is a high likelihood for respiratory, neurologic, cardiac, gastrointestinal, and immunologic immaturity that will require neonatal intensive care.

The obstetric practitioner has several tools available to help answer the preceding questions. First and foremost is the identification of maternal conditions that may predispose the fetus to in utero compromise. Examples of such conditions include type 1 diabetes mellitus, chronic hypertension, collagen vascular disease, antiphospholipid antibody disease, maternal cardiac or pulmonary disease, preeclampsia, blood group isoimmunization, in utero infection, PROM, and maternal substance abuse. This list is not all-inclusive but demonstrates several commonly encountered conditions for which antepartum fetal surveillance is warranted.

Once the decision is made to assess fetal well-being, four modalities are available in general practice to help the practitioner and patient answer questions about the optimal environment for the fetus at any given time—fetal movement counts, the contraction stress test (CST), the NST, and the fetal biophysical profile. Two additional tools often used by maternal-fetal medicine specialists in certain clinical situations are Doppler flow studies and percutaneous umbilical cord blood sampling (PUBS). None of these tools is used as the sole determinant for delivery; rather, each is used in conjunction with the entire clinical picture. The choice of testing method also is clinically driven; each method is useful in certain clinical settings, but no one method is the correct choice in all situations.

Although most of the procedures used to monitor fetal well-being are decidedly high-tech, the simple "kick count," or *fetal movement survey,* is a low-tech, low-cost screening tool. Many women with an intrauterine fetal demise have no identifiable risk factors that would place them in a fetal testing protocol. **Fetal motor activity reflects the fetal condition in utero, and a decrease in or absence of fetal movements often presages fetal death.** This is one reason that many institutions ask their patients to begin a fetal movement counting protocol at 26 to 32 weeks of gestation. Although there are continuing study results, some centers have demonstrated a significant decrease in the incidence of fetal mortality rates after the institution of a fetal movement counting protocol.

There are several different approaches to fetal movement counting. None has been shown to be superior.[10] One approach is to have the patient choose a certain time every day to rest in the lateral position and count fetal movements. The perception of 10 distinct fetal movements within 2 hours constitutes a reassuring session. The most important aspect of this type of testing is to emphasize to the patient the importance of notifying her practitioner immediately if the fetal movement counting has not met the established criteria. A system must be in place in which patients have immediate access to health care personnel 24 hours per day.

The CST is used in an attempt to evaluate fetal response to uterine contractions.[84] The principle behind the CST is that uterine contractions cause a transient interruption in uteroplacental perfusion. With normal fetal reserve, this intermittent interruption is well tolerated. With inadequate or exhausted reserve, late fetal heart rate decelerations appear. Because late decelerations during labor had been associated with fetal hypoxia and acidosis, it was reasoned that similar interpretations could be applied to contractions induced in the antepartum patient. **Thus the CST is considered a test of uteroplacental reserve.**

During a CST, uterine contraction activity is evoked with either the use of maternal nipple stimulation or an intravenous infusion of oxytocin. The fetal heart rate is charted using graph paper attached to a monitor that uses a continuous wave ultrasound transducer placed on the maternal abdomen over the uterus. The minimum number of spontaneous or evoked contractions necessary for adequate testing is three contractions of 40 seconds' duration in a 10-minute period. The results are interpreted as follows:

- A negative CST result is one in which no late fetal heart rate decelerations occur during the examination.
- In a positive CST result, late decelerations occur after 50% or more of the contractions, even if contraction frequency is fewer than three in 10 minutes.

- A suspicious or equivocal finding is one in which intermittent late or significant variable decelerations occur.
- A CST result is considered unsatisfactory if fewer than three contractions occur per 10 minutes or a poor-quality tracing is obtained.

In many clinical situations, a positive CST warrants delivery of the fetus because of suspected in utero hypoxemia during periods of uterine contraction. However, there are numerous exceptions to this rule. For example, if a positive CST is noted in the presence of maternal diabetic ketoacidosis, a correction of the underlying metabolic process may reverse the fetal acidosis and a negative CST may be obtained subsequently. Thus the delivery of a neonate who has metabolic acidosis and is preterm can be avoided.

The NST is a tool used to indirectly assess the integrity of the fetal autonomic nervous system. The fetal heart is under the dual influences of the sympathetic and parasympathetic nervous systems. By approximately 28 weeks of gestation, 85% of fetuses demonstrate fetal heart rate accelerations in response to fetal movement. Lack of these intermittent fetal heart rate accelerations usually indicates a fetal sleep cycle. However, many other intrinsic and extrinsic factors, including fetal acidosis, may lead to an absence of these intermittent accelerations in heart rate. Examples include but are not limited to medication exposure, maternal smoking, uteroplacental insufficiency, and fetal structural or chromosomal anomalies. Factors leading to maternal acidosis (severe anemia, congenital heart disease, and sepsis) also can result in fetal acidosis and nonreactive NST.

The NST is performed with the patient in a semi-Fowler's or lateral tilt position. As in the CST, the fetal heart rate is monitored with an external transducer. NSTs are interpreted as either reactive or nonreactive. An accepted definition of a reactive NST is an increase in fetal heart rate of 15 beats/min for 15 seconds above the baseline heart rate occurring twice in a 20-minute period.[10] A nonreactive NST is defined as lacking the necessary fetal heart rate accelerations during a 40-minute period. The following may be candidates for nonstress testing:

- Women who have diabetes that must be controlled with medication
- Women who have pregnancy-induced hypertension, preeclampsia, or intrinsic renal disease
- Women in whom fetal IUGR, oligohydramnios, or postdate pregnancy has been determined
- Women who have reported decreased fetal movement

The NST has certain advantages over the CST. It does not entail the production of uterine contractions, and so there are fewer potential problems or contraindications to the NST. Because the NST is quicker and easier to conduct, it is often the first-line screening test of fetal well-being. Its disadvantages are that it does not evaluate uteroplacental reserve and that it has a higher false-positive rate than the CST.

When the NST is nonreactive, an option that is often used in lieu of the CST or delivery of the fetus is the *biophysical profile* (BPP) (Table 2.2). This test combines the NST with real-time ultrasound

TABLE 2.2 BIOPHYSICAL PROFILE SCORING

BIOPHYSICAL VARIABLE	NORMAL (2)	ABNORMAL (0)
Fetal breathing—At least one episode of at least 30 seconds during a 30-minute observation	Present	Absent
Gross body movement—At least three body or limb movements during a 30-minute observation	≥3	≤2
Fetal tone—One episode of extension or flexion of limbs or trunk during a 30-minute observation	Present	Absent
Reactive nonstress test—At least two episodes of 15 beats/min fetal heart rate accelerations during 30-minute observation	Yes	No
Amniotic fluid volume—A pocket of fluid that measures at least 2 cm in two planes perpendicular to each other (2 × 2–cm pocket)	Present	Absent
Normal Score: 8–10		

evaluation of the fetus. Although there are several different BPP scoring systems, the one most generally accepted assigns a numerical score of 0 or 2 for the absence or presence, respectively, of five different parameters: fetal movement, tone, "breathing" movements, amniotic fluid volume, and the NST. One advantage to evaluation of several different fetal biophysical variables is enhanced specificity of testing with a diminished incidence of delivery for false-positive results. The presence or absence of acute markers (movement, tone, breathing, and NST) helps reflect fetal status at the time of testing. However, the absence of a given marker may be difficult to interpret, because it may simply reflect normal periodicity.

The biophysical activities that mature first in fetal development disappear last as acidosis worsens. Fetal tone (flexion and extension) is present at 7½ to 8½ weeks after the last menstrual period. This activity, as well as gross body movement, is mediated in the cortex and nuclei of the CNS. Fetal movement is present by 9 weeks. Fetal breathing movements (i.e., rhythmic breathing movements of 35 seconds or more) can be seen by 20 weeks of gestation. The CNS center responsible for control of this activity is the ventral surface of the fourth ventricle. The final acute marker to mature is fetal heart rate acceleration in response to movement (reactive NST) seen in the later second trimester. The posterior hypothalamus and medulla control this activity. Given that the first marker to appear in development is the last to disappear with worsening fetal acidosis, the absence of fetal tone has been found to be associated with high perinatal morbidity and mortality rates. Chronic sustained fetal hypoxia or acidosis may produce a protective redistribution of cardiac output away from less vital fetal organs (e.g., kidney, lung) toward the essential organs (e.g., brain, heart, adrenal glands). Redistribution of fetal blood flow may be so profound that renal perfusion decreases to the point that oligohydramnios is established. When the largest vertical amniotic fluid pocket within the uterus is less than 1 cm, the perinatal mortality rate is as high as 110 per 1000.[42,78]

A BPP score of 8 or 10 is normal; a score of 6 is equivocal, and the profile should be repeated in 12 to 24 hours. A score of 4 or less is abnormal. Management in the presence of an abnormal BPP depends on the gestational age and the maternal and/or fetal factors contributing to the altered state.

The BPP employs the advantages of real-time ultrasonography to observe fetal behavior.[51] One of its major advantages is as an intermediate step in the evaluation of a fetus with a nonreactive NST before a time-consuming CST is performed. It is also a useful tool for patients with contraindications to the CST, such as premature labor, PROM, placenta previa, malpresentation, unexplained vaginal bleeding, or multiple gestation. The modified BPP, which combines an acute marker (NST) with the chronic marker of fetal well-being (amniotic fluid index [AFI]), has been shown by some centers to be as predictive of fetal well-being as the full BPP. Because evaluation of the AFI is less time-consuming and requires less technical skill, this may be an acceptable alternative for many centers. Finally, it should be noted that though widely used, there is insufficient evidence from RCTs to support the use of BPP as a test of fetal well-being in high-risk pregnancies.[10,51]

No matter which of these testing modalities is used, the patient should be counseled as to the predictive value of a "normal" test. The incidence of stillbirth within 1 week of a reactive NST is 1.9 per 1000; for a negative CST, it is 0.3 per 1000; and for a normal BPP, it is 0.8 per 1000.[10] Although some investigators have reported a decreased incidence of fetal mortality after initiation of a fetal movement counting program for "low-risk" patients,[141] more recent studies have found no difference in perinatal outcomes with fetal movement counting.[54] More controlled studies are needed.[54,104]

The role of *Doppler flow assessment* of the fetal arterial and venous systems in the prediction of in utero well-being is also accepted. Measurement of umbilical artery velocity is used as a method of fetal surveillance for growth-restricted fetuses. Specifically, decreased or absent end-diastolic flow may appear days before conventional antenatal tests become abnormal. In cases such as these, at a minimum, intensive fetal surveillance is advised.[51] **Reversal of diastolic flow is highly predictive of in utero fetal demise within 24 hours and warrants immediate intense investigation or delivery.[51]**

The dramatic improvement in ultrasound image quality over the past 15 years also has made it possible to directly sample fetal blood and tissue. The technique of *percutaneous umbilical blood sampling (PUBS)* has given the obstetrician access to

the fetal circulation with relative safety for both the fetus and mother. In this procedure, real-time ultrasonography is used to guide the insertion of a needle into the umbilical vein or artery. Samples of fetal blood can be obtained, or, as in the case of red cell isoimmunization, transfusions can be carried out. The fetal loss rate is generally quoted as 1% to 2%.[143]

3 PERINATAL TRANSPORT AND LEVELS OF CARE

MARIO AUGUSTO ROJAS, AMANDA FLAHERTY, HEATHER FURLONG BROWN, AND TAMARA RUSH

Perinatal transport is the timely and appropriate transfer of high-risk pregnant mothers to health care facilities in which expertise and resources for optimal care are available to improve mortality and morbidity of both the mother and her fetus. If transfer of the mother is not possible because of risk outweighing potential benefit, the objective then shifts to optimizing delivery, and birth of the high-risk infant. In the latter situation, it is **necessary to have adequately trained professionals to resuscitate and stabilize the infant before his or her transfer to a medical center that has the appropriate expertise and resources.**

For perinatal transport to effectively support high-risk mothers and their fetuses, as well as sick newborn infants, each country, state, or region must identify its perinatal resources with respect to physical and human capabilities. This review should include classification of levels of care and expertise, as well as mapping of resources as they exist within specific geographic areas. **Classification of perinatal resources according to the different levels of care as recommended by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (ACOG) in their *Guidelines for Perinatal Care*[4] will direct organization, identification of resources, and roles of patient referral and retrieval centers, as well as reveal the natural elevation of care within the geographic area of question** (Table 3.1). Historically, regionalization has been recommended as the most effective and cost-efficient use of perinatal resources.* The implementation of this important strategy is subject to qualitative variance depending on the characteristics of the health care system and resources where it is applied. In countries in which universal health care is the norm, regionalization is more easily implemented, whereas in market-driven health care systems in which de-regionalization is predominant, these provisions for care become more challenging.† Whatever the circumstances, perinatal providers must use innovative strategies to maintain regionalization of services and high-quality perinatal transport systems.[25,31]

Because all hospitals cannot provide all levels of perinatal care, interhospital transport of pregnant women and neonates is an essential component of any regional perinatal effort. Women who are at risk for complications and pose significant risk for adverse outcomes or whose neonates are likely to require intensive care support should be considered candidates for referral during the antepartum period.[32] Similarly, it is accepted medical practice to transfer a neonate to a hospital that can provide the services needed or anticipated to be needed if the birth hospital cannot provide that level of sevice.‡

Once resources are identified and classified, a model for integration of perinatal services may be constructed. Strategic planning at this level will direct the design of the organizational structure of the perinatal transport system, including identification of leadership functions, the different member nurseries/units and their roles, and the definition and process for perinatal elevation of care. This integration will then allow for the creation of a system for continuous data collection and analysis, facilitating a systems approach to problem solving and the implementation of quality improvement strategies within the system.[78]

TABLE 3.1 LEVELS OF PERINATAL AND NEONATAL CARE AND THEIR EXPECTED CAPABILITIES*

	PERINATAL CARE	PERSONNEL
	All institutions providing perinatal care should be capable of neonatal resuscitation and stabilization	
Birth Center: Peripartum care of low-risk women with uncomplicated singleton pregnancies with a vertex presentation who are expected to have an uncomplicated birth. Example: Term, singleton, vertex presentation	• Capability and equipment to provide low-risk maternal care and a readiness at all times to initiate emergency procedures to meet unexpected needs of the woman and newborn within the center, and to facilitate transport to an acute setting when necessary • An established agreement with a receiving hospital with policies and procedures for timely transport • Data collection, storage and retrieval • Ability to initiate quality improvement programs that include efforts to maximize patient safety • Medical consultation available at all times	• Every birth attended by at least two professionals: Primary maternal care providers CNMs, CMs, CPMs, and licensed midwives who are legally recognized to practice within the jurisdiction of the birth center; MDs (FPs: Ob-Gyns) • Availability of adequate numbers of qualified professionals with competence in level I criteria and ability to stabilize and transfer high-risk women and newborns
Level 1: Basic Care Care of uncomplicated pregnancies with the ability to detect, stabilize, and initiate management of unanticipated maternal-fetal or neonatal problems that occur during the antepartum, intrapartum, or postpartum period until patient can be transferred to a facility at which specialty maternal care is available. Examples: Any patient appropriate for a birth center plus capable of managing higher-risk conditions such as: • Term twin gestation • Trial of labor after cesarean delivery • Uncomplicated cesarean delivery • Preeclampsia without severe features at term	Ability to begin emergency cesarean delivery within a time interval that best incorporates maternal and fetal risks and benefits with the provision of emergency care • Available support services, including access to obstetric US, laboratory testing, and blood bank support supplies at all times • Protocols and capabilities for massive transfusion, emergency release of blood products, and management of multiple component therapy • Ability to establish formal transfer plans in partnership with a higher-level receiving facility • Ability to initiate education and quality improvement programs to maximize patient safety, and/or collaborate with higher-level facilities to do so	Birth center providers plus • Continuous availability of adequate number of RNs with competence in level I care criteria and ability to stabilize and transfer high-risk women and newborns • Nursing leadership has expertise in perinatal nursing care • Obstetric care provider with privileges to perform emergency cesarean available to attend all deliveries • Anesthesia services available to provide labor analgesia and surgical anesthesia
Level II: Specialty Care Level I facility plus care of appropriate high-risk antepartum, intrapartum, and postpartum conditions, both directly and admitted and transferred from another facility. Examples: Any patient appropriate for level I care, plus higher-risk conditions such as: • Severe preeclampsia	Level I facility capabilities plus • CT scan and ideally MRI with interpretation available	Level I facility providers plus • Continuous availability of adequate numbers of RNs with competence in level II care criteria and ability to stabilize and transfer high-risk women and newborns who exceed level II criteria

TABLE 3.1 LEVELS OF PERINATAL AND NEONATAL CARE AND THEIR EXPECTED CAPABILITIES* — cont'd

	PERINATAL CARE	PERSONNEL
• Placenta previa with no prior uterine surgery	• Basic US services for maternal and fetal assessment • Special equipment needed to accommodate the care and services needed for obese women	• Nursing leadership and staff have formal training and experience in the provision of perinatal nursing care and should coordinate with respective neonatal care services • Ob-Gyn available at all times • Director of obstetric services is a board-certified Ob-Gyn with special interest and experience in obstetric care • MFM available for consultation on-site, by telephone, or by telemedicine, as needed • Anesthesia services available at all times to provide labor analgesia and surgical anesthesia • Board-certified anesthesiologist with special training or experience in obstetric anesthesia available for consultation • Medical and surgical consultants available to stabilize obstetric patients who have been admitted to the facility or transferred from other facilities
Level III: Subspecialty care Level II facility plus care of more complex maternal conditions, obstetric complications, and fetal conditions. Examples: Any patient appropriate for level II care, plus higher-risk conditions such as: • Suspected placenta accreta or placenta previa with prior uterine surgery • Suspected placenta percreta • ARDS • Expectant management of early severe preeclampsia at less than 34 weeks of gestation	Level II capabilities plus • Advanced imaging services available at all times • Ability to assist level I and II centers with quality improvement and safety programs • Provide perinatal system leadership if acting as a regional center in areas where level IV facilities are not available • Medical and surgical ICUs accept pregnant women and have critical care providers onsite to actively collaborate with MFMs at all times. • Appropriate equipment and personnel available onsite to ventilate and monitor women in labor and delivery until they can be safely transferred to the ICU.	• Level II care providers plus • Continuous availability of adequate numbers of nursing leaders and RNs with competence in level III criteria and ability to transfer and stabilize high-risk women and newborns who exceed level III care criteria, and with special training and experience in the management of women with complex maternal illnesses and obstetric complications • Ob-Gyn available on-site at all times • MFM with inpatient privileges available at all times, either on-site, by telephone, or by telemedicine • Director of MFM services is a board-certified MFM • Director of obstetric service is a board-certified Ob-Gyn with special interest and experience in obstetric care • Anesthesia services available at all times on-site • Board-certified anesthesiologist with special training and experience in obstetric anesthesia in charge of obstetric anesthesia services • Full complement of subspecialists available for inpatient consultations

Continued

TABLE 3.1 LEVELS OF PERINATAL AND NEONATAL CARE AND THEIR EXPECTED CAPABILITIES* — cont'd

	PERINATAL CARE	PERSONNEL
Level IV: Regional Perinatal Health Care Centers Level III facility plus on-site medical and surgical care of the most complex maternal conditions and critically ill pregnant women and fetuses throughout antepartum, intrapartum, and postpartum care. Examples: Any patient appropriate for level III care plus higher-risk conditions such as • Severe maternal cardiac conditions • Severe pulmonary hypertension or liver failure • Pregnant women requiring neurosurgery or cardiac surgery • Pregnant women in unstable condition and in need of an organ transplant	Level III facility capabilities plus • On-site ICU care for obstetric patients • On-site medical and surgical care of complex maternal conditions with the availability of critical care unit or ICU beds • Perinatal system leadership, including facilitation of maternal referral and transport, outreach education for facilities and health care providers in the region, and analysis and evaluation of regional data, including perinatal complications and outcomes and quality improvement	Level III health care providers plus • MFM care team with expertise to assume responsibility for pregnant women and women in the postpartum period who are in critical condition or have complex medical conditions. This includes co-management of ICU-admitted obstetric patients. An MFM team member with full privileges is available at all times for on-site consultation and management. The team is led by a board-certified MFM with expertise in critical care obstetrics. • MD and nursing leaders with expertise in maternal critical care obstetrics • Continuous availability of adequate numbers of RNs who have experience in the care of women with complex medical illnesses and obstetric complications; this includes competence in level IV care criteria. • Director of obstetric service is board-certified MFM, or board-certified Ob-Gyn with expertise in critical care obstetrics • Anesthesia services are available at all times on-site • Board-certified anesthesiologist with special training or experience in obstetric anesthesia in charge of obstetric anesthesia services. • Adult medical and surgical specialty and subspecialty consultants available on-site at all times to collaborate with MFM care team
	NEONATAL CARE	**PERSONNEL**
Level I: Well Newborn Care	• Provide neonatal resuscitation at every delivery • Evaluate and provide neonatal care to stable term newborn infants • Stabilize and provide care for infants born at 35–37 weeks of gestation who remain physiologically stable • Stabilize newborn infants who are ill and those born before 35 weeks of gestation until transfer to a higher level of care	• MDs: (FPs, pediatricians) • Advanced practice nurses (NNPs, PNPs, FNPs)

TABLE 3.1 LEVELS OF PERINATAL AND NEONATAL CARE AND THEIR EXPECTED CAPABILITIES* — cont'd

	PERINATAL CARE	PERSONNEL
Level II: Special care nursery	• Level I capabilities plus • Provide care for infants born at 32 weeks of gestation or later and weigh 1500 g or more who have physiologic immaturity or who are moderately ill with problems that are expected to resolve rapidly and are not anticipated to need subspecialty services on an urgent basis • Provide care for infants convalescing after intensive care • Provide mechanical ventilation for brief duration (less than 24 hours) or continuous positive pressure airway pressure, or both • Stabilize infants born before 32 weeks of gestation and weigh less than 1500 g until transfer to an NICU facility	Level I health care providers plus • Neonatologists • Pediatric hospitalists • Neonatal nurse practitioners
Level III: NICU	• Level II capabilities plus • Provide sustained life support • Provide comprehensive care for infants born before 32 weeks of gestation and weigh less than 1500 grams and infants born at all gestational ages and birth weights with critical illness • Provide prompt and readily available access to a full range of pediatric medical and surgical subspecialists, pediatric anesthesiologists, and ophthalmologists • Provide a full range of respiratory support that may include CMV and/or HFV, and iNO. • Provides advanced imaging, with interpretation on an urgent basis, including CT, MRI, and echocardiography	Level II health care providers plus • Pediatric medical subspecialists† • Pediatric anesthesiologists† • Pediatric surgeons† • Pediatric ophthalmologists†
Level IV: Regional NICU	Level III capabilities plus • Located within an institution with the capability to provide surgical repair of complex congenital or acquired conditions • Maintain a full range of pediatric medical and surgical subspecialists, and pediatric anesthesiologists on-site • Facilitate transport and provide outreach education	Level III health care providers plus • Pediatric surgical subspecialists

*Includes all health care providers with relevant experience, training, and demonstrated competence

†At the site or at a closely related institution by prearranged consultative agreement.

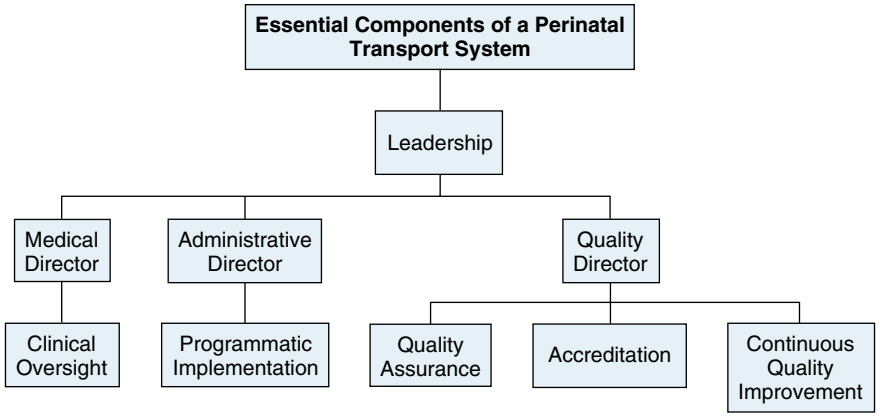

FIGURE 3.1 Organizational structure of neonatal/perinatal transport system.

REGIONAL PERINATAL REFERRAL AND TRANSPORT SYSTEM

Independent of the health care system with which one identifies (universal versus market driven), **the referral system must identify a subspecialty care regional perinatal center, for which the responsibility of coordinating interfacility perinatal transfer lies.** Although many different models provide clinical care in transport, the transport system should include the minimal components of (1) leadership (both medical and administrative), (2) communication, and (3) quality assurance (Fig. 3.1).

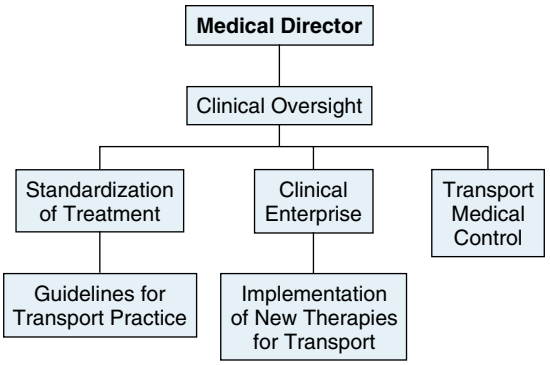

FIGURE 3.2 Role of medical director of transport services.

Leadership

One proposed model is the implementation of a leadership team that comprises a medical director, administrative director, and quality director. This team approach enables collaborative and timely oversight of the transport system with potential for growth and quality improvement. The medical director should be a physician with expertise in transport medicine and evidence-based care. The medical director's role includes overseeing the following[54] (Fig. 3.2):

- Development, implementation, and monitoring of patient care and transport standards
- Scope of practice of team members
- Team selection
- Training and continuing education
- Support of perinatal partnerships and advocacy

The administrative director working in conjunction with the medical director oversees the budget and day-to-day management of the transport process, including maintenance of equipment. The administrative director should possess clinical transport knowledge paired with strong administrative qualities, because this role includes oversight of finance, human resources, and communication operations (Fig. 3.3).[54] The quality director should be a health care provider with a professional background in continuous quality improvement, process analysis, and management. In association with the medical director and administrator, the quality director is responsible for the development and maintenance of a transport database for operational management, quality assurance, and analysis. This administrator should also be able to apply the basic concepts of quality improvement and lean management to implement novel interventions aimed at improving the perinatal transport system (Fig. 3.4).[78]

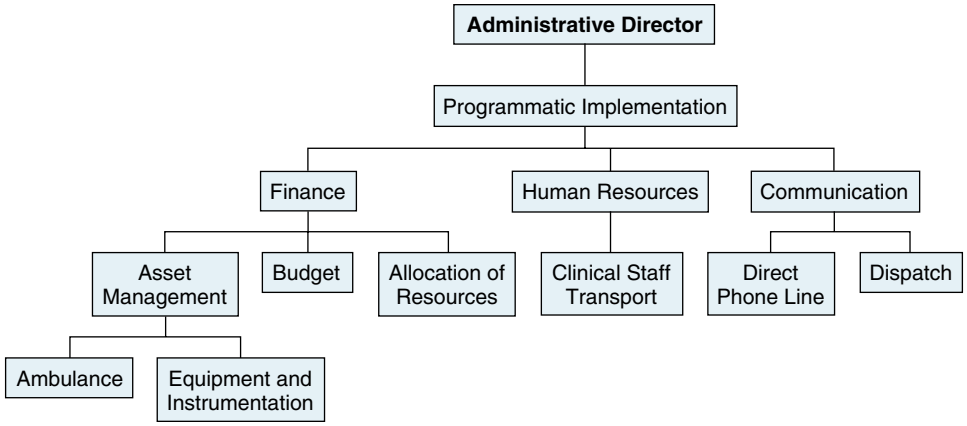

FIGURE 3.3 Role of administrative director of transport services.

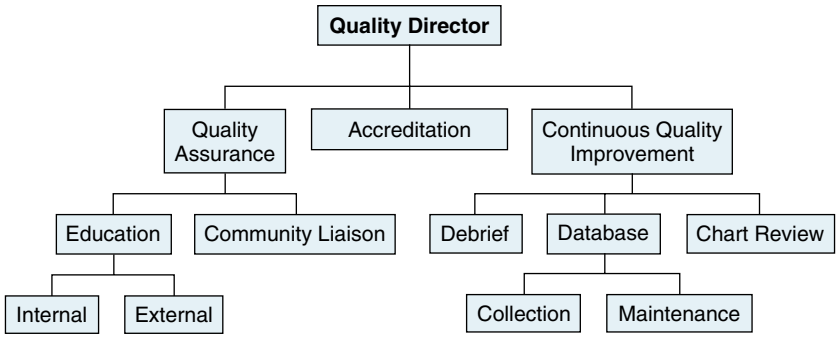

FIGURE 3.4 Role of quality director of transport services.

Communication

As indicated in Table 3.1, a regional subspecialty perinatal care center should be responsible for coordination of perinatal transport. **Integral to the regional transport system is the creation of a centralized communication center with a perinatal regional hotline.**[27] The communication center is responsible for coordinating maternal and neonatal transports within the different levels of care. Roles within this center include referring physician, dispatcher, bed locator, and transport medical control officer (obstetrician and neonatologist). The inclusion of specialized personnel in the initial communication process may support rendering institutions appropriate treatment strategies while decreasing diagnostic discordance.[68]

For purposes of basic communication, a central dedicated telephone line is recommended to provide direct, easy, and immediate access to the regional system. This access should be staffed 24 hours per day, 7 days per week and should be unencumbered. This model also includes the transfer of the referral call to the transport medical control officer, thereby greatly simplifying the process for the referral-consultation. The ability to support communication among the referring physician, the dispatcher, and the medical control officer simultaneously can speed up decision making and the initiation of transport. Once the transport is initiated, communication among the transport team, the referring physician, and the medical control officer becomes integral to the care provided (Fig. 3.5). Changes in weather, patient status, equipment needs, and bed status need to be communicated in a timely manner. This information may demand a review of the transport plan and is best facilitated through a central communication center.[27,54] **The**

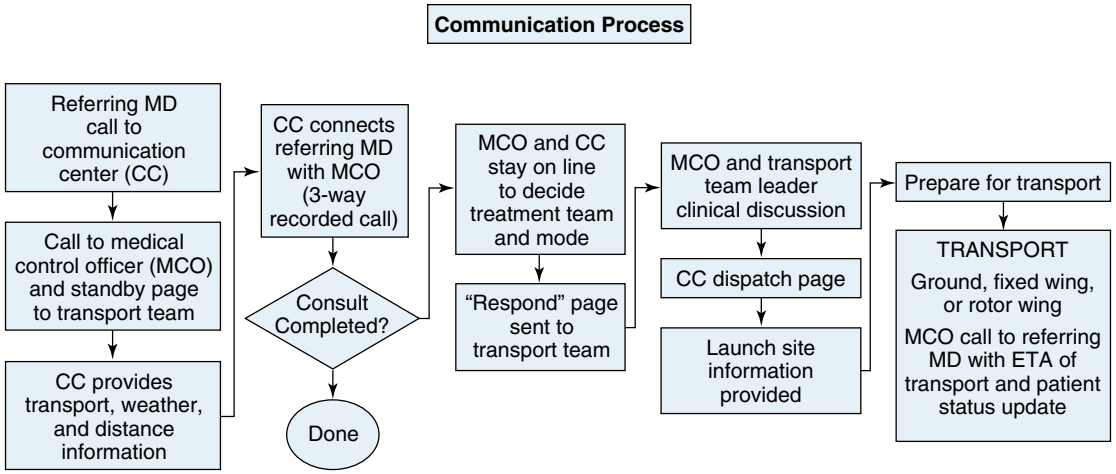

FIGURE 3.5 Working model of Vanderbilt Transport Communication Tool (unpublished), version September 2008. (Contributed by S. Brodtrick, D. Quinn, and M. Cortez.)

organization of a perinatal regional hotline has been shown to significantly increase both in utero and neonatal transports, allowing for safe, 24-hour, on-call management of perinatal transports and the collection of epidemiologic indicators relative to perinatal transfers.[27]

The rapidly advancing field of telecommunications offers a wide variety of opportunities for transmitting medical information, subject to proper consideration of privacy and confidentiality requirements. This medium permits the use of satellite technology and video-conferencing equipment to conduct a real-time consultation between medical specialists in two geographically different areas. Store-and-forward telemedicine involves acquiring medical data (e.g., medical images, bio-signals) and then transmitting these data to a medical specialist for assessment offline. It does not require the presence of both parties at the same time. These technologies may facilitate appropriate referral of patients according to complexity and may decrease incidence of inappropriate transfer or diagnostic discordance, allowing for optimal use of resources.[67,85] Furthermore, these innovative strategies have the potential to overcome de-regionalization of services by creating virtual regional networks for perinatal transport.

Telemedicine consults by neonatologists have been found to improve the quality of high-risk newborn resuscitations.[28] Fang et al. conducted a retrospective cohort study comparing newborns who received a telemedicine consult during resuscitation at a community hospital to those who did not receive a consult.[28] They found that for those who received a consult, not only was the care of the newborn enhanced, but that the remote neonatologist had a positive impact on team behaviors in the form of additional leadership and management. **The newborns in the telemedicine consult group were more likely to have had their temperature, glucose, and blood gas monitored.**[28] Fang et al. concluded that telemedicine programs had the potential to reduce disparities in access to care and increase the quality of care.[28]

Quality

The regional subspecialty perinatal care center, as noted in Table 3.1, is responsible for regional outreach support, education, and continuous quality oversight. Traditionally, quality improvement was assigned to the medical director. However, in light of current health care complexities and regulatory specifications surrounding the quality and safety of patient care, it is recommended that this role be assigned to an individual with the expertise to effectively evaluate programmatic performance at all levels of the organizational structure. This continuous evaluation of the process will facilitate modification of the transport system when potential problems are identified.[78]

The leadership team should oversee overall transport performance. The systematic collection and analysis of carefully selected performance indicators such as patient demographics, management and outcome data, safety standards, logistics, equipment malfunction, and cost will drive quality initiatives. **A quality review of individual transports, incidence reports, and occurrence debriefs will enhance this process.**[54,89] Using a validated transport physiologic score (e.g., the transport risk index of physiologic stability [TRIPS]) to evaluate patient status before, during, and after transport can assist team and transport performance.[48,51,54]

The Academy of Pediatrics Section on Transport Medicine has developed a database for neonatal/pediatric critical care transport quality metrics. The GAMUT database (Ground and Air Medical qUality Transport database) borrows its name from the expression "run the gamut." **Quality metrics include those listed in** Box 3.1. GAMUT welcomes all types of transport programs big or small, academic or corporate, adult or pediatric—all programs that wish to collaborate with others and use benchmarking to drive the quality of the care they provide. Tracking of data related to these quality metrics is just beginning. Teams' data contributions (kept anonymous from other teams) will help determine the performance benchmarking goals necessary to begin the quality improvement phase of this work.[30] Preliminary data have been published,[72] and the process is ongoing.[7]

In addition, quality assurance may be implemented through continuing education both internally and externally. **Transport programs must create individualized internal training programs that effectively provide current and continuous education to ensure maintenance of appropriate skills for high-quality perinatal transport. A similar program must be adapted to provide educational resources to the referring hospital where training in pre-transport resuscitation and stabilization is imperative.** Ensuring competence in these areas has the potential to improve short-term and long-term morbidity of sick infants, offsetting the negative effects of de-regionalization and distance between interhospital transfer facilities.[54] **Building strong relationships of trust within network delivery hospitals will facilitate this process.** Independent of the level of care, these hospitals will deliver emergency sick preterm and term infants; it is therefore imperative that local health care teams develop the expertise to resuscitate and stabilize these infants before transport if necessary. **The regional subspecialty perinatal care center is responsible for working with these hospitals to ensure they develop adequate 24/7 resuscitation and stabilization teams;** the use of scheduled team skills training with simulation and the implementation of real-time communication through advanced technologies like telemedicine will support achieving this goal.

BOX 3.1 GAMUT QUALITY IMPROVEMENT COLLABORATIVE CONSENSUS METRICS

- Ventilator use in neonates with advanced airways
- Average (mean) bedside time and average scene time at transport
- Unintended neonatal hypothermia
- Blood glucose check
- Waveform capnography for ventilated patients
- First attempt tracheal tube success
- First-attempt establishment of airway without neonatal hypoxia/hypotension
- Verification of tracheal tube placement
- Number of patients transported without hospital admission
- Medication errors on transport
- Percent of neonates undergoing rapid sequence intubation where all elements of the protocol are used
- Appropriate management of blood pressure for aortic emergencies
- Unplanned dislodgement of therapeutic devices
- Rate of serious reportable events
- Incidence of hypoxia during transport
- Management of hypertension in hemorrhagic stroke
- Percent of transported patients with accurately interpreted 12-lead ECGs
- Appropriate management of hemorrhagic shock
- Medical equipment failure
- Adverse drug event during transport
- Patient near-miss or precursor adverse events
- Reliable pain assessments
- Average mobilization time of the transport team
- Rate of transport-related patient injuries
- Rate of CPR performed during transport
- Rate of transport-related crew injury
- Use of a standardized patient care hand-off

CPR, Cardiopulmonary resuscitation; *ECG*, electrocardiogram.

High-Risk Maternal Referral

The most effective method to decrease mortality and morbidity during the perinatal and neonatal period is the timely and appropriate referral of mothers with high-risk pregnancies to medical centers in which both the human and technical resources are available to address complications.[20,27] As better clinical outcomes for very low-birth-weight (VLBW) infants (birth weight <1500 g) have been associated with birth and early care at level III centers,[17] early identification of maternal transport candidates is needed. Delivery of a VLBW infant at a level I or II center often leads to the need for neonatal transport. Robles et al. conducted a retrospective cohort study to assess the frequency of VLBW infants born at non-level III hospitals.[73] Using discharge data from 2008 to 2010 for VLBW infants, the study showed that mothers with an antepartum stay of greater than 1 day between admission and delivery occurred in 14.0% and 26.9% of VLBW births in level I and level II hospitals, respectively. Clearly opportunities for maternal transport still remain.[73]

In situations in which the risk to the mother outweighs the benefit of her transfer during active labor, the timely dispatch of the neonatal transport team from the regional perinatal center for resuscitation and stabilization of the high-risk neonate may be considered the optimal approach to delivery of care when it occurs in a timely manner.

Adequate referral of high-risk perinatal patients begins with high-quality antepartum surveillance.[74] **Indications for referral to a regional center are shown in** Box 3.2. Early identification of factors that can affect pregnancy outcome is important in developing appropriate diagnostic and treatment plans. Optimal perinatal care implies having well-trained and up-to-date obstetricians at all levels of care during both the antepartum and intrapartum period. These physicians should be experts in identifying maternal-fetal risk factors and complications through their knowledge, clinical skills, and expertise in prenatal ultrasonography and fetal monitoring.[1,22,39,66] In situations in which this level of expertise is not available, **medical and nursing personnel should be specifically trained to identify high-risk pregnancies with the objective of pursuing early referral.** Consultation and referral decisions for the high-risk mother should be based on the results of a thorough evaluation of each patient and specific guidelines. The ACOG has established a classification system for levels of maternal care. These guidelines help women receive care at centers that are prepared to provide the level of specialized care each requires.[57,73] Communication between the referral center and the regional perinatal center may be facilitated through the use of video-medicine technology.[28]

BOX 3.2 INDICATIONS FOR REFERRAL TO A REGIONAL PERINATAL CENTER

A. **Prenatal Diagnosis**
   1. Complex fetal genetic or congenital anomalies
   2. Severe intrauterine growth restriction[57]
   3. Hydrops fetalis
   4. Severe oligohydramnios and polyhydramnios
   5. Fetal airway anomalies

B. **Maternal Medical Complications**
   1. Advanced or uncontrolled diabetes mellitus
   2. Severe organic heart or lung disease
   3. Severe renal disease
   4. Maternal infection that can affect the fetus
   5. Thyrotoxicosis

C. **Maternal Surgical Complications**
   1. Acute abdominal emergency
   2. Trauma requiring intensive care
   3. Thoracic emergency requiring intensive care

D. **Obstetric Complications**
   1. Premature onset of labor
   2. Premature rupture of membranes
   3. Third trimester bleeding
   4. Severe preeclampsia or hypertension
   5. Multiple gestations
   6. Rh isoimmunization

Neonatal Referral

Despite efforts to identify high-risk perinatal patients during the antepartum period, as many as 30% to 50% of infants who ultimately require additional neonatal care may not be recognized until the late intrapartum or early neonatal period.[47] For this reason, **all hospitals that provide obstetric services must be prepared for the birth, resuscitation, stabilization, and treatment of premature or term sick infants.** The Neonatal Resuscitation Program (NRP)[66,87] sponsored by the American

Modified from Karlsen K. *The S.T.A.B.L.E Program: Post-resuscitation/Pre-Transport Stabilization Care of Sick Infants—Guidelines for Neonatal Healthcare Providers.* 6th ed. Park City, Utah: S.T.A.B.L.E; 2013.

Heart Association and the American Academy of Pediatrics is an excellent resource for training individuals and maintaining resuscitation skills in both a regional program and an individual hospital setting. **Certification (and renewal) of NRP training should be a universal standard for all delivery room and nursery staff.** The frequency of renewal will depend on the average number of resuscitations that occur on a yearly basis in each institution. Institutions with a low average number of deliveries should renew their skills training more frequently to maintain their individual and team resuscitation and stabilization skills. Beyond the immediate delivery room setting, supportive care should be offered and maintained until the transport team has arrived and assumed care (Box 3.3). The S.T.A.B.L.E. program is the only neonatal continuing education program to focus exclusively on the post-resuscitation and/or pre-transport stabilization care of neonates.[37,40]

NEONATAL TRANSPORT

Stabilization of patients and preparation for transport should begin immediately on identification of a need for transport and before the transport team arrives. The S.T.A.B.L.E. curriculum provides a comprehensive set of generalized guidelines for the assessment and stabilization of sick infants in the postresuscitation/pretransport stabilization period. The "S.T.A.B.L.E." mnemonic was created to assist with information recall and to standardize and organize care in the pretransport/postresuscitation stabilization period. Prevention of adverse events and delivery of safe patient care are stressed throughout the program.[37] In consultation, the referring center (physician) and transport medical control officer (MCO) may address additional areas of attention based on specific patient clinical assessment and presumptive diagnosis. Although the reasons for neonatal referral may be quite diverse and based on needs of infants relative to the capabilities of the referring center, the most common indication is respiratory distress of the neonate.[37] Other common indications include prematurity, congenital anomalies (surgical and nonsurgical), and suspected congenital heart disease. Stabilization and support of these infants may require frequent interhospital communication (referring physician and transport MCO) to identify specific medical interventions. The importance of this form of continuing dialogue with respect to accuracy in diagnosis, management, and changes in patient status cannot be stressed enough. Again, the use of video-telemedicine may facilitate the accuracy of these interactions.[28]

Assumption of care of the neonate is a complex issue without a straightforward answer. However, transition of care should be seamless. **Many health care professionals can have medical responsibility for a single patient at one time. The fact that one person has acquired medical responsibility does not automatically release someone else. On arrival of the transport team, collaborative management is of utmost importance.** While the patient remains in the referring facility, the referring physician cannot hand off the patient and proceed as if the patient has left the facility and his or her care. The referring facility allows the specialty team to provide care under the supervision and authority of the referring physician. **The specialty team leads the effort to prepare the patient for transport. However, leading does not command or infer sole medical responsibility.** The referring physician retains involvement and ultimate responsibility and signs the transfer certificate at the time of actual transfer. If at any time the referring physician deems it is in the best interest of the patient to intervene or cancel the transfer, it is the physician's right and responsibility to do so. **Simultaneously the transport team has a medical responsibility to the patient. A team approach is in the best interest of the patient and should involve all participants in the process.** Communication between the referring physician, the transport team, and the accepting physician is of great importance.[58] **As long as the transport team is in the referring hospital, the**

ultimate responsibility lies with the referring physician. On leaving the referring facility, the transport team and receiving facility assume responsibility and control for medical decision making.[80] In the event that a community emergency medical service (EMS) is used for transport, the referring physician retains medical control until the patient reaches the regional referral center.

Pediatric and neonatal interfacility transport teams are unique entities. Provision of intensive care in the transport environment incorporates the philosophies of neonatal and pediatric critical care, but in a mobile environment with physical and environmental constraints of staff, space, mobility, and equipment. It is important to recognize that **the physical requirements of team members are different from those who work solely in a hospital or clinic environment.** Team members will be required to lift patients or carry equipment often with little or no help. The ability to function within the confines of a moving vehicle is important. Personnel should not be unusually prone to motion sickness or have mastered the techniques to mitigate the effects of motion sickness. Weight restrictions are a consideration in regard to aircraft. Personnel with chronic illness or disability may not be able to perform all expected duties. Pregnancy may pose a temporary limitation, and medical clearance should be provided by the member's obstetrician at a minimum. In the event a team member is unable to function, patient and crew safety may be compromised because there are few options should a team member be incapacitated while on duty. For this reason, team members with certain medical conditions may be at least temporarily precluded from participation on a transport. Policies developed with human resources and legal counsel should be put into place and address the physical requirements for team members.[58]

Interfacility transport teams are a part of the continuum of care provided by the system of emergency medical services for neonates and children. Transition of care should be seamless without compromise of level of care or monitoring. Neonatal-pediatric interfacility transport teams do not "scoop and run" or "swoop and scoop" (limited evaluation at the scene with rapid stabilization and transport to an advanced care environment as the primary goal) as may be appropriate for the prehospital transport from an accident scene. **Patients transported by neonatal-pediatric interfacility teams benefit from organized, coordinated, controlled transport that does not prioritize speed over thorough stabilization described as a "stay and play" philosophy.** The exception to this principle is the patient whose outcome will be compromised without access to care not available at the referring hospital or in the transport environment.[60]

Team Composition and Configuration

Transport teams may be composed of a variety of medical personnel, including physicians, neonatal nurse practitioners, physician assistants, registered nurses (RNs), respiratory therapists (RTs), paramedics, and emergency medical technicians.[38,48,49] Karlsen et al. conducted a Web-based national survey of 335 neonatal transport teams to describe the United States Neonatal Transport Team workforce.[38] Published in 2011, variations in aspects of neonatal transport teams were described including team composition. There were a total of 26 compositions reported.[38] **The most common composition among unit-based and dedicated teams was the RN-RT composition; the same finding as a more recent survey where 30% were RN-RT.**[82] Another recent survey of transport teams listed by the AAP found that most transport teams are nurse-led and consist of an RN and one other team member (i.e., another RN, medic, RT). Many teams adjust composition based on the neonate's acuity.[64] Interfacility transport should be accomplished in the most efficient and safe manner by qualified personnel. **The composition of a neonatal-pediatric transport team should be tailored to meet the specific needs and resources of its patients and referral region.**[58] Factors that can influence team composition include program resources, program design, unit-based versus dedicated teams, transport volume, and transport mode, as well as local, state, and regional regulation agencies.[80] **As a general guideline, a transported infant or child should receive the same level of care en route as will be provided in the unit to which he or she will be admitted.**[58]

There is considerable debate regarding the presence of physicians on transport. Traditionally pediatric teams have included a resident or attending physician, but in a recent survey, less than 5% of pediatric teams used a physician for transport.[82] There is little evidence to support that such a

composition results in more favorable outcomes. **Many neonatal teams have been led by nurse practitioners or advanced practice nurses,** as described by Karlsen et al.[38] Nurse-led teams have been shown (1) to provide better continuity of care, improved documentation, better maintenance of transport equipment, improved team availability, and stronger liaisons with referring hospitals and (2) to reduce overall operating costs.[54] Leslie and Stephenson evaluated physiologic parameters of infants stabilized and transported by neonatal nurse practitioners versus physicians.[50] Though stabilization of the infants by the nurse practitioners took longer, physiologic conditions were improved for pH and Pao_2 in the pretransport period, and temperature and oxygen saturations were improved in the post-transport period when transported by nurse practitioners. King et al. reported on the effects on patient outcomes when team composition was changed from RN-physician team to nurse only.[42] There was no difference found in mortality rates between groups, and team response times were significantly shorter for the RN team.[42] Limited research has demonstrated that providers such as RNs and RTs can function safely and effectively in the transport environment without the direct supervision of a physician.[58]

Team configuration has been categorized as *dedicated* and *unit based*. **Dedicated teams are those whose members perform neonatal transport on a full-time basis.** They generally are not assigned to any other major clinical responsibilities. However, between transports, team members may assist with procedures, attend deliveries, or have other responsibilities that do not involve patient care. Dedicated teams can be based in a receiving facility or in a freestanding transport service not affiliated with a hospital.[38] **Unit-based teams are composed of members who, although available for transport, are primarily involved with other clinical duties.** Institutional factors should drive the decision about which type of team to use. These factors often include the acuity of care level managed in the unit, annual volume of transports, financial support, and national, state, or local laws regulating the expanded role of nurses and respiratory therapists in health care.[58] **Regardless of the team composition, the team must have the cumulative expertise to resuscitate, stabilize, and provide critical care throughout the transport.**

Dedicated transport teams originated in the 1970s to 1980s, when regionalized perinatal care was established[38] and large metropolitan hospitals began to experience an increase in the demand for neonatal transport. **These teams often are composed of a nurse designated as team leader and a respiratory therapist as a partner, with a physician or nurse practitioner added to the team when a neonate is critically ill and more advanced procedures may be anticipated.[42,49]** The principal advantage for dedicated teams includes their immediate around-the-clock availability and their advanced training in neonatal resuscitation and stabilization procedures. However, the additional personnel necessary for dedicated teams may make them expensive to maintain. Dedicated neonatal teams were found to transport greater distances, to have larger transport volumes, were more likely to use all modes of transport, and were more rigorous with regard to orientation, annual skills maintenance, use of protocols, and quality assurance activities.[38]

Unit-based teams **usually are made up of staff nurses and respiratory therapists within the neonatal intensive care unit (NICU).[49]** The advantage to having a unit-based, nondedicated transport team is the large pool of trained personnel available around the clock. Qualifications of team members can be based on their daily bedside critical care experience and supplemental education, such as certification as a neonatal resuscitation provider. **The primary disadvantage to this team design is that the transport nurse's patient assignments must be absorbed by the unit nursing staff until he or she returns.** However, unit-based teams are usually very cost-effective because critical care skills are maintained during regular patient care, advanced skill training may be more focused, and administrative oversight duties are diminished.[49]

The American Academy of Pediatrics' Section of Transport Medicine article "Pediatric and Neonatal Interfacility Transport: Results from a National Consensus Conference"[80] describes an additional method of categorizing transport teams. **Four types of transport systems are described: hospital based, community based, EMS based, and a hybrid (mix of the previous three systems).** Hospital-based teams are owned and operated by sponsoring institutions and serve the needs of these institutions. These systems often operate at a net loss. Indirect revenue is generated providing an

overall profit. Community-based teams are most often owned and operated by private companies and are dependent on a mix of adult transports, high volumes, and low expenses. EMS-based teams are typically subsidized by local, regional, and state government funding, including taxpayer revenue. Hybrid teams are gaining popularity with an increased awareness of cost and resource sharing and increased collaboration.[80]

Transport Education and Training

The goal for training of transport teams should be the development of a program that ensures that members will have the combined expertise to effectively assess and manage actual and potential problems in the transport environment. The training program should enable team members to demonstrate their abilities to plan, implement, and evaluate ongoing stabilization efforts and interventions during transport. The scope of this training program should reflect the team member's job description, transport responsibilities, patient population, and modalities of travel.[60,83] Training is often begun during an orientation period but must continue throughout the career of the transport team member. Orientation is accomplished through participation on transport under the supervision of an experienced team member, as well as with the use of didactic and process curricula.[58,80] Cognitive knowledge should be demonstrated in transport and medical content areas.[58] **Team members should be able to recognize and manage life-threatening conditions as appropriate for their transport population.** New team members will need training designed to enhance their current knowledge base and will need to learn and interpret certain assessments, techniques, studies, and procedures not usually expected in their standard or previous positions.[58]

Procedural skills required by transport teams will be defined by patient population, program guidelines, and legal scope of practice. Suggested skills and procedures are described by the AAP.[58] Resourcefulness is required for the development of opportunities to attain and maintain the necessary skills. Laboratory simulations are available for certain skills. Electronic computer-linked simulators are additional resources but are limited by their availability and expense to purchase and maintain. Resources exist within the hospital for attainment and maintenance of procedures and skills and include the operating room, NICU, delivery room, pediatric intensive care unit, and emergency department. Each area provides unique opportunities for skill and knowledge development.[58]

Continual education for transport team members is vitally important because as technology changes, therapies will change. Procedural skills must be maintained because some skills are only performed occasionally if ever in actual practice. Continual learning of rare conditions allows team members to be prepared to initiate appropriate management of these conditions.[58] Multiple modalities are used for continuing education and can include quality improvement initiatives, case conferences, didactics, skills laboratory sessions, case simulation, literature review, computer-based activities, and peer performance.[64,80]

Research related to simulation in health care is supporting the idea that didactic and experiential learning alone is not enough to fully prepare teams to transport patients.[15] Transport teams must maintain competency of many skills and procedures of which some may not be used frequently or at all. Simulation training can be used as an adjunct to transport team education to reinforce knowledge and skills.[15,23] The most recent survey of transport teams found that 80% use simulation as part of their education programs.[64] Procedures can be performed in a safe, controlled environment. Patient care environments (transport vehicle workspace) can be simulated. Simulation training should include interprofessional team members, providing the opportunity to learn collaboration skills and prepare teams to achieve high reliability.[15] Scenarios can be created to assess not only resuscitation skills but also team dynamics. Debriefing is a vital component to simulation. Through facilitated discussions, participants review and critique their experiences.[80]

The use of specialty-specific models has been shown to improve outcomes, collaboration, and care delivery.[34,83] The Circle of Caring Model for Neonatal Transport focuses on collaboration and evaluation, noting that teamwork is a critical component throughout the transport process. Although the model is linear for clarity, the process is very fluid and dynamic.[83] Based on experience, knowledge base, and intuition, the team must collaborate and work through complex thought processes using critical thinking skills to make patient care decisions.

This model serves as a tool to help clarify and improve the transport process, leading to safe and consistent care.[83]

Variability among neonatal transport teams exists related to length of orientation, readiness for independent transport, orientation content, procedures performed, and skills maintenance.[23,38,58,64,82] Competency assessment, based on the medical education model, has also been recommended, thus allowing teams to evaluate individual personnel, focus on educational needs, and ensure acquisition of necessary knowledge and skills.[58,80]

A minimum of 2 years of level III neonatal critical care staff experience is a basic requirement for the nursing and respiratory therapy components of most neonatal transport services. Nurses and respiratory therapists who specialize in neonatal transport should have a basic understanding of neonatal pathophysiology, resuscitation and stabilization techniques, ventilatory management, and radiographic interpretation. In the event of a critically ill patient, a nurse practitioner or physician may serve as team leader with respect to high-level procedures and patient management.[41,42]

Programs using air transport should ensure that all providers, including physicians who may be involved occasionally, have education on air safety, survival methods, and flight physiology (including air transport effects of barometric pressure, g-force, humidity change, potential temperature loss, noise, and vibration).[54,77]

Mode of Transport

The optimal transport of a neonatal or pediatric patient is facilitated by the appropriate use of resources, including staff, equipment, and vehicles. Vehicles used in transport include surface (ground) and air (rotor-wing or fixed-wing) ambulances. A fully integrated transport system would include all three modalities.[58] When initiating a neonatal transport program, the first step should be to identify the geographic catchment area, total number and location of perinatal resources, distance in miles/kilometers, and duration of transport time (ground versus air) between the different levels of care. An important factor is the particular characteristics of the topography of the catchment area, which will help determine the ratio of ground-to-air transport resources required. In areas with good roads and low traffic volume, ground transport may be the only transport system required.[20,33,54,81]

Selecting the proper mode of transport (ground ambulance, helicopter, or fixed-wing aircraft) depends on many variables. However, the safety of the patient and crew must be the foremost consideration when determining the mode of transport. Careful consideration of risks should be made before any patient transport is initiated. **Variables that affect mode of transport and benefits of ground versus helicopter include clinical status of the patient, medical care required by the patient before and during transport, urgency of the transport, and other logistical considerations.** By shortening response time and transport time in a clinically unstable patient, the selection of one mode of transport over another may be lifesaving. Logistical concerns affect the appropriate selection of mode of transport and can include distance, weather, traffic, and accessibility of area.[58]

Potential advantages and disadvantages of the available modes of transport should be considered. Ground ambulances are the most common means for interfacility transport of neonatal and pediatric patients. Ground ambulances offer many advantages over air transport. Ground ambulances are routinely available, can operate in weather conditions that restrict safe air operations, may be more user-friendly and functional with regard to the transport environment, and provide door-to-door service without need for helipad, landing zone, or runway. There are limitations to ground transport. There is a high potential for a rough ride, as well as the possibility of motion sickness for the patient, team members, or family. Ground ambulances have significant time, distance, and access constraints.[58]

Helicopters have strengths and weaknesses as well. Speed of travel is one of the unique characteristics of air transport. There is no need for a runway, and helicopters are able to avoid common traffic delays and ground obstacles and fly into areas that are otherwise inaccessible to other modes of transport. The disadvantages associated with helicopter transport include limitation in cabin size, landing zone requirements, and weather considerations.[58]

Fixed-wing aircraft travel at a greater speed and cover a greater service area compared with ground ambulances and helicopters. Other advantages include a larger patient cabin than that of a helicopter and the ability to fly above or around inclement weather. The greatest limitation of fixed-wing

aircraft is the need for an airport landing that may be a distance from the referral and receiving facilities. Ground transport is needed between referral and receiving facilities and the airport.[58]

Selection of the appropriate mode of transport is not a simple decision, and no single vehicle is ideal for all patients or transport teams. The risks, benefits, advantages, and disadvantages of each mode should be considered, as well as the mission of the team and needs of the patient.[58] In general, when transport time exceeds 2 hours, air transport is more appropriate.[54] However, local ground transport capabilities to and from a referring hospital and airport must be known when fixed-wing air transport is used.

Equipment and Medications

Transport teams should be self-sufficient with dedicated, organized supplies for quick, efficient access.[58] The equipment and medications necessary for neonatal transport are similar to those used in the NICU. Equipment must be light, compact, durable, and motion and g-force tolerant. All electronic equipment should have its own independent power supply (AC/DC capability), adequate visual and audio alarms, and lack of electromagnetic interference.[20,54] Compatibility of all equipment is of vital importance to prevent potential interruption in therapy. Maintenance of equipment should be scheduled on a routine basis and be performed by competent, well-trained biomedical technicians. Equipment should be secured in all transport vehicles by approved methods.[58]

Storage packs should be organized, maintained, and checked on a routine basis by transport team members. It should not be standard practice to rely on or plan to borrow equipment or medications from referral facilities.[58]

Medication storage is of the utmost importance for the delivery of safe care. Special considerations are needed for certain medications such as surfactant and prostaglandins that require refrigeration. Security of controlled substances must be maintained as mandated by institutional, state, and federal regulations.[58]

Sample supply lists for equipment and medications needed for ground and fixed-wing transports of neonates and pediatric patients are available.[58] Table 3.2 **provides a list of common transport equipment and medications.**

Novel Interventions

Because the objective of the perinatal transport team is to bring the intensive care environment to the newborn infant, it is also important **that initial resuscitation and stabilization of the infant be performed by skilled practitioners; this will enhance the role of the transport team to successfully continue to offer appropriate high-quality intensive care during the transport of the baby.** Level II centers should be equipped with surfactant, nasal continuous positive airway pressure (NCPAP) systems, and oxygen-air blenders to give prompt and effective respiratory support while maintaining blood saturation levels within acceptable limits awaiting the arrival of the transport team. Adequate management of the premature infant with surfactant deficiency will include supporting adequate recruitment of the lung and minimizing barotrauma. **It is essential that practitioners have the skills needed for noninvasive surfactant administration and appropriate intubation so they can administer early NCPAP to improve morbidity and mortality and decrease the need for mechanical ventilation.* These requisite skills are necessary in situations in which duration of transport may be prolonged for hours because of unforeseen delays. The use of early NCPAP in the delivery room for infants with respiratory distress is recommended for the management of premature infants with respiratory distress syndrome and term infants with mild to moderate respiratory failure.**[5] Because surfactant is an expensive medication, level II centers can maintain one or two ampules in their pharmacy to be restocked as needed. The use of NCPAP during transport has been evaluated and has been shown to be a safe and efficacious intervention for respiratory support.[59]

The use of a resuscitation device such as the T-piece infant resuscitator (Neopuff Infant Resuscitator, Fisher & Paykel Healthcare, Auckland, NZ) may help decrease the variability of pressures administered to the neonate during resuscitation, stabilization, or administration of surfactant. This device also has the potential to minimize lung damage while supporting lung recruitment with the use of positive end-expiratory pressure.[10,63] This system can also temporarily replace the need for mechanical ventilation if NCPAP is unsuccessful in maintaining respiratory stability.

TABLE 3.2 EQUIPMENT AND MEDICATIONS FOR NEONATAL TRANSPORT*

PHYSIOLOGIC MONITORING AND SAFETY	AIRWAY AND SUCTION EQUIPMENT	RESPIRATORY EQUIPMENT	PROCEDURE EQUIPMENT	IV FLUID AND ACCESS	MEDICATIONS	REFRIGERATED MEDICATION
BP cuffs, #2–#4 (2 each)* Electrodes (2 of each available size) Pulse oximeter probes (2) Dispensable thermometers (2) Skin temperature probes (8) Rectal probe (1) Warming pad portable: chemical (2) 4×4 gauze pads (2) Nonstick gauze pads (2) Bowel bag (1) Sterile rolled gauze (2) Ear protectors (2) Hats (2) Flashlight (2) Tape measures (2)	Laryngoscope (2) Laryngoscope blades (2 of each size) Laryngoscope light bulbs (3) AA batteries (4) Endotracheal tubes (3 of each size) Stylets (4) CO_2 detector (2 self-contained, sterile) Closed suction catheter (2 of each size) Meconium aspiration device (2) Bulb suction (2) Suction catheters (2 of each size) Saline bullets (4) Replogle (2 of each size) Orogastric tubes (2 of each size)	Anesthesia bags (2 per T-PICU infant resuscitator) Self-inflating bag (2) Oxygen mask (2) Facemasks (2 of each size) Infant nasal cannula (2) CPAP prongs (2 of each size) Neonatal flow sensor (2) CPAP circuit (1) Ventilator circuit (1) Point-of-care blood gas equipment (1–2)	Sterile towels (1) UAC tray (1) Single-lumen umbilical catheters (2 of each size) Double-lumen umbilical catheters (2 of each size) Umbilical tape (2) Povidone-iodine (3) Scalpels #11 and #15 (1 each) 4.0 silk suture (4) Dressing for umbilical line (2) Needle aspiration/chest tube kit (2) Transducer (2) Chest tubes, 10 Fr/12 Fr (2 of each size) Heimlich valve (2) Sterile gloves (5 of each size)	D_5W 50 mL (2) NS 250 mL (1) $D_{10}W$ 500 mL (1) $D_{50}W$ 50 mL (1) Heparin sodium 1000 mcg/mL vial (3) Syringes, 3 mL/1 mL (6 each) IV catheter, #22 and #24 gauge (5 each) Access kit, including dressing, tourniquet (2) Butterfly needle (3 of each size) Arm board (2) Heel warmers (2) Lancets (2 of infant and preemie size) Syringes (5 of each size)	Epinephrine 1:10,000 (2) Naloxone 1 mg/1 mL (2) 4.2% sodium bicarbonate (2) Dopamine (2) Dobutamine (2) Acyclovir (1) Ampicillin (2) Gentamicin (2) Vitamin K for injection (1) Eye ointment (2) Lidocaine HCl (1) Adenosine (1) Vecuronium (1) Sterile saline for injection (2) Abboject needle (2) Fentanyl (2) Midazolam (2) Phenobarbital (2)	Exogenous surfactant (1) PGE (2)

*( ) designates numbers of pieces of equipment to be carried in transport kit.

BP, Blood pressure; *CPAP*, continuous positive airway pressure; *NS*, normal saline; *PGE*, prostaglandin E; *UAC*, umbilical artery catheter; *T-PICU*, T-piece infant care unit.

Early mobilization of the transport team for an impending premature delivery or delivery of a sick neonate allows for earlier implementation of tertiary care in the community. There has been a change in philosophy regarding departure of the transport team. The patient need not be born to mobilize a team. Close monitoring of aborted or prolonged transports is necessary to avoid inappropriate use of resources in a region. Time spent awaiting the delivery must also be monitored.

Neonatal transport brings ICU care to the patient including many of the same modes of ventilation as in the NICU. Conventional ventilation as well as high-frequency ventilation can be used to transport infants. During the past 10 to 15 years, **the use of noninvasive respiratory support on transport has increased for all gestational ages.** Multiple reasons may have contributed to this including: increased use of antenatal steroids, surfactant replacement therapy, improved resuscitation protocols, and improved knowledge and availability of noninvasive modes.[61] Nasal cannula, nasal CPAP, and high-frequency nasal ventilation are all examples of noninvasive modes being used (see Chapter 23).

Another important intervention for perinatal transport is the **administration of prostaglandin E_1 (PGE_1) for patients in whom a suspicion of**

cyanotic congenital heart diseases is supported with a positive hyperoxia test and measurement of upper and lower extremity blood pressures. Adequate knowledge of dosing and preparation is fundamental to the successful use of this medication, which can prevent patients with ductal dependent lesions from becoming clinically unstable and developing severe hypoxemia and metabolic acidosis before the arrival of the transport team. The need for intubation and ventilator support to prevent apnea varies depending on the anticipated length of transfer and the dose of PGE_1 necessary to maintain the infant asymptomatic.[13,29] A recent retrospective chart review found that apnea began within 1 hour of initiation of the PGE_1 infusion in neonates diagnosed prenatally with ductal-dependent heart disease. Beginning the transport after the first hour of infusion may make prophylactic intubation unnecessary.[76] Knowledge by the referring physician of the performance and interpretation of the hyperoxia test will facilitate the decision to start PGE_1 and should be part of the maintenance-of-skills program. Level II nurseries should maintain a vial of PGE_1 in stock.

Inhaled nitric oxide (iNO) is used during transport to support term and near-term infants with hypoxemic respiratory failure that does not respond to conventional mechanical ventilation.[14,55] The use of iNO can be lifesaving and may decrease associated morbidities. Use of pre- and post-ductal saturations facilitates the identification of neonates who can benefit from this therapy. During transport, certain adaptations for both ground and air transport must be made to use iNO safely and effectively.

Therapeutic hypothermia is only offered at high-level NICUs and is neuroprotective for infants with moderate to severe hypoxic ischemic encephalopathy (HIE). Passive cooling can be initiated by turning off external heating devices and can be continued on transport.[6] However a 10-year retrospective study of passive cooling found that the therapeutic temperature zone was met in only 52.6% of the neonates during transport.[46] A recent retrospective study evaluated both passive and active cooling on transport and concluded that active cooling increased the odds that the infant would arrive at the receiving center within the therapeutic temperature range.[79] These and other researchers suggest that if cooling is considered on transport, active servo-controlled therapeutic hypothermia be used.[2,53,79] Other considerations while actively or passively cooling a patient during transport include: mode and length of transportation, external temperatures, and the inclusion of ice packs on the transport equipment list.

Neonates managed during transport with other more complex interventions, such as high-frequency jet ventilation (HFJV) and extracorporeal membrane oxygenation (ECMO), have been reported. Mobile ECMO units in Sweden,[12] France,[71] and Italy[24] found that although ECMO during transport is safe, many complications are possible, thus a highly skilled ECMO team is required. The use of HFJV during transport is feasible and has resulted in safe transport of infants needing ECMO[56] and those with congenital diaphragmatic hernia.[91] Use for routine transport cannot be recommended, because of the complexity of training, equipment, and logistics required for HFJV and ECMO. Every country and regional perinatal center must determine its priorities for transport based on epidemiologic studies conducted in its catchment area to support the demand with appropriate resources for adequate perinatal transport.

FAMILY-CENTERED CARE FOR TRANSPORT

Separation of the infant and mother is often a consequence of neonatal transport. This physical separation affects both bonding and attachment, increasing the stress surrounding the delivery of an ill infant.* Creative ways to minimize the negative effects of this separation must be incorporated into the transport process. Whenever possible, transport should allow for the presence of a family member.[58]

Principles of family-centered care used in the inpatient setting should apply to the transport environment. Despite the evidence of benefits, there is no universal acceptance or implementation of family-centered care in transport. Transport members cite multiple reasons for excluding parents, including anticipated difficulty caring for the patient if the parent needs attention, potential difficulty dealing with distraught parents, difficulty controlling the child with the parent present, and general team member anxiety in providing care with parent(s) watching.[58] **Before departure from the referring facility, the transport team**

*References 3, 32, 40, 43, 44, 45, 60,62.

should meet with the parents of the infant, communicating the plan for transport, providing information with regard to the receiving hospital (including phone numbers, directions, and unit-specific guidelines), and answering any questions the parents may have. The transport team should identify a phone number that may be used to communicate with the parents once the infant is transported. In addition, **the transport team should enable the parents to see and touch the infant before departure and should provide the parents with a photograph of their infant.**[54]

Enabling parents to be present during provision of critical care is the cornerstone of family-centered care. The presence of the family during resuscitation continues to gain support. The presence of the family allows them to continue to act as allies in the care of their child and enables them to see firsthand that team members did their best and treated their child with respect, dignity, and empathy.[58]

With the presence of the family during transport, safety should remain the priority. All vehicle occupants should wear appropriate restraints. Family members should be educated if it is unsafe for them to ride in the transport vehicle or in a particular location in the transport vehicle. **The transport team has the responsibility to define a standard of family-centered care during the transport of sick neonates and pediatric patients.**[58]

If family is unable to accompany the child during transport, **upon arrival at the receiving medical center, a transport team member should call the parents to update them on the condition and the safe arrival of their child in the receiving facility.** At this time, the transport team should give the parents the names of those who will be responsible for the care of the infant. Once the infant is admitted into the receiving unit, the receiving physician should communicate directly with the parents and referring physician. Engaging the parents in the caregiving process as soon as possible empowers parents and assists the health care team in devising a care plan that will be mutually acceptable and in the best interest of the infant.

Facilitation of bonding between parents and infant may be improved with the use of webcam technology in the NICU.[75] Webcam technology provides virtual visitation with the infant for the family regardless of the geographic distance between them at the time.

FUTURE OF NEONATAL TRANSPORT

Research, innovation, and enhancement of regionalization networks represent the future for perinatal transport. The mandate for highly motivated leadership able to apply epidemiologic, research, and quality-improvement methodology to the area of perinatal transport is essential for progress. The development and evaluation of new interventions, as well as the evaluation of what we consider "standard therapies," are imperative to more favorable outcomes. An example of the need for further evaluation is the excessive physical strain of the transport process on VLBW infants who are at high risk for intraventricular hemorrhage and specifically looking at ways to decrease sound and vibration during ground and air transport.[8,70] The inclusion of continuous quality improvement at the top leadership level of the organizational structure of the perinatal transport system and the systematic collection of relevant data within an identified perinatal region represents the backbone for research in standing and new technologies. The use of evidenced-based practices is crucial to the improvement of survival without severe morbidity, especially for very preterm infants. A recent prospective multinational population-based observational study found that the combined and simultaneous use of four practices for infants born before 28 weeks of gestation lowered in-hospital mortality and morbidity, corresponding to an estimated 18% decrease in all deaths without an increase in severe morbidity.[90] These evidence-based practices include: (1) delivery in a maternity unit with appropriate level of neonatal care, (2) administration of antenatal corticosteroids, (3) prevention of hypothermia, and (4) surfactant administration within 2 hours of birth and/or early nasal continuous positive pressure.

Special attention must be focused on the referral community to improve resuscitation and stabilization efforts. In addition, benchmarking with regard to morbidity and mortality outcomes for transported patients will provide clarity for evaluation of the transport experience. The ultimate focus of this effort is to improve maternal and neonatal outcomes. Ultimate success will depend on the level of multidisciplinary participation of government, community, and private industry stakeholders.

4 CARE AT BIRTH

SUSAN NIERMEYER AND SUSAN B. CLARKE

A GOLDEN OPPORTUNITY

The initial evaluation and management of the newly born infant focus on promoting normal adaptation to extrauterine life and integration of the mother–baby dyad as well as detecting significant medical problems so that they can be evaluated and treated appropriately. In adjusting to extrauterine life, the newly born infant experiences a complex series of physical and physiologic changes. These changes result from a variety of processes, including perinatal surges in hormones, labor, delivery, ventilation and oxygenation of the lungs, umbilical cord occlusion, decreased environmental temperature, and activation of the sympathoadrenal system.

Such complex changes are essential for survival. **Every infant must successfully complete this transition in order to survive in the extrauterine environment.** For a small percentage of infants, transition is never achieved; for a slightly larger number, transition is delayed or complicated; however, for most infants, transition is so smooth it appears uneventful.[2] It has been estimated that in **approximately 10% of live births, the active intervention of a skilled individual or team is necessary to ensure a successful transition.**[34] Consequently, the optimum care of the neonatal patient during this period needs to be prospective and anticipatory.

The purpose of immediate care after birth is to support the normal physiologic changes in a newborn's respiratory and circulatory transition from fetal to neonatal life. Normal physiologic changes at birth include expansion of the lungs with air, initiation of gas exchange across the alveolar membrane, and closure of circulatory shunts that were necessary during intrauterine life. **When delivery is complicated by perinatal conditions leading to perinatal depression, the aim of resuscitation is to reverse hypoxia, hypercarbia, and acidosis.** The survival and outcome of distressed newborns depend on timely and effective intervention in the first few minutes after birth.

All resuscitation efforts begin with the basic techniques of drying, providing warmth, and stimulating, with clearing of the airway only as needed.[3,81] Advanced resuscitation includes assessment of oxygenation, supplemental oxygen administration (if needed), bag-and-mask ventilation, endotracheal intubation, chest compressions, and the use of epinephrine and volume expansion. Emergencies at birth may require resuscitation, as well as more advanced procedures during stabilization in the delivery area and transition to the neonatal care unit. **Finally, truly successful resuscitation depends on care of the family, collaborative perinatal decision making, and teamwork and communication among health care professionals.**

PHYSIOLOGY

At birth, a rapid physiologic transition must occur from the intrauterine to extrauterine environment.[43,67] **Effective, regular respirations should begin within the first minute after delivery.**[2,24] Environmental factors, such as a relatively cool ambient temperature and tactile stimulation, assist in initiating respiration. The changes in Pao_2 and $Paco_2$ during birth affect chemoreceptors and aid in the reflexive initiation of respiration. **The initial breath may generate from 20 to 70 cm H_2O**

BLUE type highlights content that is particularly applicable to clinical settings.

of negative intrathoracic pressure to replace lung liquid with air inside the alveoli.[69] A rapid decrease in pulmonary vascular resistance and an increase in pulmonary blood flow occur after expansion of the lungs with air and filling of the pulmonary circuit with blood. This results in increased pulmonary perfusion and oxygenation.[68] Resorption of fetal lung liquid across the respiratory epithelium accelerates during labor, resulting in net clearance of liquid from the potential airspaces.[12] Colloid osmotic pressure and the relatively lower postnatal hydrostatic pressure of blood within the pulmonary circuit assist in absorbing alveolar fluid after delivery. During this process, fetal right-to-left shunts through the ductus arteriosus and foramen ovale gradually close[23] (Fig. 4.1; Table 4.1).

ASPHYXIA AND APNEA

***Asphyxia* is defined as inadequate tissue perfusion that fails to meet the metabolic demands of the tissues for oxygen uptake and waste removal. Asphyxia is characterized by progressive hypoxemia (↓Po_2), hypercarbia (↑Pco_2), and acidosis (↓pH).** Hypoxic tissues convert from aerobic metabolism to anaerobic glycolysis, producing lactate and metabolic acidosis that is initially buffered by bicarbonate.[17] When the buffering capacity is exhausted, acidosis occurs. Acidosis and hypoxemia initially result in reflexive, compensatory cardiovascular changes. After early tachycardia, cardiac output decreases, and generalized peripheral vasoconstriction occurs to maintain a blood pressure adequate for perfusion of the heart and brain. **Prolonged asphyxia results in eventual bradycardia and hypotension as severe acidosis and cardiac failure develop.**

Asphyxia may occur in utero or postnatally. In either circumstance, a well-defined series of respiratory events follows (Fig. 4.2).[17] During ***primary apnea*, respiratory movements cease after a brief period of rapid breathing.** At the same time, the heart rate falls, and neuromuscular tone diminishes. Intrapartum-related events may result in the passage of meconium before birth. If the hypoxic-ischemic event continues, the heart rate falls further, blood pressure falls, hypotonia worsens, and a series of spontaneous deep gasps occurs. Gasping continues but becomes weaker and more irregular and then finally ceases. **After the last gasp, a period of *secondary apnea* begins.**[17,81] Another

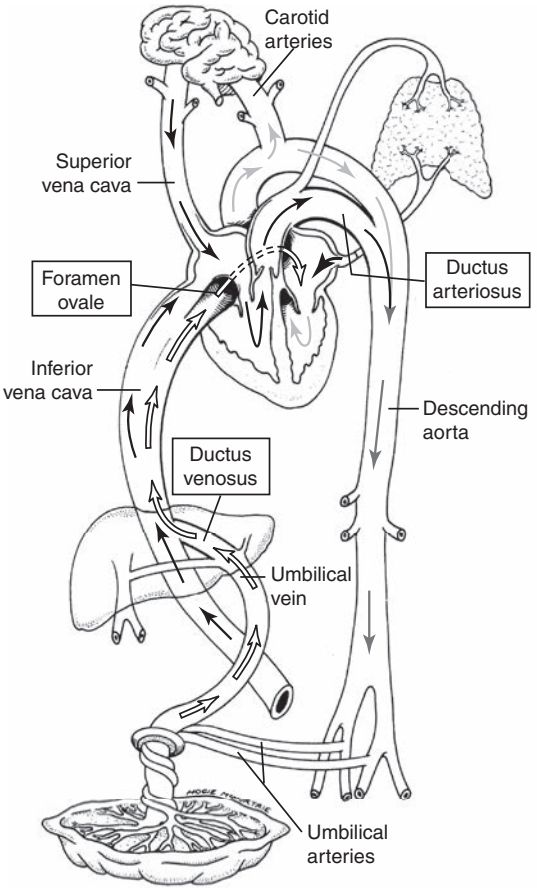

FIGURE 4.1 **Circulatory pattern before birth.** (From Goldsmith JP. Delivery room resuscitation of the newborn. In: Martin RJ, Fanaroff AA, Walsh MC, eds. *Fanaroff and Martin's Neonatal-Perinatal Medicine*. 9th ed. St. Louis: Elsevier Mosby; 2011.)

simple, **functional definition of asphyxia used by the World Health Organization is the failure to establish effective breathing at birth.**[71]

Delivery may occur at any point during an intrapartum-related hypoxic event and the progression to biochemical asphyxia. **If an infant is born during primary apnea, stimulation will usually induce respirations. If delivery occurs during secondary apnea, the infant will not respond to stimulation. Spontaneous respirations will not resume until resuscitation is initiated with assisted ventilation.**[17,81] **In the clinical setting of birth, primary and secondary apnea are essentially indistinguishable.** The infant who is not breathing may have a heart rate of less than 100

TABLE 4.1 COMPARISON OF VASCULAR AND PULMONARY FUNCTIONS BEFORE AND AFTER BIRTH

BODY STRUCTURE	FETAL FUNCTION	EXTRAUTERINE FUNCTION
Aorta	Carries oxygenated blood from left ventricle and deoxygenated blood from pulmonary arteries to fetal organs and placenta	Carries oxygenated blood from left ventricle into systemic circulation
Ductus venosus	Shunts most of the oxygenated blood from placenta to inferior vena cava	Disappears within 2 weeks after birth; becomes ligamentum venosum
Foramen ovale	Connects right and left atria; permits oxygenated blood from right atrium to bypass right ventricle and pulmonary circuit and go directly into left atrium	Functionally closes soon after birth; anatomically seals during childhood
Ductus arteriosus	Shunts blood from pulmonary artery directly into aorta	Functionally closes soon after birth; eventually becomes ligamentum arteriosum
Umbilical arteries and vein	Carry blood to and from placenta, the organ of respiration before birth	Clamped at birth, obliterating placental connections; become ligaments
Lungs	Distended with fluid; minimal pulmonary circulation; fetal respiratory movements	Expanded and aerated; pulmonary circulation allows CO_2 and O_2 exchange; organ of respiration

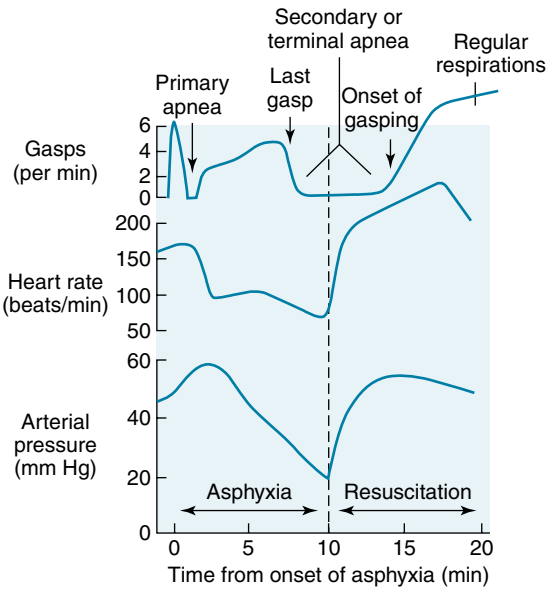

FIGURE 4.2 Changes in physiologic parameters during asphyxiation and resuscitation of rhesus monkey fetus at birth. (From Dawes GS. *Foetal and Neonatal Physiology: A Comparative Study of the Changes at Birth.* St. Louis: Mosby; 1968.)

beats/min and may be hypotonic. **Thus, any infant who is apneic at delivery must be assumed to be in secondary apnea, and intervention should begin immediately.**

The longer the initiation of ventilation is delayed after an infant's last gasp in secondary apnea, the longer the time necessary during resuscitation for the return of the infant's spontaneous respiration. **For every 1-minute delay, the time to the first gasp increases by about 2 minutes, and the time to the onset of spontaneous breathing is prolonged by more than 4 minutes.**[17] In the absence of effective resuscitation after delivery, apnea and decreased cardiac output result in progressive biochemical deterioration.[17]

Severe fetal and neonatal asphyxia impair the physiologic transitions to extrauterine life. The normally high fetal pulmonary vascular resistance may not decrease in the presence of pulmonary hypoexpansion, persistent acidosis, and hypoxemia. As part of persistent pulmonary hypertension of the newborn, pulmonary blood flow and oxygen transfer are impeded, perpetuating hypoxemia, and normal closure of fetal shunts is delayed.[68] This results in persistent right-to-left shunting through the ductus arteriosus and foramen ovale. Lung fluid clearance also may be delayed because of poor lung

inflation or pulmonary hypoperfusion and hypoxemia. In addition, intraalveolar fluid may accumulate as a result of leakage from damaged pulmonary capillaries, resulting in pulmonary edema. **With worsening hypoxemia and acidosis, myocardial function begins to fail, cardiac output falls, and systemic perfusion decreases to the brain, kidney, and intestine, setting the stage for postasphyxial injury of these organs.**[6]

CLAMPING OF THE UMBILICAL CORD

The optimal timing for cord clamping remains a subject for debate, as it has been for decades, but only recently has **management of the umbilical circulation been considered as part of stabilization or resuscitation of the newly born infant.**[58] The approach to the timing of cord clamping is variable worldwide; however, **practice guidelines now generally recommend a delay in cord clamping of 1 to 3 minutes as the standard of care.**[5,87] Maintaining placental circulation during the onset of spontaneous respirations and inflation of the lungs with air smooths the immediate cardiovascular transition. Until pulmonary blood flow increases to supply left ventricular preload, cardiac output and systemic circulation depend on umbilical flow to the right atrium and streaming across the foramen ovale to the left atrium. Premature disruption of the umbilical circulation can result in bradycardia and fluctuations in systemic blood flow and pressure.[11]

Placental transfusion, the amount of blood that flows from the placenta to the infant at birth before cord clamping or cessation of cord pulsations, mediates blood volume as a second major aspect of cardiovascular transition.[27] **A delay in clamping the cord for 30 to 120 seconds after birth facilitates the transfer of an additional 30 to 150 mL of blood from the placenta to the newborn,** with most of the transfer occurring in the first minute.[31] The maximal mean volume of placental transfusion has been reported between 24 and 32 mL/kg of body weight or an additional 30% to 40% of blood volume in the first 3 minutes after birth.[44] **Immediate clamping of the umbilical cord after delivery blocks the normal transfer of blood from the placenta to the infant, resulting in a deficit of as much as 25% of normal blood volume.**[55] The quantity of blood transferred to the infant appears to be influenced by the route of delivery (vaginal, cesarean), the timing of cord clamping, the initiation of respiration and cry, the position of the newborn relative to the placenta (gravity), manipulation of the cord (milking), and the intensity of uterine contractions at the end of the second stage of labor.[52,54,58] **Experimental evidence suggests that the onset of respirations is crucial in optimizing placental transfusion, and the physiologic sequence of delayed cord clamping (DCC) is clamping after the onset of respirations.**[11]

Studies conducted in term infants suggest that early cord clamping (ECC), compared with DCC, results in a greater risk of anemia in infancy.[54] **Late clamping acts as a low-cost intervention to reduce anemia during the first 6 months of life.**[32,36] Despite concerns that the increase in neonatal blood volume with DCC may result in neonatal jaundice and polycythemia, randomized trials in term infants have not substantiated an increased need for special care related to these diagnoses.[44] In fact, **a recent meta-analysis of trials in preterm infants showed a reduction in mortality with DCC.**[30] **Several recent reviews evaluating the potential benefits and risks of late versus early cord clamping in the preterm and term population summarize the evidence that DCC after birth is beneficial to both preterm and term infants.**[31,44,54,65] **In preterm infants, these studies report benefits in terms of improved physiologic stability and reduction in the relative risk of intraventricular hemorrhage and the need for transfusion.**

Although there may be physiologic benefits to delayed clamping, few studies have examined the timing of cord clamping with respect to the need for or response to resuscitation at birth.[9,46] In the event of fetal distress and neonatal depression, immediate clamping of the cord has usually been performed so that the infant can be resuscitated. Ongoing large, randomized clinical trials are examining resuscitation with the cord intact.[13,84] **Clinicians who are charged with the care of the newborn at delivery and thereafter should be part of the decision making around the time of cord clamping, document the time of cord clamping as part of the resuscitation record, and be aware of the implications of either early or delayed clamping for subsequent care.**

RESUSCITATION OF THE NEWBORN

Preparation for Resuscitation

Immediate, effective resuscitation of the newborn infant can reduce or prevent morbidity and mortality. **Much of neonatal resuscitation focuses on accurate assessment and initiation of ventilation. Basic interventions are often all that is necessary to successfully resuscitate a depressed infant.**[35,56,62] **However, effective resuscitation requires anticipation, adequate preparation of equipment and personnel, and teamwork.**[29,83]

In the mid-1980s, the American Heart Association and the American Academy of Pediatrics addressed the need for a national training program for neonatal resuscitation in the United States by developing the **Neonatal Resuscitation Program (NRP). The NRP provides the training necessary for health care professionals to put into practice the scientific consensus established and updated periodically by the International Liaison Committee on Resuscitation (ILCOR).** The ILCOR Consensus on Science is revised according to a rigorous process of evidence evaluation.[63] Changes are then incorporated into regional guidelines and the *Textbook of Neonatal Resuscitation*.[81,88] **The program's widespread acceptance ensures consistent awareness of current scientific consensus, use of proper equipment, and preparation of personnel to work as a team using shared knowledge and performance skills.** *Helping Babies Breathe,* a program for basic resuscitation in resource-limited settings, shares the same evidence base as the NRP; however, it emphasizes the initial steps of resuscitation through bag-and-mask ventilation with air for resource-limited settings where both mother and baby may be cared for by a single birth attendant and advanced interventions are not universally available.[2,57]

The seventh edition of the NRP recommends the following guidelines.[81]

At every delivery, there should be at least one person capable of initiating resuscitation whose only responsibility is the baby. Either this person or another who is immediately available should have the skills necessary to perform a complete resuscitation, including endotracheal intubation and administration of medications.

When a high-risk delivery is anticipated, two persons whose sole responsibility is resuscitation of the infant should be present, and their roles should be designated in advance. Multiple births require a full team of personnel with complete equipment for each newborn.

Care providers responsible for the newborn must be familiar with the prenatal and intrapartum history of the mother and fetus because this information guides preparation for resuscitation. Preterm/postterm gestation; multiple gestation; meconium-stained amniotic fluid; and risk factors in the medical, obstetric, intrapartum, and social history may identify the infant who may require skilled resuscitation at delivery (Box 4.1).[1,8,90] However, **any normal pregnancy may become high risk at the onset of previously unexpected or undetected intrapartum complications, including maternal hemorrhage, cord prolapse, and meconium staining of the amniotic fluid.** Although prevention,

BOX 4.1 CONDITIONS THAT MAY REQUIRE AVAILABILITY OF SKILLED RESUSCITATION AT DELIVERY

Intrapartum Problems

- Fetal distress
  - Persistent late decelerations
  - Severe variable decelerations without baseline variability
  - Bradycardia
  - Meconium-stained amniotic fluid
  - Cord prolapse
- Prolonged, unusual, or difficult labor
- Emergency operative or assisted delivery
- Breech presentation with vaginal delivery
- Narcotic administration to mother within 4 hours of delivery

Medical/Obstetric/Genetic Problems

- Diabetes mellitus
- Suspected or confirmed maternal infection
- Preeclampsia
- Abnormal amniotic fluid volume
- Multiple gestation
- Fetal growth deviations
- Prematurity
- Isoimmunization/hydrops
- Fetal congenital anomalies

BOX 4.2 EQUIPMENT USED DURING NEONATAL RESUSCITATION

Thermal Management
- Radiant warmer
- Warmed blankets or towels
- Infant stocking cap
- Food-grade plastic wrap or polyethylene bags
- Chemically activated warming pad

Airway
- Bulb syringe
- Mechanical suction
- Suction catheters—5 to 6, 8, 10, and 14 Fr
- 8-Fr feeding tube and 20-mL syringe
- Meconium aspirator/suction device
- Shoulder roll

Breathing
- Bag-and-mask ventilation
  - Oxygen source with flowmeter and tubing
  - Neonatal resuscitation bag with 21% to 100% oxygen capability and manometer or pressure release valve and/or T-piece device
  - Facemasks—newborn and premature sizes
  - Oral airways—newborn and premature sizes
  - Pulse oximeter with neonatal probe
  - Oxygen blender and compressed air source
- Intubation
  - Laryngoscope with extra batteries
  - Straight blades—No. 0 and No. 1 with extra bulbs
  - Endotracheal tubes—2.5-, 3.0-, 3.5-, and 4.0-mm internal diameter
  - Stylet
  - Tape, skin preparation
  - Scissors
  - CO_2 detector
  - Laryngeal mask airway

Circulation
- Stethoscope
- Wall clock or stopwatch
- Cord clamp
- Medications (epinephrine, normal saline)
- Sterile gloves
- Chlorhexidine sponges, povidone-iodine solution
- Umbilical vessel catheterization tray
- Umbilical catheters—3.5 and 5 Fr
- Three-way stopcocks
- Umbilical tape
- Suture material
- Intravenous catheters, tubing, fluid
- Needles—25, 23, 22, 20, and 18 gauge
- Syringes—1, 3, 5, 10, 20 or 30, 50, or 60 mL
- Cardiorespiratory monitor and temperature probe (for prolonged stabilization)
- Procedure light

detection, and treatment of fetal asphyxia are the responsibilities of the obstetric team, coordination between obstetric and neonatal services in a "prebriefing" before delivery is vital to ensure timely and effective resuscitation.

Resuscitation equipment, supplies, and drugs (Box 4.2) should always be readily available, functional, and assembled for immediate use in a designated location—ideally in a specific area of the delivery/birthing room or on a radiant warmer/intensive care bed equipped with easily accessible storage (Figs. 4.3 and 4.4).

Prepare to facilitate normal transition or provide neonatal resuscitation by performing the following:

- **Conduct a prebriefing** (Gestation? Amniotic fluid clear? Expected number of babies? Other risk factors?) and **designate roles among the resuscitation team.**
- **Prepare the mother for skin-to-skin care and DCC.**
- **Preheat the radiant warmer.**
- **Assemble basic supplies:** warm linens, head covering for infant, suction device, cord clamp, and appropriate personal protection.
- **Check suction device and equipment for function;** set the vacuum regulator control not to exceed 100 mm Hg.
- **Turn on the air/oxygen flow to the ventilation bag or T-piece device, and check all connections, flow-control valves, the pressure-release valve, and manometer function to enable the ventilation device to deliver a pressure of up to 30 to 40 cm H_2O.** Select the appropriate oxygen concentration for initiation of positive-pressure ventilation. Prepare an appropriate-size facemask and a pulse oximeter with a neonatal probe.

FIGURE 4.3 Labor/delivery/recovery (LDR) room resuscitation area prepared for high-risk delivery. Blended oxygen is available from wall outlets via T-piece device incorporated into the radiant warmer. Flow-inflating bag and manometer are prepared with self-inflating bag as backup. Bulb suction device and catheter for use with wall suction are available. Other supplies for airway suctioning and intubation are stored in the drawers of the supply cart. Resuscitation drugs and umbilical catheterization trays are kept in a separate resuscitation cart accessible from all LDR rooms. (Photo courtesy of Children's Hospital Colorado, Maternal Fetal Care Unit. Photo by Tia Brayman.)

FIGURE 4.4 Patient area of radiant warmer prepared for a delivery. Supplies needed for initial steps and ventilation include warm blankets *(left rear)* for drying, overhead heater for warmth, head covering, suction devices, ventilation bag and masks, pulse oximetry probe and patient connector, stethoscope, and cord clamp. Temperature probe and cardiorespiratory monitor connector are available for prolonged stabilization. (Photo courtesy of Children's Hospital Colorado, Maternal Fetal Care Unit. Photo by Tia Brayman.)

- **Check the laryngoscope** for a bright light source and appropriate blades (size 0 for premature infants and size 1 for term infants); tighten the bulb.
- **Check the availability of appropriate-size endotracheal tubes** (2.5 to 3.5 mm internal diameter).
- **Locate a stethoscope** of appropriate size and confirm that it is functioning properly.
- **Identify a cardiac monitor and leads** for use if positive-pressure ventilation is necessary.
- **Check the ancillary equipment** (e.g., umbilical catheter supplies, intravenous solutions, unexpired resuscitation drugs, alternative airway).
- **If the clinical situation warrants, draw up and label emergency medications** for ready administration, using the estimated fetal weight, and obtain O-negative packed red blood cells for emergency transfusion.

The steps of transition and neonatal resuscitation follow the standard ABCs of resuscitation:

A—Airway
B—Breathing
C—Circulation

With the ABCs as an overall framework for neonatal resuscitation, the components of the procedure can be examined sequentially:

A—Establish an airway:

Position the infant.
Clear secretions from the mouth and nose as needed.
Perform endotracheal intubation or use alternative airway, such as a laryngeal mask, if necessary.

B—Initiate breathing:

Dry thoroughly.
Provide specific tactile stimulation to breathe, if necessary.
Provide free-flow oxygen or positive-pressure ventilation with oxygen based on gestational age and time-specific oxygenation targets (Table 4.2).

C—Maintain circulation:

Delay umbilical cord clamping for at least 1 minute in term and preterm infants. Take steps to establish respirations before umbilical cord clamping.
Provide chest compressions.
Administer epinephrine and volume expander, if indicated.

Each step of the resuscitation procedure, whether uncomplicated or extended, is guided by

TABLE 4.2 TIME-SPECIFIC SATURATION TARGETS AFTER BIRTH

TIME AFTER BIRTH (MINUTES)	SATURATION (%)
1	60–64
2	65–69
3	70–74
4	75–79
5	80–84
10	85–95

the evaluation/decision/action cycle. Evaluation includes assessment of respirations, heart rate, and oxygen saturation (Fig. 4.5).[81] The importance of providing warmth, establishing an airway, drying, and stimulating the newly born to initiate breathing cannot be overemphasized in neonatal resuscitation. **Expansion of the lungs with air and adequate ventilation are the keys to successful resuscitation.** Successful performance of these steps often obviates the need for further intervention, but **inadequate lung expansion and ventilation cannot be overcome by performing chest compressions or administering medications.**

Apgar Score

The Apgar score provides a comprehensive, objective measure of the infant's condition in the first minutes after birth (Fig. 4.6). **The Apgar score does not serve as an indicator of the need for resuscitation; rather, it quantifies an infant's response to the extrauterine environment and resuscitative measures.** In term and preterm infants, the Apgar score remains a valuable predictor of infants who will need ongoing support in the immediate perinatal period and those who are at higher mortality risk in the neonatal period.[16]

Although perinatal asphyxia may be associated with low Apgar scores, it is possible for an infant to have a low Apgar score without having asphyxia.[50] For example, an infant born to a mother who received general anesthesia may be flaccid and have depressed reflexes and poor respiratory efforts. Such infants usually respond

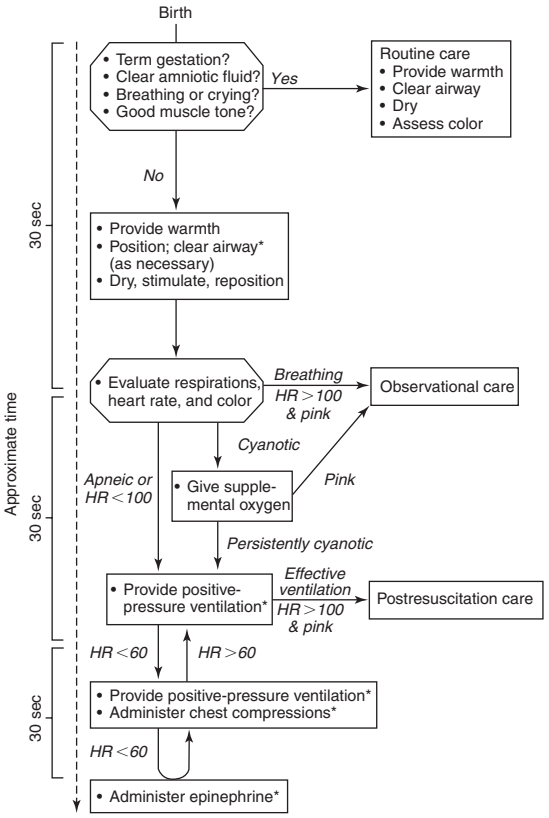

FIGURE 4.5 Throughout resuscitation, the infant's respirations, heart rate (HR), and oxygen saturations are evaluated as a basis for decisions and actions. (From Weiner GM, ed. *Textbook of Neonatal Resuscitation.* 7th ed. Elk Grove Village, IL: American Academy of Pediatrics and American Heart Association; 2016:9.)

rapidly to bag-and-mask ventilation, and no further intervention is necessary. However, an infant may have an equally low Apgar score as a result of intrauterine asphyxia and may require prolonged resuscitative efforts. An infant with a midrange Apgar score between 6 and 7 may be using homeostatic mechanisms to maintain adequate central blood pressure and cardiac output. **Apgar scores should be assigned at 1 and 5 minutes and every 5 minutes thereafter until the score is 7 or greater.** A complete description of the timing and nature of resuscitative measures is vital to interpreting a low Apgar score.[4]

Although the Apgar score is not used to guide resuscitation, **the experienced clinician performs a rapid visual assessment of an infant at the**

moment of birth. This rapid assessment incorporates two elements from the Apgar score, as well as a key question that influences the overall conduct of the resuscitation.

Rapid Assessment after Birth

In the first few seconds after birth, a rapid visual assessment of the baby should be performed to answer the following questions[88]:

- Is the baby term?
- Is the baby breathing or crying (respiratory effort)?
- Is there good muscle tone?

If the answer to all of these questions is "yes," the baby can remain with the mother in skin-to-skin contact to receive routine care as described in the Routine Care and Initial Steps of Resuscitation section that follows.

If the answer to any of the questions is "no," the infant will need further evaluation.[80]

Routine Care and Initial Steps of Resuscitation

The care of every infant at birth includes (1) drying, (2) providing warmth, (3) clearing the airway (positioning and suctioning if needed), and (4) support of breathing with tactile stimulation as necessary.

Whether part of routine care or during the initial steps of resuscitation, many of the actions can be performed simultaneously, especially if more than one person is caring for the infant.

DRY AND PROVIDE WARMTH

- Dry the infant thoroughly, remove wet linens, and place him or her directly on the mother's abdomen; cover both with warm linens during a delay in clamping the cord (routine care).

  or
- If the infant requires positive-pressure ventilation, dry thoroughly and clamp and cut the cord, and place the infant under a radiant heat source.

  or
- Wrap preterm infants less than 32 weeks of gestation in a polyethylene sheet or bag of food-grade plastic from the shoulders to the toes (without drying), with the right arm exposed for pulse oximetry probe placement; clamp and cut the cord; and place under a radiant heat source.[81,88]

POSITION AND CLEAR THE AIRWAY (AS NECESSARY)

- **Ensure that the infant's neck is slightly extended** when positioning him or her on the mother's chest; **wipe secretions from the mouth and nose or clear the airway with a bulb suction device if secretions are blocking the airway or the amniotic fluid contains meconium (routine care).**
  or
- **Position the infant on a flat surface with the neck slightly extended.**
- Turn the head (or the head and body) to the side to allow secretions to pool in the cheek, and then remove with a cloth or suction device. **Suction the mouth and then the nose to clear the airway. The mouth is suctioned first to clear the largest volume of secretions; when the nasopharynx is suctioned, a reflex cough, sneeze, or cry often results.** Deep pharyngeal suctioning in an infant not requiring positive-pressure ventilation or intubation should not be performed during the first few minutes after birth to avoid vagal stimulation, resultant bradycardia, and a delay in the rise of Pao_2.[14,26]

STIMULATE AND REPOSITION

- **Provide tactile stimulation by briefly rubbing** the back for infants who are not breathing or crying after drying.
  or
- **Continue gentle rubbing of trunk, extremities, or head to support early respiratory efforts** in the newborn.
- **Keep the head and neck in a slightly extended position to maintain an open airway.**

Evaluate the Infant

Evaluation of the infant is a continuous, ongoing process. Subsequent action is guided by evaluation during each step of resuscitation and decisions about whether the response is adequate.

EVALUATE RESPIRATIONS

- **Rate and depth of respirations** (chest wall movement, air exchange) must be adequate; **apnea and gasping respirations both require positive-pressure ventilation.**

EVALUATE HEART RATE

- **The heart rate should be greater than 100 beats/min.** Listen over the left side of the chest with a stethoscope to count the heart rate. Count the heart rate in 6 seconds and multiply by 10 for the beats per minute. Indicate each beat for other team members by tapping the forefinger on the bed or tapping the thumb and index finger together.
- **If the heart rate is <100 beats/min or the infant requires respiratory support, heart rate can be measured continuously with pulse oximetry or an electrocardiogram (ECG) monitor.**

EVALUATE OXYGENATION

- **Term, healthy babies may take more than 10 minutes to achieve a preductal oxygen saturation above 95%** and nearly an hour to achieve the same level in the postductal circulation.[19,39,66,73]
- **Give free-flow oxygen and place a pulse oximeter probe on the right hand/wrist if the infant is breathing but remains centrally cyanotic.** Peripheral cyanosis (acrocyanosis) is *not* an indication for supplemental oxygen. **The goal of oxygen administration should be normoxia based on time-specific oxygenation targets, not hyperoxia.**[19,63]

Respiratory Support With Positive Pressure

Consider continuous positive airway pressure (CPAP) for infants who have labored breathing and are unable to maintain SpO_2 within the target range despite increasing oxygen concentration.

Indications for positive-pressure ventilation in the newborn infant include the following:

- **Apnea or gasping respirations despite a brief period of tactile stimulation**
- **A heart rate of less than 100 beats/min**
- **Central cyanosis despite free-flow oxygen or oxygen administered with CPAP**

Prolonged tactile stimulation or administration of supplemental oxygen to a baby who is not breathing effectively or who has a heart rate of less than 100 beats/min only delays appropriate treatment. If supplemental oxygen is unavailable, positive-pressure ventilation should be provided with room air. **When supplemental oxygen is available, it should be administered with the goal of achieving normoxia and avoiding hyperoxia.**[19,63] **Research in animals and humans has demonstrated that room air is equivalent to 100% oxygen for positive-pressure ventilation**

in many newly born infants. The exclusive use of 100% oxygen for postnatal resuscitation, as previously recommended, can result in hyperoxia and changes induced by the generation of oxygen free radicals.[75,77] The concentration and duration of supplemental oxygen administration should be individualized to patient needs. Pulse oximetry, initiated as soon as feasible, can help guide oxygen administration.[18] The ability to administer oxygen in concentrations from 21% to 100% in the delivery setting is a standard of care that has special importance for preterm infants who are more vulnerable to oxygen injury yet may need concentrations greater than 21%.[26,47,61,78,81] Positive-pressure ventilation should be initiated with 21% oxygen for infants >35 weeks. Preterm infants <35 weeks may require 21% to 30% oxygen initially to achieve target saturations. Frequently, preterm infants who have received antenatal corticosteroids and resuscitation with low oxygen concentrations wean back to room air by admission to the neonatal intensive care unit (NICU).

IMPROVE VENTILATION

- The best indication of good mask seal and adequate lung inflation is a rising heart rate and bilateral breath sounds. Oxygen saturation should also rise, and chest movement should be seen with each inflation.
- If heart rate and oxygenation do not improve, take steps to improve ventilation by reapplying the mask and repositioning the head, suctioning mouth and nose and opening the mouth, increasing ventilation pressure, and considering an alternative airway (endotracheal tube or laryngeal mask airway).

Chest Compressions

- If, after 30 seconds of effective positive-pressure ventilation, the heart rate is less than 60 beats/min, intubate or insert an alternative airway, begin chest compressions (two-thumb technique), and increase the oxygen concentration to 100%. Call for help to prepare for possible umbilical venous catheter (UVC) placement and administration of emergency drugs.

Administration of Epinephrine and Volume Expansion

- If the heart rate remains below 60 beats/min despite ongoing positive-pressure ventilation and chest compressions, ensure that ventilation and chest compressions are being given effectively.
- If the heart rate remains below 60 beats/min after 45 to 60 seconds of coordinated chest compressions and effective ventilation, administer epinephrine.
- If the baby is not responding to resuscitation, including administration of epinephrine, and there is evidence of blood loss or hypovolemia, consider administration of a volume expander.

The initial steps in resuscitation should be accomplished rapidly so that the baby is breathing spontaneously or receiving positive-pressure ventilation by 1 minute after birth. The initial rapid assessment can be performed in the first few seconds after birth to determine whether routine care can be provided to the infant in skin-to-skin contact with the mother or whether more extensive evaluation and resuscitation will be necessary during the initial steps. The initial steps of resuscitation can be performed concurrently with evaluation of heart rate, respirations, and oxygen saturations, especially if more than one person is present to care for the infant. Positive-pressure ventilation should be performed for at least 30 seconds before moving to the next level of intervention. When oxygen concentrations of less than 100% are used with positive-pressure ventilation and an adequate response in heart rate does not occur, steps to improve lung inflation should be taken, and then the oxygen concentration can be increased before initiating chest compressions. Chest compressions should be continued for 60 seconds before pausing for assessment. If the resuscitation proceeds to the use of epinephrine, reassessment should occur after 60 seconds to allow the epinephrine to circulate.

An infant who has received more than the initial steps of resuscitation will require close monitoring for additional or recurrent problems during the postnatal transition and may need supportive care such as continued oxygen administration. Infants who require more than brief positive-pressure

ventilation should be monitored in a nursery setting in which they can receive ongoing care.[4]

Skills Necessary for Neonatal Resuscitation

INITIAL STEPS: SUCTIONING FOR MECONIUM-STAINED AMNIOTIC FLUID

Meconium-stained amniotic fluid may be seen in infants who are more than 34 weeks of gestational age and occurs most often in term and postterm neonates. Passage of meconium may be associated with asphyxia. Severe fetal acidosis can result in fetal gasping, leading to in utero aspiration of meconium.[10] Suctioning the mouth and hypopharynx at the delivery of the head and again after complete delivery was advocated in the past to help prevent meconium aspiration. Current evidence no longer advises routine intrapartum suctioning for infants with meconium-stained amniotic fluid.[63,74]

Resuscitation for infants with meconium-stained amniotic fluid should follow the same principles as for infants born through clear fluid. The NRP no longer recommends that any infant with meconium-stained amniotic fluid at birth receive routine tracheal intubation for suctioning because this may delay ventilation beyond 60 seconds after birth.

Nevertheless, **any infant born with meconium-stained amniotic fluid who develops signs of airway obstruction or ineffective positive-pressure ventilation should have tracheal intubation performed for suctioning of any meconium present.** For this reason, **newborns with meconium-stained amniotic fluid require notification and availability of an appropriately credentialed team with full resuscitation skills, including endotracheal intubation.**

ADMINISTRATION OF FREE-FLOW OXYGEN

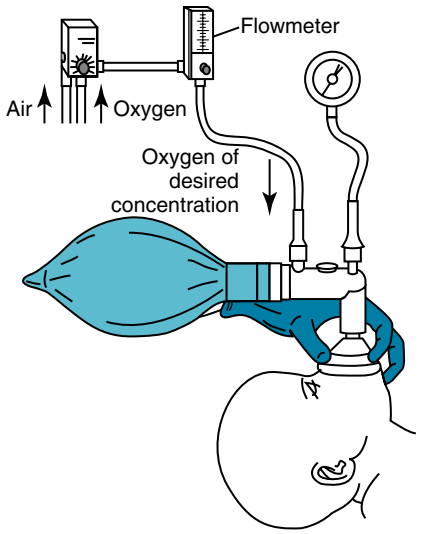
Supplemental oxygen should be administered after the initial steps if the infant remains centrally cyanotic.[88] The administration of oxygen is guided by pulse oximetry to achieve time-specific saturation targets (see **Table 4.2**).[20,91] Oxygen delivered at a flow rate of 5 L/min may be administered by mask or by holding the oxygen tubing in a cupped hand over the infant's face. The delivered oxygen concentration decreases rapidly as the tubing or mask is withdrawn from the face.

Once the target oxygen saturations are achieved, gradually withdraw the oxygen tubing or the mask from the infant's face. If cyanosis persists, reevaluate the quality of respirations and the heart rate, perform a brief physical examination, and consider bag-and-mask ventilation or intubation if there is evidence of respiratory distress.

BAG-AND-MASK VENTILATION

The indications for bag-and-mask ventilation include (1) apnea unresponsive to brief stimulation or gasping respirations, (2) heart rate less than 100 beats/min, and (3) persistently low oxygen saturation despite free-flow oxygen or CPAP with increasing oxygen concentration. The equipment for bag-and-mask ventilation can be either a self-inflating bag with an oxygen reservoir and pressure-release valve or pressure gauge, a flow-inflating bag (anesthesia bag) with a flow-control valve and pressure gauge, or a T-piece resuscitation device.

Although used widely, *self-inflating bags* **do not deliver consistent tidal volumes or inflation pressures, even in the hands of providers who resuscitate frequently.** Some data suggest, however, that self-inflating bags may offer advantages over flow-inflating bags in the hands of inexperienced operators.[41] **Self-inflating bags cannot be used reliably to deliver free-flow oxygen, and they require a special adapter to deliver CPAP** (Fig. 4.7). Ideally, they would be fitted with a CPAP device and a manometer for use with newborns. *Flow-inflating bags* **require a complete seal between mask and face to deliver a tidal volume. They offer the capability to achieve high peak pressures, deliver positive end-expiratory pressure (PEEP) and CPAP, and administer free-flow oxygen.** The volume of the bag should generally be between 200 and 750 mL.[81] Larger bags are more difficult to handle and predispose to overly large tidal volumes, especially for preterm infants. A *T-piece resuscitation device,* as opposed to a bag, can **achieve desired inflation pressures and respiratory times more consistently (at least in mechanical models) but requires setting the inspiratory pressure and PEEP before use and may be more difficult to adjust during resuscitation** (see Fig. 4.7).[20,28,41]



Flow-inflating bags. Flow-inflating bags contain an inflatable gas reservoir that must be connected to a compressed gas source to refill between breaths.

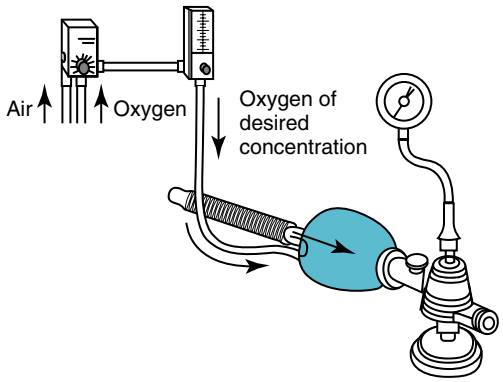
Advantages:

- Ability to deliver 21% to 100% oxygen, depending on the source
- Ability to maintain a positive end-expiratory pressure and measure with manometer
- Easy to determine when there is a seal around the neonate's face
- Ability to deliver free-flow oxygen at concentrations up to 100% depending on the source

Disadvantages:

- Requires an external compressed gas source to inflate
- Requires a tight seal between mask and face to remain inflated
- Requires use of pressure gauge (manometer) to monitor pressure delivered with each breath.

A



Self-inflating bags. Self-inflating bags fill with ambient air and are independent on an external oxygen or compressed air source.

Advantages:

- Will always refill after being squeezed, even with no compressed gas source
- Pressure-release valve makes overinflation less likely

Disadvantages:

- Will inflate even if there is not a seal between the mask and the neonate's face
- Requires an oxygen reservoir to provide high concentration of oxygen
- Cannot be used to deliver free-flow oxygen reliably through the mask
- Cannot be used to deliver continuous positive airway pressure (CPAP) and can deliver positive end-expiratory pressure (PEEP) only when a PEEP valve is added and pressurized gas is entering the bag

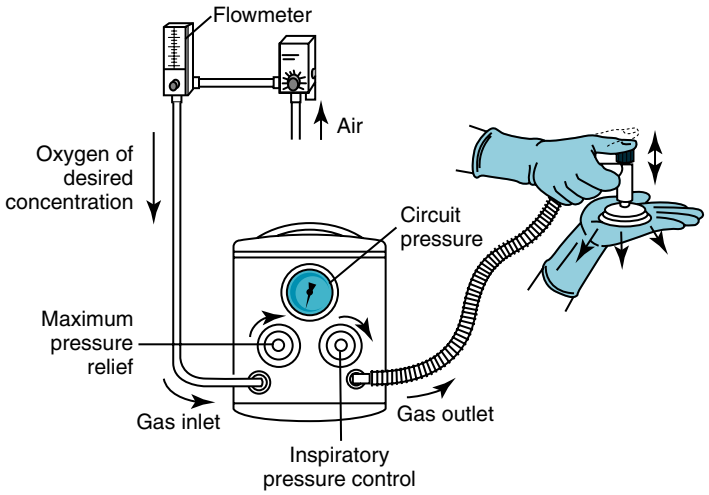
B

FIGURE 4.7 **A**, Flow-inflating bag. **B**, Self-inflating bag. **C**, T-piece resuscitator. (From Weiner GM, ed. *Textbook of Neonatal Resuscitation.* 7th ed. Elk Grove Village, IL: American Academy of Pediatrics and American Heart Association; 2016.)

The facemask should be selected to ensure that it is the appropriate size to cover the chin, mouth, and nose but not the eyes. Masks are commonly available in term and premature sizes to fit even very low-birth-weight infants. **Flexible, translucent masks with a cushioned rim generally provide the best seal with minimal trauma and allow monitoring of mouth position and secretions.**[85,86]

Perform the following steps:

- **Set the flowmeter to deliver 5 to 10 L/min.** Flow rates at the higher end of the range are necessary to achieve higher pressures and faster ventilation rates with a flow-inflating bag.
- **Test equipment before use.** Equipment failure can cause resuscitation failure!
- **Position the infant with the neck slightly extended, place the mask on the chin, and roll it over the mouth and nose (but not the eyes) to make a firm seal.**[86] Avoid compression of the soft tissues of the neck by holding the mask to the face with the thumb and index finger and providing gentle upward pressure with the third finger under the chin.



T-piece resuscitator.
Advantages:
- Consistent pressure
- Reliable control of peak inspiratory pressure (PIP) and positive end-expiratory pressure (PEEP)
- Reliable delivery of 100% oxygen
- Operator does not become fatigued from bagging

Disadvantages:
- Requires compressed gas supply
- Requires pressures to be set prior to use
- Changing inflation pressure during resuscitation is more difficult
- Risk of prolonged inspiratory time

C

FIGURE 4.7, cont'd

- **Ventilate at a rate of 40 to 60 breaths/min with pressures of 15 to 20 cm H_2O for normal lungs or up to 20 to 40 cm H_2O for diseased lungs.** Most apneic preterm infants respond to initial inflation pressures of 20 to 25 cm H_2O.[81] Pressure as high as 30 to 40 cm H_2O may be necessary in term infants not breathing spontaneously. When surfactant is administered immediately after birth, rapid compliance changes may require equally rapid adjustment of ventilation pressures and oxygen concentration.
- **Place ECG leads and connect to a cardiac monitor.** Check the heart rate after 15 seconds of positive-pressure ventilation. Prompt improvement in heart rate is the best indicator of adequate ventilation. If the heart rate is <100 beats/min and chest rise is adequate, continue ventilation. If the chest is not rising, perform the corrective steps of MR SOPA: (1) **reapply the facemask** for a better seal, (2) **reposition** the head, (3) suction **secretions**, (4) **open** the infant's mouth slightly, (5) increase **pressure**, and (6) consider an **alternative** airway.[81]
- **Reevaluate respirations, heart rate, and oxygen saturation after 30 seconds of positive-pressure ventilation.** If the heart rate is <100 beats/min, call for additional help and prepare for intubation or insertion of laryngeal mask airway.
- **Provide CPAP after spontaneous respirations have returned.** End-expiratory pressure decreases lung injury and improves compliance and gas exchange.[45,72] CPAP may have a role in maintaining lung volumes in premature infants and aiding the absorption of lung fluid.[56]
- **Insert an orogastric catheter** (8-Fr feeding tube) after several minutes of bag-and-mask

ventilation or CPAP or if there is evidence of gastric distention.

- **Measure the insertion depth of the catheter** by holding the tip at the bridge of the nose and measuring to the earlobe and then midway between the xiphoid and the umbilicus.[81]
- **Insert the catheter through the mouth,** not the nose, because newborns are obligate nose-breathers.
- **Aspirate gastric contents with a 20-mL syringe and leave the catheter open.**
- **Tape the catheter to the infant's cheek.**

The adequacy of bag-and-mask ventilation must be continuously assessed by monitoring of heart rate, auscultation of breath sounds, visualization of chest wall movement, and oxygen saturations. Peak inspiratory pressure should be limited to that necessary to see an improvement in heart rate and chest wall movement and to hear good air exchange on auscultation of the chest. Inspiratory pressures cannot be judged clinically; bags fitted with in-line pressure manometers or T-piece devices are recommended in the delivery room.[81] Devices that more easily and consistently deliver targeted volumes during positive-pressure ventilation are the focus of much recent research.[70] Strategies to avoid intubation, especially CPAP with limited oxygen concentration, offer the promise of a reduction in the severity of chronic lung disease.[21] Further clinical trials will help establish the optimal method(s) for achieving lung expansion while minimizing the complications of positive-pressure ventilation.[64,78]

Potential complications of bag-and-mask ventilation include trauma to the eyes or face from an improper size or position of the mask, lung injury (especially in preterm infants), air leak (pneumothorax, subcutaneous air), gastric distention elevating the diaphragm, and direct lung compression in the case of a diaphragmatic hernia (Table 4.3). Complications can be minimized by using gentle technique and equipment of the correct size, careful monitoring of pressures, and insertion of an orogastric tube when indicated.

ENDOTRACHEAL INTUBATION

Endotracheal intubation may be performed at several points during neonatal resuscitation.[81] Intubation is indicated when bag-and-mask ventilation is ineffective or prolonged positive-pressure ventilation is needed and when chest compressions are necessary. Additional indications for endotracheal intubation include surfactant administration, suspected diaphragmatic hernia, and direct tracheal suction for obstructive secretions. Equipment for intubation is listed in the "Airway" and "Breathing" sections in Box 4.2.

Select an uncuffed, uniform-diameter endotracheal tube of the correct size (Table 4.4). A variety of sizes (2.5- to 3.5-mm internal diameter) should be available because estimated weights may be inaccurate or airway anomalies may exist. **Orotracheal intubation is preferable to nasotracheal intubation during acute resuscitation because it can be performed rapidly and without additional equipment.**

Perform the following steps:

- Shorten the selected endotracheal tube to 13 cm (or the length appropriate for the fixation method used), and **prepare the laryngoscope, tape, suction, oxygen, bag, and mask.**
- **Position the infant with the neck slightly extended.**
- **Provide free-flow oxygen** as needed to achieve target saturations.
- **Hold the laryngoscope with the left hand;** open the mouth with the right index finger and gently insert the blade.
- **Lift the laryngoscope upward and away so that the blade is nearly parallel to the surface beneath the infant.**
- **Visualize landmarks;** identify the epiglottis, vocal cords, and glottis (Fig. 4.8). If the esophagus is seen, withdraw the blade until the epiglottis drops down. If only the tongue is visible, advance the blade further until it enters the vallecula or passes under the epiglottis.
- **Apply gentle external pressure over the cricoid, which may help visualize the vocal cords.** Pressure may be applied with the little finger of the hand holding the laryngoscope or by an assistant.
- **Insert the endotracheal tube from the right corner of the mouth to just beyond the vocal cord guideline at the tip of the tube,** or measure from the tragus of the ear to nasal septum and add 1 cm to confirm the depth of insertion. Gestational age can also be used to predict insertion depth (see Table 4.4).
- **Limit each intubation attempt to 30 seconds to avoid hypoxia.**

TABLE 4.3 COMPLICATIONS DURING RESUSCITATION AND STABILIZATION

PROBLEM	CAUSE	DIAGNOSIS	REMEDIES
Persistent cyanosis	Inadequate oxygenation		
	• Inadequate Fio_2	Check pulse oximetry saturation and blender setting	Always have available blended O_2
	• Disconnected O_2 line	Check all connections	Reconnect line
	• Empty O_2 cylinder	Check O_2 source	Replace O_2 cylinder
	Inadequate ventilation		
	• Inadequate face mask seal	Diminished breath sounds; little chest wall movement; air leak around mask	Readjust facemask; seal tightly against skin
	• Compression of airway	Diminished breath sounds; little chest wall movement	Apply upward force to mandible to counteract downward force holding facemask in place; extend neck slightly
	• Insufficient insufflation pressure	Diminished breath sounds; little chest wall movement	Increase insufflation pressure until breath sounds are audible and chest movement seen
	• Compression of lungs by distended stomach	Diminished breath sounds; little chest wall movement; visibly distended stomach	Place orogastric tube
	• Malpositioned ET tube	Check tube position with laryngoscope Check breath sounds	Reinsert into trachea Withdraw until breath sounds are bilaterally equal Tape ET tube in place
	Pneumothorax	Check breath sounds Check for chest asymmetry Transillumination Chest x-ray examination	Decompress tension pneumothorax
Bradycardia	Same as for persistent cyanosis	Auscultation of precordium or palpation of umbilical cord base; pulse oximeter or cardiac monitor	Same as for persistent cyanosis External cardiac compression if heart rate less than 60 beats/min after 30 sec of effective ventilation
	Vagal stimulation Perinatal myocardial ischemia	Lack of response to oxygenation, ventilation, and chest compressions	Stop oropharyngeal suctioning Emergency epinephrine/volume expander administration
Hypothermia	Evaporative heat loss; conductive heat loss	Specific signs overlap those of asphyxia and shock Low core temperature	Dry infant; remove wet linen Use polyethylene bags/warming mattress Cover wet hair Keep under radiant warmer
Hyperthermia	Excessive warming Maternal fever	Apnea High core temperature	Servocontrol of warming devices Removal of warming mattress
Hypoglycemia	Glucose stores used before birth or during resuscitation	Specific symptoms overlap those of asphyxia and shock Low blood sugar	Bolus 2 mL/kg of $D_{10}W$ Maintenance infusion of $D_{10}W$
Hemorrhage	Inadequately secured umbilical arterial or venous line	Pallor Poor capillary refilling Leakage of blood	Keep all intravascular tubing connection sites in plain view Tape UAC/UVC in place in addition to suturing lines
	Liver laceration		Perform chest compressions with correct position/depth

ET, Endotracheal; *UAC,* umbilical artery catheter; *UVC,* umbilical venous catheter.

TABLE 4.4 ENDOTRACHEAL TUBE SIZE AND DEPTH OF INSERTION

WEIGHT (G)	GESTATIONAL AGE (wk)	TUBE SIZE (mm) (INSIDE DIAMETER)	DEPTH OF INSERTION (cm FROM UPPER LIP)
<1000	<28	2.5	<7
1000-2000	28-34	3.0	7
2000-3000	>34	3.5	8
>3000	>40	3.5	9

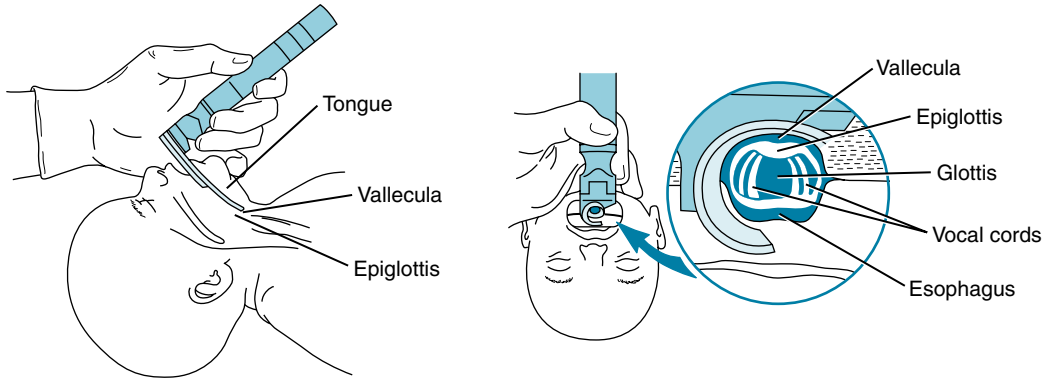

FIGURE 4.8 Anatomic landmarks that relate to intubation. (From Weiner GM, ed. *Textbook of Neonatal Resuscitation.* 7th ed. Elk Grove Village, IL: American Academy of Pediatrics and American Heart Association; 2016.)

- **Confirm endotracheal tube position by exhaled CO_2 detector and by auscultation for bilaterally equal breath sounds in the axillae and absence of breath sounds over the stomach. Observe chest wall movement. Note the centimeter marking at the lip** (see Table 4.4).
- **Secure the endotracheal tube and obtain a chest radiograph.**
- Shorten the endotracheal tube to 4 cm beyond the lips, if necessary.

Complications of intubation include hypoxia caused by prolonged intubation attempts or lack of supplemental oxygen; tube malposition; apnea or bradycardia caused by hypoxia or vagal stimulation; and trauma to the oropharynx, trachea, vocal cords, or esophagus (see Table 4.3). Exhaled CO_2 detection devices may be helpful even in newborn infants weighing less than 2 kg.[89] Color change in detection devices may be delayed in extremely preterm infants, especially if cardiac output is low, as during bradycardia. To prevent complications, provide free-flow oxygen during intubation, use gentle technique, and limit each intubation attempt to 30 seconds.

CHEST COMPRESSIONS

Indications for chest compressions include a heart rate of less than 60 beats/min despite effective positive-pressure ventilation for 30 seconds. Follow the sequence of (A) airway, (B) breathing, and (C) circulation in providing resuscitative support. **Even if the heart rate is less than 60 beats/min shortly after delivery, the airway should be cleared, and positive-pressure ventilation should be given for 30 seconds before beginning chest compressions. Often, adequate ventilation alone will result in a rapid increase in heart rate.**[62] Beginning chest compressions too early may interfere with the effectiveness of positive-pressure ventilation and actually delay an

infant's response to resuscitation.

Perform the following steps:

- **Attach ECG leads and intubate** if not already done.
- **Position the infant** with the neck slightly extended.
- **Provide firm support for the back.**
- **Increase oxygen concentration to 100%**
- **Perform compressions from the head of the bed using the two-thumb technique** (Fig. 4.9). The person providing ventilation moves to the side of the warmer once the intubation is complete and the tube is secured.
  - *Position:* Lower third of sternum[88]
  - *Rate:* 90 times/min
  - *Depth:* One third of the anterior-posterior diameter of the chest
  - *Support:* Encircling fingers
- Provide **90 compressions/min and interpose 30 breaths/min with a 3:1 ratio of compressions to breaths (120 events/min).**[88]
- **Evaluate the heart rate after 60 seconds** by ECG monitoring.
- **Continue chest compressions until the heart rate is greater than 60 beats/min.**
- Administer epinephrine if the heart rate remains less than 60 beats/min **after 60 seconds of coordinated and effective chest compressions with 100% oxygen.**

When the response to positive-pressure ventilation and chest compressions is poor, reevaluate for technical problems and conditions interfering with ventilation. Confirm that oxygen is connected properly and that oxygen has been increased to 100% (see Table 4.3). Ventilate with pressures to expand the chest and breaths interposed between compressions. Evaluate the infant for pneumothorax, diaphragmatic hernia, or hypovolemia (see **Delivery Room Emergencies** later in this chapter).

Complications of chest compressions include liver laceration, rib fractures, and pneumothorax. To prevent complications, check the position of compressions, maintain contact with the chest during the release portion of the compression cycle, and avoid excessive force during compressions.

MEDICATIONS

The indications for drug administration during newborn resuscitation include the following:

- **Epinephrine:** Heart rate less than 60 beats/min despite 60 seconds of coordinated ventilation via endotracheal tube and chest compressions
- **Volume expanders:** Evidence of acute bleeding or signs of hypovolemia; poor response to other resuscitative measures

Perform the following steps:

- **Calculate the correct dosage** of each drug based on the newborn's (estimated) weight.
- **Prepare each drug for administration,** draw up the appropriate concentration and volume, and label the syringe.
- **Administer each drug by the correct route** and at the **proper rate.**
- **Reevaluate for desired effect** and take follow-up action.

Epinephrine increases the rate and strength of cardiac contractions. Perhaps more important during resuscitation is its action as a peripheral vasoconstrictor, directing cardiac output to the central circulation and increasing coronary perfusion pressure.[82] **Epinephrine is most effective when administered by umbilical venous catheter in a dose of 0.1 to 0.3 mL/kg (0.01 to 0.03 mg/kg). Endotracheal administration in a one-time dose of 0.5 to 1 mL/kg (0.05 to 0.1 mg/kg) can be considered while obtaining venous access.** Expansion of plasma and blood volume may also be necessary to maintain cardiac output, blood pressure, and peripheral perfusion.

Volume expansion should be considered when there is evidence of acute blood loss (e.g., placental abruption, bleeding from placenta previa, fetal-maternal hemorrhage, umbilical cord tear, acute neonatal hemorrhage) or poor response to resuscitation (e.g., pallor, bradycardia, exaggerated tachycardia). **Normal saline is the preferred solution for volume expansion in a dose of 10 mL/kg by umbilical venous catheter.**

Complications of drug administration include extravasation with intravascular administration, hepatic injury with low umbilical venous catheters, and unpredictable absorption with endotracheal administration. The use of resuscitation drugs also may result in complications from their adverse pharmacologic effects. Epinephrine, administered in high doses, increases the risk for significant hypertension and a hyperadrenergic state, which may result in germinal matrix hemorrhage or myocardial damage. Absorption of epinephrine after

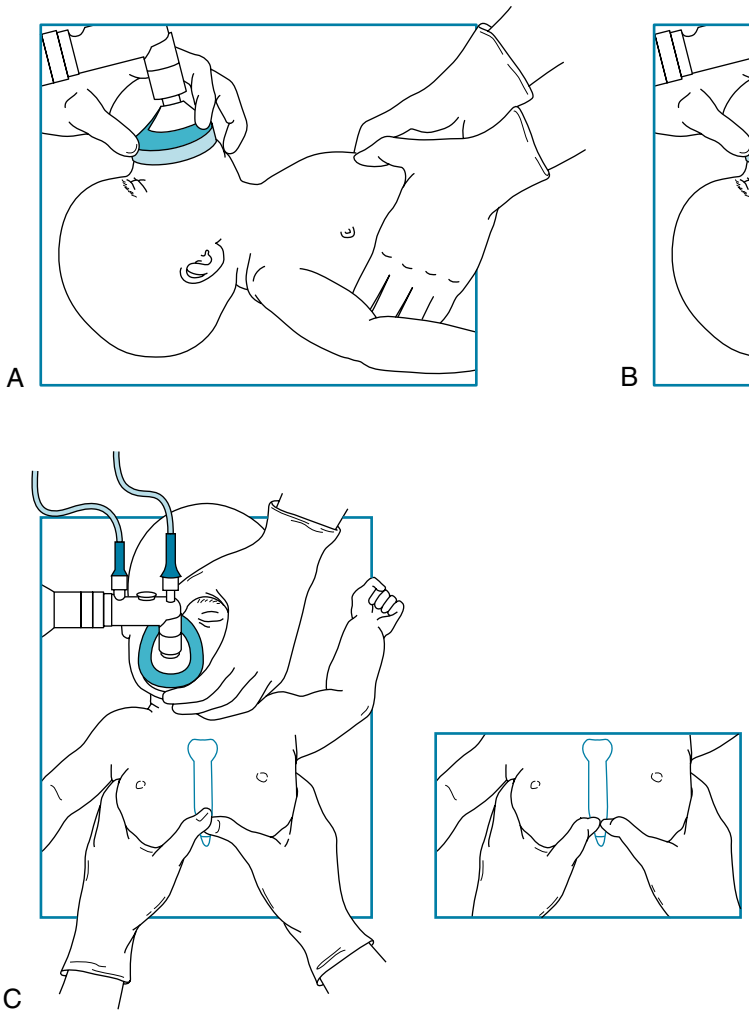

FIGURE 4.9 Two-thumb method of chest compression. Two thumbs placed one over the other or side by side (depending on the size of the baby) compress the sternum; the fingers support the spine. Providing chest compressions from the head of the bed facilitates emergency UVC placement. (From Weiner GM, ed. *Textbook of Neonatal Resuscitation.* 7th ed. Elk Grove Village, IL: American Academy of Pediatrics and American Heart Association; 2016.)

endotracheal administration is erratic.[82] Volume overload may result from administration of repeated doses of volume expanders. Rapid volume expansion, resulting in acute elevation of systolic blood pressure, has been associated with intraventricular hemorrhage.[33]

Distressed newborns have impaired autoregulation of cerebral blood flow, with blood flow directly related to the systolic blood pressure. Increased cerebral blood flow and elevated systolic pressures may be responsible for intraventricular hemorrhage in the presence of a capillary bed insulted by acidosis and hypoxia.[53] Autopsy studies also suggest that increased cerebral venous capillary pressure can initiate intraventricular hemorrhage. **Volume**

expansion should be performed cautiously in preterm or asphyxiated infants, infusing 10 mL/kg aliquots of fluid over a 5- to 10-minute period and evaluating the response before administering repeated aliquots of fluid. The exception to this rule is the infant who has experienced acute perinatal hemorrhage with hypovolemia. These infants should have the circulatory fluid volume restored as rapidly as possible. Complications of medication administration can be prevented by choosing the correct dose, rate, and route of administration and positioning umbilical lines carefully. The infant should be evaluated for adverse effects and response to fluid volume after each medication/volume dose.

Sodium bicarbonate is no longer recommended for use during resuscitation immediately after birth. Although acidosis frequently persists after a prolonged resuscitation, many infants correct an acidosis spontaneously once the asphyxiating circumstances are relieved and adequate ventilation is established. Metabolic correction of pH is a slow process that takes several hours, and treatment with sodium bicarbonate is not necessary. Sodium bicarbonate results in worsened acidosis in the setting of impaired ventilation; bicarbonate also may worsen intracellular acidosis. Furthermore, bicarbonate adds a high sodium load, which may directly depress myocardial performance.[7]

Naloxone hydrochloride is indicated during acute resuscitation only in the very specific circumstance of severe neonatal respiratory depression and narcotic administration to the mother in the last 4 hours. Naloxone is not part of the routine resuscitation of an apneic infant.[81] Establishment of gas exchange with positive-pressure ventilation is the first priority for any infant who does not have adequate spontaneous respirations after birth. Furthermore, naloxone hydrochloride is contraindicated in infants of narcotic-addicted mothers because administration can result in severe abstinence syndrome, including seizures.

Calcium and atropine have little role in delivery room settings. Calcium is indicated for hypocalcemia or hyperkalemia, both of which are infrequent problems in the delivery room. Atropine may mask hypoxia-related bradycardia.

DELIVERY ROOM EMERGENCIES

Certain conditions can present as emergencies in the delivery room (Table 4.5). These conditions may require extensive resuscitation or result in a poor response to resuscitation. **Some situations require special intervention immediately; most merit the involvement of a neonatal nurse practitioner, pediatrician, and/or neonatologist for management.** Coordinated teamwork, with techniques and communication skills acquired through simulation training, can help ensure rapid and effective stabilization.[37,83] Surgical intervention is necessary to complete the treatment of diaphragmatic hernia, abdominal wall defects, and neural tube defects. See Box 4.3 for an outline of emergency procedures in the delivery room setting.

CARE DURING THE TRANSITION FROM THE DELIVERY ROOM TO THE NURSERY

After the infant is stabilized and vigorous, perform elective procedures, such as clamping and shortening the umbilical cord, footprinting, and identification. A head covering prevents heat loss from the large surface area of the head and wet hair. **A vigorous, stable infant may remain in skin-to-skin contact with the mother and breastfeed immediately. The stable infant may complete the transition period with the parents under appropriate observation.**

The infant who has required more extensive resuscitation in the delivery room should be transferred to a special care or intensive care nursery when the infant has been dried and protected from excessive heat loss, adequate spontaneous or controlled ventilation has been established, and the heart rate is greater than 100 beats/min. Note the time of the infant's first respiratory effort and when sustained, regular respirations occur. **Transfer the infant in a warmed transport incubator with necessary support measures, such as supplemental oxygen or positive-pressure ventilation and pulse oximetry monitoring of heart rate and oxygen saturations.[42] Delay elective procedures until the infant is physiologically**

TABLE 4.5 DELIVERY ROOM EMERGENCIES

CONDITION	SIGNS AND SYMPTOMS	ONGOING PROBLEMS	INITIAL RESPONSES
Pneumothorax	Cyanosis, respiratory distress, unequal breath sounds, bradycardia, displaced heart sounds	Continuing asphyxia, shock (poor venous return)	Transilluminate chest, perform needle thoracentesis, evaluate chest tube placement
Choanal atresia; oral/pharyngeal airway anomalies	Noisy respirations, pink when crying but cyanotic when quiet, cannot pass suction catheter per nares	Respiratory distress, intermittent hypoxemia and bradycardia	Supplemental oxygen, oral airway, and prone positioning; or intubation (lower airway anomalies may require emergency tracheostomy)
Extreme prematurity	Respiratory distress	Continuing hypoxemia, hypothermia, possible sepsis, hypovolemia	Intubate, place umbilical lines, evaluate for artificial surfactant, begin antibiotics, consider transport to neonatal center
Sepsis	Respiratory distress, hypotonia, poor perfusion, foul odor	Continuing hypoxemia, shock	Intubate, place umbilical lines, administer antibiotics
Severe asphyxia	Prolonged apnea, bradycardia, poor perfusion, pallor, hypotonia, seizures	Hypoxemia, shock, multiorgan system injury	Intubate, place umbilical lines, give volume expander and vasopressors for shock, consider transport to neonatal center
Hydrops fetalis	Body wall edema, ascites, pallor, poor perfusion, respiratory distress, possibly unequal breath sounds (pneumothorax), distant heart sounds (pericardial effusion)	Hypoxemia, anemia, shock, potential for multiorgan system injury	Intubate, perform posterolateral needle thoracentesis bilaterally if unable to ventilate; consider paracentesis if ascites compromises ventilation; place chest tube for pneumothorax, place umbilical lines, evaluate need for partial exchange transfusion, consider transport to neonatal center
Pulmonary hypoplasia and oligohydramnios	Respiratory distress; flattened, deviated nose; infraorbital creases; low-set, crumpled ears; small chin; deformities of the extremities	Hypoxemia, pneumothorax, pulmonary hypoplasia	Intubate, place umbilical lines, monitor closely for pulmonary air leak, consider transport to neonatal center
Congenital diaphragmatic hernia	Respiratory distress with asymmetric breath sounds, barrel chest and scaphoid abdomen, point of maximal cardiac intensity shifted to side opposite hernia	Hypoxemia, pulmonary hypertension, contralateral pneumothorax	Intubate, decompress bowel with orogastric tube to low intermittent suction, place umbilical lines, arrange transport to neonatal center
Abdominal wall defect	Midline abdominal wall defect at base of umbilical cord (omphalocele) or lateral to cord insertion (gastroschisis) with externalization of abdominal contents	Hypovolemia, respiratory distress, hypothermia, ischemic injury to externalized abdominal contents, infection	Protect exposed tissue with evaporative barrier; begin parenteral fluids at 1.5 times maintenance; place an orogastric tube to low intermittent suction, position infant side-lying with support of exposed organs, monitor temperature and urine output, arrange transport to a neonatal center with pediatric surgery
Neural tube defects	Open spinal defect (myelomeningocele), cranial defect with outpouching brain tissue (occipital or frontal encephalocele), failure of formation of skull and brain (anencephaly)	Prolonged apnea, infection, hypothermia	Provide supportive care unless prenatal diagnosis of lethal anomaly has allowed formation of a plan for limited support; protect exposed tissue with gauze soaked in warmed saline and evaporative barrier; arrange transport to a neonatal center with specialists in spinal defects

BOX 4.3 EMERGENCY PROCEDURES IN THE DELIVERY ROOM

A. Umbilical vessel catheterization (see Chapter 7)
B. Thoracentesis and chest tube placement (see Chapter 23)
C. Partial exchange transfusion for anemia (see Chapter 20)
   1. Indications: Profound chronic anemia (hematocrit [Hct] <25%), as in the setting of hydrops. Distinct from situations of acute loss of blood volume, chronic anemia results in normal blood volume per kilogram, necessitating partial exchange transfusion to rapidly raise the hematocrit.
   2. Procedure
      a. Obtain O-negative packed red blood cells (PRBCs) by emergency release if necessary. PRBCs should be as fresh as possible to minimize risk for hyperkalemia.
      b. Insert a low umbilical vein catheter, and attach a four-way stopcock (exchange set).
      c. Perform an isovolumetric exchange by alternating withdrawal and infusion of 5- to 10-mL aliquots of patient blood and PRBCs to a total exchange volume of approximately 20 mL/kg. The formula is as follows:

$$\text{Exchange volume} = \text{Estimated dry wt} \times \text{Blood volume/kg} \times \frac{\text{desired Hct} - \text{current Hct}}{\text{Hct of PRBCs}}$$

      This equation can be used to estimate the rise in hematocrit for a given exchange volume and a given hematocrit of exchange blood.
      d. Alternatively, place both a low umbilical vein catheter (UVC) and an umbilical artery catheter (UAC). Withdraw from the UAC while infusing PRBCs per the UVC at the same rate to the total exchange volume.
   3. Risks
      a. Thrombotic, embolic events
      b. Infection
      c. Bleeding (from mechanical complications or depletion of clotting factors)
      d. Hyperkalemia (consider use of washed PRBCs for nonemergent partial volume exchanges)
D. Prophylactic administration of exogenous surfactant (see Chapter 23)
   1. Indications
      a. Prematurity
      b. Respiratory distress
      c. Presumed surfactant deficiency
   2. Procedure
      a. Calculate the appropriate dose of surfactant based on birth weight.
      b. Confirm correct endotracheal tube position by centimeter markings at the lip (see Table 4.4) and careful auscultation. Chest x-ray film confirmation is ideal if surfactant is administered during stabilization in the nursery.
      c. Suction the endotracheal tube to clear secretions.
      d. Monitor heart rate and oxygen saturation with pulse oximetry.
      e. Administer surfactant according to manufacturer's directions. Administration options include rapid bolus and gradual infusion combined with positioning of the infant and hand or mechanical ventilation.
      f. Refrain from suctioning for at least 4 hours after surfactant administration.
      g. Monitor chest wall rise, saturations, and arterial blood gases, and adjust ventilator support accordingly.
   3. Complications
      a. Hypoxemia
      b. Air leak
      c. Pulmonary hemorrhage

stable.[48] Depending on the level of care required by the infant and the level of care available in the institution, the infant may need to be transported from the birth setting to receive appropriate care after resuscitation (see Chapter 3).

In the intensive care nursery, place the infant on a preheated open warmer with servocontrol. Avoid overwarming because hyperthermia may be associated with respiratory depression and worsened neurologic outcome after asphyxial insults.[51,61] **Continue adequate cardiopulmonary monitoring, including electrocardiogram, respiratory rate and pattern, and monitoring of oxygen saturation with pulse oximetry** (see Chapter 7). **Obtain serum glucose by heelstick and blood pressure by a Doppler device and blood pressure cuff.** If a UVC was inserted during the initial resuscitation for medication administration, place a peripheral intravenous line and remove the low-lying UVC or replace it with a central umbilical line for maintenance fluid administration. **If blood glucose is low or volume expansion is indicated, begin a glucose infusion or volume expansion via either route.** Evaluate for placement of an arterial line for blood sampling and continuous arterial pressure monitoring. Confirm endotracheal tube and umbilical line placement with an x-ray examination.

Debriefing after resuscitation and stabilization of the infant in the NICU gives those

who attended the delivery an opportunity to have a conversation and reflect on their care, teamwork, and communication. Debriefing identifies aspects of the resuscitation that went well and those that could be improved, with the goal of practice and systems change for continuous improvement.

CARE OF THE FAMILY AND PERINATAL DECISION MAKING

Encouraging the presence of the father or another mature support person at birth is common obstetric practice and should not interfere with care after birth. Ideally, members of the obstetric and neonatal resuscitation team should introduce themselves to the parents/birth companion before the delivery. **Parents have a great deal of anxiety concerning procedures performed on their newborn; a few moments spent describing routine procedures will help allay their fears and avoid misinterpretation.** When problems are anticipated, a calm, professional explanation of neonatal assessment and life-support measures is necessary. **Parental awareness that the medical and nursing staff have anticipated and prepared for possible problems can partially relieve their anxieties.** Care must be taken, however, to avoid instilling undue alarm. Care providers should understand ethical principles and the impact of their personal moral and ethical beliefs on decisions made about resuscitation.[40]

If an infant requires resuscitation or prolonged assessment and support, the attending staff's primary obligation is to provide this care and communicate with the parents. **Parents should be encouraged to have contact with their baby, but the presence of the father or a support person should not interfere with or delay the delivery of care. The pediatric staff should tell the parents what is happening at the earliest possible opportunity because a lack of communication prolongs anxiety for the parents.** A few brief statements to explain the status of the baby and procedures can relieve the anguish of silence. **Especially when a difficult resuscitation is anticipated, it is ideal to designate, in advance, a team member who can keep parents informed.**

When severe perinatal problems are suspected prenatally and confirmed after birth, such as extreme prematurity (gestational age less than 23 weeks, birth weight less than 400 g), anencephaly, or other potentially lethal anomalies, **discussions may be held in advance with obstetric care providers and the family about limiting the extent of resuscitative measures** (see Chapter 32).[40,60] When problems are unanticipated, information is uncertain, or there has been no time for decision making before delivery, intervention in the delivery room may be warranted.[22] This approach allows time for complete information to be gathered and discussed with the family. **If appropriate, support measures can be withdrawn later in the nursery.** When an infant fails to respond to intensive resuscitative measures in the delivery room, a decision, in consultation with the parents, must be made as to when to stop support. **Survival is unlikely if no heart rate has been obtained after 10 minutes.[15,38,49] Discontinuation of resuscitation may be appropriate if, after 10 minutes of full resuscitative effort, there is no return of spontaneous circulation.** The data for infants who have an inadequate response to resuscitation remain less clear. **The probability of survival diminishes and the probability of cerebral palsy increases with the length of time during which Apgar scores remain below 4**. For example, if the Apgar score remains below 4 at 20 minutes, the probability of cerebral palsy in surviving infants is greater than 50%.[47] It is essential to rapidly identify remediable causes of poor response to resuscitation.

Anticipation and recognition of fetal and neonatal problems indicating delivery room resuscitation depend on a knowledgeable and prepared staff working as a team to effectively and efficiently communicate and respond in a critical situation. By applying current evidence in performing the skills necessary for neonatal resuscitation, evaluating the infant's response, and taking the time to discuss resuscitation options and outcomes with the parents and resuscitation team, successful delivery room care and stabilization of the newborn is more likely.

5 IMMEDIATE NEWBORN CARE AFTER BIRTH

SANDRA L. GARDNER AND SUSAN NIERMEYER

A neonate must demonstrate a condition of well-being before being considered a normal, low-risk infant. **All neonatal intensive care professionals must understand the normal neonate to care for the sick neonate.** This chapter discusses the initial assessment, transitional period, and gestational age characteristics that are fundamental for providing quality initial care after.

Physical and physiologic changes occur so rapidly after birth that the assessment of the newly born can be divided into four distinctive periods: delivery, transition, the first 24 hours of life, and discharge. Each of these assessments has a specific purpose. These evaluations occur in relation to the age of the newborn infant (minutes, hours, days, and weeks) rather than the location of the mother and infant in the hospital or arbitrary nursery routines.

The evaluation at delivery is aimed at determining the condition of the infant at the time of birth and at detecting potentially life-threatening emergencies. The examination during the next few hours *(transitional period)* **is used to evaluate the infant's adjustment to extrauterine life. The complete newborn examination by a qualified health care provider should ideally be delayed until after initiation of breastfeeding, but completed by 12 to 24 hours.**[8] It is the most important examination, because many findings can be treated or complications can be avoided. Finally, the assessment/evaluation at discharge is of the utmost importance. Although it is not as detailed as the complete examination, it is aimed at **establishing the infant's readiness to leave the hospital and to be cared for by the mother.**

Both the initial complete examination and the discharge examination can be performed with parents present to demonstrate the baby's unique abilities and to answer the parents' questions. These are excellent opportunities to provide support and encouragement as the parents begin to incorporate the new member into their family.

ASSESSMENT AND CARE AT BIRTH

Before the birth, one should obtain pertinent facts about the pregnancy, such as parity, gravidity, fetal losses, estimated birth weight (BW) and gestational age (GA) of the fetus, and, of course, any problems present in the current pregnancy.[116] The results of prenatal screening tests should be available to the clinician at birth. Health care providers should note whether the mother was screened for group B streptococcus and whether she received any antibiotic treatment.[8,44]

During labor, one can observe the frequency and duration of contractions and the maternal and fetal reaction to contractions. Fetal distress, passage of meconium, prolonged rupture of membranes, malodorous fluid, and other signs will alert the attendants to impending problems.

At birth, the most common way to assess the infant's condition is to use the Apgar scoring system.[10] This score provides a comprehensive, objective measure of the state of an infant at given times after birth, traditionally at 1 and 5 minutes (see Chapter 4, Figure 4.7). **The Apgar score standardizes initial newborn assessment and continues to be a predictor of neonatal survival.**[10,146,182] The Apgar score should not be used as the primary indicator for resuscitation because it is not normally assigned until 1 minute of age. **Immediate assessment of respiratory effort is paramount to begin resuscitative**

BLUE type highlights content that is particularly applicable to clinical settings.

procedures if the infant is limp and not breathing (see Chapter 4). If the baby is vigorous, the care provider may place him or her on the mother's abdomen or in her arms; the first Apgar assessment can be done with the infant in skin-to-skin during the delay before umbilical cord clamping. Scoring is repeated at 5 minutes. **Between the 1- and 5-minute Apgar scores, one systematically evaluates the baby for potential or apparent medical emergencies.**

Most infants are vigorous, cry at birth, and breathe easily thereafter. A healthy, vigorous infant generally does not even need suctioning after birth. **With appropriate ongoing monitoring, most infants can be given directly to the mother for skin-to-skin care after birth without compromising the infant.**

Shortly after birth, a *quick estimate of GA* is done. Several tables, charts, and graphs have been developed over time to assist the clinician in performing this task. With practice and experience, the professional will be able to identify approximate GA from the physical appearance. Additional discussion on GA is presented later in this chapter. **Immediately following birth, *a brief but complete initial examination* should be performed on each newborn to assess the condition of the infant** and to ensure that there are no major anomalies or birth injuries, that the infant is pink, and that breathing is normal. **The entire body must be assessed, including overall size, proportionality and contour, respiratory pattern and presence of distress, posture, tone, and state of alertness.** This usually allows the clinician to reassure parents that their infant is well and appears normal. A more detailed evaluation/examination is described later.

The most severely ill neonates are usually apparent after birth. Most of them will have been identified prenatally (e.g., serious congenital anomalies, extreme prematurity), their presence anticipated, and a management plan is made before delivery (see Chapter 4).

EVALUATION AND CARE DURING THE TRANSITIONAL PERIOD

Physiologic Changes and Clinical Stages

The initial evaluation, assessment, and management of a newborn must be directed toward promoting and facilitating normal adaptation to extrauterine life and early detection of significant health problems so that they can be evaluated and treated promptly and appropriately.[91]

The obligatory change of environment at birth necessitates adjustment to the extrauterine environment in a complex series of changes essential for survival. Every infant must complete this process of transition successfully to survive in the extrauterine environment. For a small percentage of newborns, transition is never achieved; for a slightly larger number, transition is delayed or complicated. For most newborns, transition is so smooth it appears uneventful.

With the first breath, all neonates begin the transition from intrauterine to extrauterine life. Three major changes take place at birth. First, fluid in the alveoli is reabsorbed and air fills the alveoli, allowing for gas to diffuse into and out of the pulmonary blood vessels. Second, when the umbilical arteries and vein are clamped, the low-resistance placental circuit is gone and systemic blood pressure increases. Third, pulmonary vascular resistance decreases as a result of mechanical distention of the alveoli and increased alveolar oxygen content. Oxygen is a potent pulmonary vasodilator.

During the first few hours after birth, the normal newborn progresses through a fairly predictable sequence of events, recovering from the stress of birth and adapting to extrauterine life. Intrapartum and immediate neonatal events result in sympathetic discharges reflected in changes in heart rate, color, respiration, motor activity, gastrointestinal function, and temperature. **Awake and sleep states affect a neonate's behavior and ability to respond to the environment.** A newborn may go from one state to another quite frequently after birth and at home (see Critical Findings: Newborn States and Considerations for Caregiving in Chapter 13). Fig. 5.1 **shows the classic description by Desmond of the transitional period, which includes the three stages shown in** Box 5.1. Failure to establish this pattern of transition requires careful observation and investigation.

Management of the Newborn during Transition

Traditionally, "normal newborn" care was based on the optimistic assumption that most newborns have no difficulty with transition after birth and that

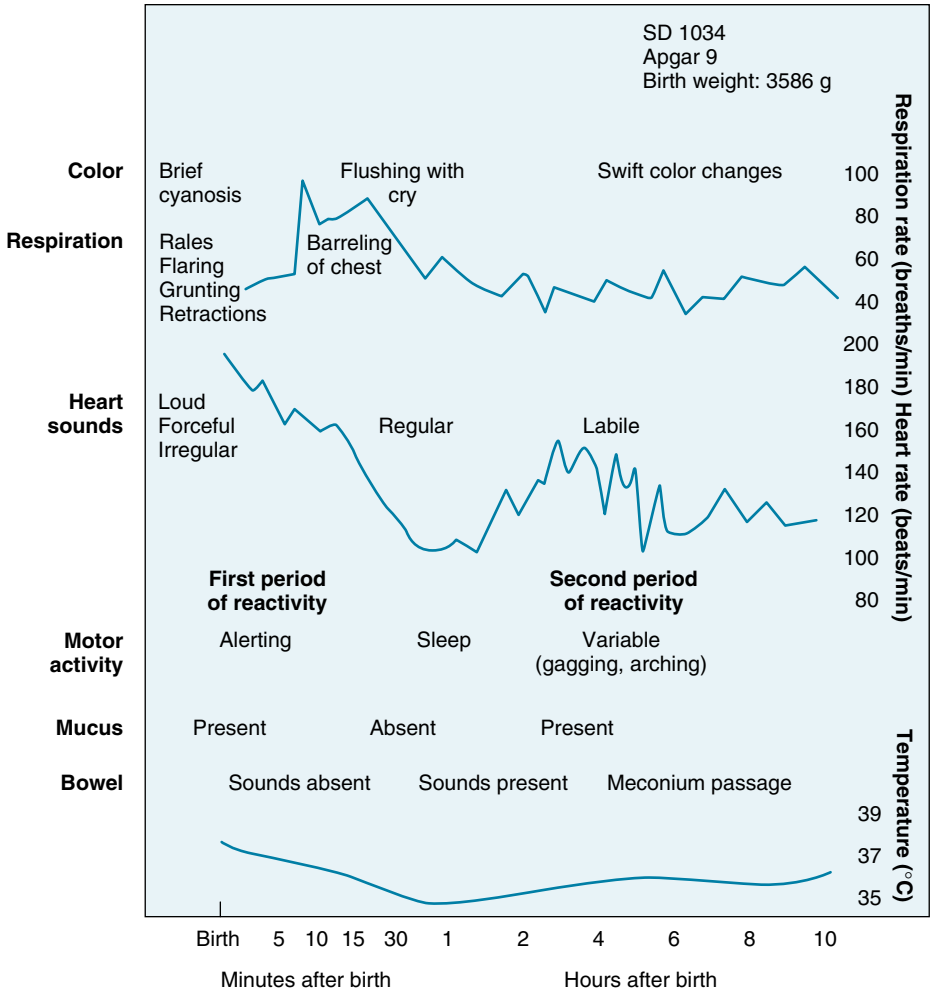

FIGURE 5.1 Critical findings: Neonatal transitional period. (From Desmond MM, Rudolph AJ, Phitaksphraiwan P, et al. The transitional care nursery: a mechanism for preventive medicine in the newborn, *Pediatr Clin North Am.* 1966;13:651.)

term infants, in particular, do exceedingly well.[91] Individualized newborn care recognizes the complexity of transitioning to extrauterine life, the need to support that transition, and the reality of serious disease, even in term newborns.

Newborn Should Be Treated as a Recovery Patient

SKILLED PROVIDERS SHOULD CARE FOR THE NEWBORN

Current standards of care[8] require skilled health care providers (24 hours/day) to care for newborns during the first minutes after birth (e.g., in the delivery room, at the birth center) and in the transitional period (e.g., in the birth room, mother-baby area, newborn nursery).[91] All personnel caring for the newborn must be familiar with the transitional changes after birth and deviations from normal transitional events. After a normal, low-risk pregnancy and birth, primary evaluation and care of the newborn must be provided by nurses with neonatal-perinatal competencies who consult advanced practice nurses and/or physician(s) when appropriate.[8,91]

BOX 5.1 TRANSITIONAL PERIOD

First Stage (0 to 30 Minutes) = First Period of Reactivity

- Rapid increase in heart rate to the range of 160 to 180 beats/min (0 to 15 min)
- Gradual decrease in heart rate over 30 minutes to baseline rate between 100 and 120 beats/min
- Irregular respirations (first 15 minutes), peak respiratory rates between 60 and 80 breaths/min
  - Rales present on auscultation
  - Grunting, flaring, and retractions may be noted, and brief periods of apnea (<10 seconds in duration)
  - Plethora
  - Alert with spontaneous startle reactions, gustatory movements, tremors, crying, and side-to-side head movements
  - Decrease in body temperature
  - Generalized increase in motor activity, with increased muscle tone
  - Bowel sounds absent, and abdomen distended
  - Production of saliva minimal

Second Stage (30 Minutes to 2 Hours) = Period of Decreased Responsiveness

- Newborn either sleeps or has a marked decrease in motor activity
- Muscle tone returns to normal, but responsiveness is diminished
- Fast, shallow, synchronous breathing (60 breaths/min) without dyspnea occurs
- Newborn's color is pale but pink with excellent perfusion and capillary refill
- Increase in anterior-posterior diameter (barreling) of the chest is usually present
- Heart rate decreases into the range of 100 to 120 beats/min or lower; the newborn is relatively less responsive to external stimuli
- Abdomen is rounded, and bowel sounds are audible; peristaltic waves may be visible, and meconium may be passed
- Oral mucus is absent
- Spontaneous jerks and twitches are common, but the newborn quickly returns to rest

Third Stage (2 to 8 Hours) = Second Period of Reactivity

- Return of and possible exaggeration of responsiveness
- Labile heart rate: periods of tachycardia
- Brief periods of rapid respirations: At 2 hours of age: median respiratory rates: 46 breaths/min; 95th percentile respiratory rates of 65 breaths/min; 5th percentile: respiratory rates 30 to 32 breaths/min.[186] Rates higher when awake, rather than asleep, boys higher than girls, and after heavy meconium staining of amniotic fluid; no difference in rate between vaginal versus cesarean birth.[186]
- Abrupt changes in tone, color, and bowel sounds
- Possible prominence of oral mucus; gagging and vomiting not unusual
- Possible clearing of meconium from the bowel
- Increased responsiveness to endogenous and exogenous stimuli
- Newborn hunger cues; quiet alert periods when maternal bonding is established

Modified from Hernandez JA, Thilo E. Routine care of the full-term newborn. In: Osborn LC, DeWitt TG, First LR, et al, eds. *Pediatrics.* St Louis, MO: Mosby; 2005.

STANDARDS FOR ROUTINE CARE AND PHYSIOLOGIC MONITORING DURING TRANSITION MUST BE MAINTAINED

Parent-infant bonding, skin-to-skin care, early breastfeeding, and careful neonatal monitoring during the transitional period should be addressed in delivery/birth room and other facility routines. After birth, the stable, pink newborn whose Apgar score is greater than 7 at 5 minutes can remain skin-to-skin with the mother.[148] **Immediate skin-to-skin contact in the first hours after birth facilitates early initiation of breastfeeding in the setting of a stable neonate under continuous monitoring. After birth, at 15-minute intervals, *every* newborn must be assessed for general condition, respiratory effort, color, muscle tone, and temperature; all assessments must be documented.[91] The mother and infant should not be left alone in the first hours after birth.**

Skin-to-skin care benefits parents, premature neonates, and full-term neonates after vaginal, operative vaginal, and cesarean birth (see Table 5.1 and Fig. 5.2). Skin-to-skin care not only prevents hypothermia[26] but also is effective in treating hypothermia.[131] In a randomized study of skin-to-skin versus incubator care for rewarming low-risk hypothermic neonates, **skin-to-skin care** was shown to be more effective (90%) than incubator care (60%)[51] (see Chapter 6).

Even newly born, **low-birth-weight (LBW) infants (1500 to 2500 g) transitioned by skin-to-skin care with their mothers have been shown to stabilize their cardiorespiratory function better than LBW infants cared for in incubators.** This randomized controlled trial (RCT) also found that

TABLE 5.1 BENEFITS OF SKIN-TO-SKIN CARE FOR PARENTS AND NEWBORNS AFTER VAGINAL AND CESAREAN SECTION BIRTHS

BENEFITS AFTER VAGINAL BIRTH	BENEFITS AFTER CESAREAN BIRTH
Psychological (Parental)	***Psychological (Parental)***
Promotes maternal and paternal infant bonding as a result of increased release of oxytocin[47,58,143,148]	Enhances family bonding, attachment, and satisfaction[174]
Facilitates the process of becoming a parent; either restores or drains energy[12,13]	Increases vocal interaction with newborn[192]
Increases positive activities with the newborn and growing infant[148]	
Decreases expense because infant formula does not have to be purchased	
Psychological (Maternal)	***Psychological (Maternal)***
Enhances birth experience[93]	Enhances perception of own health, quality of life, and satisfaction with birth experience[79]
Increases confidence and competence[148]	Decreases anxiety and pain;[148,198] decreases administration of medications for anxiety and pain[198]
Decreases postpartum cortisol levels, postpartum depression[28] and anxiety[58]	Rise in maternal salivary alpha-amylase directly after delivery when baby held skin-to-skin intraoperatively[107]
More positive maternal interactions at 1 week, 2 months, and 3 months of age[29]	Decreases maternal oxidative stress[207]
Decreases maternal pain during episiotomy repair[163]	Describes skin-to-skin care with father as the formation of the family[78]
	Prefers father to provide skin-to-skin if mother unable, rather than newborn be alone on a radiant warmer[78]
Psychological (Paternal)	***Psychological (Paternal)***
Promotes parental role attainment[164]	Increases conversation with mother[192]
Increases involvement and sensitivity toward newborn[191]	Facilitates more equal parenthood[139] because togetherness with infant enables the father to immediately and gradually change to "father" as he assumes the primary parenting responsibility and role with his newborn[70]
Exhibits more caring[191] and interactive behaviors[164]	No influence on initiation of breastfeeding or exclusive breastfeeding rates at 3 or 6 months of age when compared to maternal skin-to-skin contact.[85]
Increases confidence and comforting behaviors toward neonate	
Facilitates more equal parenthood[143]	
Decreases cortisol levels, stress, and anxiety[58,164]	
Decreases relationship problems with mother of baby[130]	
Physiologic (Maternal)	***Physiologic (Maternal)***
Decreases postpartum hemorrhage[157] as a result of increased oxytocin secretion[58,157] with breastfeeding	Significant reduction in blood pressure and respiratory rate[139]
Breastfeeding	**Breastfeeding**
Earlier initiation of breastfeeding[50,84,88,114,193] Increases incidence and duration[29,50,84,194]	Initiates earlier breastfeeding, infants were exclusively or predominantly breastfeeding at discharge, 3 months,[79,85] and 6 months of age.[85]
Assists in resolution of early breastfeeding problems such as latch-on[180]	More likely still breastfeeding at 1 month and 4 months of age/more successful[128]
Increases breastfeeding self-efficacy[5,138]	
Full Term Newborn	
Novel bioactive substances in human colostrum may assist in postnatal adaptation related to thermoregulation, vascular adaptation, glucose metabolism, lung function, and fluid homeostasis[32]	
Breastfeeding within the first hour of life decreases neonatal mortality by 33%[167]	
Higher breastfeeding rates[153] and breastfeeding exclusivity at 6 weeks,[128,163] 1 month,[115,128] 4 months,[128] and 6 months of age.[128]	
More likely to breastfeed successfully during first feeding[128]	
Enhances breastfeeding benefits: fewer postnatal infections (ear, gastrointestinal, and respiratory); decreased incidence of SIDS and chronic illnesses (obesity, diabetes, cardiovascular)[179]	
Dose-dependent relationship between the use of fentanyl administered by epidural and synthetic oxytocin and the inability of the newborn to initiate suckling in the first hour of life while skin-to-skin with mother.[34]

TABLE 5.1 BENEFITS OF SKIN-TO-SKIN CARE FOR PARENTS AND NEWBORNS AFTER VAGINAL AND CESAREAN SECTION BIRTHS—CONT'D

BENEFITS AFTER VAGINAL BIRTH	BENEFITS AFTER CESAREAN BIRTH
Physiologic (Neonatal)	***Physiologic (Neonatal)***
Full-Term Newborn	**Full-Term Newborn**
Decreases cortisol levels resulting from less birth stress[122,181] and a larger decline in neurosteroid levels with more skin-to-skin contact[122]	Decreases newborn stress[159] resulting in less crying (within 15 minutes of starting skin-to-skin care with father),[71] calmer and better relaxation[71,144,192]
Improves thermal stability: less hypothermia, improved ability to remain in thermal neutrality[140,164,172,193]	Reaches drowsy state sooner (within 60 minutes after birth)[71]
Promotes earlier cardiopulmonary stabilization:[128,181] Higher Spo_2 and slower heart rate combined with a slower increase in the first 3 minutes; Less tachycardia and more bradycardia in the first minutes after birth[166]	Prefeeding behaviors facilitated[71]
Improves blood glucose regulation; higher blood glucose levels.[128]	Initiates vocalization with parents (within 15 minutes of initiating skin-to-skin care), which further promotes bonding and attachment[192]
Nonpharmacologic intervention for neonatal pain resulting in less crying and lower pain scores[1,83,164]	Thermal stability[22,79]
Premature Newborn	Lower transfer rates to NICU[150,158]
Improves physiologic stability: better temperatures, oxygen saturations, heart rate and blood glucose levels;[141] similar first body temperatures and blood glucose levels in moderately preterm infants (34–35 weeks gestational age) when compared to incubator care[110]	Fewer suspected neonatal infections[150]
Nonpharmacologic intervention for neonatal pain[141,142]	
Decreases late preterm infant's cortisol reactivity to handling, improves concordance between mother/infant salivary cortisol levels[130]	
Improves infant-to-parent bonding because of close proximity	

FIGURE 5.2 Skin-to-skin care and family bonding in the first hours after birth.

LBW infants transitioned with skin-to-skin care had less need for respiratory support, intravenous fluids, and antibiotics during their hospitalization.[49] Because of the extensive research evidence, the World Health Organization (WHO), American Academy of Breastfeeding Medicine (ABM),[2] American Academy of Pediatrics (AAP),[8,73] Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN).[13] International Childbirth Education Association (ICEA),[96] Neonatal Resuscitation

Program (NRP),[200] and Centers for Disease Control and Prevention (CDC)[45] recommend skin-to-skin contact for the term newborn after birth. **The AAP and ABM recommend that full-term neonates be placed in immediate skin-to-skin contact after birth and remain there until after the first breastfeeding.[2,8] The CDC[45] recommends that the full-term newborn remain skin-to-skin throughout the postpartum period as a strategy to facilitate breastfeeding.**

The triad of nearly continuous skin-to-skin care, exclusive breastfeeding, and close follow-up after discharge comprises kangaroo mother care (KMC) or kangaroo care (KC). Promoting universal KC, the International Network on Kangaroo Mother Care recommends KC as soon after birth as possible for as long as appropriate.[141] Even in the LBW infant, continuous KC that is initiated early results in a significantly higher proportion of exclusive breastfeeding at 6 months.[135] **Using skin-to-skin care after birth should be standard practice that is vigorously promoted by all maternal-neonatal health care providers.**[93,197] Skin-to-skin contact in the first hour of life is estimated to occur in only 1 of 4 newborn infants.[76] Globally breastfeeding within the first hour of life occurs in only 2 of 5 newborns.[187] Initiation of breastfeeding later than the first hour of life increases the risk of neonatal mortality by 33%, while initiation after 24 hours of life increases neonatal mortality by 50%.[187] Challenges to the implementation of early and prolonged skin-to-skin care and strategies to address these barriers are listed in Table 5.2.

Following a period of 60 to 90 minutes after birth, with close monitoring during skin-to-skin care and initiation of breastfeeding, routine care includes a complete physical examination and preventive interventions. Routine care can be provided at the mother's bedside. Elements include eye prophylaxis, administration of vitamin K_1, as well as glucose screening when indicated (see Table 5.3). **By 60 to 90 minutes of age, *every* newborn, regardless of where the baby is being cared for, must be examined by a nurse with neonatal-perinatal competencies. During the first 6 hours after birth, heart rate, respirations, blood pressure, degree of alertness, and color of skin and mucous membranes should be assessed frequently and the findings recorded.** This period is when clinical signs of the most threatening infections, cardiopulmonary diseases, and major congenital abnormalities appear. **Table 5.4 presents a useful scoring system for assessing the pattern of respirations for signs of respiratory distress; findings should be documented. The range of blood pressure in term infants during the first few hours of life is 65 to 95 mm Hg systolic and 30 to 60 mm Hg diastolic, with an average mean blood pressure of 50 to 55 mm Hg.** The blood pressure value will steadily increase from birth over the transitional period.[91]

Abnormal Transition

Regardless of GA or route of delivery, the sequence of clinical behavior just described is common to all well newborns. Preterm infants may exhibit variations in the duration of the transitional phases—shorter phase 1 or longer phase 2—but the patterns are similar. **Knowledge of the normal changes occurring during transition enables early recognition of a newborn who is not making a normal extrauterine adaptation.**[91]

Failure to make a normal transition to extrauterine life may result from obstetric anesthesia or analgesia, neonatal illness, or stress of intrapartum hypoxic-ischemic events. **If the infant's pulse, respirations, color, and activity have not stabilized within the normal ranges *after 1 hour of life,* a problem should be suspected and investigated.**

Observation for risk factors for abnormal transition is essential. A variety of conditions may result in significant deviation from the normal sequence of events during transition. Table 5.5 lists factors that may alter the sequence or pattern of changes expected to occur after birth and that result in either a healthy newborn or a newborn with significant illness. **The health care provider's challenge is to discriminate between signs of diseases that produce an ill newborn and the dynamic, rapidly changing features that accompany the physiologic adjustments of normal or altered transition but that still result in a healthy neonate.**[91] Box 5.2 lists clinical manifestations of abnormal transition.

PHYSICAL ASSESSMENT OF THE NEWBORN

Data Collection

HISTORY

Good perinatal care requires the identification of social, demographic, and medical-obstetric risk factors that correlate with fetal outcome. This must

TABLE 5.2 CHALLENGES TO THE IMPLEMENTATION OF EARLY AND PROLONGED SKIN-TO-SKIN CARE AFTER BIRTH

CHALLENGE/BARRIER	STRATEGY FOR CHANGE
Professional (level of education, years of experience, and primary practice settings)[197] and parental beliefs, attitudes, and knowledge about skin-to-skin care.	Professional education about parental and neonatal benefits, recommendations for use of skin-to-skin care and implementation strategies.* Parental education about the benefits of skin-to-skin care: (a) beginning in childbirth education classes and during clinic visits and (b) reinforced postpartally by all members of the health care team.[93,94,108,210]
Institutional culture that does not value skin-to-skin care as a standard of practice for all parents and newborns.	A written policy that establishes skin-to-skin care as the standard practice for the maternal-newborn department, as well as all departments providing services to mothers and their babies.[15,62,175] The policy defines expectations for use of skin-to-skin care, who is responsible, who is eligible, and how safe skin-to-skin care is to be provided.[63,73,93,108] Using an implementation algorithm to analyze the implementation of skin-to-skin care in the first hour after birth[33,41] Establishing universal use of skin-to-skin care as a quality improvement activity[30,129] Dedicating quality improvement champions to educate, promote, and advise colleagues on changing practice to improve the use of skin-to-skin care at birth and throughout inpatient care.[37,93,177] Institutional expectation that the entire maternal-neonatal health care team collaborate on educating, advocating for, and facilitating the use of skin-to-skin care with parents and other professionals such as anesthesia, laboratory, respiratory therapy, operating room, and recovery room staff.
Professional concerns about care of the newborn: (a) safety, (b) assessment, (c) maintenance of physiologic stability, and (d) loss of professional control.	A qualified neonatal /perinatal professional is responsible and controls newborn care after birth through (a) assessment of neonatal condition, (b) performance of routine care, and (c) provision of a supportive/stress-free environment that nurtures neonatal transition with skin-to-skin care.[73] Interruptions of early skin-to-skin contact interfere with early breastfeeding.[153] Parental presence during care does not remove control from the health care provider; rather it provides an opportunity for professionals to teach new parents about their newborn, how to read and interpret cues, and how to respond in a developmentally appropriate way. It is an opportunity to engage parents as partners in care of their neonate by modeling, role-modeling, and teaching them to care for and advocate for their baby.
Professional concerns about lack of time or inadequate staffing.[175]	If mothers and their newborns are recovered together after birth, the nurse caring for them must be able to provide the standard of neonatal as well as maternal care. Provision of neonatal care while the mother or father holds the newborn skin-to-skin is no different than caring for the newborn in a crib, except that the baby is more comfortable. Routine care during transition (see Table 5.3) does not differ whether the baby is being held skin-to-skin or is in a crib or radiant warmer. Parental proximity provides a more efficient opportunity for teaching and mentoring new parents, thus enabling them to begin providing care to their newborn with professional supervision.
Professional perceptions/misperceptions about willingness of parents to provide skin-to-skin care because of culture, ethnicity, or religion.[77]	Partner with parents to provide care. Individualize the experience of skin-to-skin care[93] by including parents in the decision of how it is to be done—after drying the baby; after clothing the baby; with baby wrapped in a blanket—any way the parents prefer to skin-to-skin with their baby is the "right way" to do it.
Interruptions of new mothers/families by visitors, large groups of visitors, and those who stay at the bedside of the new family for more than 1 hour.[80]	Initiation of a family bonding time (i.e., mothers/newborns resting together in their rooms, limiting interruptions to medically necessary procedures or upon the request of the mother) as a quality improvement project that significantly increased exclusive breastfeeding rates.[80]

*References 73, 93, 108, 175, 185, 197, 210.

TABLE 5.3 ROUTINE CARE DURING TRANSITION

ROUTINE CARE	TIME	DRUG/DOSE	COMMENTS
Glucose screening (see Chapter 15)	At 30–60 minutes of age	By POC glucometer device	Abnormal screen: glucose <40 mg/dL
Eye prophylaxis	Within 1 hour of age	Erythromycin (0.5%) or tetracycline (1%) eye ointment: apply ribbon in each conjunctival sac	Eye prophylaxis for ophthalmia neonatorum[188] Bactericidal effect depends on tissue concentration of drug and microorganisms.
Vitamin K_1	Within 1 hour of age	0.5–1 mg IM as a single dose for infants <1.5 kg or >1.5 kg *or*	Prophylaxis for hemorrhagic disease of the newborn. Vitamin K concentrations are physiologically low in breast milk so that exclusively breastfed infants are at increased risk for vitamin K deficiency, as are infants with fat malabsorption (e.g., biliary atresia, cystic fibrosis, α_1-antitrypsin deficiency), and prolonged treatment with antibiotics. Use sucrose, breastfeeding, kangaroo care, and topical analgesia for pain relief during injections (see Chapter 12)
		2 mg PO	Repeated oral dosing (e.g., first feed, 1 week, 4 weeks, 8 weeks) is necessary; increased risk for late-onset hemorrhagic disease when infant receives only one dose. Oral intake is contraindicated in preterm infants, sick infants with diarrhea or cholestasis, or those receiving antibiotics.

*Routine care is required wherever the newly born infant is cared for after birth (e.g., labor-delivery-recovery; labor-delivery-recovery-postpartum; birth center; mother-baby unit; nursery).
IM, Intramuscular; *PO,* orally; *POC,* point-of-care.

TABLE 5.4 CLINICAL RESPIRATORY DISTRESS SCORING SYSTEM*

	0	1	2
Respiratory rate (breaths/min)	60	60–80	>80 or apneic episode
Cyanosis	None	In room air	In 40% F_{IO_2}
Retractions	None	Mild	Moderate to severe
Grunting	None	Audible with stethoscope	Audible without stethoscope
Air entry†	Clear	Delayed or decreased	Barely audible

*The respiratory distress syndrome score is the sum of the individual scores for each of the five observations.
†Air entry represents the quality of inspiratory breath sounds as heard in the midaxillary line.
F_{IO_2}, Fraction of inspired oxygen; *RDS,* respiratory distress syndrome.
From Downes JJ, Vidyasager DD, Boggs TR, et al. Respiratory distress syndrome in newborn infants: I. New clinical scoring system (RDS score) with acid-base and blood-gas correlates. *Clin Pediatr.* 1970;9:325.

TABLE 5.5 MATERNAL, OBSTETRIC, AND NEONATAL CONDITIONS THAT INCREASE THE RISK OF ABNORMAL TRANSITION

Maternal Factors	Chronic hypertension Preeclampsia Diabetes mellitus Renal disease Infection Abuse of tobacco, alcohol, or illicit drugs Collagen vascular diseases Hemizygous hemoglobinopathies Certain maternal medications
Obstetric Factors	Rh or other isoimmunization Fetal growth restriction Decreased fetal movements Multiple gestation Oligohydramnios or polyhydramnios Premature rupture of membranes Third-trimester bleeding Delivery by cesarean section
Neonatal Factors	Prematurity (<37 weeks) Postmaturity (>42 weeks) Small for gestational age Large for gestational age Infection Metabolic abnormalities Birth trauma Major malformations Anemia Apgar 0-4 at 1 minute or need for resuscitation at delivery

From Hernandez JA, Thilo E. Routine care of the full-term newborn. In Osborn LC, DeWitt TG, First LR, et al, eds: *Pediatrics*. St Louis, MO: Mosby; 2005.

be an ongoing process, because high-risk patients may be identified on the first prenatal visit, during follow-up prenatal visits, or not until the intrapartum and postpartum periods. **Review of the perinatal history is important in determining significant factors for neonatal health management.** Identification of an at-risk maternal situation is essential to plan and organize care for an at-risk neonate. Review of the perinatal history includes antepartum and intrapartum events (see Chapter 2) and early neonatal events, both in the delivery room and during transition.

BOX 5.2 NEONATAL CLINICAL MANIFESTATIONS SIGNALING ABNORMAL TRANSITION

- Persistent tachypnea, flaring, grunting, and retractions (respiratory score >4; duration >first hour of life); fixed bradycardia
- Diffuse and persistent rales, retractions, flaring, and grunting (respiratory score >4; duration >first hour of life)
- Persistent cyanosis (persistent oxygen saturation <90% in room air) and prolonged requirements for supplemental oxygen (after 2 to 3 hours of age)
- Episodes of prolonged apnea (>20 seconds) and bradycardia (<80 beats/min)
- Marked pallor or ruddiness
- Temperature instability, persistently (after 2 to 3 hours of age) low temperature (<36.5°C)
- Poor capillary filling (>3 seconds) and blood pressure instability
- Unusual neurologic behavior (lethargy, decreased activity with marked and persistent hypotonia, irritability, excessive tremors and jitteriness)
- Excessive oral secretions, drooling, and choking/coughing spells, cyanosis

Modified from Hernandez JA, Thilo E. Routine care of the full-term newborn. In: Osborn LC, DeWitt TG, First LR, et al., eds. *Pediatrics*. St Louis, MO: Mosby; 2005.

SIGNS AND SYMPTOMS

Unlike the verbalizing adult patient, the nonverbal neonate communicates needs primarily by behavior. **Through objective observations and evaluations, the neonatal care provider interprets this behavior into information about the individual infant's condition. Initial newborn assessment includes the following:**

- Assessment of GA and fetal growth
- Newborn classification to estimate neonatal mortality and morbidity risk
- Physical and neurologic examination
- Assessment of neurobiologic development

ASSESSMENT OF GESTATIONAL AGE AND FETAL GROWTH

Optimal management of the pregnant woman and her fetus is entirely dependent on an accurate knowledge of the age of the fetus. **An assessment of GA should be done on *all* newborns to establish maturity and pattern of fetal growth at birth.**[116]

Pattern of Fetal Growth. With the use of anthropometric measurements, including weight, length, and head circumference, together with GA, fetal growth standards have been determined for different ref-

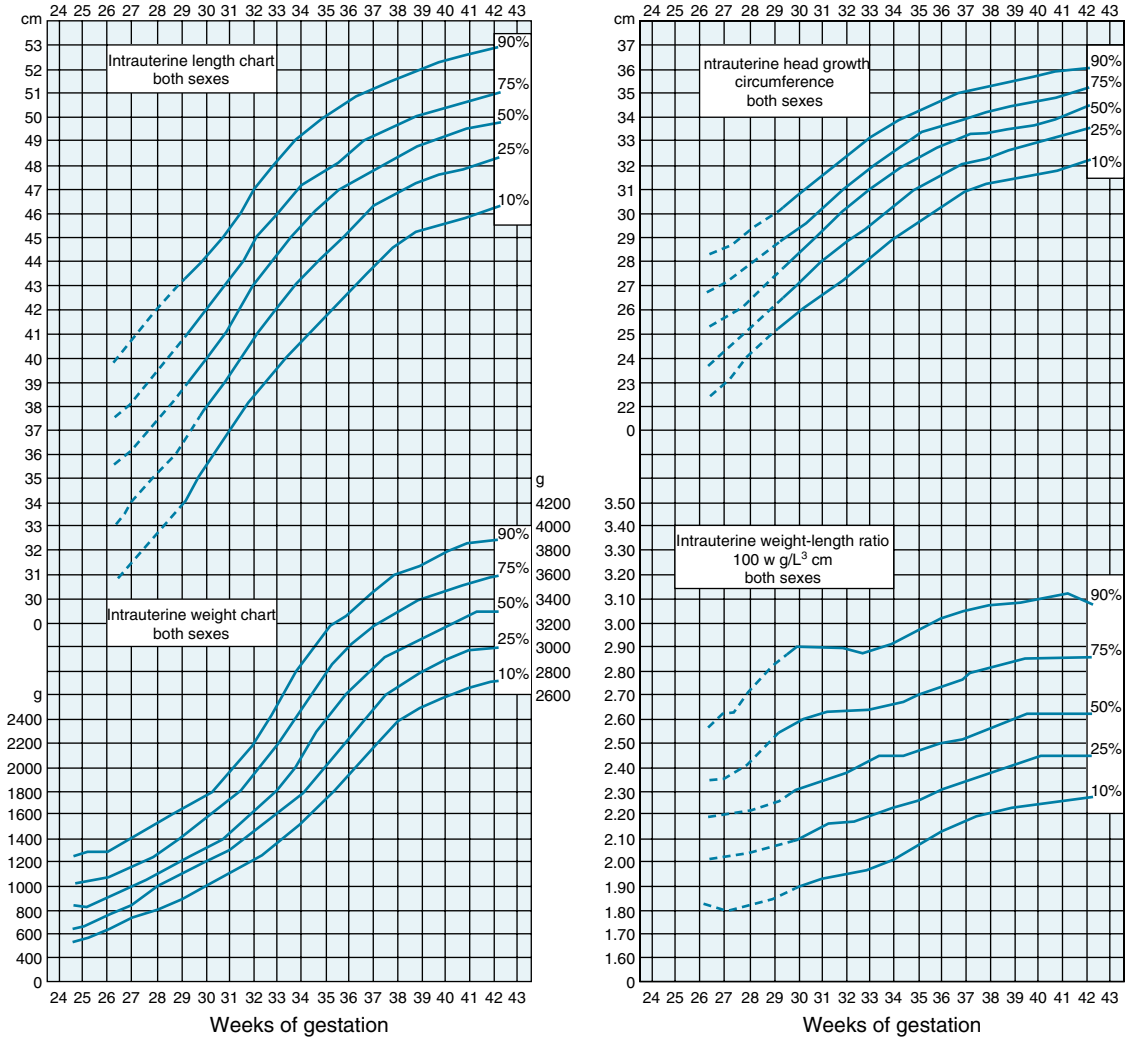

FIGURE 5.3 Colorado intrauterine growth charts. (From Lubchenco LO, Hansman C, Boyd E, et al. Intrauterine growth in weight, length and head circumference as estimated from live births at gestational ages from 26–43 weeks. *Pediatrics.* 1966;37:403.)

erence populations from various locations. From these data, it is apparent that there are variations in "normal" weight at any given GA from one locale to another. This variation is related to a number of factors, including sex, race, socioeconomic class, and even altitude. The Colorado intrauterine growth curves presented by Lubchenco and colleagues in the 1960s (Fig. 5.3) are unique in that each anthropometric measurement was related to GA. **The graphic display of this relationship provides a useful and simple method for determining the appropriateness of growth with respect to GA.** New fetal growth graphs include the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD) Fetal Growth Studies,[38,39] the INTERGROWTH-21st project,[145] and the WHO Multicentre Growth Reference Study.[105] Even though such curves differ in details, all demonstrate nearly linear growth between 20 and 38 weeks of gestation, with slowing thereafter. **In 1967, Battaglia and Lubchenco used the GA/BW relationship to categorize those infants whose BWs were less than the 10th percentile as *small for gestational age (SGA),* those weigh-**

ing more than the 90th percentile as ***large for gestational age (LGA),*** and the remaining 80% as ***appropriate for gestational age (AGA)*** (Fig. 5.4).[19]

Gestational Age. GA can be assessed by obstetric methods and by pediatric methods. **The most reliable antenatal method combines early ultrasound evaluation with information about the mother's last menstrual period (LMP).** Dating gestation based on the mother's LMP can be highly accurate if the mother is sure of the dates of her last menstrual period and the cycles are regular (see Chapter 2). Early antenatal ultrasonography appears to have 95% confidence intervals of less than 7 days.[199] Ultrasonography is preferred because it confirms conception, assesses gestation, and evaluates fetal growth.

Pediatric methods of determining GA are based on physical characteristics and neurologic examination. Within 2 hours after birth, every newborn should have an assessment of GA by physical characteristics.[8] Physical criteria are used because they progress in an orderly fashion with increasing gestation. Neurologic criteria involve the assessment of posture, passive and active tone, reflexes, and righting reaction. Numerous tables, charts, and graphs are available for determining GA. Some tables are more subjective and laborious than others, and each has proponents and detractors. **There is no perfect system, and all require the examiner to be familiar with and have experience in their use. At least one form should be adopted and consistently used by each nursery.**

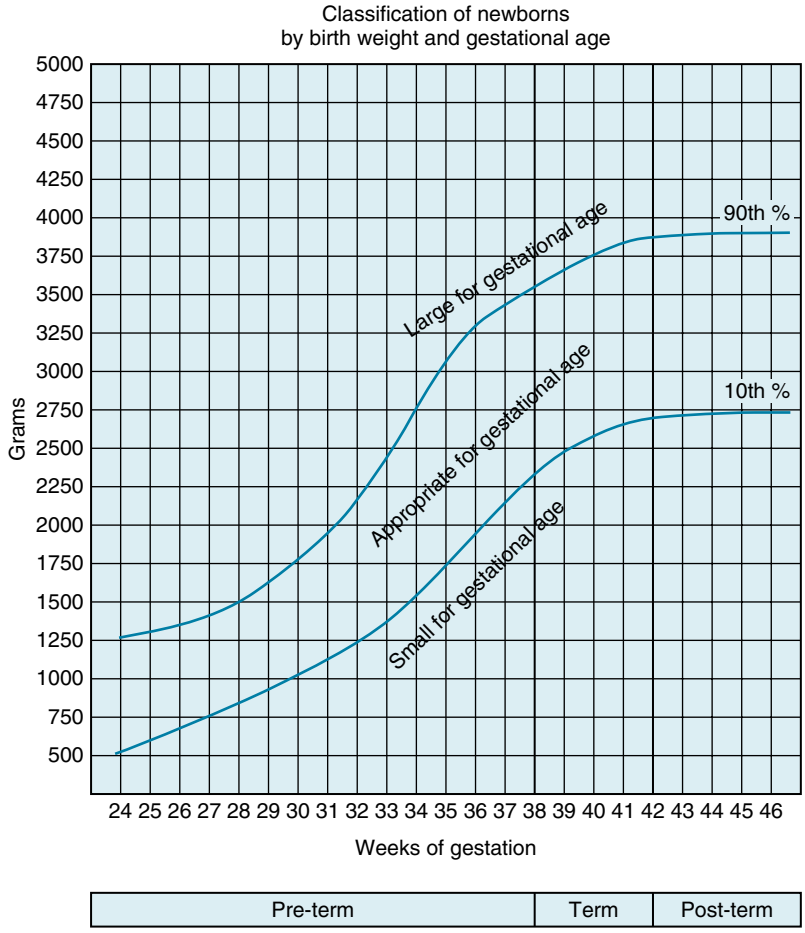

FIGURE 5.4 Classification of newborns by birth weight and gestational age. Birth weight of liveborn singleton white infants at gestational age from 24 to 42 weeks. (From Battaglia F, Lubchenco LO: A practical classification of newborn infants by weight and gestational age. *J Pediatr.* 1967;7:159.)

GA can be assessed most accurately by combining the physical criteria and the neurologic assessment. The revised Ballard system[9] displayed in Fig. 5.5 is a combined scoring system that is widely used. The Ballard system incorporates physical maturity (six characteristics) and neuromuscular maturity (six criteria) on an equal basis and includes assessment for extremely premature infants. The score for the neuromuscular and physical maturity is added and noted under the maturity rating column. Weeks of gestation are assigned according to the maturity rating score.

Assessment of Gestational Age in Very-Low-Birth-Weight and Extremely Premature Infants. Accuracy in estimation of GA is important because, for VLBW and extremely premature infants, small differences in GA result in large differences in outcome and may influence treatment and decision making by parents and professionals.[65] Research has shown that estimation of GA in very immature preterm infants is inaccurate. For preterm infants of 22 to 28 weeks of gestation, estimates of GA (by the scoring system shown in Fig. 5.5) exceeded the GA (by dates) by 1.3 to 3.3 weeks.[65] These inaccuracies must be considered in decision making, and better scoring systems are needed, particularly in the delivery room.

Neuromuscular maturity

	−1	0	1	2	3	4	5
Posture							
Square window (wrist)	>90°	90°	60°	45°	30°	0°	
Arm recoil		180°	140°–180°	110°–140°	90°–110°	ωωω90°	
Popliteal angle	180°	160°	140°	120°	100°	90°	<90°
Scarf sign							
Heel to ear							

Physical maturity

Skin	Sticky, friable, transparent	Gelatinous red, translucent	Smooth pink, visible veins	Superficial peeling and/or rash, few veins	Cracking pale areas, rare veins	Parchment deep, cracking, no vessels	Leathery, cracked, wrinkled
Lanugo	None	Sparse	Abundant	Thinning	Bald areas	Mostly bald	
Plantar surface	Heel-toe 40–50 mm: −1 <40 mm: −2	>50 mm no crease	Faint red marks	Anterior transverse crease only	Creases ant. 2/3	Creases over entire sole	
Breast	Imperceptible	Barely perceptible	Flat areola, no bud	Stippled areola 1–2 mm bud	Raised areola, 3–4 mm bud	Full areola, 5–10 mm bud	
Eye/ear	Lids fused loosely: −1 tightly: −2	Lids open; pinna flat, stays folded	Sl. curved pinna; soft, slow recoil	Well-curved pinna; soft but ready recoil	Formed and firm, instant recoil	Thick cartilage, ear stiff	
Genitals male	Scrotum flat, smooth	Scrotum empty, faint rugae	Testes in upper canal, rare rugae	Testes descending, few rugae	Testes down, good rugae	Testes pendulous, deep rugae	
Genitals female	Clitoris prominent, labia flat	Prominent clitoris, small labia minora	Prominent clitoris, enlarging minora	Majora and minora equally prominent	Majora large, minora small	Majora cover clitoris and minora

FIGURE 5.5 Clinical estimation of gestational age. (From Ballard JL, Khoury JC, Wedig K, et al. New Ballard score, expanded to include extremely premature infants. *J Pediatr.* 1991;119:417.)

One quick and effective way to estimate GA in VLBW infants is by *measuring foot length*. **Foot length of AGA preterm infants has been correlated with GA (Table 5.6).** In short gestation (i.e., 24th to 34th week), there is a predictable increase in the mean foot length of 0.5 cm every 2 weeks. Measurement of foot length from the posterior prominence of the heel to the tip of the first (great) toe with a millimeter ruler is a rapid and simple method of assessing maturation of all newborns, even the very ill, VLBW, moderate intrauterine growth restricted (IUGR) infant. With this method, as with other physical measurements of GA, one must consider the standard deviation in interpreting results.

In areas where obstetric ultrasonography is not readily available and birth attendants do not estimate GA, research on other methods of determining GA is ongoing. Methods being investigated include DNA methylation in cord blood,[106] measurement of newborn fetal hemoglobin levels,[202] measurement of newborn metabolic markers,[154] and noninvasive measurement of cell-free RNA transcripts.[137]

TABLE 5.6 FOOT LENGTH BY GESTATIONAL AGE*

	FOOT LENGTH (cm)				
GESTATIONAL AGE (WEEKS)	NO. OF INFANTS	MEAN	MEDIAN	SD	RANGE

From Hernandez JA, Lazarte R, Pisano D, et al. Foot length and gestational age in the very-low-birth-weight infant. The Children's Hospital Pediatric Update. September 1987; 4.

SIGNS OF PHYSICAL MATURITY

To use these charts accurately, the examiner must assess the following physical characteristics[116,189]:

Vernix. At 20 to 24 weeks, vernix is produced by sebaceous glands. Vernix is high in fat content and protects the skin from the aqueous amniotic fluid and bacteria. At 36 weeks, the white, cheeselike material begins to decrease and disappears by 41 weeks **Note the amount and distribution of vernix on the baby's skin (best done in the delivery room).**

Skin. **In early gestation, the skin of the fetus is very transparent, and veins are easily seen. As gestation progresses, the skin becomes tougher, thicker, and less transparent.** By 37 weeks, very few vessels are visible. From 36 weeks to delivery, fat deposits begin to form and grow. In a postterm infant, desquamation will be prominent at the ankles, wrists, and possibly palms and soles. As gestation progresses, the loss of vernix and subcutaneous tissue causes wrinkling. **Note skin turgor, color, texture, and the prominence of vessels, especially on the abdomen.**

Lanugo. At 20 weeks, fine, downy hair (lanugo) appears over the entire body of the fetus. At 28 weeks, it begins to disappear around the face and anterior trunk. At term, a few patches of lanugo may still be present over the shoulders. **Note the distribution of lanugo, first on the face and anterior trunk and then on the rest of the body.**

Hair on the Head. Hair appears on the head at 20 weeks. At 20 to 23 weeks, the eyelashes and eyebrows develop. From 28 to 36 weeks, the hair is fine and woolly and sticks together. It appears disheveled and sticks out in bunches from the head. At term, the hair lies flat on the head, it feels silky, and single strands are identifiable. **Note the quality and distribution of the hair, and feel its texture.** Scalp hair abnormalities (e.g., growth pattern, hypopigmentation, quantity, distribution, texture) may be external markers of genetic, metabolic, and neurologic disorders.

Sole Creases. Sole creases develop from toe to heel, progressing with GA. An infant with IUGR and early loss of vernix may have more sole creases than expected. **By 12 hours after birth, the skin has dried to a point that sole creases are no longer a valid indicator of GA.** Note the extent of sole creases (Fig. 5.6).

Eyes. In the third month of fetal life, the eyelids fuse; they reopen between 26 and 30 weeks. **In neonates of 27 to 34 weeks of gestation, examination of**

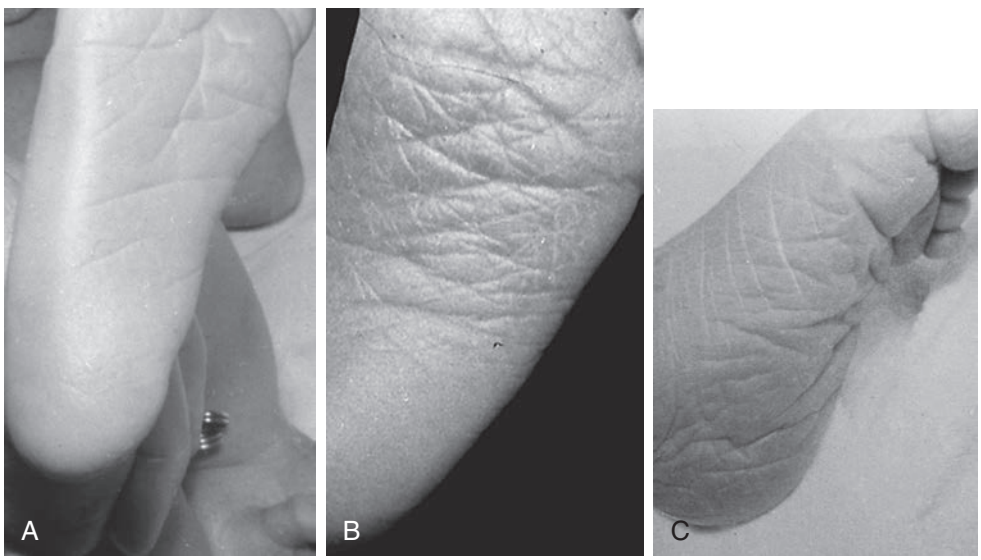

FIGURE 5.6 Sole creases at different gestational ages. **A**, Age 31 to 33 weeks of gestation. **B**, Age 34 to 38 weeks of gestation. **C**, Term.

the anterior vascular capsule of the lens is useful in assessing GA. GA is determined by assessing the level of remaining embryonic vessels on the lens (Fig. 5.7). Before 27 weeks, the hazy cornea prevents visualization of the vascular system. After 34 weeks, only remnants of the vascular system are visible. Because rapid atrophy occurs in the vascular system, an ophthalmoscopic examination should be performed during the first physical examination or within 24 to 48 hours after birth.

Ears. Before 34 weeks, the pinna of the ear is a slightly formed, cartilage-free double thickness of skin. When it is folded, it remains folded. **As gestation progresses, the pinna develops more cartilage, resulting in better form, so that it recoils when folded** (Fig. 5.8). Check ear recoil by folding the ear in half or into a three-corner-hat shape. Consistently folding it the same way helps the care provider develop a baseline for judging maturity. **Note the form and cartilage development of the ear. Examine both ears to be sure they are the same and without defects.**

Breast Development. Breast development is the result of the growth of glandular tissue related to high maternal estrogen levels and fat deposition. The areola is raised in an infant at 34 weeks of gestation. **Note the size, shape, and placement of both breasts.** Palpate the breast nodule, and determine its size. If the infant is growth restricted, breast size may be less than expected at term.

Genitalia

Male Genitalia. At 28 weeks, the testes begin to descend from the abdomen. By 37 weeks, they are high in the scrotum. By 40 weeks, the testes are completely descended, and the scrotum is covered with rugae. As gestation progresses, the scrotum becomes more pendulous (Fig. 5.9). **Note the presence of rugae on the scrotum and its size in relation to the position of the testes.** When examining the baby for descended testes, put the fingers of one hand over the inguinal canal to prevent the testes from ascending into the abdominal cavity, and palpate the scrotal sac with the other hand.

Female Genitalia. Early in the female's gestation, the clitoris is prominent with small and widely separated labia. By 40 weeks, the fat deposits have increased in size so that the labia majora completely cover the labia minora (Fig. 5.10). **Note the labial development in relation to the prominence of the clitoris.**

NEWBORN CLASSIFICATION AND NEONATAL MORTALITY AND MORBIDITY RISKS

At birth, after establishing fetal maturity and pattern of fetal growth, the next step is to ensure appropriate assignment of a clinical newborn classification,

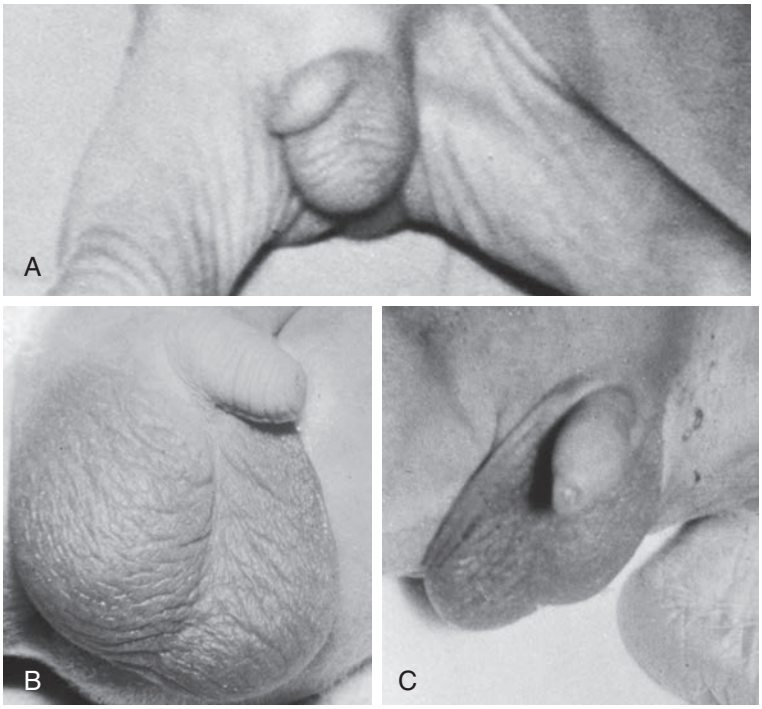

FIGURE 5.9 Male genitalia and gestational age. **A**, Age 28 to 35 weeks of gestation. **B**, Term. **C**, Age 42 or more weeks of gestation.

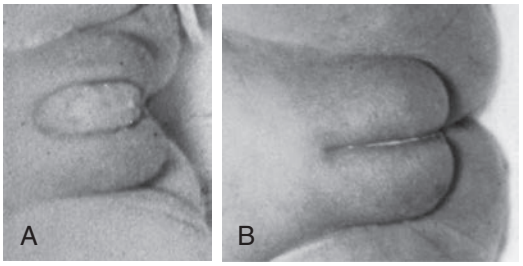

FIGURE 5.10 Female genitalia and gestational age. **A**, Age 30 to 36 weeks of gestation. **B**, Term.

determine neonatal mortality risk, generate a problem list of potential morbidities, and quickly initiate appropriate supportive care as well as screening procedures and/or interventions for recognized morbidities.

NEWBORN CLASSIFICATION

The neonatal population can be classified by the use of BW, GA, fetal growth pattern, and a combination of all of them into the following categories:

By Birth Weight.

- Normal birth weight (NBW): 2501 to 3999 g
- Excessive birth weight (EBW): 4000 g and above
- Low birth weight (LBW): 2500 g or less, with the following subcategories: moderate low birth weight (MLBW): 1501 to 2499 g, very low birth weight (VLBW): 1500 g or less, and extremely low birth weight (ELBW): 1000 g or less

By Gestational Age.

- Full-term (FT): 37 to $41^{6/7}$ weeks (259 to 293 days)
- Postterm (PoT): 42 or more weeks (294 or more days)
- Preterm (PT)[44]: Less than 37 weeks ($36^{6/7}$ weeks or less than 259 days), with the following subcategories: late preterm (LPT): $34^{0/7}$ to $36^{6/7}$ weeks (238 to 259 days), moderate-severe preterm (MSPT): 28 to $33^{6/7}$ weeks (196 to 237 days), and extreme preterm (EPT): $27^{6/7}$ or less weeks (less than 196 days)

By Fetal Growth Pattern. Using the intrauterine growth chart for the 10th and 90th percentiles, newborns can be classified as follows: those below the 10th percentile, SGA infants; those between the 10th and 90th percentiles, AGA infants; and those above the 90th percentile, LGA infants.[19]

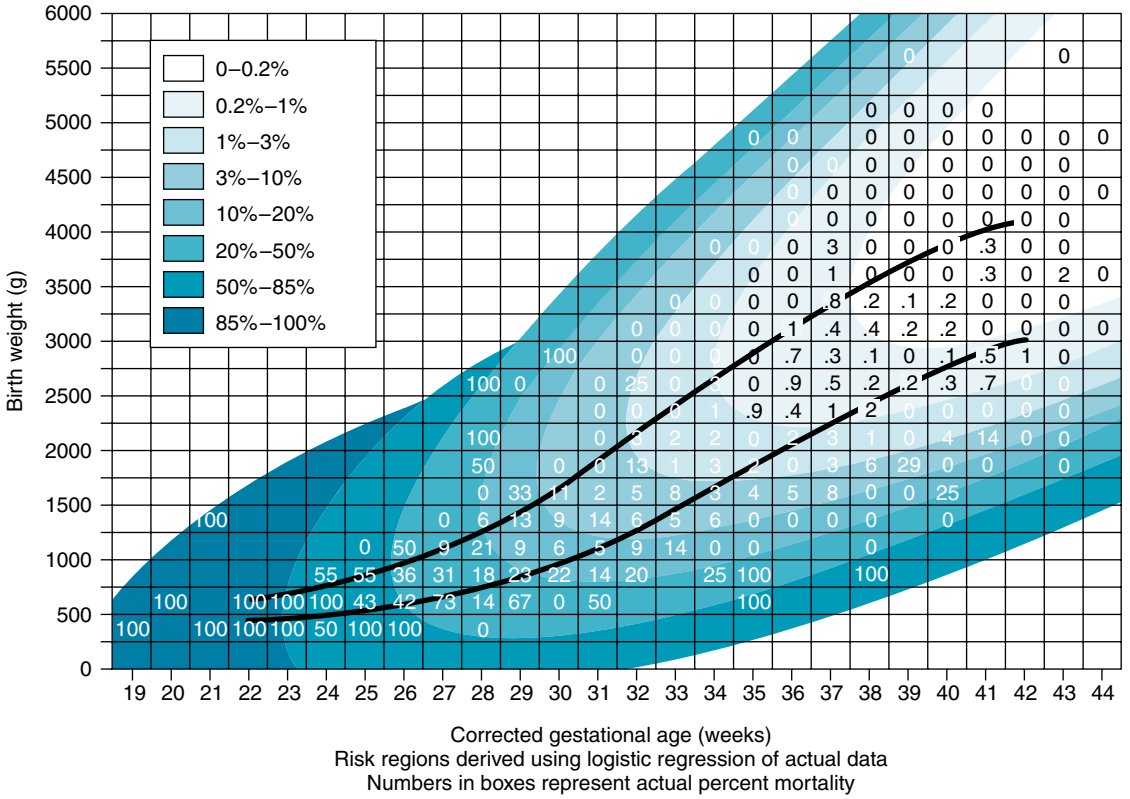

FIGURE 5.11 Neonatal mortality risk by birth weight and gestational age. (From Johnson JL, Merenstein G, Coll J, et al. Colorado intrauterine growth curve, 1980–1992: the new Lubchenco growth curve. *Pediatr Res.* 1994;35:274A.)

By combining GA in weeks, BW in grams, and intrauterine growth pattern, nine categories of newborns were thus defined (see Fig. 5.4). This type of classification allows clinicians to anticipate likely problems in the immediate neonatal period and potential morbidities in the long term.

NEONATAL MORTALITY RISK

Significant advances in obstetrics and perinatal-neonatal care during the past six decades have resulted in a remarkable decline in the rate of neonatal mortality (see Chapter 2). Although BW is considered to be the best predictor of neonatal survival, with exponential improvement evident with the achievement of optimum BW, it is apparent that **neonatal mortality risk could be predicted more accurately for any individual infant based on the relation of two factors: BW and GA.**[19,109]

Neonatal mortality risk (NMR), the chance of dying in the neonatal period, can be determined from mortality graphs based on BW and GA, such as that shown in Fig. 5.11. This figure was constructed based on the Lubchenco Perinatal Database, University of Colorado Hospital, 1980 to 1992. Mortality was calculated for each 100 g/1 week BW/GA block. On the chart, the area of least risk is the FT-AGA infant. Deviations from this area of least risk in relation to either weight or GA increase the newborn's mortality risk. **Further examination of NMR in Fig. 5.11 reveals that two infants with the same BW but with different GAs may have very different risks for death.** For example, infant A may have a BW of 2000 g and a GA of 33 weeks, and shows an NMR of 2%. Infant B, on the other hand, may also weigh 2000 g but have a GA of 39 weeks, and shows an NMR of 0.2%. Infant A thus has a mortality risk 10 times greater than that of infant B, even though they have the same BW.

Mortality risk has changed over time because an increasingly physiologic basis of care has been

used, coupled with sophisticated professional care, improved technology, new treatment modalities, transport systems, and aggressive management to handle increasingly at-risk populations. Consequently, these neonatal mortality risks need to be reviewed periodically.

Within the NICHD Neonatal Research Network, mortality rates for newborns weighing 501 to 1500 g decreased from 23% (1987 to 1988) to 17% (1993 to 1994) to 14% (1999 to 2000) to 12.4% (2000 to 2009). However, within each BW category, survival free of major morbidity (e.g., chronic lung disease/bronchopulmonary dysplasia, necrotizing enterocolitis, grade 3 or 4 intraventricular hemorrhage) did not change significantly. **Because mortality (and morbidity) rates are highest in infants of the lowest BW and GA, VLBW and ELBW infants would have more favorable outcomes when they are born in a facility that can provide the appropriate subspecialty care.[113,176,208] These research findings have prompted recommendations that high-risk mothers/infants (e.g., less than 32 weeks of GA) be delivered/born in a facility capable of providing the anticipated appropriate level of perinatal/neonatal care.[8,9]**

NEONATAL MORBIDITY RISK

Neonatal morbidity risk (Fig. 5.12) is determined by deviations of intrauterine growth and newborn classification. **Classification of the newborn assists in identification, observation, screening, and treatment of the most commonly occurring problems. For every newborn, formulate a problem list based on the morbidities common to the newborn classification. Observe, screen, intervene, and refer as necessary to prevent complications.**

SGA/IUGR infants are at increased risk for morbidities such as perinatal depression, hypothermia, hypoglycemia, polycythemia, and infection immediately after birth. Full-term SGA infants have higher morbidities, mortality (including stillbirth), and hospital charges when compared to other term infants.[72,127] LGA infants are at an increased risk for more morbidities, including hypoglycemia, polycythemia, and birth trauma.[126] There is also an association between size at birth, altered physiologic development, and long-term developmental and health problems (especially heart disease and stroke).[53]

LATE-PRETERM INFANT

In the United States, as a result of shifting distribution of GA among spontaneous live, singleton births, 39 weeks was found to be the most common length of gestation.[62] ***Preterm infants* are infants born before 37 completed weeks of gestation ($37^{0/7}$ weeks or day 259). *Late-preterm infants* refer to infants born between 34 completed ($34^{0/7}$ weeks or day 239) and less than 37 completed weeks ($36^{6/7}$ weeks or day 259).[69] *Early term infants* are infants born between $37^{0/7}$ weeks and $38^{6/7}$ weeks.[171]** In 2011, the prematurity rate in the United States was 11.7%,[81] and two-thirds (8.1%) of these were due to "late-preterm" births. From 2006 to 2014, birth rates for late preterm and early term births declined as a direct result of fewer clinician-initiated obstetric interventions.[152] However, in 2018 the CDC reported that the preterm birth rate in the United States increased from 9.57% to 9.85% from 2014 to 2016, mainly as a result of an increase in LPI, especially those at 36 weeks of gestation.[121] **Because late preterm and early term infants are at increased risk for health and developmental problems,[147] elective delivery before 39 weeks is considered a major public health concern.[95]**

A 2005 National Institutes of Health (NIH) meeting[136] adopted the description ***late-preterm* rather than *near-term* to reflect the increased morbidity (and mortality) rates of this group of biologically and physiologically immature neonates.[68]** These infants are larger than the usual premature infants, and they may be treated as mature infants, but they often manifest signs of physiologic immaturity in the neonatal period.

Morbidity and Mortality Outcomes in Late-Preterm Infants

Numerous studies have documented the high incidence of neonatal complications leading to neonatal intensive care unit (NICU) admission (30% to 59%) of LPIs.[64,69] A multicenter study found that 10% of LPIs admitted to mother-baby units required transfer to a higher level of care.[124] Table 5.7 shows a list of the most frequently encountered morbidities in LPIs. When spontaneous and medically indicated late preterm birth are compared, LPIs born because of a medical indication have **a higher incidence of respiratory complications,**

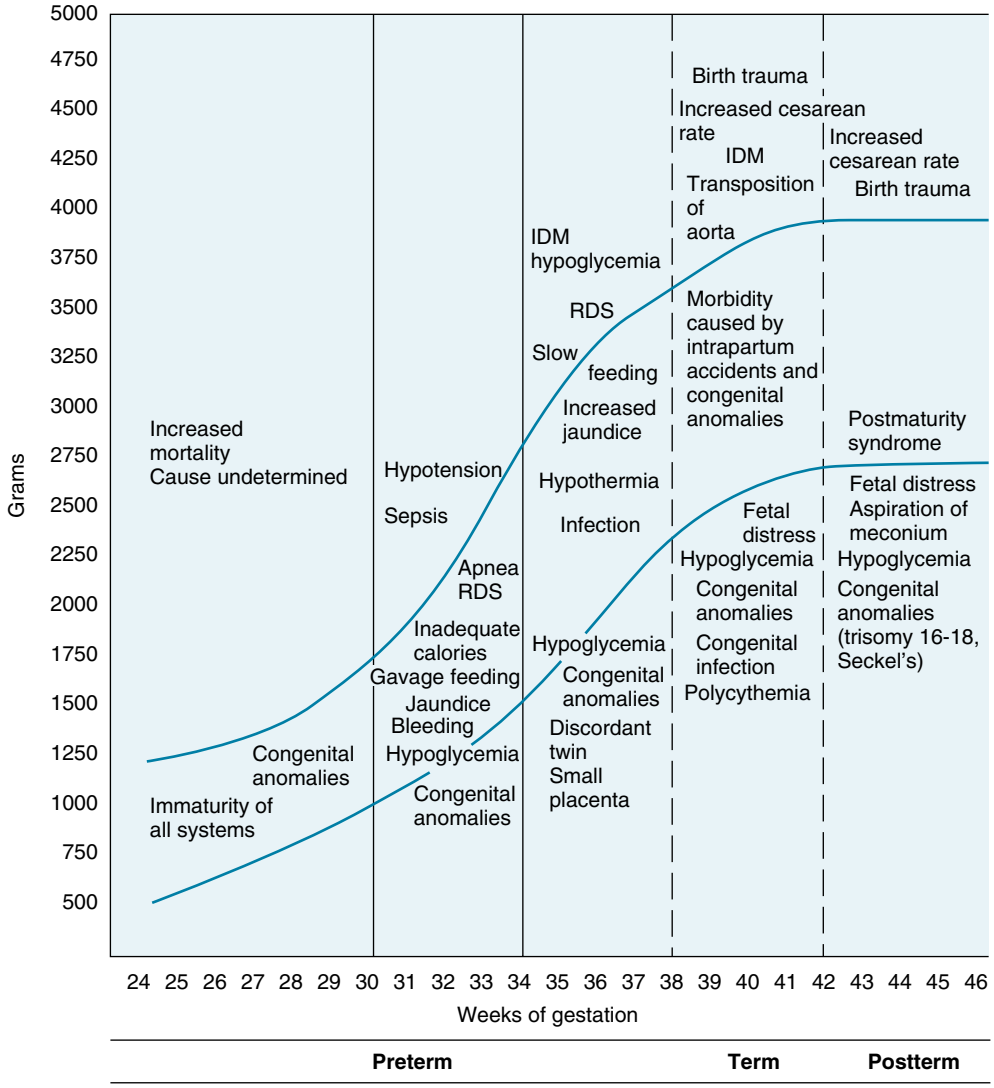

FIGURE 5.12 Specific neonatal morbidity by birth weight and gestational age based on statistics from Newborn and Premature Center at the University of Colorado Medical Center. *IDM,* Infant of diabetic mother; *RDS,* respiratory distress syndrome. (From Lubchenco LO. *The High-Risk Infant.* Philadelphia, PA: Saunders; 1976.)

such us transient tachypnea of the newborn, respiratory distress syndrome, persistent pulmonary hypertension of the newborn, respiratory failure, and respiratory depression requiring resuscitation at birth.[27,64,104,178] The incidence of these morbidities increases with decreasing GA. A single-center study showed that neonates born at 34 weeks of gestation had the highest risk for morbidities during neonatal transition to extrauterine life, including need for resuscitation at birth, hypothermia, hypoglycemia, and NICU admission.[64] This confirms the results of a previous study that also found 34-week GA LPIs with the highest morbidities.[196] **Each additional week of gestation decreases neonatal morbidity, mortality, and length of stay.**[64,119] With every additional week of gestation past 35 weeks, there is a decrease in specific and overall developmental delay in the first 2 years of life.[67]

Data from Wang M, Dorer D, Fleming M, et al. Clinical outcomes of near-term infants. *Pediatrics* 2004;114:372; Leone A, Ersfeld P, Adams M, et al. Neonatal mortality in singleton late preterm infants compared with full-term infants. *Acta Paediatr.* 2011;101:e6; Visruthan NK, Agarwal P, Sriram B, Rajadural VS. Neonatal outcome of the late preterm infant (34 to 36 weeks): the Singapore story. *Ann Acad Med Singapore* 2015;44(7):235.

LPIs not only have more morbidities but also have been shown to have *increased mortality risk.* A report from the Institute of Medicine in 2005 points out that whereas the mortality rates for full-term neonates were stable at 2.5 per 100,000 live births, the rate for moderately preterm neonates (32 to 36 weeks of gestation) rose from 8.9 to 9.2 per 100,000 live births from 2001 to 2002.[136] A more recent study compared overall and cause-specific mortality rates between singleton late-preterm and term infants.[184] This study concluded that **LPIs have higher mortality rates throughout infancy compared with term infants. LPI mortality rates were threefold higher than those of term infants (7.9 vs. 2.4 deaths per 1000 live births).**[184] In the first month of life, when evaluating deaths in the early (1 to 6 days) and late (7 to 27 days) neonatal periods, mortality rates were six and three times higher, respectively, for the LPI. Postneonatal deaths were twice as high as term infants. **During infancy, LPIs were approximately four times more likely than term infants to die.** In another study, neonatal mortality rates were significantly higher for LPIs (1.1, 1.5, and 0.5 per 1000 live births at 34, 35, and 36 weeks, respectively) compared with 0.2 per 1000 live births at 39 weeks.[123] A recent secondary analysis of the WHO multicountry survey on maternal and newborn health found that elective cesarean section was associated with reduced perinatal mortality and non-significantly associated with late preterm birth. However, labor induction was associated with increased late preterm birth and in less developed countries with an increase in perinatal mortality.[132] **Although the rate of mortality increases with decreasing GA,**[40] **two recent studies found the highest mortality occurring at 37 weeks of gestation.**[195,205]

BOX 5.3 LONG-TERM OUTCOMES OF LATE PRETERM INFANTS: RESEARCH FROM 2015 TO 2018

Growth

Higher risk for less weight gain and height in first year of life.[86] Faster head growth from 20 to 56 months of age associated with better adult neurocognitive function but not consistently associated with mental health outcomes.[155]

Higher Use of Health Care Resources

More hospital readmissions for jaundice, feeding difficulties, respiratory problems/infections, asthma, diarrhea, fever, and neurologic, and/or mental health problems from infancy[86,89,98,99,156] to adulthood.[98] More lower respiratory tract infections in preschool years, and more asthma at school age.[60] Reduction in measures of airway function.[182]

Developmental Delays

Being late preterm did not increase the risk of poorer neurocognitive functioning in adulthood. However being SGA and late preterm increases the risk of poorer neurodevelopmental outcomes.[90] No difference in IQ between LPI and full term infants.[133] Increased risk of lower cognitive ability in LPI when compared to early-term and full-term birth.[46]

At 4 and 8 Months CA[24]

- LPI at 4 months had lower fine motor scores
- LPI at 4 and 8 months had significantly lower communication and gross motor scores

At 9 Months CA[161]

- Less optimum developmental outcomes than full-term controls
- Delays not seen at 24 months CA
- Delays reemerged at preschool and kindergarten[204] (delays in reading and mathematics)

At 1 Year of Life

- Early intellectual delay (lower scores in adaptability, gross motor skills, and social competence) than full-term group[209]
- LPI admitted to an NICU increased the risk of developmental delay (i.e., communication and gross motor skills)[16]

At 18 Months CA[24]

- No significant difference in fine motor skills, gross motor skills, or communication delays seen at 4 and 8 months CA

At 2 Years CA

- Worse cognitive, language, and motor delays of moderate and LPIs compared to full term controls[48,170]
- Worse socioemotional competence of moderate and late preterm infants compared to full term controls[48]

At 3 Years CA

- Increased risk of emotional problems for girls born at late preterm and early term[173]

At 4 to 5 Years of Age

- Resolving communication problems and emerging motor problems that are comparable to early-preterm–born children but at a lower rate[92]

At 6 to 12 Years of Age

- Greater risk for emotional and behavioral problems and lower quality of life compared to full-term peers[149]

CA, Corrected age; *IQ*, intelligence quotient; *LPI*, late preterm infant; *SGA*, small for gestational age.

Long-Term Outcomes

Two large systematic reviews[18,134] comparing late-preterm infants (LPIs) with full-term infants found that the children and adults born late preterm fare worse than their full-term born peers in cognitive function, school outcomes, behavior problems, psychiatric disorders, and subtle intellectual and neuropsychological deficits. Box 5.3 lists long-term outcomes from more recent research studies not included in the systematic reviews. These retrospective reports in no way confirm causality. **Outcomes are not only the result of physiologic immaturity, but also of the biologic determinants of preterm birth interacting with GA.[36]** Neurodevelopmental follow-up of LPIs has been, until recently, a long neglected area of research. More research, including longitudinal, prospective studies, are needed to fully appreciate the impact of late-preterm birth, biologic determinants, and perinatal events on developmental and health outcomes in this population of at-risk infants.[36,151]

Clearly, LPIs are not term infants and need close observation, a high level of suspicion, assessment, and timely intervention by all care providers. Regardless of the setting of care for the LPI, these immature infants require more nursing time and care than do full-term infants. If the level of care cannot be provided in the birth setting, these infants should be transferred to a higher level of care (either in the same or a different facility) as soon as possible.

Physical and Neurologic Examination

The purpose of the physical examination is (1) to discover common variations of normal or obvious congenital defects, (2) to quickly initiate intervention or referral for deviations from normal, and (3) to establish a baseline for serial observations and comparisons. The best data are obtained from the neonate when the physical examination is organized to limit stress, maximize interaction with the examiner, and not overwhelm the newborn. **To maximize data and minimize stress, the physical examination should proceed in an orderly fashion from the least stressful to the more stressful aspects of the examination** (Box 5.4).

When one appreciates how stressful it is to the newborn to be undressed, it becomes obvious that as much as possible should be done without exposing the infant. Warm hands and instruments are essential, and a warm environment helps. Before touching the infant or removing any covers, observe the face, head, and hands as they appear.

OBSERVATION

Observation of the neonate provides pertinent data without touching him or her. General condition, anomalies, resting posture, and respirations should be observed.

GENERAL CONDITION

The general condition of the infant should be assessed by noting the color, activity, and neonatal state.

Color. **The color of the newborn is normally pink. Acrocyanosis, or peripheral cyanosis of the hands and feet, is commonly present in the first 24 hours of life and may be the result of immature circulation or cold stress.** Ecchymotic areas, especially on the presenting part, are common; however, they may be confused with cyanosis. To differentiate the two, apply pressure to the area. An ecchymotic area remains blue with pressure, whereas a cyanotic area will blanch.

General cyanosis and central cyanosis of the lips, mouth, and mucous membranes may indicate central nervous system (CNS), heart, or lung disease. Jaundice appearing at birth or within the first 24 hours of life is abnormal. Physiologic jaundice appears after 24 hours, but jaundice may indicate other abnormalities. **Pallor at or directly after birth is a sign of circulatory failure, anoxia, edema, or shock.** Pallor of anoxia is associated with bradycardia and the pallor of anemia with tachycardia. **Plethora, a beef-red color, may indicate polycythemia and is confirmed by hemoglobin and hematocrit determinations.** However, lack of plethora does not rule out polycythemia or hyperviscosity.

BOX 5.4 CRITICAL FINDINGS
PHYSICAL EXAMINATION OF THE NEWBORN

I. Observation Examination
- A. General condition
  - 1. Color
  - 2. Activity and neonatal state
- B. Crying
- C. Anomalies

  - 2. Nose
  - 3. Mouth
- C. Thorax
  - 1. Breast
  - 2. Clavicles
- D. Genitalia
- E. Rectum
- F. Back
- G. Extremities
  - 1. Upper
  - 2. Lower

Activity and Neonatal State. Activity and the neonatal state at the beginning of the examination and appropriate changes throughout the examination should be observed. If the infant is asleep, is it quiet or rapid-eye-movement (REM) sleep? Spontaneous, symmetric movements are normal. Tremors and twitching movements of short duration are normal in relation to states of coldness or startling or REM sleep. Good muscle tone is established with adequate oxygenation soon after birth.

Flaccidity, floppiness, or poor muscle tone should be noted. Spasticity, hyperactivity, opisthotonos, twitching, hypertonicity, tremors, or seizures may be indicative of CNS damage. **A lack of crying or evasive behavior in response to the manipulations of a physical examination is abnormal.**

Crying. Attempts to calm and console a crying infant during this part of the examination assist in better data collection during the quiet examination. Crying is beneficial in (1) ductal closure and transition from fetal to neonatal cardiorespiratory status, (2) improving pulmonary capacity, (3) maintaining homeostasis, (4) facilitating vocal tract development, and (5) cueing and care-eliciting behavior. Negative effects include (1) changes in cardiovascular (e.g., tachycardia, hypoxia, changes in cerebral blood flow, increased risk for brain injury and cardiac dysfunction)[117] and endocrine systems; (2) stress production and energy drainage;[117] and (3) strong, sometimes negative feelings in care providers.

Although uniquely individual, types of cries that reflect the infant's state and contextual basis have been identified as birth, distress call, hunger, pain, spontaneous, and pleasure.[52] At birth, the term neonate has a loud, lusty cry (a signal of robustness and wellness), whereas the preterm's cry may be weak or absent. Observe the infant's ability to quiet himself or herself when crying. High responsivity of the newborn to sustained handling, undressing, and being put down is associated with more infant crying.

A high-pitched cry suggests CNS irritation from increased intracranial pressure, injury, infection, or abnormality. *Weak crying,* no crying, or constant, irritable crying may indicate brain injury, infection, or abnormality. *Hoarse cries* or crowing inspirations result from laryngeal inflammation, injury, vocal cord dysfunction (e.g., paresis/paralysis), or anomalies. *A weak,* groaning cry or expiratory grunt is indicative of respiratory disease or systemic illness.

ANOMALIES

Obvious bodily malformations such as abdominal wall defects (omphalocele or gastroschisis), cleft lip and palate, imperforate anus, syndactyly, polydactyly, club foot (talipes equinovarus), or myelomeningocele should be observed and recorded as anomalies. Odd facies or body appearances that are often associated with specific syndromes also should be noted.

RESTING POSTURE

Resting posture should be observed while the infant is quiet and not disturbed. The infant's posture systematically develops according to GA: (1) from extension to flexion of the lower extremities, and (2) to flexion of the upper extremities. Asymmetry may result from intrauterine pressure or birth trauma. The infant may take a position of comfort assumed in utero.

RESPIRATIONS

Respirations should be evaluated while the infant is at rest and before any manipulation. The normal rate is 30 to 60 breaths/min. Count the respiratory rate and rhythm, noticing the infant's use of accessory muscles. Respiration is normally abdominal or diaphragmatic.

After the first hour of life, a respiratory rate of more than 60 breaths/min indicates tachypnea. Tachypnea is the earliest sign of many neonatal respiratory, cardiac, metabolic, and infectious illnesses. Tachypnea, apnea, dyspnea, or cyanosis may indicate cardiorespiratory distress. Labored respirations include retractions, flaring nares, and expiratory grunt. Maternal epidural analgesia with fentanyl has been shown to cause respiratory depression in neonates because fentanyl freely diffuses from the epidural space to maternal blood, equilibrating within 10 to 30 minutes and freely transporting across the placenta with slightly higher concentrations in the fetal compartment.[112] Neonatal respiratory depression secondary to fentanyl epidural analgesia is more common when mothers receive large amounts of fentanyl during labor; naloxone administration reverses the respiratory depression.[112]

If the infant is swaddled, the observation examination will not be as extensive as is possible when

the infant is unclothed in an incubator or under a radiant warmer. If the infant is swaddled, unwrap gently so that observations of the thorax, abdomen, genitalia, and extremities may also be done during this phase of the examination.

Without touching the infant, one can rule out a multitude of conditions. In fact, more than 80% of the newborn examination is made through observation.

QUIET EXAMINATION

***Quiet examination* is defined as any part of the examination in which data are best collected from the quiet, cooperative newborn. The heart, lungs, head and neck, scalp and skull, abdomen, eyes, and blood pressure are areas that should be checked during the quiet examination.** Using pacifiers, warming hands and stethoscopes, and holding and gently manipulating the infant are ways to avoid overwhelming the baby and to prevent crying.

AUSCULTATION

Heart. Auscultation of the heart, lungs, and abdomen is most effective when the infant is quiet. When the infant is quiet and at rest, auscultate the heart rate, rhythm, and regularity at the apex. The normal rate is 120 to 160 beats/min at a regular rhythm. Variations in heart rate occur with respiratory cycles and single premature beats are commonly heard and generally normal. The point of maximal intensity (PMI) of the neonatal heart is lateral to the midclavicular line at the third to fourth interspace. Note the PMI.

A rate of less than 80 beats/min is bradycardia. Full-term newborns in quiet sleep may have heart rates as low as 80 beats/min. Newborns with persistent bradycardia may have complete heart block caused by maternal systemic lupus erythematosus (see Chapter 2). A rate greater than 160 beats/min is tachycardia, which may be associated with respiratory problems, anemia, or congestive heart failure when accompanied by cardiomegaly, hepatomegaly, and generalized edema.

Murmurs are noted for loudness, quality, location, and timing. They are best auscultated at the base of the third or fourth interspace. Heart murmurs in the newborn period are common, perhaps as frequent as 10% of the population (see Chapter 24). Note dextrocardia—heart sounds audible on the right side of the chest. Pneumothorax, pneumomediastinum, dextrocardia, and diaphragmatic hernia result in muffled heart sounds or a shift in PMI. To complete the cardiac assessment, careful attention to the femoral pulses is necessary; diminished femoral pulses suggest coarctation of the aorta (see Chapter 24). Often newborns with serious congenital heart disease do not present with clinical signs and symptoms of their anomaly. Use of pulse oximetry to screen all newborns at 24 hours of age and before discharge for critical congenital heart disease is discussed in Chapter 31.

Lungs. Normally, the lungs and chest are resonant after birth, and fine rales may be present for the first few hours. Auscultation reveals bronchial breath sounds bilaterally. Air entry should be good, particularly in the midaxilla. A normal respiratory rate is 30 to 60 breaths/min.

Hyperresonance suggests pneumomediastinum, pneumothorax, or diaphragmatic hernia. *Decreased resonance* is a result of decreased aeration—atelectasis, pneumonia, or respiratory distress syndrome. Expiratory grunt suggests difficulty in aeration and oxygenation. Peristaltic sounds heard in the chest may be caused by a diaphragmatic hernia.

Abdomen. Bowel sounds are normally heard shortly after birth.

PALPATION

Palpation of the fontanels and abdomen is best accomplished before the infant begins crying, because guarded muscles and the normally tense fontanels of the crying infant give little useful data.

Scalp and Skull. Temporary deformation of the head is caused by pressures during labor and delivery. The head circumference measurements may be altered so that the occipitofrontal circumference on the first day of life may be smaller than on the second or third. *Caput succedaneum* is an edematous area over the presenting part of the scalp that extends across suture lines and resolves in 24 to 48 hours. A *cephalhematoma* is a soft mass of blood in the subperiosteal space on the surface of the skull bone. The blood mass does not extend across suture lines and resolves in 6 to 8 weeks.

Deviating from the normal, **skull fractures may be linear or depressed, palpable or nonpalpable.**

Skull fractures are more common with forceps delivery. *Craniotabes,* softening of the skull bones, is caused by maternal vitamin D deficiency.[206]

The *anterior fontanel,* a diamond-shaped space normally measuring from 1 to 4 cm, may be gently palpated at the junction of the sagittal suture and coronal suture and between the two parietal bones. Normally the anterior fontanel softly pulsates with the infant's pulse, becomes slightly depressed when the infant sits upright and is quiet, and may bulge when the infant cries. Within 24 to 48 hours after birth, the initial molding of the head and overlap of the sutures resolve, resulting in a larger fontanel and in suture lines that should be palpated as depressions.

The *posterior fontanel,* formed at the juncture of the sagittal suture and the lambdoidal suture, is palpated between the occipital and parietal bones. Normally it is triangular shaped and barely admits a fingertip.

A *bulging, tense, or full fontanel* **may be associated with increased intracranial pressure caused by birth injury, bleeding, infection, or hydrocephalus.** A *depressed fontanel,* a very late sign in the newborn, may indicate dehydration. A *third fontanel,* located along the sagittal suture between the anterior and posterior fontanels, may be a sign of congenital infection or Down syndrome or may be a normal variant.

Sutures are palpable ridges between skull bones. The coronal suture is located between the frontal and two parietal bones. The sagittal suture intersects the two parietal bones, and the lambdoidal suture lies between the occipital and the two parietal bones. With increasing GA, the suture edges become firmer and with gentle palpation are felt as hard ridges. Sutures may be open to a varying degree or may be overlapped because of molding. Lack of normal expansion may indicate microcephaly or craniosynostosis. Abnormally rapid expansion indicates hydrocephalus or increased intracranial pressure.

Abdomen. The abdomen will appear slightly scaphoid at birth but will become distended as the bowel fills with air. The technique of palpating the abdomen with one hand beneath the back as the other hand defines organs and masses is quite useful. Gentle palpation of the abdomen for organs or masses reveals that the spleen tip can be felt from the infant's left side and is sometimes 2 to 3 cm below the left costal margin. The liver is palpable 1 to 2 cm below the right costal margin. Superficial veins over the abdominal wall may be prominent.

A markedly scaphoid abdomen coupled with respiratory difficulty may indicate a diaphragmatic hernia. Abdominal distention and lack of bowel sounds may occur because of intestinal obstruction, paralytic ileus, ascites, imperforate anus, meconium plug, peritonitis, omphalocele, Hirschsprung's disease, or necrotizing enterocolitis. The abdominal wall should be inspected for defects, such as umbilical hernia, omphalocele (a herniation into the base of the umbilical cord), and gastroschisis (a defect of the abdominal wall).

The umbilical cord may also be observed and inspected while the abdomen is being palpated. The diameter of the cord varies, depending on the amount of Wharton's jelly present. **Two arteries and one vein are normally present in the umbilical cord.** The umbilical cord begins to dry soon after birth, becomes loose from the skin by 4 to 5 days, and falls off by 7 to 10 days. Redness/umbilical erythema, foul odor, or wetness/oozing of the cord may indicate omphalitis. Persistent drainage may indicate a patent urachus, umbilical fistula, or cysts.

INSPECTION

Head and Neck. The head and neck of a newborn make up 25% of the total body surface. The head is usually 2 cm larger than a newborn's chest. Normal head circumference ranges between 32 and 38 cm for a FT-AGA infant. Note the size, shape, symmetry, and general appearance.

Microcephaly is characterized by a small head size in proportion to body size. *Craniosynostosis* is a small head size caused by early closure of sutures. *Hydrocephalus* is a condition in which an increase in cerebrospinal fluid creates an abnormally large and growing head.

Eyes. Inspection of an infant's eyes is best accomplished when the infant is found in the quiet alert state or when the infant has been aroused to wakefulness during the examination. The eyes cannot be observed while the baby is crying. Tipping the baby backward and raising him or her slowly or shading the infant's eyes from bright light often causes the eyes to open.

The newborn's eyes open spontaneously, look toward a light source, fix, focus, and follow. Uncoordinated eye movements are common. Subconjunctival or scleral hemorrhages are a

common result of the pressures of labor and birth. The size, shape, and structure of the eye should be noted.

The pupils of the normal newborn respond to light by constricting. *Red reflex* is normally present and indicates an intact lens and unobstructed visual path to the retina. Tears are not normally produced until 2 months of age. The iris is usually dark blue until 3 to 6 months of age. Doll's eye maneuvers are normally associated with eyes that follow movement of the head, often with a lag and/or nystagmus.

Discharge from the eyes may represent irritation or infection. A lateral upward slope of the eyes with an epicanthal fold may indicate syndromes of mental, physical, or chromosomal aberrations. The **absence of red reflex** may indicate tumors or congenital cataracts accompanying rubella, galactosemia, or disorders of calcium metabolism. Chorioretinitis is often found in congenital viral diseases such as cytomegalovirus and toxoplasmosis. White speckles on the iris known as *Brushfield's spots* are associated with Down syndrome and developmental delay or are a normal variant. **Scleral blueness is associated with osteogenesis imperfecta and scleral yellowness with jaundice.** Brain injury may be indicated by a constricted pupil, unilaterally dilated fixed pupil, nystagmus, or strabismus.

Blood Pressure. **Blood pressure (BP) with noninvasive Doppler devices is best determined (1) by using the appropriate-size cuff for upper and lower extremities (e.g., using the same size cuff for the leg pressure that was used for the arm pressure results in a falsely elevated leg pressure), (2) by obtaining the measurement when the infant is asleep or before the infant is upset, and (3) by using the mean BP to monitor changes.**[61] **BP increases in the first 24 hours of life,** is higher in more mature infants (e.g., BW and GA) and in newborns whose mothers smoke,[82] and increases with increasing postnatal age.[59]

The BP should be checked in all four extremities to screen for coarctation of the aorta. Because the BP proximal to the area of obstruction is higher than the BP distal to the area of obstruction, BP in the upper extremities is higher (more than 15 mm Hg higher) than in the lower extremities (Figs. 5.13 and 5.14).

The only study to evaluate the efficacy of upper and lower extremity BP variations was conducted on 40 healthy neonates.[61] This study showed that with the current Doppler devices, normal neonates may have a wide variation in BPs between limbs. The researchers concluded that a difference of 20 mm Hg is more likely caused by random variability than coarctation and recommended that if weak/absent pulses are present and coarctation is suspected, an echocardiogram is necessary.[61]

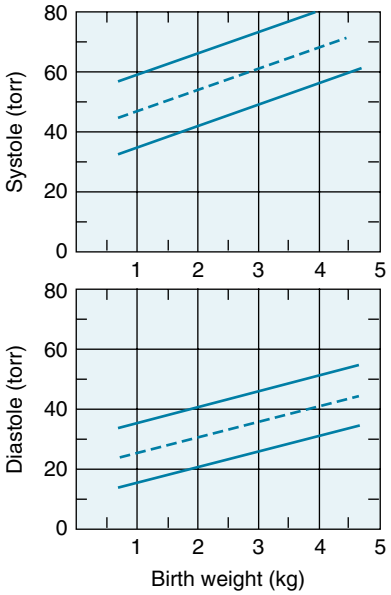

FIGURE 5.13 Aortic blood pressure during first 12 hours after birth. Linear regression *(broken lines)* and 95% confidence limits *(solid lines)* of systolic and diastolic blood pressures on birth weight in healthy newborn infants. (From Versmold HT, Kitterman JA, Phibbs RH, et al. Aortic blood pressure during the first 12 hours of life in infants with birth weight 610 to 4220 grams. *Pediatrics.* 1981;67:607.)

Head-to-Toe Examination. **The infant's crying will not affect the data to be gathered in the head-to-toe examination.**

Skin. **As each body part is examined, the skin is also inspected.** *Vernix,* a white, cheeselike material that contains quantities of α-tocopherol and surfactant proteins that provide significant protection from infection, normally covers the body of the fetus and decreases with increased GA. Discoloration of the vernix occurs with intrauterine distress, postmaturity, hemolytic disease, and breech presentations.

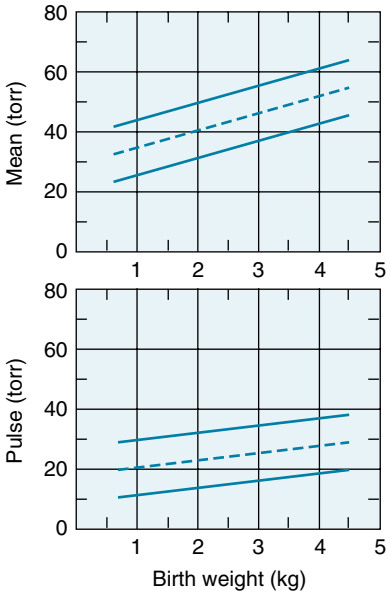

FIGURE 5.14 Mean aortic and pulse pressures during the first 12 hours after birth. Linear regression *(broken lines)* and 95% confidence limits *(solid lines)* on birth weight in healthy newborn infants. (From Versmold HT, Kitterman JA, Phibbs RH, et al. Aortic blood pressure during the first 12 hours of life in infants with birth weight 610 to 4220 grams. *Pediatrics.* 1981;67:607.)

The color of the skin is normally pink. *Mongolian spots* caused by the presence of pigmented cells may cover the sacral-gluteal areas of infants of color (e.g., black, Hispanic, Asian). The degree of generalized pigmentation varies and is less intense in the newborn period than later in life. *Nevus flammeus* may be present at the nape of the neck or on the eyelids.

Note the size, shape, color, and degree of ecchymosis, erythema, petechiae, or hemangiomas. Meconium staining, which occurs in 10% to 20% of newborns, is indicative of prior fetal distress. *Erythema toxicum* appears as a generalized red rash in the first 3 days of life. *Milia* caused by retained sebum are pinpoint white spots on the cheeks, chin, and bridge of the nose.

The normal texture of a neonate's skin is soft. A preterm infant's skin is more translucent than a term infant's skin. Slight desquamation **may occur as skin becomes dry.** Moderate to severe desquamation **occurs in postterm infants with IUGR.** Puffy, shiny skin is symptomatic of edema. Localized *edema* of a presenting part is caused by trauma and is only temporary. Edema should be distinguished from increased subcutaneous fat. *Lanugo* coverage decreases with increasing GA.

Tissue turgor is the sensation of fullness derived from the presence of hydrated subcutaneous tissue and intrauterine nutrition. Test the elasticity of the skin by grasping a fold of skin between the thumb and forefinger. When released, the skin should promptly spring back to the surface of the body. **A loss of normal skin turgor resulting in peaking of the skin is a late sign of dehydration.** A generalized hardness of the skin is a sign of *sclerema* that occurs in debilitated, stressed infants.

Ears. Cartilage development and ear form progress according to GA. Observe the external ears for size, shape, and position. **The angle of placement** of the ears is almost vertical. If the angle of placement is greater than 10 degrees from vertical, it is abnormal. The level of placement is determined by drawing an imaginary line from the outer canthus of the eye to the occiput. If the ear intersects the line, it is placed normally. Slapping hands or other sharp noises will normally elicit a twitching in the eyelid or a complete Moro reflex.

Malformed or malpositioned (low-set or rotated) ears are often associated with renal and chromosomal abnormalities and other congenital anomalies. **Abnormalities such as skin tags or sinuses may be associated with renal tract abnormalities or hearing loss.** Forceps or difficult deliveries may injure the outer ear. Congenital deafness is suspected if the infant does not respond to noise. It is confirmed by standardized hearing screening tests and follow-up.

Nose. Note the shape and size of the nose. Deformities caused by intrauterine pressure may be temporary. **Neonates are obligatory nasal breathers and must have patent nasal passages. Check the patency of the alae nasi by (1) obstructing one nostril, closing the mouth, and observing breathing from the open nostril; (2) placing a stethoscope under the nostrils that will "fog" the diaphragm and auscultate breathing; or (3) passing a soft catheter (if necessary).**

Abnormal configuration may be associated with congenital syndromes. Obstructions can be caused by drugs, infections, tumors, nasal discharge, nasal

cysts, and mucus. *Choanal atresia,* a membranous or bony obstruction in the nasal passage, may be unilateral or bilateral. **Choanal atresia is characterized by the noisy breathing, cyanosis, and apnea of the quiet infant (mouth closed) as opposed to the pink color of the same crying infant (mouth open).**

Mouth. The mouth may be examined here or at the end of the examination when the infant is crying loudly with a wide-open mouth. **At birth, a normal infant can suck and swallow (this ability develops at 32 to 34 weeks of gestation) and root and gag (this ability develops at 36 weeks of gestation). Elicit each.**

Lips and mucous membranes are normally pink. Observe the lips and mucous membranes for pallor and cyanosis. If the infant is well hydrated, the membranes should be moist. Open the mouth to look for anomalies. **Palpate the hard and soft palates for a membranous cleft or submucous cleft.** *Epithelial pearls* are common along the gum margins and the palate.

Natal teeth may be present and may require removal to prevent aspiration. A large tongue (macroglossia), cleft lip or palate (including submucous cleft), or high-arched palate may be associated with abnormal facies or be an isolated finding. If copious secretions or distress in feeding is present, it is often the result of esophageal atresia or tracheoesophageal fistula.

Thorax. Conformation of the newborn chest is cylindric with an anteroposterior ratio of 1:1. Note the shape, symmetry, position, and development of the thorax. *Asymmetry of the chest* may be caused by diaphragmatic hernia, paralysis of the diaphragm, pneumothorax, emphysema, pulmonary agenesis, or pneumonia. **Fullness of the thorax** caused by increased anteroposterior diameter occurs with an overexpansion of the lung. **Retractions, an inward pull of the soft parts of the chest while inhaling,** indicate air-entry interference or pulmonary disease.

Breasts. Breast tissue systematically develops according to GA. Enlargement of breasts because of maternal hormones occurs in either sex on the second or third day. Milky secretions may be present. Unilateral redness or firmness indicates infection.

Clavicles. Observe and palpate the area above each clavicle. A fracture of the clavicle is evidenced by a palpable mass, crepitation, tenderness at the fracture site, and limited arm movements on the affected side.

Genitalia. Male and female genitalia systematically develop according to GA. *Ambiguous genitalia* result from incomplete or altered differentiation and require urology consultation.

Male Genitalia. Inspect the genitalia for the presence and position of the urethral opening. Palpate the testes either in the inguinal canal or scrotum. The scrotum appears large and pendulous with the presence of descended testes. A tight prepuce may be found. In dark-skinned races, darker pigmentation of the genitalia is normal. *Hypospadias* exists if the urethral opening is on the ventral surface of the penis. *Epispadias* exists if the opening is on the dorsal surface. **Inguinal or scrotal swelling, discoloration, palpable masses, and pain/tenderness with palpation may indicate an inguinal hernia, testicular torsion, trauma, tumor, or *hydrocele*—**a collection of fluid in the scrotal sac.

Female Genitalia. Inspect the genitalia for the presence and position of the urethral opening. The introitus is posterior to the clitoris. A vaginal skin tag is a visible hymenal ring.

Edema of the genitalia in both sexes is common in breech presentation. Note the presence of a hydrocele or hernia. Fecal urethral discharge may indicate **rectourethral fistulas.**

Rectum. Visualize and check the patency of the anal opening by waiting for meconium passage. DO NOT use rigid objects such as glass rectal thermometers. Observe the anatomy, and feel the muscle tone. Meconium is normally present during the first days of life.

Imperforate anus, irritation, or fissures may be present. Meconium passage before birth suggests fetal intrauterine distress. Failure to pass meconium within 48 hours suggests obstruction. *Meconium ileus* is associated with cystic fibrosis.

Back. Place the infant in the prone position, and observe for a flat and straight vertebral column. Separate the buttocks to observe the coccygeal area. To check incurving reflex, stroke one side of the vertebral column. The baby will turn the buttocks toward the side stroked.

Deviations from normal include curvature of the vertebral column, pilonidal dimple, pilonidal sinus, spina bifida, or myelomeningocele. A study of spinal congenital dermal sinuses found an increased incidence (greater than 50%) of neurologic deficit, intradural tumors, or tethered cords; recommendations included a prompt radiologic evaluation and neurosurgical consultation so that timely intervention could preserve or improve neurologic function.[3]

Extremities

Upper Extremities. **Note the size, shape, and symmetry of the arms and hands.** Observe and feel for fractures, paralysis, and dislocations. Count and inspect the fingers. The hands are normally clenched into fists. The infant is capable of adduction, flexion, internal rotation, extension, and symmetry of movement. Note the tone of the muscles. Flexion develops with increasing GA.

Single transverse palmar creases may indicate chromosomal abnormalities that are frequent causes of deformity. *Polydactyly and syndactyly* of the fingers may be found. *Osteogenesis imperfecta* is characterized by multiple fractures and deformities. *Palsies* caused by fractures, dislocations, or injury to the brachial plexus are recognized by limited movement of the extremity. *Fractures* may also be present with edema, palpable crepitus, or the "palpable spongy mass sign" over the clavicle.

Lower Extremities. **Note the size, shape, and symmetry of the feet and legs.** Note the normal position of flexion (develops according to GA) and abduction. Note symmetry of movement, thigh folds, and gluteal folds. A full range of motion is possible, including the "frog position"—a rotation of the thighs with the knees flexed. Observe and feel for fractures, paralysis, and dislocations. Palpate femoral pulses.

Polydactyly and syndactyly of the toes may exist. *Osteogenesis imperfecta,* a rare genetic defect of collagen production that results in brittle bones, manifests as multiple fractures and deformities. Paralysis of both legs is caused by severe trauma or congenital anomaly of the spinal cord. **Unilateral or bilateral developmental dysplasia of the hip (e.g., congenital dislocated hip),[97] which is more common in females and breech presentations, causes a hip clunk when the baby's legs are abducted into the frog position.** Although soft clicks are common, a sharp click indicates dislocation. **Fractures may be present and are characterized by limited movement and edematous, crepitant areas.** Chromosomal abnormalities are frequent causes of deformity.

Recoil is a test of flexion development and muscle tone. Recoil appears systematically as flexion first develops in the lower extremities and then in the upper extremities. Extend the legs and then release. Both legs should return promptly to the flexed position in accordance with the GA of the infant. Then extend the arms alongside the body. On release, prompt flexion should occur at the elbows.

NEUROLOGIC EXAMINATION[6,7,66]

The neurologic examination of the newborn is an integral part of the evaluation of the newborn infant. This evaluation often receives little attention, and in too many instances the infant is dismissed from the nursery as "normal" when, in fact, little effort was expended to determine the baby's neurologic status. **The evaluation and documentation of the development of the nervous system in the normal newborn should be of paramount interest to all the health care clinicians caring for the newborn. Some portions of the neurologic examination are carried out as a component of the general physical examination of the newborn** *(activity, resting posture, symmetry, head size and morphology, rooting reflex, muscle tone, primitive reflexes, tremors and twitching, cry, recoil).* Performing a complete and thorough physical examination of the newly born is paramount.

Clinical, anatomic, and encephalographic studies of full-term and premature neonates have confirmed that the CNS of the human fetus matures in a consistent pattern.[66] However, there are recognized limitations and challenges in performing an accurate neurologic evaluation. First, because a newborn is recovering from the stress of birth, the neurologic examination is not reliable until after the infant has successfully completed the transition to extrauterine life. **Therefore, the neurologic examination should be performed after the first 12 to 24 hours of life.** Second, if the infant was born by cesarean section, or is ill and requiring NICU care, the neurologic examination may not be accurate, even after 24 hours. Third, newborns are born at different stages of brain development. Fourth, there are few tests that reflect the status of the cerebrum in the newborn.

Nevertheless, in spite of these limitations, it is still possible, with a systematic and detailed neurologic examination, to obtain enough information to gain a basic understanding of many neurologic problems in the newborn (see Chapter 26).

Assessment of Gestational Age

It is important to remember that **neurologic maturity and appropriate developmental milestones correlate with GA rather than BW.** As previously discussed, for an accurate estimation of GA, most clinicians favor systems that combine neurologic and physical signs of maturation. **Each portion of the neurologic examination is objective and easy to perform, relying on muscle tone, posture, reflex movements, and degree of extremity flexion.** The most commonly used neurologic signs for GA are posture, square window (wrist), arm/leg recoil, popliteal angle, scarf sign, heel-to-ear maneuver, head lag, ankle dorsiflexion, and ventral suspension.

Assessment of Neurologic Normality and Abnormality

The neurologic examination is most helpful if carried out systematically on an infant during quiet wakefulness between feedings, generally 1 hour before the next meal. **The examiner should be especially observant of the general alertness, spontaneous activity, symmetry of posture and spontaneous movements, muscle tone and strength, head control, developmental reflexes, and responses to manipulation and handling.**

- *State of alertness:* **Alteration in level of consciousness is an extremely important sign in determination of the neurologic status of the newborn.** A normal term infant shows a semiflexed posture and smooth spontaneous movements of all extremities. The hyperalert neonate has the appearance of increased vigilance with eyes wide open, often decreased blinking, overreaction to minimal stimulation, and reduced sleeping. Decreased state of alertness could be lethargy, stupor, and coma.
- *Posture:* **Observation of posture is one of the first steps in the neurologic examination.** Much can be predicted from the position of the limbs at rest. **Term infants should have a preponderance of flexor tone** during wakefulness and sleep with the normal semiflexed posture of the elbows and ankles. The **hand position typically shows a partially closed fist. A tight cortical thumb can be normal, but when it is persistent and obligatory, it suggests a corticospinal abnormality.** In prone position, the pelvis is elevated by hip and knee flexion. Alterations of expected patterns of posture suggest neurologic abnormalities, which can be focal or generalized.
- *Tone:* **Muscle tone is evaluated by resistance to passive movement. Pronounced hypotonia characterizes the premature infant below 29 weeks of gestation,** and tone increases in a caudal-rostral direction over the ensuing weeks. There is an orderly progression from a limp "rag doll" at 28 weeks to the flexed "frog legs" posture at 34 weeks and the fully flexed supine posture at term. **When evaluating tone in the newborn, the head should be in the midline position to avoid eliciting a tonic neck response, and a comparison should be made between the two sides of the body and between the upper and lower extremities.**
- *Neonatal hypotonia:* **Term infants with decreased tone will show less flexor posture, less resistance to passive movements, and more head lag.** The infant becomes limp and floppy, with little control. **The most frequent etiology for hypotonia is generalized depression of the CNS.** Other causes include neuromuscular disorders, CNS dysfunction, sepsis, and congenital and genetic disorders.
- *Neonatal hypertonia:* Although decreased tone in the newborn is obvious, at times the determination of increased tone can be more of a problem. **Infants with increased tone will show extensor posturing of extremities in supine and prone positions. Extensor posturing of the legs with arms held tightly fisted against the midline points to hypertonicity.** The most severe degrees of hypertonia lead to *opisthotonos.* Pronounced hypertonia is usually caused by many of the same conditions that can lead to hypotonia, but usually tends to point to more chronic or subacute conditions. Common etiologies include hypoxic-ischemic encephalopathy (HIE), sepsis and meningitis, congenital structural malformations of the brain, and intraventricular hemorrhage.
- *Developmental reflexes:* The developmental reflexes used to evaluate the newborn are best described as "primitive," because they do not require

functional brain above the diencephalon and probably not above the mesencephalon. Many such reflexes have been described; however, it is unlikely that all can be elicited in an infant at any given time. It is **better to use six to eight usually present in all newborns and to evaluate them consistently:** *Moro's reflex, tonic neck reflex, stepping reflex, Galant reflex (truncal incurvation), palm and plantar grasp reflex,* and *Babinski's reflex*.

Reflexes are complex responses to specific stimulation, probably representing integration of the brainstem and spinal cord level. **Asymmetries are always abnormal;** these reflexes should never be mandatory or persistent, and a reduction or absence of all developmental reflexes may represent generalized depression of all cerebral activity from any cause such as infection, medications, hypoxemia, or metabolic diseases.

Because the responses vary with the state of alertness of the infant, and the newborn's tolerance for prolonged examination is limited, eliciting a perfect response to each maneuver should not be expected. When the examination is not fully reassuring, repeating selected parts of the examination at a later time may be more helpful in clarifying findings than attempting an extended examination at one time.

Assessment of Neurobehavioral Development

In addition to neurologic examination, **the assessment of neurobehavioral development is an important step in the evaluation of the newborn infant.** All newborns requiring intensive care, particularly preterm infants, are going to continue their development in extrauterine settings at a time when their brains are growing more rapidly than ever in their life span. Understanding the potential role of illnesses, therapeutic interventions, and NICU environment on their neurobehavioral development is paramount for the provision of quality newborn care during this highly vulnerable phase of brain development.

Caregivers need to become knowledgeable of the tools available for the assessment of the neurobehavioral development and the potential interventions. There are numerous tools for the assessment of neurobehavioral development.[9,31] Chapter 13 offers a detailed and comprehensive review of this subject.

THE BRAZELTON SCALE

The Neonatal Behavioral Assessment Scale (NBAS) is a comprehensive behavioral assessment of the newborn.[31] The NBAS psychological scale enables assessment of the infant's individual capabilities for social relationships. Clinical application of the Brazelton scale includes neonatal research and clinical evaluation of newborn infants after illness, prematurity, or maternal medications.

The NBAS focuses on an interactive approach and highly individualized parameters of newborn functioning. Later editions of the NBAS have added supplemental items, which further qualify the behavior of the newborn, particularly of preterm infants.

A modified version of the Brazelton examination is useful in teaching parents about their individual infant's patterns of behavior, temperament, and states. By understanding the uniqueness of their infant, parents may more intelligently assess and interpret their baby's cues for interaction and distance. If the parents know their infant's individual strengths and weaknesses, they will react more realistically to him or her. It is important for the provider to elicit the parents' assessment of their infant's behavior and responsiveness. Unrealistic expectations or incorrect parental perceptions may exist. This is an excellent opportunity for parent teaching, and possibly referral. The NBAS is distinguished from other programs in its use as an intervention with parents and medical staff. Employed in this manner, it is **intended to improve and enhance the caregiver's attitude to and interaction with the infant.**

The Brazelton examination is usually performed at 2 to 3 days of life, at discharge, or on the follow-up visit at 1 to 2 weeks. This examination assesses the infant's best performance in response to stimulation and handling by the examiner. For research purposes, scoring by a certified examiner is sufficient. For clinical use, knowledge of the specific techniques and interpretations of results is all that is required. Knowledge of the infant's state is necessary (see Chapter 13, Table 13.3). **Performing the examination with the parents present provides the opportunity for teaching, parental participation, and observation of their infant's response.**

Maternal use of antidepressants, opioids and smoking have been shown to alter the newborn's neurobehavioral examination (see

Chapter 11). Neonates exposed to selective serotonin reuptake inhibitors late in pregnancy exhibit the following mild and spontaneously resolving behaviors: tremors/tremulousness, restlessness/irritability, abnormal crying, rigidity, fewer state changes, and more active sleep with startles and arousal.[75]

CARE OF THE WELL NEWBORN INFANT

Mother-Infant Bonding and Interventions

FREQUENCY OF ASSESSMENTS

During the transitional period, vital signs should be recorded frequently enough to monitor the infant's condition and provide appropriate care:

- If the **infant is distressed** (elevated heart rate or respiratory rate, retracting and/or nasal flaring), **vital signs may be required every 30 minutes.**
- If the baby's **vital signs are normal on admission** (heart rate 120 to 160 beats/min, respiratory rate 30 to 60 breaths/min, and temperature 36° to 36.5°C), **vital signs may be required every 30 to 45 minutes until the infant's condition has remained stable for 2 to 4 hours.**
- **Vital signs should be recorded at least once every 8 hours.**
- Measuring the temperature rectally is *contraindicated* in newborns because of the risk for rectal perforation (see Chapter 6).

Weight, length, and head circumference should be graphed on the appropriate intrauterine growth chart to determine at which percentile the baby falls. **Determination of the weight/length ratio (see Fig. 5.3) normally increases with fetal age because the fetus becomes heavier for length as term approaches.** In IUGR, the weight/length ratio decreases because the rate of growth in weight is affected more than length. Severe and prolonged intrauterine malnutrition may affect head, weight, and length ratios.

PREVENTIVE PRACTICES

Assessment of the infant's GA provides a reference point for individualizing care. Whether the infant is term and admitted to the normal newborn nursery or preterm and admitted to the intensive care nursery, attention to care practices that support development and neurologic integrity is essential in preventing iatrogenic disruptions or injury.

In utero, the fetus depends on the mother's physiologic systems to automatically regulate its own. At birth, the neonate's basic physiologic needs are met in new and different ways. Emerging from physiologic dependence into a physiologically independent neonatal state introduces new variables for both mother and baby in the development of their extrauterine relationship. **For both term and preterm newborns, the primary developmental task is to reestablish biorhythmic balance by (1) establishing homeostasis through self-regulation of states (e.g., arousal and sleep/wake cycles); (2) processing, storing, and organizing internal and external stimuli; and (3) establishing a reciprocal relationship with primary care providers and the environment.**

Although biorhythmic balance is internally determined, caregiving interaction between newborn and parent or caregiver either facilitates or disturbs this transition. **After birth, balance is facilitated by contact with familiar surroundings (the mother's body).**[74,148,181] The mother's sensorimotor (auditory, tactile, visual), thermal, and nutrient stimuli provide regulatory effects on the infant's behavior (activity level, sucking, sleep and wake cycles, stress management, and circadian rhythms) and physiology (endocrine secretion, oxygen consumption, and cardiovascular status).[74,148] **Full-term newborns placed on the mother's chest immediately after delivery (within 5 minutes) and longer (more than 60 minutes) display the following stereotypic innate sequence of prefeeding behavior**[181,201]**:**

- Significantly lower salivary cortisol levels and more stable cardiopulmonary function
- No sucking activity in the first 15 minutes
- Rooting and sucking activity begins and reaches maximum intensity at 45 minutes
- First hand-to-mouth movement at 35 minutes
- Spontaneous and unassisted finding of nipple and initiation of breastfeeding at about 55 minutes of age

Within the first 90 minutes after birth, neonates cared for in close body contact with the mother are quiet. However, infants separated from their mothers during this period and cared for in a crib cry and exhibit a *separation distress call* (also seen in several other mammalian species) that ceases at reunion.[52]

AVOIDANCE OF CERTAIN CARE PRACTICES

Certain care practices (e.g., separation of the mother and infant, gastric suction, noise levels in the newborn nursery) have become "routine" in some maternal/child care settings. **These practices are based on few scientific foundations, disrupt maternal and infant regulation and establishment of innate behaviors, may have hidden consequences that surpass human adaptability, and may contribute to behavioral changes that result from violations of an innate agenda.**[81] For example, gastric suction after birth evokes aversive reflexes (e.g., retching, combative movements, alterations in arterial blood pressure and heart rate, including bradycardia), disrupts development of early feeding behaviors, is unpleasant, and has no advantages in a healthy term infant following a normal pregnancy and normal vaginal delivery.[11,81] Use of maternal analgesia may interfere with the newborn's spontaneous breast-seeking and breastfeeding behavior.

During transition of a term neonate, prone position has been shown to improve oxygenation, decrease heart and respiratory rates, and encourage more favorable behavioral states.[159] In the newborn nursery, the lack of diurnal rhythm in noise levels and care-providing activities disrupts reestablishment of biorhythmic balance. **Significant differences in nighttime sleep and wake patterns exist between newborns cared for in the nursery (exposed to more light, noise, crying, and noncontingent care) and newborns rooming with the mother (more quiet sleep and less crying).**[102] Term infants exposed to soothing music in the newborn nursery spent less time in high arousal states (i.e., nonalert waking and crying) and had fewer behavioral state changes.[101]

MINIMIZING PROCEDURAL PAIN IN NEWBORN CARE

Placing full-term and preterm infants skin-to-skin in whole-body contact with their mothers or breastfeeding during heelstick procedures reduces heart rate, crying (by 91%), and grimacing (by 84%)[1,43,83,100] (see Chapter 12). When possible, breastfeeding throughout the procedure, rather than offering pumped breast milk, offers more comfort because of the synergism between skin-to-skin contact with the mother, sucking, and reception of breast milk by the infant.[3] Either breastfeeding/breastmilk or glucose/sucrose should be used to alleviate a newborn's procedural pain rather than positioning alone or no intervention.[162,165] The proximity and caregiving of the mother provide term and preterm infants with a barrier against outside stimulation and an ability to increase their threshold to noxious stimuli.[74]

One barrier to using skin-to-skin care and breastfeeding to relieve neonatal pain during invasive procedures such as heelstick and injections is the uncomfortable position of the professional performing the procedure. An ergonomically sound protocol using an adjustable-height stool has been developed and tested in the clinical setting. This approach has resulted in a more comfortable position for the professional and greater use of skin-to-skin care and breastfeeding for neonatal pain relief during procedures.[57]

NURSERY CARE PRACTICES AND ADAPTATION TO EXTRAUTERINE LIFE

Adaptation of full-term neonates is influenced either positively or negatively by nursery care practices (early care and handling). **The influence of these practices in the adaptation of preterm or sick neonates may be even greater.** Stress-reduction techniques to prevent fluctuations in BP, vital signs, and oxygenation often are not initiated until after the preterm infant has been admitted and stabilized in the NICU. **Individualized developmental care (e.g., dimmed lights, decreased noise, gentle handling, contingent stimuli) (see Chapter 13) may be delayed in the presence of urgent expeditious assessment, diagnosis, and life-supporting interventions in the delivery room and on admission to the nursery.** Consequently, the physiologic, anatomic, and psychological transition to extrauterine life makes at-risk neonates extremely vulnerable to the stress of resuscitation and initial nursery care.

MINIMIZING STRESS DURING RESPIRATORY AND CIRCULATORY SUPPORT

Minimizing stress and conserving energy should accompany establishing and maintaining an airway, adequate oxygenation and ventilation, and circulatory support. An immature preterm infant (less than 32 weeks of gestation) (see Chapter 13) who is physiologically unstable may deteriorate if not handled gently and protected from overstimulation. **Rapid fluctuations in oxygenation and blood pressure, overwhelming stimuli, too-rapid volume expansion, suction, unrelieved pain, and hypothermia contribute to the incidence of intraventricular hemorrhage that occurs most commonly**

in the first 24 hours after birth (see Chapters 4, 6, 12, 23, and 26). In preterm infants, "routine" procedures such as bathing[19,190] result in increased heart rate and BP, motor stress behaviors, changes in stability and reorganizational behavior, hypoxia, and increased intracranial pressure (see Chapter 13). Overwhelmed by external stimuli, a neonate's global response to stress may be apnea and bradycardia.

Based on the infant's ability to tolerate an intervention and the benefits of early assessment and intervention, the admission process should be prioritized to (1) provide life-supportive care, (2) conserve energy, and (3) collect data and complete the health care record. Table 5.8 outlines developmental interventions for neonatal admissions and care after birth that decrease stress, reduce energy consumption, improve oxygenation and respiratory and heart rates, and prevent iatrogenic stress and injury. **Developmentally supportive care should begin immediately after birth.**

SURVEILLANCE FOR POTENTIAL COMPLICATIONS

Complications of common morbidities (see Fig. 5.12) are prevented by classification, assessment, and screening of all newborns at birth. These morbidities and their complications are thoroughly discussed in the appropriate chapters. Close monitoring and surveillance of these groups of infants, and long-term follow-up studies, would allow us

TABLE 5.8 DEVELOPMENTAL INTERVENTIONS DURING ADMISSION AND INITIAL NURSERY CARE

Oxygenation	Apply noninvasive monitor (see Chapter 7) Titrate Fio2 to maintain saturation at 92%–94% (see Chapters 7 and 8) Handle gently, minimally (see Chapters 13 and 23) Skin-to-skin care improves gaseous exchange, especially in preterm infants <1000 g (see Chapter 13) Position prone to maximize oxygenation (see Chapter 13 and below) Delay or defer bathing[35,55,118] (see Chapters 6 and 19)
Thermoregulation	Maintain temperature axillary (36.5°C–37.5°C in term infants); skin (36°C–36.5°C in preterm infants) (see Chapter 6) Skin-to-skin contact (kangaroo care) provided by mothers or fathers to preterm/term newborns warms better than incubator care[26] Prewarm linen, scales, radiant warmer; incubator (see Chapter 6) Decrease heat loss with position (i.e., prone, flexion) (see Chapters 6 and 13) Use warm water on skin before applying probe, electrodes (see Chapter 19) Thermoregulation is the primary consideration in the timing and location of the first bath:† • Healthy term infants with axillary temperature >36.8°C can be bathed after 1 hour of age when appropriate care is taken to support thermal stability.[20,190] However, two newer studies show that: (a) bathing at 1 hour of age increases the incidence of hypothermia even when skin-to-skin care is used after the bath,[25] and (b) routine newborn care, including bathing delays thermoregulation[169] • First bath delayed till 2–4 hours of age, after vital signs and temperature are stable.[14] • First bath delayed till the next day for full-term baby[203] • Delay first bath and use swaddled, immersion bathing by parents instead of sponge bath[35,42] (see Chapters 6, 13, and 19) • Sponge bathing of healthy neonates (≥37 weeks of gestation) by an RN in mother's room at 3, 6, or 9 hours of age resulted in an initial reduction of skin and axillary temperatures that recovered after the bath.[103] Offer parents the opportunity to bathe[20,35,125] (see Chapters 6 and 13)
Nutrition	Screen at-risk and symptomatic infants for hypoglycemia (see Chapter 15) Provide fluids and/or calories (orally or intravenously) (see Chapters 14 to 17) Decrease energy expenditures by decreasing internal stressors (e.g., hypothermia, hypoxia) and external stressors (e.g., noise, light) (see Chapters 13 and 15)
Pain	Minimize painful stimuli (see Chapters 12 and 13) Use venipuncture rather than heelstick (see Chapter 12) Relieve pain with nonpharmacologic interventions: • Provide comfort measures (e.g., pacifier, containment, grasping) (see Chapters 12 and 13) • Use sucrose, skin-to-skin care, and/or breastfeeding during painful procedures.‡ Relieve pain with pharmacologic interventions (see Chapter 12)

Continued

TABLE 5.8 DEVELOPMENTAL INTERVENTIONS DURING ADMISSION AND INITIAL NURSERY CARE—CONT'D

Environmental stimuli	*Tactile* (see Chapter 13): Handle gently and minimally Support and contain in flexion Provide rest periods between procedures, handling Early (within 5 minutes of birth) and longer (>60 minutes) skin-to-skin care stabilizes cardiopulmonary systems and reduces newborn stress after birth[181] *Visual* (see Chapter 13): Shield from bright, direct light Dim lights as soon as possible Cover oxygen hood, face with washcloth Cover incubator with blanket or cover *Auditory* (see Chapter 13): Talk quietly Respond quickly to alarms Parents talk softly to infant Keep ill neonates away from crying babies[102]
Position	Promote flexion in side-lying position with blankets, rolls (see Chapter 13) Prone (oxygenation better; less apnea; quiet, more restful sleep; decreased caloric expenditure; decreased reflux) (see Chapter 13) Swaddle (see Chapter 13) Avoid supine if newborn is hypoxic and has an oxygen requirement; otherwise, always position all well term newborns supine (see Chapter 13)
Assess and interpret newborn cries	Assess avoidance and approach behaviors so that care is individualized (see Chapter 13) Support infant strengths and adaptive and coping behaviors (see Chapter 13) Modulate environmental and caregiver stimuli based on infant cues (contingent on cues rather than noncontingent stimuli and interaction) (see Chapter 13) Teach parents infant cues (see Chapter 13)

to establish patterns of potential outcomes for each specific subgroup. For example: Preterm SGA/IUGR infants are at increased risk for mortality, more gross motor and neurologic dysfunction, more cognitive disorders needing special education, but less cerebral palsy compared with AGA infants.

PARENT TEACHING

Transitional care, neonatal assessment, and initial care do not necessarily take place in a nursery in which the newborn and family are isolated from each other. Alternative settings for initial care include birthing rooms, recovery rooms in which family and baby are kept together, the mother's postpartum room, or at a home visit. **In fact, keeping the family together not only facilitates bonding but also provides an excellent opportunity for teaching parents about the individuality of their newborn.**[125]

The assessments of GA and physical condition are best performed with the mother and father in attendance so that deviations from normal such as caput, cleft lip, cleft palate, or clubfoot can be explained. Eliciting parental cooperation is important. For example, when the major concern is "Will the procedure hurt?" a response such as "It is routine" will not comfort and reassure well-informed, noninterventionist consumers. Rather, a more physiologically oriented explanation about the condition being screened, why their particular infant is at increased risk, and what interventions are available encourages parental cooperation.

Professional care providers are only temporary caregivers. It is our responsibility to help parents become confident, primary caregivers of their own infants. **Actively involving parents in the care and treatment of their newborn further solidifies their position as primary caregivers.**[125] Encouraging active parental involvement enhances the parents' self-esteem and confidence in their abilities; thus our actions must tell and reassure the parents, "You are able to care for this baby." An RCT comparing the ability of parents to perform the baby's first bath in the mother's room versus a nurse bathing the baby in the admission nursery found no difference in temperature changes irrespective of who bathed the baby or where the bath was given.[125] The newborn heat loss experienced with bathing was significant and returned to normal in 1 hour. **Parents in the study wanted the opportunity to bathe their infants and gained confidence in their parenting skill/ability.** With the supervision of the nurse, ensuring an environment to reduce heat loss (e.g., warm, draft-free room, temperature assessment, warm water, use of kangaroo care after the bath) and using the bath as a teaching opportunity, parents can bathe their own infants.

At discharge, performing the physical examination in the room with the parents offers a final opportunity to teach, counsel, and advise them before they take their new baby home. Information about feeding, cord care, bathing, elimination patterns, safety, signs of illness, medications, and the importance of follow-up care is essential for parents of a full-term, healthy newborn (Box 5.5). It is also essential for parents taking home an

BOX 5.5 PARENT/CAREGIVER TEACHING[69,168]

- Every encounter with the parents is a teaching opportunity, so that by the time of discharge, parents are totally competent to care for their infant. Assess each individual family's ability to care for their infant and readiness for discharge.
- Teach parents how to care for the newborn's skin, umbilicus, and circumcision site and the appropriate urination/stooling patterns for newborns.
- Teach parents about the nutritional needs of their newborn, how to breast/bottle feed, and how to burp their baby. Develop a feeding plan with the parents for the late-preterm infant, and teach parents how and why to adhere to the plan for a late-preterm infant.
- Teach parents how to take an axillary temperature on their newborn and maintain the axillary temperature between 36.5° and 37.4°C (97.7° and 99.3°F) with clothes, blankets, and an appropriate environmental temperature.
- The presence and clinical significance of jaundice are determined before discharge (see Chapter 21), appropriate follow-up care has been determined, and the importance is stressed to parents. Parents are taught how to assess jaundice at home.
- Teach parents the importance of follow-up care, either at a clinic, physician's office, or home visit: (a) within 24 to 48 hours after discharge for late-preterm infants,[69] (b) within 48 hours (if discharged at ≤48 hours of age),[23] or (c) within 3 to 5 days after discharge.[87]
- Give parents the newborn immunization record with documentation of what immunizations their infant has received and the importance of follow-up for childhood immunizations.
- Teach parents appropriate safety precautions:
- Verbal and written information about recognizing signs and symptoms of a "sick"/"ill" infant, how the infant acts, and whom to notify.
- Proper use of car seats including positioning with supports, facing the rear in the backseat, middle of rear seat, preferably with an adult seated next to the preterm to enable ongoing observation of the infant during travel.
- Proper positioning supine for safe sleep: "Back to Sleep." Model "Back to Sleep" by placing babies who are in cribs only on their backs to sleep. *All* care providers (e.g., parents, grandparents, day care providers, babysitters) should sleep babies supine (see Chapter 13).
- Use of skin-to-skin care for full term infant is soothing, calming, and recommended.[54] A 50-minute session of skin-to-skin care at 5 to 7 weeks of age has been shown to decrease an infant's salivary cortisol level prior to a bath.[21] Skin-to-skin contact must be done safely—position infant prone on adult chest with head turned to one side, face visible with nose and mouth uncovered; neck is straight, not bent, and head is in the "sniffing" position; legs are flexed, and the baby is covered with a blanket. Adults do not sleep while the baby is in skin-to-skin contact.[73]
- Importance of a smoke-free environment because secondhand smoke is associated with an increased risk for developing health problems.
- *NEVER* shake the baby! Babies are shaken by frustrated caregivers when the infant continues to cry. Dangers of shaking infants include blindness, brain damage, developmental delays, seizures, paralysis, and death. (See Resource Materials for Parents at the end of this chapter.) Education of parents about normal sleep and crying patterns, techniques for soothing infants, possible medical causes for crying, and parent self-care advice lowers parental depression and enhances parent confidence in caregiving.
- Information, in writing, about all medications for their infant including name, action, dose, route, side effects, and schedule (see Chapter 10).
- Proper swaddling technique: Safe swaddling includes positioning the baby's extremities in slight flexion and abduction; baby should be able to freely move lower extremities. Placing an infant's hips and knees in an extended position with swaddling increases the risk of hip dysplasia and dislocation.[97]
- Teach parents the importance of their own self-care: need for adequate sleep/rest, nutrition/hydration, privacy, stress management, recreation, and sex.

infant after prolonged hospitalization. In addition, a modified version of the Brazelton examination on all neonates enables parents to become familiar with a newborn's competencies for reacting to and shaping his or her environment and with strategies for parental intervention. Developing written materials for parents about normal newborn care and documenting teaching sessions and return demonstrations ensure that no important information is forgotten (see Chapter 31 for discharge planning and teaching strategies).

6 HEAT BALANCE

SANDRA L. GARDNER AND BETSY H. CAMMACK

Adaptation to extrauterine life involves the newborn infant in a series of biologic adjustments to a totally new set of environmental conditions. Prime among these is the accommodation to a **new thermal environment that represents a distinct "cold challenge."** Failure to adjust to this cold stress has historically been recognized, particularly in premature and low-birth-weight (LBW) infants, with the development of variable degrees of hypothermia and increased morbidity and mortality rates. At birth, the body temperature of the newborn infant will approximate or slightly exceed that of the mother. Within minutes of birth, however, core temperature begins to fall precipitously, particularly in infants with birth weights less than 1500 g. **These infants have a diminished capacity for metabolic heat production, a high surface area to volume ratio, and immature epidermal barrier leading to extraordinarily high evaporative heat losses.** Consequently, they are highly vulnerable to the development of hypothermia. **Thermal management has become a cornerstone in neonatal intensive care.** Earlier studies conducted in term and preterm infants worldwide concluded that **maintenance of body temperature through control of the thermal environment is paramount for the reduction of morbidity and mortality risks in LBW infants.**[102,105,114]

Over the past several decades, researchers and clinicians have gained insight into the physiology of thermoregulation and developed the technology to maintain thermal neutrality in the tiniest and sickest neonates.[65,89,93,132,135] Although the staff of modern neonatal intensive care units (NICUs) have the expertise and equipment to avoid or minimize the consequences of inadequate thermoregulation, determining the **most appropriate ways of getting the best temperature balance (normothermia)** is the subject of ongoing investigation. This chapter discusses the current knowledge of the physiology and pathophysiology of neonatal thermoregulation and techniques used not only to prevent heat loss but also to manage heat balance.

HISTORICAL MILESTONES[23,90,97]

The *first incubator for neonates* was introduced in the early 1830s. Dr. Stephane Tarnier, Chairman of Obstetrics of the University of Paris, first applied the principle of graded incubation (commonly used in chick embryos) in developing a covered incubator chamber that has been widely recognized as the first attempt to systematically provide a warmed environment for premature infants. In 1835 in St. Petersburg, Russia, Von Ruehl introduced an incubator described as a double-walled box that circulated warmed water within the interspace.[110] Tarnier's students, Budin and Auvard, modified Tarnier's incubator by adding a thermometer and regulatory alarms to alert the infant's nurse attendant to either increase or decrease the incubator's prescribed temperature. The care of newborns was delegated to Madame Henry, Midwife-in-Chief, who oversaw the building of a pavilion specifically for the care of these weakling newborns.[128] This pavilion housed 12 incubators, in which fragile newborns were warmed over a hot-water reservoir attached to an external source of heat. These were impressive first steps in attempting to control the fragile heat balance of weak preterm infants. Over the next 60 years, in Tarnier's and Budin's clinic, refinements of incubation techniques resulted in an increased survival from 38% to 66% in infants weighing between 1200 and 2000 g. Dr. Tarnier's successor, Dr. Budin, continued this important early practice of neonatology, focusing on the home care of these

BLUE type highlights content that is particularly applicable to clinical settings.

high-risk babies. Alexandre Lion improved the design of incubators and charged spectators a fee to see them in action, which led to a very popular show at the Berlin Exposition of 1896. An associate of Lion, Martin Couney, brought the incubator shows to the United States, where Dr. Joseph DeLee adopted the technology and opened an "incubator station" in 1900 at the Chicago Lying-in Hospital. Nearly all of the large expositions in America hosted "Incubator Baby Side Shows." These began in 1898 with the Trans-Mississippi Exposition and continued on to the New York World's Fair in 1939.

Dr. Couney's display of incubators at Luna Park on Coney Island and at a second park named *Dreamland* hosted premature babies from New York hospitals that lacked the facilities to care for them. These infants were lined up under heaters in incubators, and they breathed filtered air. At least 8000 babies passed through these incubators, and at least 6000 were saved. Servocontrolled radiant heat in incubators was initially reported by Agate and Silverman in 1963.[110]

Today's *radiant warmer* is an evolution from the original idea of Agate and Silverman. Radiant energy as the sole source of heat from an overhead panel was described in 1969 by Due and Oliver. Widespread use of the warmer in the delivery room was readily accepted and soon led to its use in the NICU. The factors that affect heat loss and heat production were elucidated. As intensive care became more readily available, easy accessibility to the infants became increasingly necessary and the open warmer became more readily used.[66]

Changes in the radiant warmer have included the introduction of incubators that are interchangeable with and convert to radiant warmers. The use of humidification in the incubators has also been improved to allow for varying humidification based on the infant's gestational age and weight. These new beds allow the caregiver to rotate the mattress 360 degrees for easy patient access and provide an in-bed scale. In recent years, new approaches to thermal care of the newborn preterm baby have been extensively studied,* including occlusive wrapping, placing on heated mattresses, and skin-to-skin (kangaroo) care. The role and clinical significance of these approaches will be discussed later.

PHYSIOLOGIC CONSIDERATIONS

Animals that maintain their body temperature within a narrow range through a wide range of environmental temperatures are known as *homeotherms.* **Humans, as homeotherms, maintain a "normal" body temperature by balancing the amount of heat lost from the body with the amount of heat generated from within the body.** Our ability to cope with changing thermal environments improves physically and physiologically with age. Eventually we are physically able to move to a different place with a more suitable environment or dress more appropriately when the temperature is uncomfortable.

Babies, especially preterm or small-for-gestational-age (SGA) babies, of course cannot physically respond as older children would, and even their physiologic responses are different and limited. Adults lose some thermoregulatory control during rapid-eye-movement sleep. Although newborn infants spend much time in active sleep, their thermoregulatory control is not impaired during this period of active sleep,[71] which indicates the developmental importance of both thermoregulation and active sleep in the maturation of newborn infants.

Neutral Thermal Environment

Physiologic responses to a cold environment include metabolic reactions that consume substrate and oxygen and result in heat production. **A neutral thermal temperature is the body temperature at which an individual baby's oxygen consumption is minimized (Fig. 6.1). Thus a minimal amount of the baby's energy is expended for heat maintenance, and energy is conserved for other basic functions and for growth.** Minimal metabolic activity is possible within a narrow range of temperatures, so temperatures that are too high or too low add stress and increase metabolic rate. Extreme deviations from this range overwhelm the thermoregulatory mechanisms, leading to body temperature imbalances and potentially death.

The goal in controlling a neonate's environment is to minimize energy expended by him or her to maintain a "normal" temperature, thus eliminating thermal stress. This neutral thermal environment is the sum total of factors at which a baby with a normal body temperature has a minimal metabolic rate and therefore minimal oxygen consumption (Fig. 6.2). Both traditional indirect calorimetry and

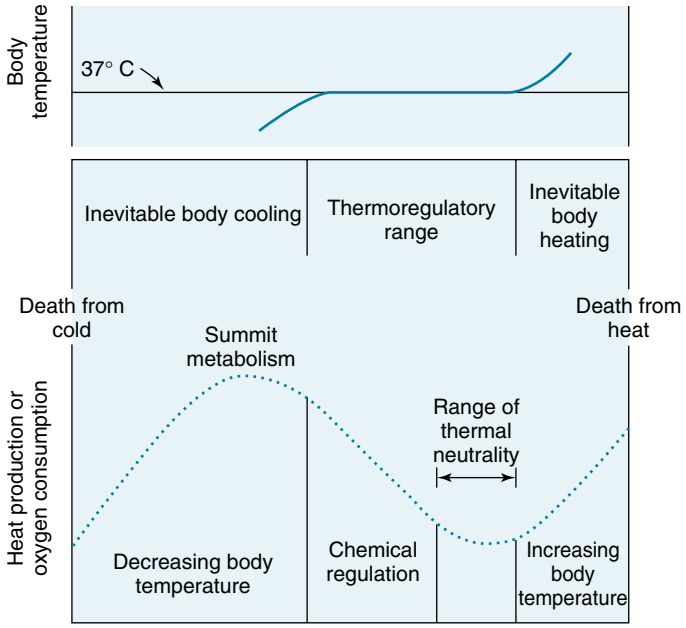

FIGURE 6.1 Temperature versus oxygen consumption. Effect of environmental oxygen consumption and body temperature. (From Klaus M, Fanaroff A. *Care of the High-Risk Neonate,* 2nd ed. Philadelphia, PA: Saunders; 1979.)

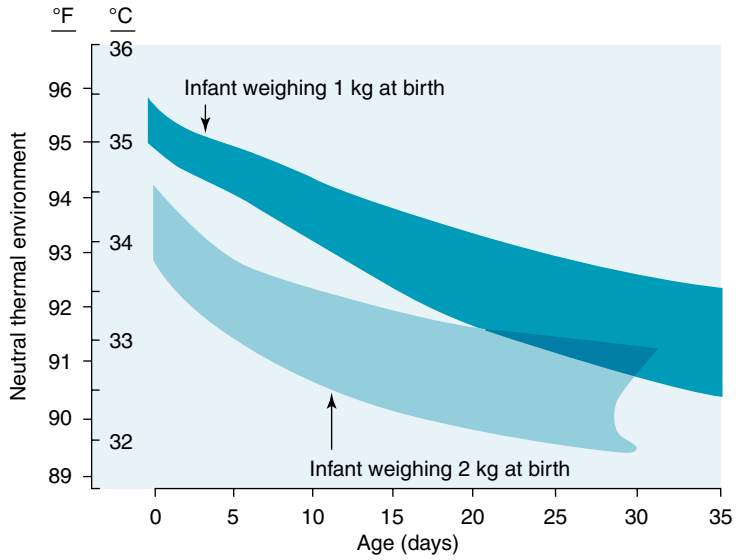

FIGURE 6.2 Neutral thermal environments. Range of temperature to provide neutral environmental conditions for infant lying naked on warm mattress in draft-free surroundings of moderate humidity (50% saturation) when the mean radiant temperature is the same as air temperature. Shaded areas show average neutral temperature range for healthy infant weighing 1 kg *(dark)* or 2 kg *(light)* at birth. Optimal temperature probably approximates to lower limit of neutral range as defined here. Approximately 1°C (1.8°F) should be added to these operative temperatures to derive appropriate neutral air temperature for single-walled incubator when room temperature is less than 27°C (80°F) and more if room temperature is much less. (From Hey EN, Katz G. The optimum thermal environment for naked babies. *Arch Dis Child.* 1970;45:328.)

the more accurate and sensitive direct calorimetry are used to study the production and expenditure of heat in newborns. Factors such as ambient air temperature, airflow velocity, relative humidity (RH), and temperature and composition of objects in direct contact with the infant or to which heat may be radiated compose the infant's thermal environment.

Maintaining Heat Balance (Heat Production vs. Losses)

When exposed to a cold environment, a neonate senses the reduced skin surface temperature (using sensors in the skin, primarily the face) and senses core body temperature (using sensors along the spinal cord and in the hypothalamus). Information from these various sensors is processed (probably in the posterior hypothalamus), including average temperature, rate of temperature change, and size of the stimulated area. **Cold stress results in the initiation of a series of reactions to increase heat production and decrease heat loss.** In adults, the most significant involuntary method of heat production is shivering. **Neonates rarely shiver and must rely on nonshivering, or chemical, thermogenesis to produce the needed heat.** This process is initiated in the hypothalamus and transmitted through the sympathetic nervous system, leading to the release of norepinephrine at the site of brown fat. ***Brown fat,* found mostly in the nape of the neck, axillae, and between the scapulae of newborns, is a specialized type of fat.** It is unique in that it contains thermogenin, which is the key enzyme regulating nonshivering thermogenesis. Norepinephrine causes the release of free fatty acids, which with thermogenesis undergo combustion in the mitochondria of brown fat cells, releasing heat. Lipoprotein lipase also provides further triglyceride substrate for heat production.

Oxygen and glucose also are consumed during nonshivering thermogenesis. Thus an infant who already has low oxygen or glucose levels may become hypoxemic or hypoglycemic if added thermal stress occurs. **Preterm babies do not possess sufficient brown fat stores to mount a significant heat production response to compensate for even minimal cold stress.[36] When servocontrol is used, the thermistor must not be placed over an area of brown fat (such as in the axilla), which may directly heat the overlying skin, causing a decrease in servocontrolled heat output.[3]**

Heat generated within the body is transferred by conduction through tissues along a gradient from warmer to cooler areas such as the skin surface. **An initial response to a cold environment is to constrict superficial blood vessels to minimize the transfer of heat from the core to the surface of the body.** Superficial vasoconstriction, which gives the skin a mottled appearance in response to cold stimulus, results in a lower skin temperature reading to the thermocontroller and consequently causes an increase in the incubator temperature. **The smaller the body size, the less effective vasoconstriction is in conserving heat.**

Compared with adults, **newborns have a very large surface area to body mass ratio and therefore have a relatively large area exposed to the environment from which heat can be lost.** More mature infants may try to minimize their surface area by changing positions to decrease exposed surface area when faced with cold stimulus, but immature infants cannot flex the trunk and extremities effectively. They also have little subcutaneous fat tissue (which acts as insulation) to help prevent heat conduction to the body's surface, where the heat would be lost.

Heat is transferred from the infant's body to the environment (i.e., everything in proximity to the baby) along a temperature gradient from warmest to coolest. **Heat losses occur by four principal mechanisms: *radiation, conduction, evaporation,* and *convection*.** Fig. 6.3 illustrates these four mechanisms and identifies interventions to minimize their effects.

Much less frequently, a newborn must call on physiologic responses to an environment that is too warm, and these responses are somewhat limited. **As skin temperature rises, superficial blood vessels dilate, increasing the transfer of core body temperature to the surface. Increasing the temperature gradient between the skin and the environment increases heat loss from the body.** When exposed to elevated environmental temperatures, preterm babies generally cannot generate sweat to eliminate heat by evaporation. Maturing babies develop this eccrine gland function first on the forehead, followed by the chest, upper arms, and more caudal areas.

Thermoregulation requires energy (caloric) expenditure:

- Basal metabolic rate: 50 kcal/kg/day
- Thermoregulation: 10 kcal/kg/day
- Thermic effects of feeding: 8 kcal/kg/day[6] (see Chapter 17)

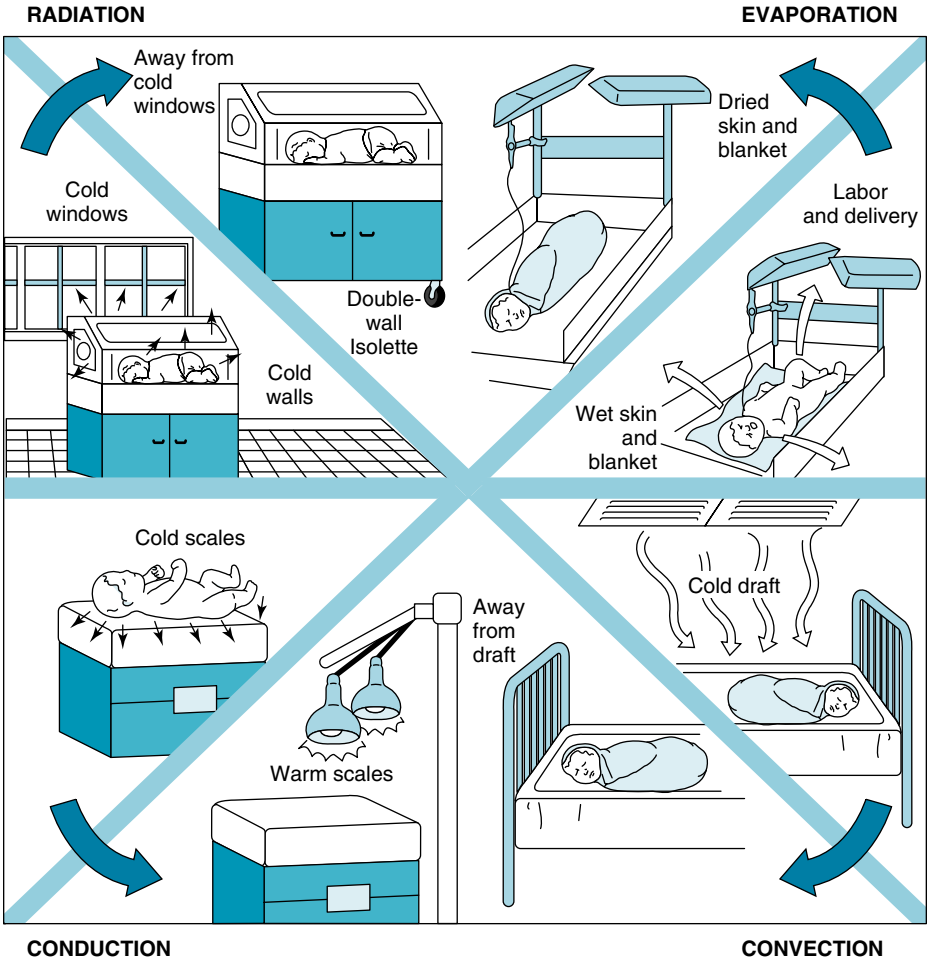

FIGURE 6.3 Radiation, or heat loss in the form of electromagnetic photons, occurs from warm skin surfaces to a cooler object not in contact with the newborn (e.g., inside the incubator wall, nursery wall, window). Radiant heat loss is independent of ambient air temperature and is the main source of heat loss because of the infant's large exposed body surface area. Conduction is the loss of heat to a cooler object in direct contact with the newborn (e.g., cold scale, unwarmed bed, stethoscope, examiner's hand). Convection is the loss of heat to moving air at the skin surface and depends on the air's velocity and temperature. Evaporation of water from the skin and mucous membranes also causes heat loss, especially in the delivery room. The thinner stratum corneum layer of skin of very-low-birth-weight infants makes evaporative heat and water loss and fluid management ongoing problems. (Courtesy Lynn Jones, RN.)

Methods of Measuring Temperature

A neonate's temperature can be determined by various methods.[123] Deep body (core) temperature may be measured in the rectum or esophagus and on the tympanic membrane. Rectal thermistors are thin, flexible probes that must be inserted at least 5 cm to obtain an accurate reading. Insertion of a rigid rectal thermometer to this depth increases the risk for perforation, because the sigmoid colon makes a right-angle turn approximately 3 cm from the anal opening. Esophageal and tympanic readings are difficult to obtain and usually impractical.

Continuous monitoring of abdominal skin temperature with the newborn lying supine is a noninvasive method that has good correlation with rectal temperatures in preterm[35] and very-low-birth-weight (VLBW) preterm infants.[131] *Only* abdominal skin

BOX 6.1 ALTERATIONS IN OXYGEN CONSUMPTION WITH CHANGES IN ABDOMINAL SKIN TEMPERATURE: RESEARCH BASIS[118,119]

- Abdominal skin temperature of 36.5°C (97.7°F) results in minimal oxygen consumption.
- Abdominal skin temperature of 35.9°C (96.6°F) results in an increase in oxygen consumption of 10%.
- Abdominal skin temperature of 37.2°C (98.9°F) results in an increase in oxygen consumption of 6%.

temperature has been shown to be an effective monitor of neutral thermal environment. Box 6.1 clearly illustrates that even a slight change (less than 1°C) in abdominal skin temperatures affects oxygen consumption and basal metabolic rates. Therefore the **range of thermal neutrality illustrated in** Fig. 6.1 **is a very narrow range—less than 1°C on either side of abdominal skin temperature of 36.5°C (97.7°F).**

Because of the risks involved, rectal temperatures should not be taken on a routine basis in neonates. Axillary temperatures require disturbing and handling, minimal exposure due to undressing (which may lower temperature), and result in crying and restlessness in some neonates.[38,74] Axillary temperatures are measured by using glass, electronic, or disposable thermometers. The tip of the thermometer should be held firmly in the midaxillary area for at least 3 minutes in preterm infants and 5 minutes in term infants. **When taken properly, axillary temperatures provide readings as accurate as rectal and core temperature methods.[45] Approximating rectal temperatures from axillary temperatures is clinically possible by adding 0.3°C (difference in axillary and rectal values in preterm neonates) to 0.4°C (difference in axillary and rectal values in term neonates) to the axillary value.[68] In term infants, axillary temperatures should be maintained at 36.5°C to 37.5°C (97.7°F to 99.5°F). For preterm infants, the normal axillary temperature ranges between 36.3°C and 36.9°C (97.3°F and 98.4°F).[110]**

A randomized study comparing temperature values from three skin probe positions with digital axillary temperature values was conducted in healthy preterm infants.[115] **There was no statistically significant difference in any of the three probe site temperature values or between the probe site values and the digital axillary temperatures.[115]** The results of this study are similar to a previous study conducted in healthy full-term infants.[126] Because of the small size of the sample and methodology followed, the results of these studies *cannot* be generalized to all preterm infants, especially those with extremely low birth weight (ELBW). **Both researchers recommend consistency in temperature measurement and evaluation of trends and patterns over time, along with evaluation of the entire clinical picture of each individual infant.[115,126]**

In search of a quicker, noninvasive, less disruptive mode of temperature taking, the accuracy of noninvasive infrared thermometers in the neonatal population has been evaluated in studies in premature[38,74] and in healthy late-preterm and term infants.[50] **These studies found the readings between the infrared midforehead and temporal artery and axillary readings to be very comparable.** A more recent study of temporal artery measurement found it no more accurate than axillary or rectal temperatures in 49 neonates.[125] For neonates in incubators the temporal artery measurement was less accurate than for neonates in cribs. As postmenstrual age (PMA) increased, the accuracy of temporal artery measurements of neonatal temperature also increased.[125] More research with various populations of neonates, in various environments (cribs, incubators, radiant warmers), and using larger numbers of study subjects is necessary.[123] During the first week of life, infrared thermal imaging has been studied to evaluate the full body temperature and perfusion differentials of extremely preterm infants in heated incubators.[67]

In critically ill infants, the skin temperature is usually routinely monitored in addition to axillary temperature readings. A skin probe is secured to the right upper quadrant of the abdomen. The temperature probe should not be placed under the axilla or any other position except as recommended by the manufacturer. **Because an infant responds to cold stress by vasoconstriction, a drop in skin temperature may be the first sign of hypothermia.** The core temperature may not fall until the infant can no longer compensate. The axillary temperature may remain normal (or even be elevated) because of proximity to brown fat stores.

ETIOLOGY OF HEAT IMBALANCES

The ambient temperature range in which a healthy full-term infant maintains a stable core temperature is narrower than the temperature range in which an adult maintains a normal temperature. When measures are taken to provide a neutral thermal

environment for the neonate, excessive heat losses or gains are avoided and heat balance is maintained. Recognition of infants at risk for heat imbalance is essential in the prevention of thermal stress.

Premature infants have a limited ability to control body temperature and are extremely susceptible to hypothermia. Factors that contribute to temperature instability include very thin skin, large surface area relative to body mass, limited substrate for heat production, decreased subcutaneous tissue, and an immature nervous system. These infants often have multiple health problems that necessitate frequent interventions by health care providers with consequent disruption of the infant's neutral thermal environment.

A premature infant's very thin skin and larger surface area to body mass ratio allow for increased evaporative heat loss. Term infants can reduce surface area by flexing their extremities onto their trunk, a skill that increases with gestational age. Unable to maintain flexion, a preterm infant lies primarily with extremities extended. **Care providers may reduce the surface area by positioning infants in flexion and supporting them with blankets and rolls.** The shortened gestation limits lipid supplies, brown fat, and the accumulation of subcutaneous tissue. The immature nervous system delays or mutes the infant's response to thermal stress.

The premature infant is likely to experience other complications (e.g., respiratory distress, sepsis, intraventricular hemorrhage, hypoglycemia) that may increase basal metabolic rate and oxygen consumption, thus interfering with the ability to maintain thermal stability. Numerous procedures and interventions (e.g., medication administration, placement of intravascular catheters, obtaining vital signs) may impede efforts to maintain a neutral thermal environment. **Care providers should routinely check the infant's temperature before initiating treatments. If the temperature is low, treatment should be delayed until a more normal temperature is obtained. If interventions are prolonged, temperature should be monitored frequently, an external heat source provided, and the intervention stopped if hypothermia occurs.**

***Late-preterm infants* are predisposed to morbidities because of their developmental immaturity (see Chapter 5).** Less adipose tissue for insulation, less brown fat for chemical thermogenesis, more heat loss, and a larger ratio of surface area to weight contribute to problems with heat balance in these infants. Morbidity associated with heat balance in the late-preterm infant is 10% compared with 0% for term infants.[41]

Low-Birth-Weight Newborns

LBW (<2500 g) infants can be divided into two groups: the VLBW infant (<1500 g) and the ELBW infant (<1000 g). Preterm infants in each of these groups have specific needs for thermoregulation. Heated incubators, radiant warmers, and skin-to-skin care are all methods for maintaining the temperature and promoting weight gain of the VLBW infant. With caregiving, VLBW infants in servocontrolled incubators decrease their abdominal skin temperature with incubator opening in proportion to the type and length of the procedure being done.[32] **Infants weighing between 1500 and 1600 g may be weaned to an open crib if all criteria are met.**[6,7,84] (see Fig. 6.5 for weaning criteria).

During the first 12 hours of life, ELBW preterms become hypothermic with procedures such as intubations, chest x-ray examinations, intravenous (IV) line placement and manipulation, suctioning, repositioning, and vital signs. Like the late-preterm and the LBW infant, ELBW infants have even less brown and subcutaneous fat for maintaining body temperature. Their thin skin also contributes to increased insensible water loss (IWL).

***SGA infants,* like preterm infants, have a large surface area relative to body mass and decreased subcutaneous tissue, brown fat, and glycogen stores, all of which contribute to heat imbalance.** Decreased placental blood flow frequently contributes to the small size. The relatively large surface area of an SGA infant increases evaporative and radiant heat loss, whereas limited brown fat stores and subcutaneous tissue contribute to a decreased ability to produce and conserve body heat. Some flexion of the extremities may be present because flexion depends on gestational age and not weight. SGA infants have a higher metabolic rate compared with infants at similar weights who are appropriate for gestational age (AGA). This is believed to be caused by the larger brain size relative to body weight. **Hypoxia in utero may depress the infant's central nervous system (CNS) and alter the ability to regulate temperature.** Increased energy requirements coupled with limited glycogen stores may result in hypoglycemia and limited ability to produce heat. SGA infants may require numerous interventions that disrupt the neutral thermal environment. **Care providers should ensure that the infant has a normal and stable temperature before initiation of treatments. If treatments are prolonged, temperature should be monitored frequently, an external**

heat source provided, and treatments stopped if hypothermia occurs.

Infants with neurologic damage or depression may experience difficulty maintaining a stable temperature. Hypoxia before, during, or after delivery, neurologic defects, and exposure to drugs such as analgesics and anesthetics may depress the infant's neurologic response to thermal stress. Hypoxia decreases the effect of norepinephrine on nonshivering thermogenesis, the main route of thermal regulation in the newborn infant. Hypoxia may also reduce the oxidative capacity of the mitochondria in brown fat and skeletal muscles, which are involved in thermogenesis. Infants who have experienced hypoxia in utero may have increased norepinephrine concentrations, which result in peripheral vasoconstriction. This may cause a delayed metabolic response to cold stress and delayed vasodilation in response to heat stress.

Neurologic defects that affect the hypothalamus also may interfere with heat balance. The hypothalamus coordinates temperature input from various sensors. Drugs such as analgesics and anesthetics cause CNS depression and reduce the infant's ability to respond to thermal stress. Neuromuscular blocking agents inhibit the infant's ability to maintain a flexed position, increasing exposed body surface and heat loss. **Care providers must be alert to the effect of drugs on the CNS and the infant's ability to regulate temperature.**

Infants with sepsis may have hypothermia or hyperthermia. In a newborn, an elevated temperature may begin as a response to cold stress, with peripheral vasoconstriction and thermogenesis. Heat production continues as the infant attempts to achieve a higher core body temperature. Exogenous and endogenous pyrogens may enhance thermogenesis.

Initially, an infant with sepsis may feel cool to the touch and may have a low body temperature. As fever progresses, temperature may rise and the infant feels warm to the touch. **Infants nursed in servocontrolled incubators may not have an elevated temperature. The lower heater output in response to increasing skin temperature (by manual or servocontrol adjustment) may mask a fever by keeping the baby's temperature within normal limits. The care provider should be alert to a sudden decreased need for incubator heat support in a previously stable infant.**

Hyperthermia may be iatrogenic, caused by inappropriate control of the neonate's environmental temperature. The most common cause is the inappropriate use of external heat sources. Dehydration may also contribute to hyperthermia. **Infants nursed with the use of external heat sources should have their temperatures monitored frequently. Phototherapy, sunlight, and the use of excessive clothing and blankets contribute to overheating.** Dehydration may be avoided by early recognition of infants at risk for increased fluid loss. Increased IWL occurs in preterm infants because of increased skin permeability and the use of phototherapy and radiant warmers. Vomiting, diarrhea, gastric suction, and ostomy drainage also increase fluid loss. These infants should receive additional fluids to replace the increased losses (see Chapter 14).

PREVENTION OF HEAT/COLD STRESS

Management of the thermal environment is paramount for newborn well-being. Heat balance is determined by the amount of heat lost to the baby's environment offset by the amount of heat generated by the body plus the amount of heat supplied from outside sources. Because a smaller, more immature, and sicker baby is less able to regulate body temperature, it is crucial that care providers understand the physical and physiologic principles of heat balance and be able to maintain a neutral thermal environment. **Two broad categories of interventions foster thermal neutrality[1]: blocking avenues of heat loss, and providing external heat and environmental support to maintain temperature within the normal range of 36.5°C to 37.5°C (97.7°F to 99.5°F).** The theoretical neutral thermal environment necessary for neonates of 1 and 2 kg at a given age is graphed in Fig. 6.2. **Newborns of less than 800 g are not adequately addressed in currently available tables but should have a starting environmental temperature setting of 36.5°C (97.7°F).**

Delivery/Birthing Room

Attention to the details of these interventions begins in the delivery/birthing room, in which the first step is to adjust the ambient delivery room temperature higher than ordinary operating rooms or patient rooms. **The air temperature in newborn care areas should be kept at 23.8°C to 26.1°C (75°F to 79°F), and humidity should be kept at 30% to 60%.[110]** Warming the room and placing the resuscitation table away from doors or drafts minimizes convective heat

loss. **Raising the delivery room temperature to 24°C to 26°C, as recommended by the World Health Organization (WHO), decreases cold stress in preterm infants less than or equal to 32 weeks of gestation.**[60] One study that increased the ambient temperature of the operating room from 20°C to 23°C reduced the rate of neonatal hypothermia on admission from 50% to 35%.[39] A retrospective cohort study found that raising the delivery room's ambient temperature from 28°C to 34°C resulted in fewer VLBW premature infants with hypothermia (<36.5°C) on admission to the NICU, and an increase in hyperthermia (>37.5°C).[61] Box 6.2 lists important components of the "warm chain" advocated by the WHO.

The newborn's skin temperature may drop by as much as 0.3°C/min, with core temperature dropping more slowly after delivery. At birth, most heat loss results from evaporation of amniotic fluid from the baby's skin surface. Drying the infant with prewarmed towels and immediately replacing used ones with dry, warm towels minimize evaporative heat loss. Dry towels conduct heat poorly when contacting the neonate's skin. However, cold examiner hands, stethoscopes, scales, and bare mattresses are good heat conductors and can add significant cold stress if not warmed before coming in contact with the newborn. Early skin-to-skin care for the first 24 hours of life decreases hypothermia for the first 48 hours of life in late preterm and term newborns.[106]

Because hypothermia on admission to the NICU is associated with higher morbidity and mortality,[30,83] prevention of hypothermia is one of four evidence-based interventions (delivery in an appropriate level of care; antenatal asteroids; surfactant within 2 hours of birth, or early nasal continuous positive airway pressure) **that improve the outcomes of very preterm infants.**[138] Recent rates of hypothermia on admission to the NICU in VLBW newborns were 12.9% to 53.4% in a large cohort in 11 European countries[133]; 36% in a Canadian study[83]; 51% in a Brazilian study[30]; and 79% in a single-center US study.[107] Another study found that the incidence of hypothermia in preterm infants between 27 to 30 weeks' gestational age was 93% in the first 3 hours after admission.[70] A cohort study in 11 European countries found that 88.2% of very preterm infants were born in units with one or more hypothermia-prevention strategy, but 50.9% of these infants were hypothermic on admission to the NICU.[134] Admission hypothermia rates were 73.2% in very preterm infants born in units without systematic hypothermia-prevention strategies. The most recent study from 18 centers in the NICHD Neonatal Research Network found that low and high admission temperatures were more common in the extremely preterm than in the moderately preterm infants[69] (see Box 6.3). The probability of being

BOX 6.2 THE WARM CHAIN[135]

1. Maintain thermal care in a draft-free delivery room (ambient temperature in delivery room at least 25°C to 28°C; prewarm all linens and surfaces that will be in contact with the infant's skin). Turn radiant warmer on 20 to 30 minutes before birth, on manual mode with 100% heater output.
2. Warm resuscitation—more preterm infants resuscitated with heated, humidified gas were normothermic on admission to the NICU than those who received cold, dry gas[94]
3. Immediate drying after birth from head-to-toe, covered with dry towel/blanket and hat placed on head.
4. Skin-to-skin contact with the mother after delivery, during transfer and in the postpartum area to prevent hypothermia and to treat cold stress.
5. Breastfeeding as soon as possible after birth, preferably within the first hour. Provides caloric intake for heat generation.
6. Postponing bathing and weighing. In a full-term newborn, bathing should be postponed until the next day. Weighing should be postponed till baby is adequately covered and making a zero correction for clothing.
7. Clothing/Bedding. Newborns should be covered in one to two layers of clothes, a hat, and hands covered. Swaddling, a custom of wrapping bands should be avoided.
8. Rooming-in between mother and baby should be encouraged and facilitated so that frequent skin-to-skin contact and breastfeeding occur.
9. Warm transportation within the institution, between institutions, or discharge home must be provided to protect thermal stability. Stable babies (including preterm and LBW infants) should be transported well-wrapped and skin-to-skin with their mothers. VLBW and/or unstable admitted babies should be transported in a prewarmed incubator. Temperature should be monitored before and after transport. In utero transport to a regional center is the preferred mode of transport.
10. Education. All neonatal care providers must be adequately educated and informed about the principles of the warm chain.

BOX 6.3 ADMISSION TEMPERATURES OF EXTREMELY AND MODERATELY PRETERM NEWBORNS

Digitalizing Schedule	Extremely preterm newborns (< 29 weeks' gestation)		Moderately preterm newborns (29–33 weeks' gestation)
	(2012–2013)	(2002–2003)	(2012–2013)
< 36.5°C	40.9 %	32%	38.6%
36.5°C–37.5°C	56%	6.2%	57.3%
> 37.5°C	52.9%	2%	4.2%

Data from: Laptook AR, Bell EF, Shankaran S, et al and the Generic and Moderate Preterm Subcommittee of the NICHD Neonatal Research Network: Admission temperature and associated mortality and morbidity among moderately and extremely preterm infants. *J Pediatr.* 2018;192:53.

hypothermic on admission to the NICU increased with decreasing gestational age[69,134] and in-hospital mortality is inversely related to admission temperature.[69] Higher admission temperatures in preterm infants after delayed cord clamping (see Chapter 4) have been demonstrated in two studies.[7,43]

The benefit of using *polyethylene plastic bags* and wraps for babies born at 26 to 30 weeks of gestation to preserve body heat and prevent hypothermia at admission has been shown in numerous studies.* This type of warming is ideal for a preterm infant (at birth and the immediate hours following) awaiting transportation to a tertiary care facility or indeed a baby born in a tertiary care facility. **The baby is placed on a warm towel (but not dried) and placed under a radiant warming heating device. The baby (excluding his or her head) is placed fully in the polyethylene bag or is wrapped in the polyethylene sheet. The baby should remain under the radiant warmer, as the heat, acting through the covering on the baby's moist skin, creates a warm thermal environment. Cutting an appropriate-size hole through the covering over the area of insertion can facilitate the introduction of any catheter or cannula.** Polyethylene bags for warmth have been adopted by the Neonatal Resuscitation Program (NRP) (see Chapter 4).

*References 20, 22, 34, 47, 57, 64, 73, 76, 78, 89, 112, 113, 120, 124

NRP guidelines emphasize how hypothermia may reduce the extent of brain injury after hypoxia and that hyperthermia may worsen the extent of brain injury during reperfusion after hypoxic events. **The recommended goal is to maintain normothermia for the infant and avoid iatrogenic hyperthermia in resuscitated newborns, especially those late preterm and term neonates who meet the criteria for neonatal cooling for hypoxic-ischemic encephalopathy (HIE)** (see Chapter 26, Box 26.7).

Resuscitation should take place on a preheated radiant warmer so that the adverse consequences of hypothermia are avoided. Use of heated, humidified oxygen (rather than cold, dry oxygen) given from birth through NICU admission results in normothermia of preterm newborns on admission to the NICU.[90,94] In an attempt to maintain heat balance, the neonate increases cellular metabolism and oxygen consumption, which increases the risk for hypoxia, cardiorespiratory problems, and acidosis. **Hypoglycemia is also a risk factor, because the infant must consume more glucose for heat production.** Other complications include clotting disorders, neurologic problems, hyperbilirubinemia, and even death if the untreated hypothermia progresses.

Because a significant amount of heat is lost through the surface area of the head, with its abundant blood supply and the brain's high heat production, **covering the infant's head with some insulating material conserves heat** during transfer to the nursery or NICU and afterward. Stockinet material is relatively ineffective for this purpose and provides poor insulation. The best material is thick, maintains its shape with use, and has a high percentage of air volume trapped in the fibers. Knitted wool caps, plastic caps, or Thinsulate material may provide the best results.[88] Combining polyethylene body wraps and polyethylene caps results in better temperatures in preterm infants than use of polyethylene wraps and a cotton cap.[116]

Occlusive plastic wrap alone is not totally effective in preventing hypothermia after birth in the very preterm infant. Several recent studies using plastic wrap and self-heating gel mattresses together to prevent heat loss in preterm infants less than 31 weeks of gestation have been conducted.[58,89,112,120,122] These studies have found **significant reduction in the incidence of hypothermia with the use of gel mattresses** compared with the incidence of

hypothermia on admission in very preterm infants who were born before the use of gel mattresses (3.3% vs. 22.6%).[58] **Several of these studies have also noticed a higher incidence of hyperthermia on admission.[58,89,112] Three nursing interventions (occlusive wrap, occlusive wrap and chemical mattress, and increasing delivery room temperature)** were studied to determine if they normalized admission temperatures in ELBW (<1000 g) and LBW (<1500 g) preterms.[12,76] **Each intervention resulted in a normal admission temperature without the risk of hyperthermia.[12,76]** Several other studies using occlusive wrap have elevated the initial temperature of VLBW infants without producing hyperthermia.[34,112,113] Quality improvement programs using bundled interventions have been successful in reducing the incidence of hypothermia in VLBW preterm infants,[19,29,52,108,111,136] as well as late preterm and LBW infants in mother-baby units.[6] Monitoring admission temperatures is recommended as a resuscitation quality indicator by the Australian and New Zealand Committee on Resuscitation Guidelines.[79]

There are a variety of ways to maintain thermal neutrality. Accessibility, IWL, servocontrol versus manual control of temperature, and safety are major considerations when determining the method to use for an individual neonate.

Incubators

Incubators provide a controlled, enclosed environment that is heated convectively with warm air. **The temperature in an incubator may be *servocontrolled* to maintain a desired skin temperature or air temperature.** As the temperature varies from the desired "set point," proportional control units gradually increase or decrease heat output to maintain a constant temperature (without the wider temperature fluctuations seen with simple on-off controllers). **Incubators controlled by abdominal skin servocontrol have been found to reduce neonatal death rates in LBW, and especially in VLBW, neonates.[121] In setting the servocontrolled incubator to the desired skin temperature, the sensor should be attached to the right upper quadrant of the abdomen with insulated temperature patches. The sensor should not be placed over areas of brown fat deposits, because the higher-than-expected temperature information to the controlling unit will result in a lower-than-desired heat output.[3]**

Inadvertent cooling may take place if the sensor is covered with clothes or a blanket or if the baby lies on it. Lying prone on the abdominal skin probe results in warmer temperatures than those recorded from probes not entrapped between the skin and mattress, resulting in a cooler incubator than intended.[14] If the sensor becomes disconnected from the skin, unwanted heating may occur because an erroneously low temperature reading causes an unwanted increase in heat output.[101] One must also consider that when an insulated patch is used to cover the thermistor, skin temperature is sensed as being higher than if tape covers the thermistor, resulting in decreased heat output by the warming device. **The desired skin temperature used for skin servocontrol is generally 36.0°C to 36.5°C (96.8°F to 97.7°F).[85]** Modern incubators also can be servocontrolled to a desired air temperature. This mode has been shown to provide a more stable thermal environment and less temperature variation compared with skin servocontrol.

Air servocontrol maintains a constant ambient air temperature when other factors such as phototherapy, external radiant heat, unstable room temperature, or direct sunlight are not confounding variables. **Infants who were managed with skin servocontrol had more variable but higher air temperatures and spent more time in a neutral thermal environment. Babies managed with air servocontrol had less variability in air temperatures but more variability in infant body temperature. A review of published trials concluded that VLBW babies whose skin servocontrol is set at 36°C had a lower mortality rate than those managed with air servocontrol at 31.8°C.[121]** A newer study of air temperature control versus skin servocontrol in preterm neonates less than 32 weeks gestational age found that a body temperature of 37°C was associated with lower energy costs and greater weight gain in the first 11 days of life.[31] The question of air versus skin servocontrol or manual control is still debatable for any given situation, and probably neither is the perfect solution for all babies. Fig. 6.4 depicts a research-based algorithm for weaning from servocontrol to air control in an incubator.

Radiant heat loss to cooler incubator walls, especially in single-walled incubators, is a significant source of heat loss. **The use of *double-walled incubators*** (with the inner wall warmed to the ambient air temperature inside the incubator) **results in less radiant heat loss from the baby.** With a skin-set servocontrol temperature, the decreased radiant heat loss (because of warmer incubator walls) is offset by

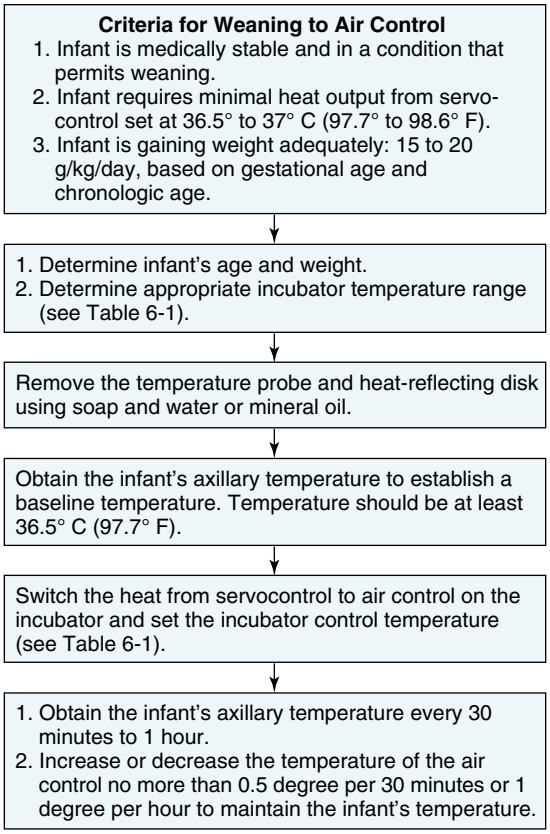

FIGURE 6.4 Research-based algorithm for weaning from servocontrol to air control mode in an incubator. (Courtesy Vivian Brown, RN.)

increased convective heat loss (because the ambient air temperature necessary for the desired skin temperature is lower). Consequently, there is no net change in the mean environmental temperature. **Double-walled incubators provide less temperature fluctuation when doors are open, thus providing a more stable caregiving environment.** Evaporative heat loss is not appreciably different with single- and double-walled incubators. One may increase the humidity in incubators to decrease the infant's metabolic rate only if a neutral thermal environment cannot be achieved by increasing the ambient temperature.

In one study, addition of a double-walled roof to a single-walled incubator resulted in less radiant heat loss but more convective and evaporative skin heat loss that was off-set by increasing the incubator's ambient temperature by 0.15 to 0.20°C.[33]

The tiniest neonate has a large evaporative heat loss, and maximum air temperature is limited by the incubator controls, thus making it difficult to reach an air temperature high enough for thermal support. **In such cases, hypothermia can be avoided by increasing the ambient humidity within the incubator by using the water reservoir or supplying warmed humidified air into the incubator with respiratory humidifiers. Humidification has been shown to decrease fluid requirements and decrease the incidence of electrolyte imbalances in babies weighing less than 1000 g.**[46] Careful attention should be given to preventing bacterial growth in the humidification system (see Chapter 23). Incubator temperatures may also be manually controlled by estimating the appropriate temperature for the baby's age and weight and setting the incubator to that temperature (see Table 6.1).

Regardless of whether one is using skin or air servocontrol or manual temperature adjustments, the baby's temperature and the air temperature must be monitored and recorded regularly. The incubator should be kept away from air conditioning ducts, direct sunlight, and cool windows that may cool or warm the incubator. **Room temperature should be kept at 23.8°C to 26.1°C (75°F to 79°F), and humidity should be maintained at 30% to 60%.**[4] Seasonal mapping of one NICU showed seasonal variation in humidity level and evaporative temperature, both influences on thermal environment.[127] The researchers recommend periodic assessment of air, evaporative, and radiant temperatures, as well as humidity, in multiroom NICUs.[127] **Alarms for both high and low temperature levels always should be turned on.**

The principal disadvantage of maintaining sick newborns in incubators is the limited access to them when extensive procedures are necessary. Incubators also may be perceived by mothers as a barrier between them and their infants and prolong feelings of fear and insecurity, compared with heating methods that provide easier access to the baby. **Holding the baby in skin-to-skin contact (kangaroo care) helps promote bonding and relieves some of maternal and paternal fears** (see later). Stable preterm infants dressed in a diaper, shirt, and cap and wrapped in two blankets can also maintain a normal temperature when held close to their parent's body. **Keeping the skin probe attached to the infant and plugged into the incubator allows frequent monitoring of the infant's temperature.** We also now have an increasing awareness of and concern about the high noise levels within incubators. Such noise poses a potential deleterious effect on the

TABLE 6.1 NEUTRAL THERMAL ENVIRONMENTAL TEMPERATURES

Note: For their table, Scopes and Ahmed had the walls of the incubator 1° to 2°C warmer than the ambient air temperature. Generally, the smaller infants in each weight group require a temperature in the higher portion of the temperature range. Within each time range, the younger the infant, the higher the temperature required.

From American Academy of Pediatrics and American College of Obstetricians and Gynecologists: Guidelines for perinatal care, 2nd ed, Evanston, IL: American Academy of Pediatrics and American College of Obstetricians and Gynecologists; 1988. Data from Scopes JW, Ahmed I. Minimal rates of oxygen consumption in sick and premature infants. Arch Dis Child 1966;41:407; Scopes JW, Ahmed I. Range of critical temperatures in sick and premature newborn babies. Arch Dis Child 1966;41:417.

hearing development of preterm infants (see Chapter 13). Improved alarm technology minimizes the risk for inappropriate heating, but malfunctions still occur occasionally. When experienced nurses provide care, infants can be appropriately managed in incubators using any of the three modes of temperature control. Box 6.4 outlines "dos and don'ts" when using an incubator to provide heat and humidity.

Weaning an infant from an incubator to an open crib is an important step in preparing for discharge but may result in an increase in the resting metabolic rate for LBW infants.[36] **Indicators that an infant may be successfully weaned include weight of 1600 g or more,[8,103,104,137] 5 days of consistent weight gain, an absence of medical complications, and tolerance of enteral feeds. Earlier weaning at lower body weight does not affect weight gain or temperature stability and may result in earlier discharge.[8,103,137] Weaning may occur over several days and involves dressing the infant in a shirt, hat, and diaper and swaddling with a blanket.** The incubator temperature is manually lowered while monitoring the infant's temperature.

Abdominal skin temperature should be 36°C to 37°C (96.8°F to 98.6°F). Figs 6.5 and 6.6 are research-based algorithms for weaning infants to open cribs. After weaning has been successful, the crib should be placed in a draft-free environment. **If an infant cannot maintain his or her temperature in an open crib, he or she is returned to the incubator. An attempt at weaning should be considered again by 48 hours after the initial weaning if all criteria for weaning have been met.** The temperature in the neonatal unit should be evaluated, as well as the location of the crib in relation to air conditioner vents or drafts. There may also be other medical reasons (e.g., infection) that the infant cannot maintain his or her temperature in the open crib if all other conditions have been ruled out.[1]

Humidification and Topical Ointments

Many studies and clinical trials have demonstrated the clinical application of the uses of both humidity and topical ointment therapy (see Chapter 19) in preterm

BOX 6.4 USE OF AN INCUBATOR DOS AND DON'TS

Dos

1. Place temperature probes according to manufacturer recommendations.
2. Work through the portholes rather than opening the canopy to improve temperature control.[15]
3. Change the incubator once a month.
4. Use sterile water for humidification.
5. Keep the incubator clean and free of spills.
6. Adequately humidify the incubator according to birth weight and gestational age of the infant.
7. Keep walls locked in place to prevent falls and provide a safe environment for the infant.
8. Clean incubators after each use and between patients with recommended cleaner, by trained staff.
9. Use servocontrol when first placing neonates in an incubator.
10. Follow weaning guidelines when changing from servocontrol to air control, using the weight and age chart (see Table 6.1).
11. Change the temperature probe site as directed by the manufacturer and hospital procedure.
12. Frequently monitor and record the infant's temperature, and observe for changes in clinical condition.

Don'ts

1. *Don't* place the temperature probe in the infant's axilla.[3]
2. *Avoid* pinching lines/tubes when opening/closing portholes and sides.
3. *Avoid* placing noisy equipment inside or on top of the incubator.
4. *Avoid* tapping, hitting, or knocking the incubator when the infant is in the bed.
5. *Avoid* keeping portholes open except for care and handling.
6. *Avoid* epidermal stripping (see Chapter 19) when applying/changing temperature probe sites.
7. *Avoid* pulling out lines or extubating the infant when moving/taking him or her out of the incubator.
8. *Don't* wean the servocontrol temperature less than 36.5°C (97.7°F).
9. *Don't* wean the temperature on the air control any faster than 0.5° per 30 minutes or 1° per hour.
10. Avoid cleaning the incubator with alcohol or acetone.
11. Do not keep the incubator in an unlocked position when in use. Do not position the incubator next to an air conditioner duct or in direct sunlight from a window.

Courtesy Vivian Brown, RN.

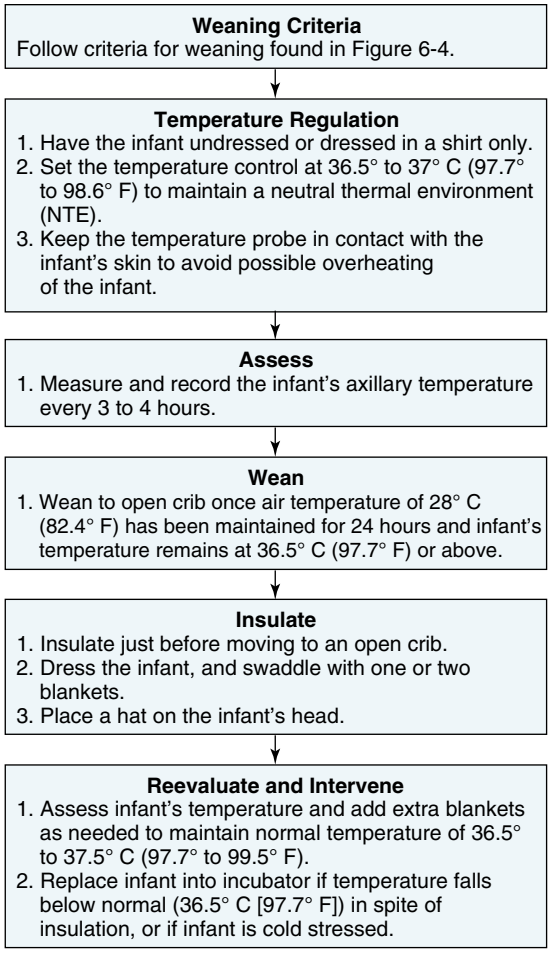

FIGURE 6.5 Research-based algorithm for servocontrolled weaning from an incubator to an open crib. (Courtesy Vivian Brown, RN.)

infants. **The optimal humidity level for the neonate is 50% RH.** This is achieved by a variety of methods such as relative humidity (RH) closed humidified incubators and humidity "tents." **In the first 2 weeks of life, extremely premature infants may require up to 85% RH.** Box 6.5 describes the advantages and disadvantages of using heated, humidified air for ELBW infants while in an incubator.

Radiant Warmers

Radiant warmers provide infrared energy to heat the baby's skin while he or she lies naked on an open bed. The radiant warmer must generate enough energy to offset the tremendous amount of radiant heat lost to

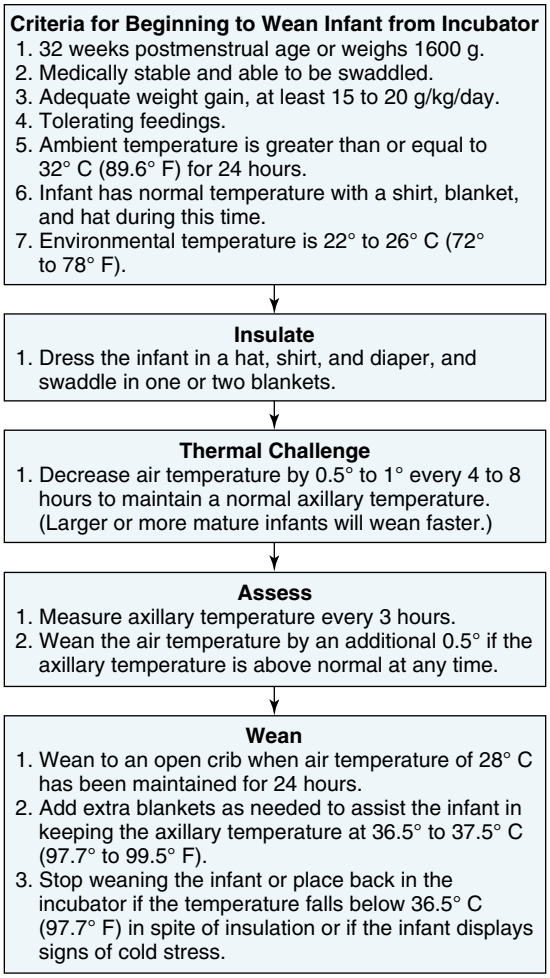

FIGURE 6.6 Research-based algorithm for air mode/manual weaning from an incubator. (Courtesy Vivian Brown, RN.)

the room by a naked baby lying in an open environment. Heat output can be servocontrolled or manually controlled. Because with manual control no feedback from the infant is used, this poses a greater risk for overheating or overcooling. **Therefore manual control should not be used routinely, except for short periods (e.g., while initiating resuscitation).** The servocontrol sensor measuring skin temperature must be protected from the infrared heat source, or the probe will sense a temperature higher than the skin temperature and decrease radiant heat output, leading to cold stress. Conversely, insulating the sensor with an aluminum reflective patch protects the underlying skin from the radiant heat and keeps the protected skin cooler than the surrounding skin. When the skin under the patch is warmed to the desired temperature, the rest of the skin may be overheated. Vasodilation then may increase convective heat loss, resulting in an effective, although precarious, heat balance. **Caregivers must use caution to ensure that the sensor does not become detached from the skin; otherwise the baby could be exposed to excess heat and become hyperthermic.**

Insensible water loss (IWL) for babies cared for under radiant warmers is increased by 40% to 50% compared with losses in incubators. Directly related to the amount of heat necessary from the warmer, this loss also is influenced by other factors (e.g., low RH and convective air currents) on an open bed. Even though transepidermal water loss is increased under radiant warmers, there is evidence that the hydration

BOX 6.5 RESEARCH-BASED ADVANTAGES AND DISADVANTAGES OF HEATED HUMIDITY IN THE INCUBATOR OF ELBW INFANTS

Advantages

1. Decreased transepidermal water loss (e.g., insensible water loss [IWL], evaporative water loss, and epidermal heat loss) from the skin of infants less than 31 weeks of gestation. IWL is inversely proportional to the gestational age of the infant.
2. Increased ability to maintain the infant's temperature.
3. Improved maintenance of fluid and electrolyte balance.
4. Improved energy balance—fewer calories expended in temperature maintenance.
5. Improved skin integrity.
6. Possible reduction in the incidence of (1) PDA, (2) IVH (grades III/IV), and (3) BPD because of improved fluid and electrolyte balance.

Disadvantages

1. Increased risk for infection associated with contamination of the humidifier reservoir with bacteria.
2. Moist environment impairs adhesion of equipment (e.g., electrodes, ETT, dressings).
3. Unstable temperatures when procedures are performed and the incubator door is open. In modern incubators, loss of humidity is not significant during clinical procedures that last less than 5 minutes. Based on the number of open portals and an open incubator door, these incubators are able to restore humidity within 1 to 15 minutes of a procedure lasting longer than 5 minutes.[86]
4. Delayed maturation of skin barrier.[2]

BPD, Bronchopulmonary dysplasia; *ELBW,* extremely low birth weight; *ETT,* endotracheal tube; *IVH,* intraventricular hemorrhage; *PDA,* patent ductus arteriosus.

of the stratum corneum is not affected; therefore the barrier function of the skin remains the same.[85] **With very premature infants, severe dehydration may occur if water intake is not increased to replace the inordinate IWL** (see Chapter 14). Plexiglas heat shields and polyethylene blankets (plastic wrap) have been used in an attempt to prevent large IWLs. Using plastic covers over preterm infants (28 to 30 weeks gestational age) in the first few days of life has been shown to result in higher mean body temperatures, even when the warmer was set on low temperature.[130] The microenvironment created by these blankets undergoes drastic change every time the blanket is removed for procedures or routine nursing care. Even without such blankets, the baby may experience wide swings in heat balance when the infrared heat is blocked from reaching him or her by hands, heads, or drapes during a procedure. These blankets should not be used while the infant is in an incubator, because the purpose is to have the humidity and heat reach the infant.

Both incubators and radiant warmers are effective in maintaining an appropriate thermal balance in sick and preterm infants. Evidence is insufficient to show a clear advantage of one method over the other with the caveat that IWL is significantly higher under radiant warmers.[44] The method chosen should be individualized to the infant and to the situation. Experience, skill, and nurse preference often influence the choice of heating methods. These factors also influence the extent to which incubators are perceived to interfere with the performance of care providers' tasks. Basic principles of care (e.g., keeping bed linens dry to prevent evaporative heat loss) apply to use of both heating methods. Box 6.6 lists advantages and disadvantages of open radiant warmers and incubators for temperature management in premature infants.[85]

Radiant warmers provide easy access for performing procedures—a definite advantage over incubators, in which procedures must be done through portholes. Performing invasive procedures on a radiant warmer protects premature infants from hypothermia better than performing invasive procedures in the incubator.[51] Advances in equipment technology now make it possible to convert a single unit from radiant mode to convection mode without moving the baby from one platform to another. This is an efficient way to provide the improved access needed when a baby's condition changes while maintaining appropriate warming without the potential risks of moving the baby.[37] These hybrid devices improve care of ELBW infants by enhancing growth velocity, improving electrolyte balance, decreasing fluid intake, and maintaining stable body temperature.[63] Fluid management is easier for infants in incubators because humidity is easily added to the enclosed environment, and there are fewer losses from radiation and convection. The large flux of heat exchange among the radiant heat source, the baby, and the environment

BOX 6.6 ADVANTAGES AND DISADVANTAGES OF OPEN RADIANT WARMER VS. INCUBATOR USE FOR PREMATURE INFANTS

Advantages: Open Radiant Warmer

1. Easy access to the infant and larger surface on which to work
2. Useful for initial admission procedures (e.g., intubation, line placement, x-ray examination)
3. Decreased risk for infection without the use of humidity
4. Decreased risk for unplanned extubation and lines being pulled out
5. Better access by parents and staff

Disadvantages: Open Radiant Warmer

1. Increased insensible water loss[44,51] (without humidification or plastic blanket)
2. Active induction of acute bouts of heat imbalance resulting in fluctuations in skin and rectal temperatures. Transient bouts of heat storage do not exacerbate physiologic strain (increased heart and respiratory rates and mean arterial pressure), but could occur in longer bouts of heat imbalance.[96]
3. Increased stimulation from external noise and light
4. Decreased growth and weight gain patterns
5. Decreased ability to wean the infant slowly from the heat source
6. Better access by parents and staff

Advantages: Incubator

1. Less insensible water loss with use of humidity
2. Acts as a barrier with more difficult access that decreases tactile contact; easier to use minimal stimulation
3. Increased weight gain
4. Heat provided by two methods: convection and conduction
5. Ability to wean temperature control from servocontrol to air control, and from air control to an open crib
6. Ability to cover the incubator to decrease exposure to light

Disadvantages: Incubator

1. Decreased access for treatments, line placements, intubations, and laboratory draws
2. Increased chance of infection with humidity
3. Increased risk for extubation or accidental clamping of lines

makes wide fluctuations in heat balance more likely when compared with the more easily controlled temperature within an incubator. Many variables influence oxygen consumption using these two heating methods. The metabolic rate and oxygen consumption of infants under radiant warmers are slightly higher than in incubators; however, the clinical significance of this finding is uncertain. Infection rates are comparable between the two methods.[92] **Regardless of the type of heat supplied, care must be taken to minimize thermal instability during nursing interventions. Radiant warmers may be able to rewarm a baby faster than an incubator with convective heating after a procedure.**[101] Organizing interventions (i.e., clustering care) so their frequency and duration limit as much as possible the exposure to a thermally unstable environment can minimize thermal instability. In the first 10 days of life, opening the incubator for nursing procedures negatively affects weight gain in healthy, moderately preterm (32 to 34 weeks of gestation) infants.[77] Box 6.7 outlines dos and don'ts when using a radiant warmer for providing heat.

Other Methods

In the tiniest preterm infants, a conductive heat source (e.g., a heating pad) may also be needed to raise and maintain body temperature. Heated water mattresses provide a neutral thermal environment for less critically ill babies lying in open cribs (making access easier than in closed incubators). This may also provide a feasible and effective means of rewarming hypothermic infants. Heated, water-filled mattresses are most useful in the newborn units of developing countries.

Electric warming mattresses filled with water provide additional moist heat when caring for the infant in surgery, to use for rewarming techniques, or when caring for the LBW or ELBW infant. In a randomized controlled trial, the use of a thermal blanket for VLBW premature infants (<1500 g) reduced the incidence of hypothermia, and hypotension without causing hyperthermia.[54] Manufacturer's recommendations should be followed, and the **temperature is usually set at 100°F (37.8°C). Heat is provided by conduction; therefore a linen layer should be placed between the mattress and the infant to avoid skin burns.** The temperature of these mattresses should be weaned before weaning any temperature of the open warmer or incubator.

BOX 6.7 USE OF OPEN RADIANT WARMER DOS AND DON'TS

Dos

1. Use the automatic mode (skin probe/servocontrol) for continuous thermal support.
2. Use the manual mode for short-term warming *only;* check the infant's condition and temperature at least every 15 minutes.
3. Place the sensor on the skin surface exposed to the warmer and never beneath the infant. (Follow manufacturer's recommendations.)
4. Check sensor attachments frequently. Poor skin contact causes poor temperature control.
5. Change temperature probe sites according to unit policy and manufacturer's recommendations.
6. Be familiar with the radiant warmer in use as the effectiveness varies among commercial devices.[129]
7. Adjust fluid replacement to compensate for increased insensible water loss.

Don'ts

1. *Don't* forget to switch from manual to servocontrol after weighing the infant. When removing the infant from the radiant warmer, keep the bed on servocontrol and silence the alarm until the infant is returned to the radiant warmer.
2. *Never* use a rectal temperature probe for warmer control. Before normal core temperature is reached, the infant's skin may be burned.
3. *Don't* place anything flammable on top of or under the radiant warmer.
4. *Never* just reset alarms; instead, determine the cause of any alarms.
5. *Never* use your hand to estimate the amount of heat reaching the infant. Set the temperature control point at 36.5°C.
6. *Avoid* use of thermal blankets (e.g., bubble wrap); may cause incorrect skin temperature sensing and overheating.

Some **portable, disposable, warming mattresses** containing a gel that is chemically activated by squeezing may be used for initial stabilization of the infant and for transport. **Because heat is provided by conduction, a linen layer is placed between the infant and the mattress surface. The usual temperature for these mattresses is 100°F.**

Heel warmers, which are pads that are chemically activated by squeezing, are used to warm the heels of infants before obtaining blood and are especially necessary when obtaining capillary blood gases. **The temperature should never exceed 104°F.**

Swaddling materials include various types of infant wrappings (e.g., blanket, clothing, foil, or bubble wrap). The use of swaddling materials makes

observation of the infant more difficult and blocks heat from overhead radiant warmers. **Before one wraps the infant in insulating materials, the infant must be warm, because these merely retain body warmth and do not generate heat.**

Oxygen and air delivered to the neonate should be warmed and humidified to minimize convective and evaporative heat loss (see Chapter 23). More premature infants (i.e., less than 28 weeks gestational age) who received heated, humidified gas for resuscitation were more normothermic on admission to the NICU than those who received cold, dry gas. In this study, only 2% of the preterm infants receiving heated, humidified gas were hypothermic compared to 12% who received cold, dry gas.[94]

Skin-to-skin (kangaroo) care provides a safe and effective alternative method of caring for premature infants. Both AGA and SGA infants experience a beneficial warming effect and a stable skin and core temperature when held skin-to-skin.[82] In LBW preterm infants, skin-to-skin care is also associated with less hypothermia.[27] **Mothers exhibit thermal synchrony with the infants so that their body temperature increases or decreases to maintain the infant's thermal neutrality.[12,81]** Regardless of the care provider (e.g., father, adoptive parent, grandparent) during skin-to-skin care, heat loss does not occur and temperature rises and can be maintained within acceptable parameters (see Chapter 5). In one study, each mother's skin temperature met the neutral thermal environmental zone of her particular infant. **Mothers also preferred this method for holding their infant, compared with the traditional method of wrapping the infant in a blanket and the infant being cradled in the parent's arms.** Heat loss may occur during the transfer process from bed to parent. Having a protocol in place that uses one or more staff to help with the transfer and covering the infant with a blanket will reduce the transfer time and subsequent heat loss[82] (see Chapter 13).

Skin-to-skin contact between mother and infant reduces conductive and radiant heat loss and is an excellent way to maintain a neutral thermal condition for the healthy newborn.[13,100] If the infant remains with the parents for an extended time, temperature should be monitored. In the case of a preterm infant in stable condition, the use of an additional heat source (e.g., a radiant warmer) enables parents to spend more time with their infant before transfer to the NICU. Thermal stability of 26 extremely preterm infants (22 to 26 weeks; 2 to 9 days of age) in early skin-to-skin care has been studied. **During skin-to-skin care, extremely preterm infants were able to both maintain and increase their body temperature after the drop that occurred during transfer from the incubator.[62]** Another study of skin-to-skin care of 22 extremely preterm infants (mean gestational age of 25⅐ weeks and mean weight of 702 g) found that these infants maintained adequate skin temperature and physical stability.[84]

Analyzing 70 skin-to-skin sessions in another study found lower variation in body temperature in 25- to 28-week gestational age preterms compared with the 29- to 32-week gestational age group at 33 to 36 weeks postmenstrual age (PMA). These very preterm infants exhibited an advanced maturation of thermoregulation compared with the higher gestational age group.[109]

Bathing removes blood and body fluids from the newborn's skin, prevents the transmission of infections, and promotes bonding when performed by parents. **Sponge bathing is traditionally done in the NICU and newborn nursery and can result in significant heat loss. Immersing the stable, swaddled infant in a tub of water reduces evaporative heat loss and helps maintain a normal temperature.*** Even late preterm infants, who are prone to hypothermia, have better thermal stability (i.e., higher temperatures and less temperature variability) when immersion bathing was compared with sponge baths.[80] Because preterm infants have limited ability to compensate for heat loss, they are more prone to the morbidities of cold stress (see Box 6.8) and the vicious cycle resulting from cooling (see Fig. 6.7) and should not be bathed (see Chapters 5 and 19).

Transport

The same principles of heat balance that apply to infants in NICUs apply to infants during transport. Infants should have a normal and stable temperature before transport. The infant should be transferred from nursery to transport incubator rapidly to prevent prolonged exposure to an uncontrolled thermal environment. Transport incubators that can provide thermal stability inside the transport vehicle must be used. Oxygen provided during transport also should be warmed and humidified. The infant's temperature should be monitored continuously or at least every 30

BOX 6.8 MORBIDITIES OF COLD STRESS[26,91]

- Hypothermia
- Hypoglycemia
- Respiratory distress
- Increased basal metabolic rate
- Increased caloric use to maintain thermal stability
- Increased oxygen consumption/need
- Respiratory and cardiac alterations (see Fig. 6.7) with decreased cardiac output (hypotension), shock, and renal failure
- Alteration in cerebral blood flow, the final common pathway to intraventricular hemorrhage (IVH)

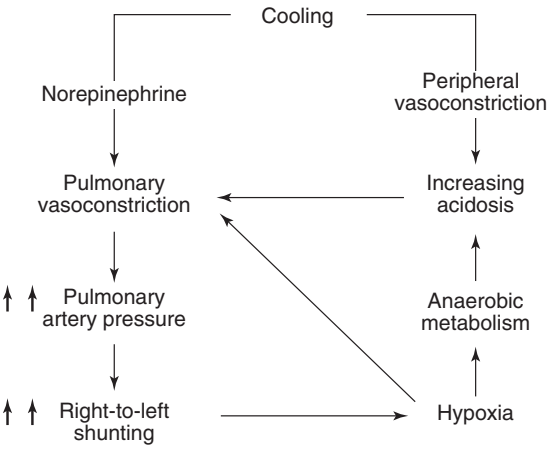

FIGURE 6.7 The vicious cycle resulting from cooling in the neonate. (From Fanaroff AA, Klaus MH. The physical environment. In: *Klaus and Fanaroff's Care of the High-Risk Neonate,* MI, USA: Elsevier Inc 66th ed; 2013:137.)

minutes. Thin plastic wrap may be useful in decreasing IWL and convective and radiant heat loss. Chemically heated mattresses can also be used to provide a short-term heat source.

Polyethylene bags that prevent hypothermia at birth also are effective in reducing the rate of hypothermia of VLBW infants during transport.[55]

After Cesarean Delivery

Most cesarean (C-section) deliveries are performed using an epidural or spinal anesthesia so the mother is awake and able to hear her infant as soon as he or she is born. **Once the baby is assessed after birth, he or she is then placed skin-to-skin on the mother's chest, and both are wrapped with a warm blanket.** After operative delivery, term newborns placed skin-to-skin with their mothers had: (1) no temperature change (21%), (2) increase in temperature (35%), and (3) a decrease in temperature (44%).[13] When the infant recovers in the same room as the mother, skin-to-skin contact and bonding are facilitated.[92] If the mother and baby do not recover together in the same room and the mother must return from the operating room, skin-to-skin care is still possible. **The father may provide skin-to-skin care and keep the baby warm after C-section until the mother returns to her postpartum room.** In a study of elective C-sections, 34 pairs of mothers and their newborns were randomized to skin-to-skin or routine nursery care within the 2 hours after the mother returned from the operating room.[48] Mean temperatures in both groups were equivalent, but the skin-to-skin care babies attached to the breast earlier, were exclusively or prevalently breastfed at discharge and 3 months, and mothers were highly satisfied with skin-to-skin contact with their babies[48] (see Chapter 5).

Providing Thermoregulation for the Surgical Patient

The chilled environment of the surgical suite poses extra challenges to the newborn for thermoregulation.

A case-control study of 108 infants in the NICU receiving operative procedures either in the operating room (OR) or the NICU found that hypothermia developed in 40% of the infants during the perioperative period.[99] When neonates were treated in the OR there was a higher rate of perioperative hypothermia (65% vs. 13% in NICU) as well as during and after the operation. Sequelae from hypothermia included respiratory distress and interventions to treat, need for thermal interventions, and need for cardiac support interventions.[99] A more recent study found that 90% of neonates were normothermic leaving the NICU, but only 24% were still normothermic at the beginning of surgery and 52% were normothermic on returning from the OR.[37] Quality improvement interventions reduce the rate of perioperative hypothermia in vulnerable neonates.[42] Heat losses occur by (1) evaporation during surgery, (2) conduction when placed on cold surfaces, (3) convection with cold drafts around the infant,[121] and (4) radiation of heat from opened body cavities. Coordination between neonatal and surgical staff will be necessary to prevent heat imbalance, as follows:

- Prewarm transport incubator.
- Use portable, disposable mattresses in the incubators and on the operating table.
- Use radiant heat in the operating suite.
- Wrap the infant's extremities in warmed soft cotton material.
- Prewarm all surfaces, as well as all fluids for cleansing and irrigation of body cavities.
- IV fluids should be at room temperature and prewarmed if stored in refrigeration.
- Temperatures should be monitored/documented before, during, and after surgery.

THERMAL IMBALANCE: CLINICAL DISORDERS

Data Collection

Anticipation and early recognition of the infant at risk for temperature instability are important in the management and prevention of complications associated with both hypothermia and hyperthermia. The perinatal history and ongoing neonatal evaluation identify events and early risk factors of temperature instability.

History

Events during pregnancy and the early neonatal period may increase an infant's risk for thermal instability. Review of the maternal history should include estimated date of confinement because preterm infants at delivery are at increased risk for hypothermia. Exposure to viral agents (e.g., herpes), as well as vaginal and cervical colonization, increases the risk for acquiring an infection before or during delivery (see Chapter 22). Intrapartal use of analgesics and anesthetics may depress the infant's CNS and mute the thermoregulatory ability.

Fetal stress manifested as fetal decelerations, meconium-stained fluid, or low Apgar scores may suggest an impaired thermoregulatory response. Neonatal interventions that may depress the CNS and thermal response include resuscitation and administration of analgesics, anesthetics, or neuromuscular blocking agents. Invasive procedures (e.g., endotracheal intubations, umbilical catheterization) increase the infant's risk for infection and need for prolonged use of antibiotics. Poor handwashing by care providers also may contribute to infectious nursery outbreaks, such as outbreaks of necrotizing enterocolitis (see Chapters 22 and 28).

Physical Examination: Signs and Symptoms

Physical assessment of the infant should include not only gestational age but also appropriateness of size. Evaluation of the infant's neurologic status (e.g., tone, activity, alertness) may give the caregiver an indication of the extent of neurologic impairment. Hypotonia results in decreased flexion, with an increased exposed surface area and resultant heat loss.

TEMPERATURE DETERMINATIONS

Temperature determinations may need to be made as often as every 30 minutes until thermostability is achieved. After that, temperatures should be recorded every 1 to 3 hours in LBW and preterm infants and every 4 hours in the healthy term infant. Critically ill infants should have continuous monitoring of skin temperature, with axillary determinations every 1 to 2 hours.[4] Documentation should include environmental temperature (e.g., air temperature in the incubator or radiant warmer settings). Measuring the skin and core temperatures simultaneously may help differentiate fever as a result of disease versus environmental overheating. Noting that the baby's servocontrolled skin temperature is relatively stable but that the environmental temperature has dropped also may be indicative of fever as the incubator responds to the high probe reading by cooling the infant's environment.

Laboratory Data

The following may be used to evaluate metabolic derangements associated with thermal instability:

- Arterial blood gases (to assess for hypoxemia and metabolic acidosis)
- Complete blood count (to assess for sepsis)
- Blood glucose level (to assess for hypoglycemia)
- Electrolytes, blood urea nitrogen (BUN), and serum and urine osmolality (to assess hydration, acid-base balance, and renal function)

HYPOTHERMIA

As the infant attempts to conserve heat by vasoconstriction, he or she may be pale, appear mottled, and feel cool to touch, particularly on the extremities. Acrocyanosis and respiratory distress may occur as the infant increases oxygen consumption in an attempt to increase heat

production. If hypothermia continues, apnea, bradycardia, and central cyanosis may occur. The hypothermic infant initially may be irritable but may become lethargic as cold stress continues. Other changes that may occur include hypotonia, weak cry, weak suck, increased gastric residuals, abdominal distention, and emesis. Infants generally do not shiver in response to cold stress, but shivering may occur in more mature babies in the presence of severe hypothermia. Chronic hypothermia may result in poor weight gain (Box 6.8).

Treatment and Intervention

To avoid the complications of hypothermia, rewarming of cold infants should begin immediately by providing external heat. However, rewarming too rapidly may further compromise the already cold-stressed infant and result in apnea. Oxygen consumption is minimal when the difference between the skin and the ambient air temperature is less than 1.5°C (2.7°F). Avenues of heat loss should be blocked, temperatures should be monitored, and iatrogenic or pathologic causes should be investigated.

If hypothermia is mild, slow rewarming is preferred. External heat sources should be slightly warmer than the skin temperature and gradually increased until the neutral thermal environmental temperature range is attained. Efforts to block heat loss by convection, radiation, evaporation, and conduction should be initiated. Skin, axillary, and environmental temperatures should be measured and recorded every 30 minutes during the rewarming period. For more extreme hypothermia (i.e., core temperatures <35°C [95°F]), more rapid rewarming with a radiant heater (servo-control 37°C [98.6°F]) or heated water mattress prevents prolonged metabolic acidosis or hypoglycemia and decreases mortality. A faster rewarming rate (>0.5°C/hour) of hypothermic ELBW preterm infants on admission resulted in a reduced incidence of respiratory distress syndrome (RDS), but no other differences between the rapid and slower rewarming groups.[98]

BOX 6.9 CRITICAL FINDINGS HYPOTHERMIA

Critical assessment findings for hypothermia are as follows:

- Pale, mottled skin that is cool to touch
- Acrocyanosis
- Respiratory distress
- Apnea, bradycardia, central cyanosis
- Irritability initially
- Lethargy developing as hypothermia worsens
- Hypotonia
- Weak cry and suck
- Gastric residuals, abdominal distention, emesis
- Shivering in more mature babies
- Metabolic acidosis
- Hypoglycemia

Complications

Hypothermia on admission to the NICU is strongly associated with increased mortality within the first week of life as well as during the first month of life.[23,30,71,83,95,133] Neonatal morbidities associated with admission hypothermia include: (1) increase in late-onset sepsis with every degree C decrease in admission,[71] (2) increase in intraventricular hemorrhage (IVH),[95] (3) increase in RDS,[23] and (4) severe neurologic damage, retinopathy of prematurity (ROP), necrotizing enterocolitis (NEC), bronchopulmonary dysplasia (BPD), and nosocomial infections.[83] However, a study of hypothermia in premature infants less than 32 weeks gestational age admitted to a Danish NICU found no association between admission hypothermia and RDS or death and BPD or death after adjusting for confounders (i.e., early-onset sepsis, gestational age, Apgar score, sex, treatment year, and birth weight).[59] A recent study of the outcomes of hypothermic preterm infants treated with oxygen or CPAP for RDS in a low-resource setting found: (1) none of the infants with a temperature below 35.8°C survived to discharge regardless of the type of respiratory support, (2) 100% of preterm infants with temperatures above 35.8°C treated with CPAP survived, and (3) if more than 50% of measured temperatures were hypothermic only 5.6% survived who were treated with CPAP.[21]

Acute cold stress results in the release of norepinephrine, which causes vasoconstriction to reduce heat loss and initiate thermogenesis, which increases metabolic rate. As glycogen stores are depleted and oxygen consumption increases, the infant uses anaerobic metabolism to increase heat production, resulting in lactic acid production (metabolic acidosis).

Pulmonary vasoconstriction, accentuated by metabolic acidosis, is associated with hypoxia, decreased surfactant production, and further acidosis (see Chapter 23). Blood flow to vital organs is diminished, and pulmonary hemorrhage and death may occur if hypothermia continues.

Hyperbilirubinemia and kernicterus may occur as nonesterified free fatty acids from brown fat metabolism compete with bilirubin for albumin-binding sites. Acidosis not only decreases the affinity of albumin for bilirubin but also increases the permeability of the blood-brain barrier, allowing bilirubin to enter brain tissue. If hypothermia continues, carbohydrate, protein, and fat supplies will be used for heat production instead of growth.

Close monitoring of the hypothermic infant is essential for early identification and prevention of complications. Evaluation of vital signs, arterial blood gases, and oxygen saturation may give early indication of hypoxia and metabolic acidosis. The infant's skin may be dusky or bright red because failure of dissociation of oxyhemoglobin occurs at low body temperatures. Respirations may be rapid, shallow, and grunting and accompanied by bradycardia. Oxygen and ventilation should be initiated as needed to reduce hypoxia. Sodium bicarbonate may be needed to correct documented metabolic acidosis. Seizures may occur as a result of hypoxia, requiring the administration of anticonvulsants.

Intravenous glucose may be necessary to prevent or correct hypoglycemia. **Blood glucose levels should be monitored hourly until stable** (see Chapter 15). **Blood pressure and urine output should be measured** to evaluate hydration and kidney function. An elevated BUN and hyperkalemia may be indicators of decreased renal perfusion and impaired renal function. As fluid is retained, edema of the extremities and face may occur.

Bilirubin should be monitored on a regular basis, and phototherapy may be initiated at a lower-than-usual level to prevent kernicterus. Adequate nutrition to promote growth should be given either intravenously or enterally. While the infant is hypothermic, nipple feedings should be avoided to conserve calories and energy for heat production and growth and to avoid aspiration. Hypothermic infants feed poorly and fail to gain weight because calories are used to generate heat for warmth instead of for growth.

During the rewarming process, the hypothermic infant should be observed for hypotension as vasodilation occurs. Volume expanders may be needed to maintain an adequate blood pressure. Apnea and seizures may occur as a result of hypoxia or decreased cerebral blood flow after vasodilation. Hypothermia as a strategy to minimize adverse outcomes from hypoxic-ischemic encephalopathy continues to be the focus of considerable research to determine safety and efficacy (see Chapter 26).

HYPERTHERMIA

The hyperthermic infant may feel warm to touch, and skin color may be ruddy as the infant attempts to increase heat loss by vasodilation. Sweating may occur in a term infant but generally is not present in infants of less than 36 weeks gestational age. Sweating may first appear on the forehead, followed by the chest, upper arms, and lower body. Hyperthermia is manifested by irritability, lethargy, hypotonia, apnea, a weak or absent cry, or poor feeding. Tachypnea or tachycardia may be seen as the infant attempts to increase heat loss.

Infants with thermal instability should be closely watched for changes in behavior, feeding patterns, and respiratory status. Temperatures should be monitored frequently in any infant exhibiting these symptoms or who feels cool or warm to touch. Early recognition of thermal instability may prevent further consequences and possibly permanent injury or death (Box 6.10).

Treatment and Intervention

The usual approach to treating the hyperthermic infant is to cool by removing external heat sources

BOX 6.10 CRITICAL FINDINGS HYPERTHERMIA

Critical assessment findings for hyperthermia are as follows:

- Reddened skin that is warm to touch
- Tachypnea
- Tachycardia
- Irritability, lethargy, hypotonia, weak cry
- Poor feeding
- Apnea
- Sweating in more mature babies
- Dehydration

and by removing anything that blocks heat loss. The most common causes of hyperthermia in intensive care nurseries are iatrogenic. Check the heating controls for proper function and thermistors for proper position. Consider other sources of heat (e.g., direct sunlight, heaters, lights) as possible causes of hyperthermia. Excessive bundling with blankets and a hat and elevated environmental temperature can cause a newborn's body temperature to rise into the febrile range. When evaluating the treatment options in the hyperthermic infant, one should consider removing extra blankets or swaddling materials. Nonenvironmental causes of hyperthermia (e.g., infection, dehydration, CNS disorders) should be considered. During the cooling process, skin, axillary, and environmental temperatures should be monitored and recorded every 30 minutes.

Complications

Recognizing late preterm and term neonates who meet the criteria for neonatal cooling for HIE (see Chapter 26, Box 26.7) and preventing hyperthermia is critical to decreasing morbidity and mortality. Outcomes of asphyxiated newborn infants who did not receive cooling in the NICHD Neonatal Research Network whole body cooling trial were studied at 18 to 22 months[72] and at 6 to 7 years.[70] Within the first 72 hours of life, asphyxiated newborns without cooling exhibited elevated temperatures that were associated with a four-fold increase in death or moderate disability.[72] Follow-up of this cohort to ages 6.7 years found that the association between their elevated temperatures and death or IQ less than 70 persisted.[70]

Vasodilation to increase heat loss may cause hypotension and dehydration as a result of increased IWL. **Seizures and apnea may also occur as a result of high core temperature.** Fluid status should be monitored by assessing intake, output, electrolytes, serum and urine osmolality, skin turgor, and mucous membranes. Fluids should be adjusted to account for IWL. **Blood pressure should be assessed to detect hypotension,** and volume expanders should be administered as needed.

Cardiorespiratory monitoring to detect apnea should be used. Ventilation may be needed if apnea persists or is unresponsive to stimulation. Subtle signs of seizures may include facial grimacing, nystagmus, tremors, apnea, opisthotonos posturing, tongue thrusting, or staring (see Chapter 26).

PARENT/CAREGIVER TEACHING

While the neonate is in the NICU, parents should be taught the importance of maintaining the newborn's normal body temperature. Temperature should be taken before parents touch the infant through the portholes of the incubator or hold their infant. **While the infant is outside the incubator, monitor the skin temperature continuously with a telethermometer.** Unwrapping the infant to check the temperature exposes him or her to cold stress. Additional heat sources (e.g., radiant warmer, hat, extra blankets) may be needed while parents hold the infant. Teach parents to monitor their infant's temperature and to notify the nurse if it rises or falls (Box 6.11).

Before discharge, teach parents to take an accurate axillary temperature and to notify their physician if it drops below 36°C (96.8°F) or rises above 37.8°C (100°F).[4] A parent should not routinely take a rectal temperature. The temperature should be taken whenever the infant feels cool or warm to the touch. The nurse should observe the parents taking the infant's axillary temperature before discharge.

The home environment should be kept at a temperature that prevents heat and cold stress. A room temperature that is comfortable for the parent usually is suitable for the infant. The infant should be in clothing appropriate for the room temperature. For example, if the parent requires a sweater to

BOX 6.11 PARENT/CAREGIVER TEACHING TEMPERATURE REGULATION

- Teach parents how to take an axillary temperature on their newborn and maintain the axillary temperature between 36.5°C and 37.4°C (97.7°F and 99.3°F).[5]
- Teach parents how to dress their infant with clothes and blankets and use an appropriate environmental temperature to maintain the baby's temperature in the above range.
- Teach parents appropriate safety precautions, which include verbal and written information about recognizing signs and symptoms of a sick/ill infant, as well as how the infant acts, including temperatures either higher than or, more commonly, lower than the range of 36.5°C to 37.4°C (97.7°F to 99.3°F).
- Teach parents to notify their infant's primary health care provider immediately or to take the infant to the nearest emergency department for temperatures out of the above range, especially if the baby's feeding pattern changes.

be comfortable, the infant probably also requires a sweater. Parents often overdress the infant or overheat the home, and this may cause hyperthermia. Parents should be given written instructions before discharge on how and when to take an axillary temperature, when to call the physician, and how to maintain a comfortable environment for their infant.

7 PHYSIOLOGIC MONITORING

KRISTI COE, WANDA T. BRADSHAW, AND DAVID T. TANAKA

Significant advances in the management of the ill preterm infants have been made in the past 70 years. The clinical usefulness of the umbilical vein was first demonstrated by Diamond in 1947 to perform an exchange transfusion to prevent kernicterus. Later, James used the umbilical artery for acid-base determination. In most neonatal intensive care units (NICU), use of these catheters has become the standard of care to assess blood gases, measure arterial and central venous pressures, administer medications and fluids, and obtain laboratory samples. The development of small, indwelling, peripherally inserted central catheters provides a route for administering the aforementioned items and may be used for laboratory sample withdrawal if no other method of obtaining blood is available. The frequency and clinical significance of complications and alternatives to these intravascular routes have been vigorously sought. The development of noninvasive physiologic monitoring devices has been a major step toward this goal. In addition, the use of point-of-care testing for various laboratory values is evolving in neonatal care. This chapter reviews the procedures and advances in physiologic monitoring.

PHYSIOLOGY

Pulmonary Physiology

Gas exchange takes place in the alveoli of the lung. Ventilation is the movement of air into and out of these airspaces. Diffusion is the movement of oxygen (O_2) from the alveolar space into the pulmonary capillary and the movement of carbon dioxide (CO_2) from the pulmonary capillary into the alveolar space for eventual exhalation. Pulmonary perfusion is the flow of blood through the pulmonary capillaries that surround the alveolar spaces. **Once oxygen diffuses through the cells lining the alveoli and into the capillaries, it is predominately bound to hemoglobin within the red blood cell.** Oxygen content in the arterial blood is the sum of the amount of oxygen dissolved in the plasma and the amount bound to hemoglobin. **Approximately 3% of the oxygen content is dissolved in the plasma, with the remaining 97% bound to hemoglobin.** PaO_2 is the partial pressure of the oxygen dissolved in arterial plasma. ***Fetal hemoglobin* has a higher affinity for oxygen than does adult hemoglobin; therefore, at any given PaO_2, more oxygen is bound to fetal hemoglobin** (Fig. 7.1). **Each hemoglobin molecule can carry four oxygen molecules. *Oxygen saturation* (SaO_2) is the percentage of oxygen bound to hemoglobin.**

Carbon dioxide content in arterial blood is the sum of the amount of carbon dioxide in the plasma plus the amount bound to hemoglobin. As hemoglobin gives up oxygen to the tissues, it is able to pick up carbon dioxide. **Each reduced hemoglobin molecule can carry four carbon dioxide molecules, thus lowering the free hydrogen ion (H^+) concentration.** Approximately 10% of the carbon dioxide content is gas dissolved in the plasma (CO_2), 60% is carbonic acid (H_2CO_3), and the remaining 30% is attached to proteins, predominantly hemoglobin. **$PaCO_2$ is the partial pressure of carbon dioxide dissolved in arterial blood.** It is a measured value that denotes the partial pressure of arterial carbon dioxide. **Carbon dioxide values fluctuate as needed to maintain the hydrogen ion concentration, or pH, within a normal range.** Carbon dioxide combines reversibly with water to yield hydrogen (H^+) and bicarbonate (HCO_3^-) ions. The formula is $CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$.

BLUE type highlights content that is particularly applicable to clinical settings.

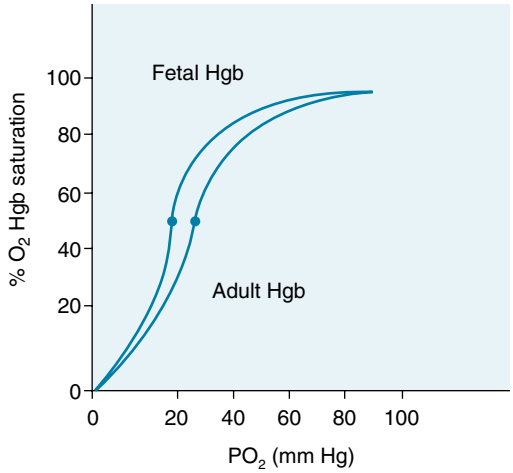

FIGURE 7.1 Oxygen dissociation curves for fetal hemoglobin (Hgb) (*left*) and adult hemoglobin (*right*).

NONINVASIVE MONITORING

Use of noninvasive technologies to monitor *all* neonates in the NICU is the standard of care. Many neonates also require invasive monitoring devices.

Oxygen and Carbon Dioxide

OXYGEN

Noninvasive monitoring of oxygenation can be accomplished by using three monitoring technologies, *pulse oximetry, transcutaneous oxygen monitoring, and near-infrared spectroscopy.* ***Oxygen saturation monitoring* is the most common and widely used method for assessing oxygenation status.** Transmission technology relies on a pulsating arterial vascular bed between a dual light source and a photoreceptor. As blood passes between the light source and the photoreceptor, different amounts of red and infrared light are absorbed, depending on the amount of oxyhemoglobin and reduced hemoglobin. With reflectance oximetry, the emitter and receptor are located beside each other. Emitted light is reflected back to the photoreceptor. This method uses the core body to obtain oxygen saturation and is useful when the patient's peripheral blood flow is diminished. **With this method, the difference in light absorption is electronically processed and displayed by the monitor as the percentage of arterial hemoglobin oxygen saturation expressed as SpO_2. Pulse oximetry probes are easy to apply and require no warm-up period, calibration, or application of heat.**

The second method of noninvasive monitoring of oxygenation is *transcutaneous oxygen tension,* **which relies on the principle of oxygen diffusing from the skin capillaries through the dermis to the surface of the skin.** To measure oxygen diffusion, it is necessary to have adequate perfusion of the site, to intermittently calibrate the sensor, and to heat the skin, which then dilates the local capillaries and arterializes the capillary bed, as well as promotes faster diffusion of the oxygen from the skin.[36]

Near-infrared spectroscopy (NIRS) is a newer method of noninvasive oxygenation measurement in the NICU. NIRS was launched in 1977 to assess cerebral oxygenation and perfusion during cardiac and neurosurgery, but its use has been expanded into neonates, initially used peri- and postoperatively for cardiac surgery.[46] This technology is based on tissue transparency to light in the 700- to 1000-nm wavelength, referred to as the *near-infrared spectrum.* Through a light-emitting diode (LED), NIRS releases two wavelengths of near-infrared light signals to maximize separation of the absorbed spectra among oxyhemoglobin and deoxyhemoglobin. The NIRS probe also contains two optodes to receive the scattered light, one from peripheral tissue and another from peripheral and deep tissues. After the peripheral value is subtracted from the other value, a tissue-specific regional oxygen saturation (RSO_2) value from a 1- to 2-cm depth is attained. In comparison with earlier technology, **NIRS signifies tissue oxygen supply and utilization, while oxygen saturation monitoring suggests (arterial) oxygen supply to tissues.** While NIRS was initially used to assess cerebral oxygenation and demand by placing the adhesive probe horizontally across the forehead, use has been expanded to deeper organs including the kidneys and intestines because of a superficial location in this age group.[46]

CARBON DIOXIDE

Carbon dioxide also can be assessed using two different devices, *transcutaneous carbon dioxide* and *end-tidal carbon dioxide* monitors. ***Transcutaneous carbon dioxide ($PtcCO_2$) monitoring works under similar principles as for transcutaneous oxygen monitoring.***[34] The probe is a glass pH electrode

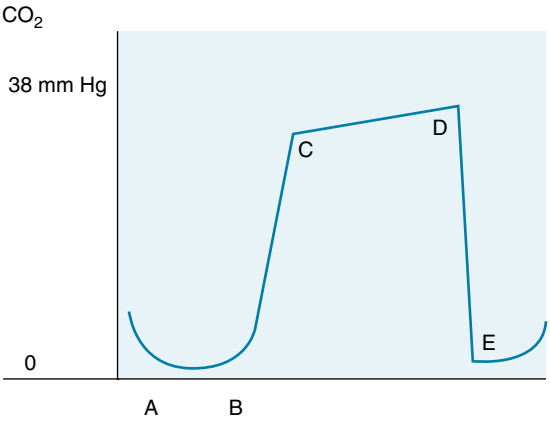

FIGURE 7.2 Variations in the content of carbon dioxide during phases of the respiratory cycle. **A,** End of inspiration. **B,** Beginning of exhalation. **C,** End of mixed gases washout (dead space and alveolar gases). **D,** End of expiration of alveolar gases. **E,** Inspiration.

that detects changes in pH caused by CO_2. Heating of the probe enhances CO_2 diffusion, providing a better correlation between the probe value and the $PaCO_2$ value. The second method used to measure the content of the carbon dioxide in the respiratory gases during the respiratory cycle is *end-tidal carbon dioxide ($PetCO_2$)* monitoring, also called *capnometry.* **With capnometry, an infrared light absorption determines the amount of CO_2 present in the sample. Capnography provides a visual graphic curve of $PetCO_2$.** The carbon dioxide content varies widely with the phase of the respiratory cycle. During inspiration, there are minimal amounts of carbon dioxide, whereas at the end of expiration, the carbon dioxide values are at their maximum level (Fig. 7.2). Until recently, the relatively fast respiratory rate of newborns, combined with the small tidal volumes, resulted in inaccurate values when measured by end-tidal carbon dioxide monitors. Advances in technology have improved the reliability of this monitoring technique for newborn infants.

COMBINED OXYGEN–CARBON DIOXIDE MONITORING

$SpO_2/PtcCO_2$ sensors combining pulse oximetry and transcutaneous carbon dioxide monitoring have been developed. The heated sensor is attached to the patient's ear. It provides rapid SpO_2 values followed by carbon dioxide information within minutes as the site is warmed and arterialized. A single probe, designed to withstand motion artifact and low perfusion states, leads from the patient to the monitor. The probe is attached to the ear, thus its removal for chest radiographs or prone positioning is not necessary. Studies on normal adults, infants, and very-low-birth-weight (VLBW) infants have shown acceptable correlation with both invasive and noninvasive monitoring techniques for oxygen. Carbon dioxide values were less reliable but allowed trending of ventilation status.[38]

Amplitude Integrated Electroencephalography

Although the gold standard for monitoring cerebral activity in neonates is continuous electroencephalography (cEEG), a tool that is complementary, amplitude-integrated electroencephalography (aEEG), is now used in many NICUs. **Infants appropriate for use of aEEG may include those with clinically evident seizure activity or those with seizure activity who have experienced a perinatal hypoxic event.**[38] Feasibility is likely improved with aEEG because this technology requires only four electrodes compared with many more channels needed for cEEG. Like other complementary tools, aEEG provides trends over time that allow clinicians to view and assess for abnormal cerebral activity allowing for prompt treatment.[38]

Cardiorespiratory Monitoring

The electrical activity of an infant's heart is picked up by chest leads (usually three) placed on the infant and recorded by a cardiorespiratory monitor. The recording is displayed on a visual screen as the infant's electrocardiographic pattern. The infant's respiratory pattern also is recorded, because the chest leads electronically detect movement of the chest with each respiration.

Blood Pressure Monitoring

***Systolic blood pressure,* measured in millimeters of mercury (mm Hg), is the pressure at the height of the arterial pulse and coincides with left ventricular systole. *Diastolic blood pressure,* also measured in mm Hg, is the lowest point of the arterial pulse and coincides with left ventricular diastole. *Pulse pressure* is the difference between**

the systolic and diastolic blood pressure. *Mean arterial pressure* is the diastolic pressure plus one-third of the pulse pressure. *Central venous pressure* is the pressure in the right atrium and may be approximated by the blood pressure (volume) in any of the large central veins.

Point-of-Care Testing

Point-of-care testing (POCT) involves testing performed at or near the patient rather than in a laboratory. This process has steadily evolved from crude blood glucose determinations to numerous types of monitoring. Currently, whole-blood glucose values, transcutaneous bilirubin, fecal occult blood, gastric pH, urine dipstick, activated clotting time, hematocrit, some electrolyte values, and arterial blood gases are part of POCT for the neonatal population.

DATA COLLECTION

The indications for using the various techniques for physiologic data collection depend on the infant's clinical situation.

Noninvasive Oxygen and Carbon Dioxide Monitoring

Oxygen monitoring is indicated in infants receiving oxygen for any reason (see Chapter 23). Acute monitoring is used as a part of the management of acute respiratory disorders. Long-term monitoring is used to wean infants with chronic lung disease from oxygen therapy. Noninvasive oxygen monitoring is useful during transport, in emergency situations, and during procedures. However, this method provides no information on hemoglobin level, adequacy of ventilation, and oxygen delivery to the tissues and should be used as one part of total oxygenation and ventilation assessment. Despite how oxygen saturation monitoring is used more, less variability in oxygen tension has been demonstrated when transcutaneous oxygen monitoring has been employed.[36]

Carbon dioxide monitoring is useful for verifying that the endotracheal tube is in the trachea (end-tidal CO_2 monitoring) and for the infant with a respiratory disease in whom retention of carbon dioxide may become clinically significant (end-tidal CO_2 and transcutaneous CO_2 monitoring).

Cardiorespiratory Monitoring

Cardiorespiratory monitoring should be used in *all* infants who require intensive or intermediate care, as well as in *all* infants at risk for apnea or rhythm disturbances.

Blood Pressure Monitoring

Blood pressure monitoring should be used in the infant requiring surgery, in the acutely ill infant with cardiorespiratory distress, and in any other illness in which hypotension may be a significant contributor to the pathologic state. Central venous pressure should be monitored in infants who may experience an excess or loss of blood volume.

Umbilical Artery Catheters

An umbilical artery catheter (UAC) is placed in those infants requiring frequent arterial blood gas determinations, continuous monitoring of arterial blood pressure, and infusion of parenteral fluids. The practice of medication administration through a UAC varies, although there are no published data in the past decade regarding this practice.[31,45] Infants who are candidates for indwelling catheters include critically ill neonates and those with congenital heart disease or disorders that cause respiratory insufficiency (e.g., surfactant deficiency, meconium aspiration syndrome, persistent pulmonary hypertension, diaphragmatic hernia). **Although use of an indwelling UAC allows arterial pressure monitoring and accessibility for parenteral infusions, it is generally not used for these indications alone.**

Umbilical Vein Catheters

Umbilical vein catheters (UVCs) are useful for exchange transfusions, central venous pressure monitoring, emergency administration of fluids or chemicals in delivery room resuscitation, and administration of parenteral fluids and medications in the NICU, as well as obtaining blood for laboratory analysis. UVCs are used with increasing frequency for initial management

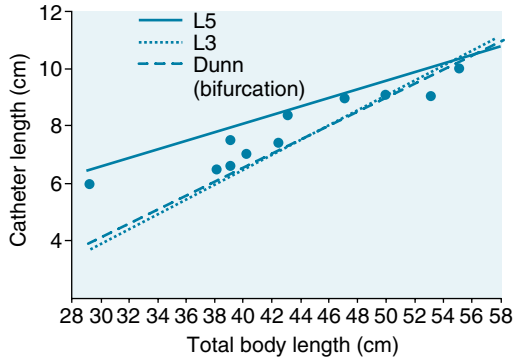

FIGURE 7.3 Graph for distance of catheter insertion from umbilical ring for low placement. (From Rosenfeld W, Biagtan J, Schaeffer H, et al. A new graph for insertion of umbilical artery catheters. *J Pediatr.* 1980;96(4):735.)

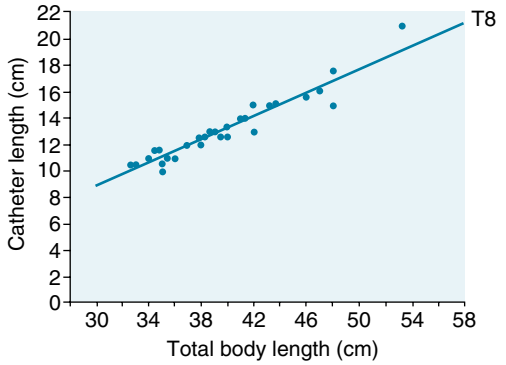

FIGURE 7.4 Graph for distance of catheter insertion from umbilical ring for high placement (T8). (From Rosenfeld W, Estrada R, Jhaveri R, et al. Evaluation of graphs for insertion of umbilical artery catheters below the diaphragm. *J Pediatr.* 1981;98(4):627.)

of extremely low-birth-weight (ELBW) infants. Catheters used to cannulate the umbilical vein are available as both single-lumen and double-lumen items. Double-lumen catheters permit the simultaneous administration of infusates and medications. Use of a UVC reduces the need for peripheral devices when multilumen UVCs are used.

INTERVENTIONS

Invasive Monitoring

Placement of UACs or UVCs and placement of a peripherally inserted central catheter (PICC) are invasive monitoring techniques.

Umbilical Artery Catheter Placement

PROCEDURE

Determine the size and length of the catheter to be inserted. **For infants weighing more than 1250 g, use a 5-Fr catheter, and for infants weighing less than 1250 g, use a 3.5-Fr catheter.** Figs. 7.3 and 7.4 correlate total body length with the length of the catheter to be inserted. Whereas these charts have worked reasonably well in larger preterm and term infants, the Wright formula (4 × birth weight in kilograms + 7) resulted in significantly better placement in VLBW infants.[22,29] A comparison of formulas for the length of UAC placement found superior correct placement of the tip of the catheter with use of the Wright formula.[29]

Place the infant in a supine position on a radiant warmer bed or in an incubator. Ensure continuous temperature monitoring. Skin temperature should remain between 36°C and 37°C (96.8°F and 98.6°F). Provide appropriate oxygenation and ventilation. Ensure cardiorespiratory and oxygen saturation monitoring. Restrain the infant's hands and feet to prevent him or her from contaminating the sterile field and interfering with the placement procedure. Don cap and mask. Open the catheterization tray; most units now use commercially available disposable trays. Catheterization tray contents are shown in Fig. 7.5. Wash hands and dry with sterile towel before the procedure. Put on sterile gown and gloves.

Connect the catheter to the stopcock, and flush and fill the entire system, including the catheter, with flush solution. Turn off the stopcock to the catheter to prevent fluid from draining out of the catheter during insertion and securing of the catheter. Cleanse the cord and base of the umbilicus with either povidone-iodine or chlorhexidine with alcohol three times and allow the site to air-dry.[33] Remove the povidone-iodine with alcohol. For infants weighing less than 1000 g, utilize sterile water. **Avoid using an excess of skin disinfectant so the infant is not lying in the solution during the procedure. Any residual skin disinfectant should be washed off the infant carefully after the procedure is completed.**

FIGURE 7.5 Argyle umbilical vessel catheter insertion tray. (Courtesy Tyco/Healthcare Kendall-LTP.)

Drape the infant by placing an eye sheet over the umbilicus. An alternative method is to use sterile drapes, as follows:

1. Hold the diagonal corners of one drape, and allow the top half to fold over the bottom half. The result is a *V* shape.
2. Place the tips of the *V* on either side of the umbilicus.
3. Repeat with another drape, and place on the other side of the umbilicus. The umbilical stump is now visible yet surrounded by drapes.

After the UAC is inserted, the drapes can be removed easily without the need to pass the stopcock and catheter through an eyehole of a drape or cut or tear the eyehole drape. **Ensure that the infant's head and feet remain visible during the procedure to assess color.** A small eye drape with adhesive backing (such as a Steri-Drape) has the advantage of being transparent, so that the infant's color can be seen, and temperature can be maintained. Towel drapes may interfere with a radiant heat source used for temperature regulation.

Place an umbilical cord tie (e.g., umbilical cord tape) around the base of the cord to control bleeding. A single overhand knot is preferred because it allows tightening as needed. Using tissue forceps, pick up the cord and cut it with a scalpel about 1 to 1.5 cm above the base. Arterial spasm allows only minimal bleeding. Identify the vessels. **There are usually two arteries and one vein. The arteries are small, thick walled, and constricted. The vein is larger, thin walled, and usually gaping open.** If the vein is at the 12-o'clock position, the arteries are usually at the 4- and 8-o'clock positions (Fig. 7.6).

Stabilize the umbilical stump by grasping the cord between the thumb and index finger or grasping the edge of the stump with a mosquito hemostat. Ensure that the hemostat does not crush the umbilical vessels. With iris forceps, dilate one of the arteries by placing the tips of the forceps in the artery and gently allowing them to spring open. This procedure may need to be repeated several times. In ELBW infants, the artery may be so small that it may be necessary to initially insert one forcep tip and then both to dilate the artery. While grasping one side of the wall of the dilated artery with small forceps, gently insert the catheter. An alternative method is to insert the catheter between the open prongs of the forceps used to dilate the artery. Instructional aids such as Baby Umb (Medical Plastics Laboratory, Inc., Gatesville,

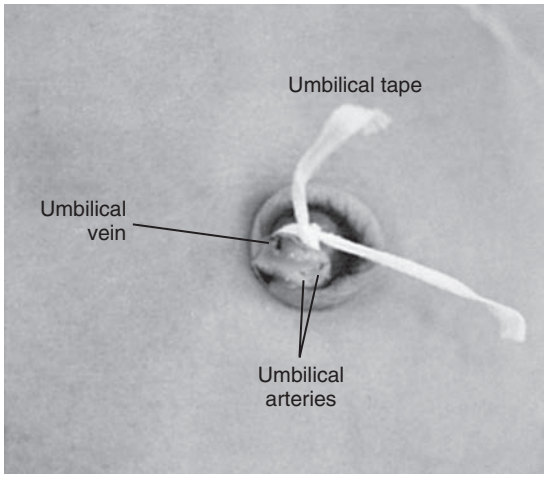

FIGURE 7.6 Umbilical tape and position of umbilical vessels.

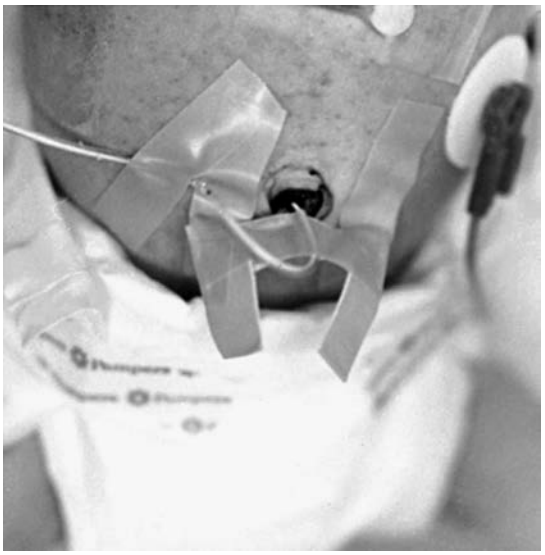

FIGURE 7.7 Umbilical artery catheter secured in "goalpost" design.

TX) and the Umbilical Artery Catheterization Slide-Tape Neonatal Educational Program (Charles R. Drew Postgraduate Medical School, Los Angeles, CA) are helpful. As the catheter passes into the artery, resistance may be encountered at several points, as follows:

- At the umbilical cord tie (tape): The tie (tape) may be tied too tightly. Loosen slightly.
- At the point at which the umbilical artery turns downward (caudal) into the abdomen: Steady, gentle pressure is important because forceful pressure may cause the catheter to perforate the artery wall and create a false channel.
- At the point at which the umbilical artery joins the external iliac artery: Once again, steady, gentle pressure is important.

Insert the catheter to the predetermined length. Aspiration on the syringe should provide immediate blood return. Lack of blood return may indicate the following:

- The catheter is not inserted far enough. Insert farther.
- The vessel wall has been perforated, or a false channel has been created. If the catheter has pierced the vessel wall, repeat the procedure using the other artery.
- The catheter is kinked. Pull back slightly and then advance.
- The stopcock is turned off. Correct the stopcock position. Return aspirated blood to the infant; then clear the catheter with flush solution.

There are several methods to secure the catheter, including suturing to the umbilical stump, use of an adhesive-type tape after using skin prep to protect the skin, use of a "goalpost" (Fig. 7.7), and use of sterile transparent dressing. The literature denotes these methods, but there is no evidence to delineate the most beneficial method. Advantages and disadvantages of each method including skin issues, cost, and ease of use need to be researched.[14]

Connect the stopcock to the intravenous (IV) solution, and set the prescribed infusion rate on the infusion pump. Ensure that no air is in the tubing, stopcock, or catheter. All connections must be secure. Automatic infusion pumps must be used for UACs because arterial pressure must be overcome to permit IV fluid infusion. Determine catheter placement by a radiologic examination (abdominal, chest, "babygram," or ultrasound depending on placement of the catheter). Fig. 7.8 shows how the UAC appears on a lateral x-ray film.

Note that the catheter enters the umbilicus and travels inferiorly before turning superiorly. This "leg loop" is characteristic of an arterial catheter. A UAC follows the aorta and is positioned slightly to the left of the patient's vertebral column. **Optimal placement is below the renal arteries and above the aortic bifurcation (L3 to L4) for a *low catheter* and below the left subclavian artery and above the diaphragm (T7 to T9) for a *high catheter*.[24] High catheter placement has fewer complications.[3]** Fig. 7.9 shows high catheter placement, and Fig. 7.10 shows low catheter placement.

FIGURE 7.8 High catheter demonstrating "leg loop."

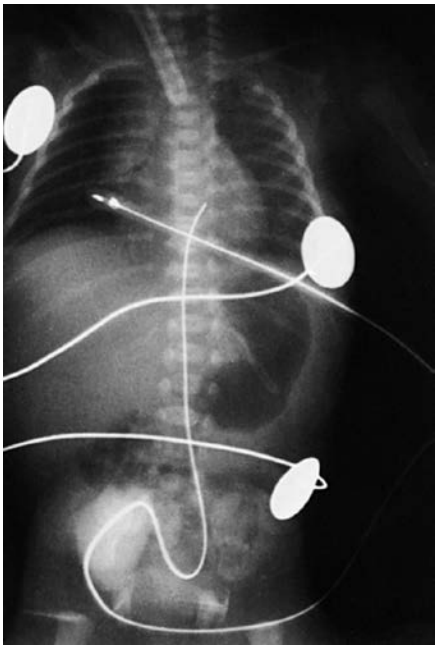

FIGURE 7.9 Umbilical artery catheter in high position (T8).

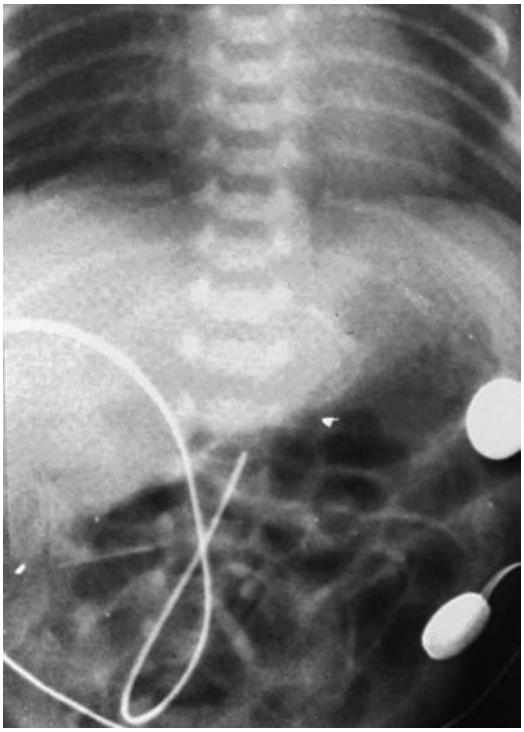

FIGURE 7.10 Umbilical artery catheter in low position (L3).

If the catheter is too high, measure on the x-ray film the distance from the tip of the catheter to the desired level, and pull the catheter back the appropriate distance. Some clinicians multiply this length by 0.8 to account for the magnifying effect of the x-ray film. **If the catheter is placed too low, the catheter cannot be advanced but must be removed and replaced because the external portion of the original catheter is no longer sterile.** Remove the umbilical cord tie (tape), or maintain the tie very loosely so as not to obstruct blood flow to the umbilical area.

As a teaching model, the umbilical cord can be used for teaching the procedure of both arterial and venous catheterization. Many of the steps can be effectively carried out using a fresh placenta. **Special UACs and monitors are available for continuous PaO_2 or oxygen saturation monitoring.**

NURSING CARE AND USE OF UMBILICAL ARTERY CATHETERS

Infants can be positioned on their sides or their backs. The abdominal position may be avoided because accidental slipping, kinking, and removal

of the catheter may occur without being immediately apparent. If the abdominal position is used, the catheter should be monitored continuously; ensure that pressure alarms are on with parameter settings that would rapidly detect pressure changes. **Care needs to be taken so that the infant is positioned to prevent dislodgement of the catheter.** Diapers are effective for preventing the feet and toes from becoming entangled in the catheter. **The diaper is folded below the umbilicus.** If the infant is receiving phototherapy and thus is not diapered, leg restraints or positioning aids may be indicated. A mitten or positioning aids are useful to prevent hands and fingers from contacting the catheter. Positioning the catheter away from the extremities lessens the chance of accidental dislodgement. **Unless using a transparent dressing to secure the UAC, a dressing over the umbilicus is unnecessary. Nontransparent dressings inhibit inspection of the umbilicus and evaluation of the catheter.** The IV tubing, connecting tubing, and stopcock should be changed daily. Clots form in the stopcock, so changing it daily prevents the likelihood of thrombus formation. Blood backing into the catheter can be caused by the following:

- Increased intraabdominal pressure, commonly caused by vigorous infant crying
- Disconnection of tubing or a loose connection
- Stopcock turned in wrong direction
- Infusion pump malfunction
- A leak in the filter or tubing or a crack in the stopcock

PROCEDURE FOR OBTAINING AN ARTERIAL BLOOD GAS SAMPLE

Drawing blood samples from an umbilical catheter is a sterile procedure. Samples may be obtained for blood gas analysis and to obtain laboratory specimens. Necessary items include a syringe for initially aspirating IV fluid and blood from the catheter, a heparinized blood gas syringe (if a blood gas sample is to be obtained), a syringe for aspirating laboratory samples (if laboratory samples are to be obtained), and a syringe containing flush solution.

The reinfusion method of obtaining blood samples is described. This practice involves returning the "discard" blood and, in theory, minimizes patient blood loss.[6] Remove the stopcock cap and place it down so that sterility will be maintained. Attach the empty aspiration syringe to the stopcock. Turn off the stopcock to the IV solution so that the IV solution stops flowing. Aspirate 1 to 2 mL from the catheter into the dry aspiration syringe (Fig. 7.11). The IV fluid is prevented from infusing, and aspiration clears the catheter of IV fluid. Turn the stopcock to the neutral position (Fig. 7.12), remove the syringe while keeping the tip sterile, and replace it with the heparinized blood gas syringe or laboratory sample syringe. The neutral position of the stopcock prevents contaminating the sample with IV fluid and prevents blood loss from the infant.

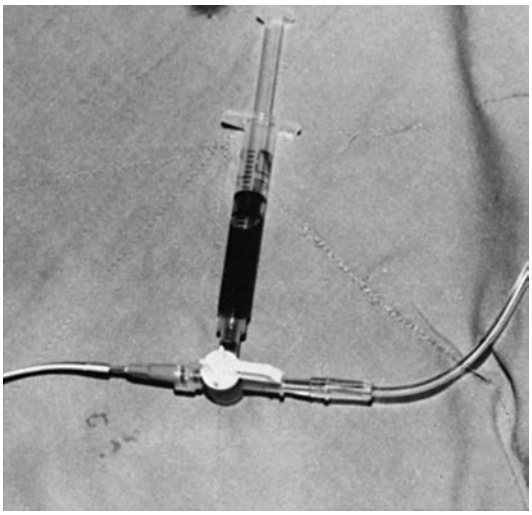

FIGURE 7.11 Stopcock off to IV solution; 1 to 2 mL aspirated into syringe.

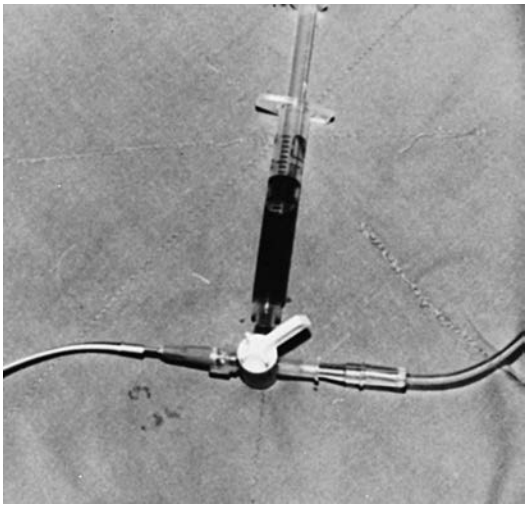

FIGURE 7.12 Stopcock in neutral position.

CAUTION: Never allow blood to drip from an open stopcock. Attach the sample syringe.

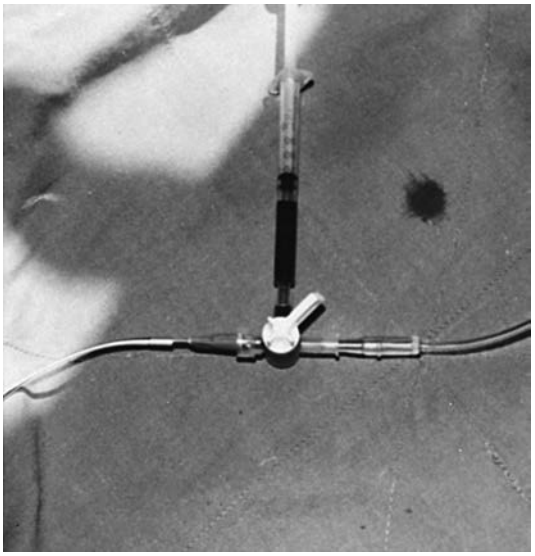

FIGURE 7.13 After blood is aspirated into heparinized 1-mL syringe, stopcock is placed in neutral position before syringe is removed.

Turn the stopcock off to the IV fluid. Using steady, even pressure, aspirate blood into the laboratory or heparinized blood gas sample syringe. Turn the stopcock to the neutral position, and remove the syringe (Fig. 7.13).

For blood gas samples, remove any air from the syringe (because air bubbles in the sample will cause an artificial rise in PaO_2 and a slight fall in $PaCO_2$), cap the end, and chill it to preserve values. Attach the aspiration syringe containing the aspirated blood and IV fluid. Slightly aspirate to remove any air in the stopcock, and then slowly infuse the aspirated blood and IV fluid. Turn the stopcock to the neutral position, and remove the aspiration syringe. Replace the now-empty aspiration syringe that had aspirated blood and IV fluid in it with the syringe filled with flush solution. Turn the stopcock off to the IV fluid. Slightly aspirate to remove any air in the stopcock, and then slowly infuse the flush solution until the catheter is clear. Return the stopcock to the off position, allowing the IV fluid to now infuse. Replace the stopcock cap. Record the amount of blood removed from the infant and the amount of flush solution used to clear the catheter. Newer methods of gradual, automatic aspiration should be considered if available to prevent abrupt changes in arterial or cerebral pressure.

To ensure the integrity of all connections, the stopcock and other connections must be visible at all times. Do not place the stopcock and other connections under linen, because this would hamper the immediate detection of an accidental disconnection that would cause severe blood loss in the infant. Immediately remove any air in the tubing or catheter because air is a potential embolus. It is best removed through the stopcock. If the air has passed the stopcock, it can be aspirated back into a syringe easily.

Obtaining an arterial blood gas specimen from a high UAC is better tolerated in premature infants when the entire procedure is done slowly. Premature and ill term infants have limited cerebral blood flow (CBF) autoregulation. Rapid drops and rises in CBF, especially in the first few days of life, can contribute to neuronal injury and intracranial bleeding. **Rapidly obtaining blood samples from a UAC has detrimental hemodynamic effects on CBF thus, sampling from the UAC should be done slowly.**[6]

Umbilical Vein Catheter Placement

PROCEDURE

Determine the size and length of the catheter to be inserted. A 5-Fr catheter is normally used in the UVC placement procedure. The ELBW infant may require a 3.5-Fr catheter. **To determine the length of the catheter to be inserted, the distance from the umbilicus to the sternal notch should be measured and multiplied by 0.6.** Complete steps for the placement procedure are found in the Umbilical Artery Catheter Placement section earlier in this chapter. The only difference is that the vein is used instead of the artery. The catheter can be advanced to the desired position easily. **The vein is usually gaping open and does not require dilation.** The catheter should lie in the inferior vena cava with the UVC above the diaphragm but below the right atrium of the heart. Catheter position must be ensured. Historically, **position confirmation was by radiologic examination**, using the anteroposterior (AP) and lateral views. **Ultrasonography is rapid and determines correct catheter tip placement** and prevention of complications such as pericardial effusion and tamponade.[18] **UVCs do not have the "leg loop" found on the lateral x-ray film of UACs.** A UVC follows the inferior vena cava and is positioned slightly to the right of the patient's vertebral column. The catheter should be secured in

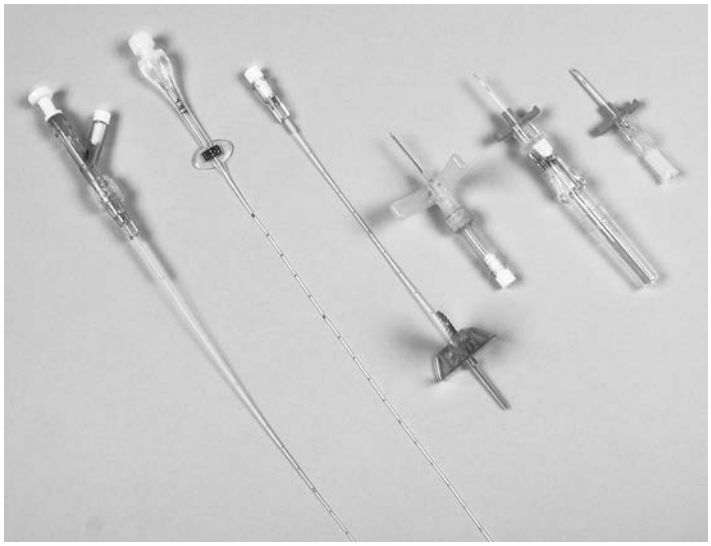

FIGURE 7.14 Peripherally inserted central catheters and introducers. (Courtesy Becton, Dickinson and Company, Franklin Lakes, NJ.)

the same manner as for a UAC. **The nursing care and procedure for drawing blood samples from a UVC are the same as those for a UAC.**

Peripherally Inserted Central Catheter Placement

PICCs are silicone or polyurethane products available in a variety of styles including single catheter and needle introducer to a complete insertion kit with instruments, skin disinfectant, and cap, mask, gown, and gloves. Some products provide a stylet and several feature breakaway (splittable) needle introducers. PICCs are available in a variety of sizes for the neonatal population from 20 gauge (3 Fr) to 28 gauge (1.2 Fr).

PICCs typically are inserted for the following reasons:

- **Infants who require IV access that is expected to be necessary for an extended period**
- **Infants with limited access**
- **As a transition from umbilical catheters for infants weighing less than 1000 g**
- **As a first-line catheter for infants weighing 1000 to 1500 g**
- **Infants with gastrointestinal anomalies, necrotizing enterocolitis, or gastrointestinal diseases that will require surgical correction**

PICCs have long been used to provide highly concentrated parenteral nutrition and hyperosmolar medications.[1,43,52] These catheters are relatively easy to insert, affordable, and low maintenance and preclude surgical placement of central venous catheters. **Due to the extensive dwell time, PICCs significantly reduce or eliminate the need for repeated painful procedures such as peripheral venipunctures, thus improving patient and parent satisfaction.**

PROCEDURE

The insertion sites for PICC lines include the brachial cephalic veins, the axilla, the scalp vessels, and the saphenous veins. This sterile procedure can be performed when the infant is on a radiant warmer or in an incubator. A video demonstrating this procedure is available.[28]

For an arm or hand insertion, measure the distance from the insertion site to the axilla and then to 1 cm above the nipple line. If the catheter is to be inserted in the scalp, measure from the insertion site to 1 cm above the nipple line, and for a leg insertion, measure from the insertion site to 1 cm above the umbilicus or to the level of the inferior vena cava.

Determine the size and length of the catheter to be inserted—PICC and introducer: 20 to 28 gauge, varying lengths 20- to 65-cm catheter (Fig. 7.14). Recommendations to trim lengthy catheters vary with manufacturer. A national survey found that 75% of respondents trim catheters. Devices supplied

by the catheter manufacturer for catheter trimming resulted in a precise cut, whereas scissors produced a ragged cut.[43]

A eutectic mixture of lidocaine and prilocaine (various manufacturers) anesthetic cream or a local anesthetic can be considered before the procedure begins, but these should be used cautiously because of variable absorption rates and the potential for cardiovascular collapse in neonates (see Chapter 12). Place the infant in the supine position on a radiant warmer bed or in an incubator. Ensure continuous temperature monitoring. Skin temperature should remain between 36°C and 37°C (96.8°F and 98.6°F). Provide appropriate oxygenation and ventilation. Ensure cardiorespiratory and oxygen saturation monitoring.

Restrain the infant's hands and feet to prevent him or her from contaminating the sterile field and interfering with the placement procedure, or swaddle the infant, with the site to be used exposed. For hand or arm insertion sites, turning the infant's head toward the insertion site will cause a slight occlusion of the jugular vein so that, as the catheter is passed into the subclavian vein, the risk for the catheter advancing upward into the jugular is diminished.[52]

Don cap and mask. Open the PICC insertion tray; most units now use commercially available disposable trays. PICC insertion tray contents are shown in Fig. 7.15. Open the PICC and introducer (if packaged separately from the PICC insertion tray). Wash hands and dry with sterile towel before the procedure. Put on a sterile gown and gloves. Connect a lipid-compatible T-connector extension tubing to a syringe of flush solution, and fill the entire apparatus.

Grasp the extremity to be used with sterile gauze so that an occlusive dressing can be applied to the distal part of the extremity, thus allowing manipulation of the extremity and precluding contamination of the insertion site by bacteria from distal sites. Cleanse the site with either povidone-iodine or chlorhexidine three times, and allow the site to air-dry. Remove the povidone-iodine with alcohol. For infants weighing less than 1000 g, use sterile water. **Avoid using an excess of skin disinfectant so the infant is not lying in the solution during the procedure. Any residual skin disinfectant should be washed off the infant carefully after the procedure is completed**. Place sterile drapes under the exposed insertion site. Reglove with new sterile gloves. Place the introducer, catheter either with or without stylet (clinician's choice), syringe, and sterile forceps on the sterile field near the planned insertion site. Insert the catheter into the introducer, being cautious if a stylet is used not to let the stylet extend beyond the tip of the introducer.

Insert the introducer tip at a flat angle to access the vein. The introducer is *not* advanced into the vein; it is used only as an introducer. At this point, there will probably be no blood return. Once the introducer is in the vein, pick up the catheter with

FIGURE 7.15 Disposable tray used for PICC insertion. (Courtesy Becton, Dickinson and Company, Franklin Lakes, NJ.)

the sterile forceps and gently advance the catheter to the premeasured length. Blood should fill the catheter. If the catheter is not advancing, pull the catheter back beyond the point of the introducer and reattempt to cannulate the vein. Once the catheter is advanced to the premeasured length, remove the stylet if used, and attach an empty sterile syringe. If a breakaway cannula is used, gently retract the cannula and slowly peel it apart to prevent premature breakage. Blood should be aspirated easily with a syringe. Flush the catheter with 0.5 to 1 mL of flush solution. Secure the catheter using sterile tape or nonfiber adhesive strips at the insertion site. Wrap extra catheter material into a coil above or below the joint to prevent occlusion. Attach the lipid-compatible T-connector extension set, and secure it to the extremity. Dress the insertion site, extra catheter loops, and PICC catheter to the T-connector area with a sterile, transparent occlusive dressing. Ensure that the dressing does not completely encircle the extremity causing a tourniquet effect. Label the dressing with the gauge and length of the catheter, the line type (PICC), and the initials of the insertion person.

Catheter position must be ensured by anteroposterior and lateral x-ray films, ultrasonography, or echocardiography.[16] **For PICC lines inserted in the upper extremities, axillae, or scalp vessels, the catheter should lie in the superior vena cava above the right atrium of the heart. Catheters placed in other vessels have a significantly higher rate of thrombus formation and infection.** An increase in PICC line infections is directly related to increased frequency of venipunctures, especially when no concurrent antibiotics are being used.[12] For **PICC lines inserted in the lower extremities, the catheter should lie in the inferior vena cava below the right atrium of the heart.** Catheter placement in the right atrium can lead to complications of dysrhythmias, pleural effusion, and perforation with cardiac tamponade.[52]

NURSING CARE OF PICCS

Infants should be positioned to prevent dislodgement or kinking of the catheter. Diapers are effective for preventing the feet and toes from becoming entangled in the IV tubing. If the infant is receiving phototherapy and thus is not diapered, leg restraints or positioning aids may be indicated. A mitten or positioning aids are useful to prevent hands and fingers from contacting the catheter dressing and IV tubing. Positioning the catheter away from the extremities lessens the chance of accidental dislodgement. The IV tubing should be changed according to the standard of care. **Observe for disconnection of tubing or a loose connection, and ensure an intact and occlusive insertion site dressing.**

The occlusive dressing should be changed only when the integrity of the dressing has been lost. A small amount of blood at the insertion site is not a reason to change the occlusive dressing. **Maintaining integrity of the occlusive dressing is instrumental in decreasing the risk for infection.**

Changing the current dressing is indicated when it is no longer occlusive. The occlusive dressing is changed under sterile conditions. The person performing the dressing change dons a cap, mask, and sterile gloves. Changing the dressing entails removing the transparent film covering the area, cleaning the insertion site with either povidone-iodine solution or chlorhexidine, allowing this to dry, and then cleaning the site with sterile water to remove the preparation agent from the skin. If the nonfiber adhesive tape or strips are no longer adhesive, they are replaced. Dress the insertion site, extra catheter loops, and PICC catheter to the T-connector area with a sterile, transparent occlusive dressing. Ensure that the dressing does not completely encircle the extremity causing a tourniquet effect. Label the dressing with the gauge and length of the catheter, the line type (PICC), and the initials of the insertion person.

Because of the small gauge, PICCs are not routinely used for blood sampling. Clotting of the catheter may rapidly occur. Because the IV tubing does not contain a stopcock, significant blood loss and introduction of air into the venous circulation can occur.

Peripherally Inserted Midline Catheter

In infants not requiring or unable to receive a central catheter (vena cava placement) yet still needing IV access for a few days such as for antibiotic therapy, a peripherally inserted midline catheter (PIMC) can be used. PIMCs are inserted to the midclavicular line. These products are similar to PICCs and are available as a single needle introducer and catheter or as a complete kit.

Removing Umbilical Artery, Vein, and Peripherally Inserted Central Catheters

When the UAC, UVC, or PICC is no longer needed, it is removed. For UAC catheter removal, make certain the cord tie is snug. Sterile gauze is needed, and a suture removal kit should be available if the catheter was sutured in place. Turn off the stopcock to the patient and the IV fluid. Withdraw the catheter to 3 cm, and leave it in place for 30 minutes before withdrawing it completely. This procedure works well for infants with respiratory or abdominal issues because it avoids the application of external pressure to the abdomen. Alternatively, withdraw the catheter slowly over several minutes, allowing for the artery to spasm. Pinch the umbilical stump with the sterile gauze for 5 minutes until hemostasis is achieved. Observe the umbilicus for active bleeding or oozing. Observe the lower extremities and buttocks for diminished perfusion secondary to a thrombus or embolus.

The procedure is similar for UVCs, with the exception that the catheter can be slowly withdrawn in one step. Pinch the umbilical stump with the sterile gauze for 5 minutes until hemostasis is achieved. Observe the umbilicus for active bleeding or oozing. Observe the patient for respiratory distress secondary to a pulmonary embolus.

For PICC removal, clamp the catheter, turn off the IV fluid infusion, and withdraw the catheter slowly and steadily. Apply pressure over the insertion site with the sterile gauze for 5 minutes until hemostasis is achieved. Observe the insertion site for active bleeding or oozing. Ensure that the entire catheter was removed.

Oxygen Saturation Monitoring by Pulse Oximetry

Oxygen saturation monitoring by *pulse oximetry* involves placing a small sensor on the infant in such a manner that his or her finger, toe, foot, or wrist comes between the light source and the photoreceptor. The light source emits wavelengths of light in the red and infrared spectrums. The difference between the absorption of the light is picked up by the receptor that is placed directly opposite the light source. **The calculation of the ratio of oxyhemoglobin and deoxyhemoglobin is displayed as the percent of oxygen saturation.** Key to accuracy of the monitor is that the light source and the receptor must be directly opposite each other over an area in which a pulse can be detected.

Oxygen saturation monitoring provides continuous and instantaneous readout of the oxygen saturation in the infant. In comparison with a blood gas analyzer, which calculates the relative oxygen saturation based on established nomograms, **the oxygen saturation monitor measures the actual saturation of the hemoglobin.** Calculated values using standard nomograms do not reflect shifts in the affinity of oxygen for hemoglobin based on changes in the patient's temperature, pH, PCO_2, or 2,3-DPG.

An inorganic phosphate produced in red cells; 2,3-DPG binds to the beta chain of reduced hemoglobin (Hb), lowering Hb's affinity for O_2 and by extension, facilitating O_2 release to tissues, causing a "right shift" of the O_2 dissociation curve. 2,3-DPG further shifts the curve to the right by lowering the red cells' pH. When transfused, red cells regain 50% of the 2,3-DPG within 3 to 8 hours and 100% within 24 hours.

The oxygen saturation monitor relies on adequate perfusion to the site and the ability to detect arterial pulsations; thus, if it is placed distal to a blood pressure cuff, the reading will be inaccurate while the cuff is inflated. Newer models of pulse oximetry reduce the artifact that results from motion and low perfusion. These newer models also are indifferent to ambient light, whereas older models were affected by light sources such as phototherapy. Newer neonatal probes have built-in external light source protectors. **Pigmentation of the patient's skin may produce artificially high readings, especially at lower oxygen levels.[37] However, a recent comparison of two commonly used pulse oximeters found no significant difference in systematic bias based on skin pigment (comparing darker to lighter pigmentation in infants with hypoxemia) with either oximeter.[16]**

Oxygen saturation is more indicative of the total oxygen content of the blood than is PaO_2 and is the most sensitive to hypoxemia when it is on the steep part of the oxygen dissociation curve (see Fig. 7.1). **Keeping the SaO_2 at 90% to 92% keeps the infant in a normoxemic state under most conditions.** Oxygen saturation monitoring by pulse oximetry generally is considered reliable and practical for use in infants over a wide range of birth

weights and postnatal ages.[2] *Pulse oximetry saturation (SpO_2)* **values vary significantly from measured arterial tension values obtained with an arterial blood gas specimen.**[37] A contributing factor may be that the calibration of pulse oximeters typically has been performed on healthy adults. A compelling argument for the use of both *pulse oximetry* and *transcutaneous oxygen monitoring* in critically ill infants can be made because each monitor has its own shortcomings.

Pulse oximetry monitoring is common in neonatal care. Many infants in NICUs require prolonged monitoring, and a long-lasting oximeter probe could offer a substantial cost savings. **No complications are associated with the use of oxygen saturation monitoring other than the potential for skin trauma caused by adhesive on the probe.** Newer probes held in position by gentle elastic pressure have no adhesive touching the infant's skin.

In the asymptomatic newly born infant, the incidence of congenital heart anomalies is approximately 1% to 2% of live births, with one-fourth of these having critical congenital heart defects (CCHDs). CCHD lesions are ductal dependent or require cardiac catheterization or surgery before 1 year of age, with most requiring intervention within the first month. If not detected early, organ hypoperfusion and hypoxemia occur as the infant continues to transition to adult circulation. **Detection of CCHDs before discharge allows medical and surgical interventions that may be lifesaving.** Multiple organizations in the United States[10,24] and globally[25,41,42] have recommended routine screening of all infants after 24 hours of life and before discharge. In 2011, the U.S. Department of Health and Human Services (USDHHS) added screening for CCHDs to the Recommended Uniform Screening Panel.[48] The American Academy of Pediatrics endorsed the USDHHS recommendation.[23] Refer to a full discussion in Chapter 31.

Noninvasive Oxygen–Carbon Dioxide Monitoring

END-TIDAL CARBON DIOXIDE MONITORING

End-tidal CO_2 monitors use either sidestream or mainstream analysis. For sidestream analysis, the endotracheal tube has a second narrow lumen that opens at the end of the endotracheal tube. Gases are analyzed from samples taken from the end of the tube. **The advantages of this system are that there is no increased dead space in the ventilator circuit and less chance of inspiratory gases contaminating the sample.** The disadvantage to this method is that secretions may pool at the tip of the endotracheal tube and occlude the sampling port. The response time to changes in carbon dioxide content is slower than when mainstream analysis is used.

Mainstream analysis of carbon dioxide samples gases in the ventilator circuit. These gases are thought to be reflective of gases at the tip of the endotracheal tube. **This method requires a separate chamber attached to the end of the endotracheal tube adapter, thus adding increased dead space and additional weight at the endotracheal tube adapter.**

A comparison of sidestream and mainstream analyses of end-tidal CO_2 found that distal values were higher than proximal values and that distal values correlated more closely with $PaCO_2$ values.[47] This discrepancy was thought to result from the mixing of end-tidal gases with fresh gases in the ventilator circuit. **In an infant with a large alveolar-arterial (A-a) gradient, $PetCO_2$ monitoring cannot be relied on for accuracy. In premature infants, it may be useful if the lung disease is mild to moderate; in infants with normal lung function, this method is reliable.**[45]

The waveform output of the end-tidal CO_2 monitor can be used clinically if the clinician understands how the waveform corresponds to the exchange of gases in the lung (see Fig. 7.2). **The waveform has a sharp rise on expiration that reflects the carbon dioxide content of various lung areas. This expiration is followed by a plateau that reflects the cessation of dead space gases and the measurement of alveolar gas. At the end of the plateau is a sharp drop that reflects the inspiration of fresh gases with minimal carbon dioxide content.** When using the monitor, the clinician should recognize that a sharp rise indicates compromised exhalation, such as in reactive airway disease. **Partially plugged and dislodged endotracheal tubes will change the angle of rise on the capnogram.** The plateau phase of the capnogram can be altered by severe hypotension or decreased cardiac output secondary to an altered minute ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch (as in pulmonary embolus, cardiac arrest,

persistent pulmonary hypertension, atelectasis). **No waveform or failure of the waveform to change indicates ineffective respiration (dislodged endotracheal tube).**

TRANSCUTANEOUS OXYGEN–CARBON DIOXIDE MONITORING

Skin oxygen tension ($TcPO_2$) and carbon dioxide tension ($TcPCO_2$) are measured by using one or two electrodes, depending on the model and brand of the monitor. The electrodes, once positioned on the skin, heat the area under the probe and cause certain physiologic changes as discussed. **Oxygen and carbon dioxide that diffuse through the heated skin are measured by the electrode, and the value is digitally displayed on the monitor. If intervals between calibration are longer than 4 hours, the readings are subject to drift.** The calibration procedures vary with the instruments used. Inherent in the calibration process is the necessity to change the position of the skin electrode on the infant. **Better correlations are found when the instrument is calibrated every 4 hours, the temperature is set correctly, and the infant is well perfused and normothermic. If the temperature of the probe cannot be maintained at 43°C to 44°C (109.4°F to 111.2°F), a lower temperature should be selected to avoid possible burns.** At a lower temperature, the $TcPO_2$ monitor can be used to monitor trends but should not be interpreted as actual PaO_2 values. The range of accuracy of $TcPO_2$ monitors is limited; hypoxia (less than 40 mm Hg) and hyperoxia (greater than 120 mm Hg) may not be accurately reflected.

In an infant with suspected significant right-to-left shunting through a patent ductus arteriosus such as in persistent pulmonary hypertension, two transcutaneous oxygen electrodes can be used: one preductally (right shoulder) and the other postductally (lower abdomen or legs). Significant right-to-left shunting through the patent ductus arteriosus is present when the preductal oxygen tension is significantly higher than the postductal oxygen tension.

The disadvantages of the use of transcutaneous monitoring are that the instrument requires frequent calibration; requires the use of a heated electrode, which may burn the skin, especially in low-birth-weight (LBW) infants; requires a 15-minute period after calibration to heat the skin to the correct temperature; and has a 15- to 20-second delay in the readings compared with the patient's real-time values. The advantages are that it is not invasive, does not require the removal of blood for analysis, and displays a continuous readout of skin oxygen–carbon dioxide tensions.

NURSING CARE OF INFANTS WITH NONINVASIVE TRANSCUTANEOUS OXYGEN AND CARBON DIOXIDE MONITORS

The electrode can be placed on any portion of the infant's body as long as good contact between the electrode and the skin is maintained. Uneven areas of skin such as over bones and joints should be avoided because of poor contact between the membrane and the skin surface. The infant should not lie on the electrode. Placing the infant on top of the electrode increases the pressure on the underlying capillaries, thus affecting the flow of blood under the probe and resulting in a drop in $TcPO_2$ values. **Because of the heat generated by the electrode (43°C to 44°C [109.4°F to 111.2°F]), small red areas resembling first-degree burns are produced on the infant's skin. To minimize trauma to the infant's skin, the electrode should be repositioned every 2 to 4 hours, depending on his or her skin sensitivity.** Grouping of nursing interventions has resulted in minimizing the time that the infant receives less-than-optimal oxygenation.

Cardiorespiratory Monitoring

The chest leads are applied in a triangular pattern on the infant's chest. Integrity of the leads must be ensured. Allowing the contact gel to dry or inadvertently dislodging the lead during procedures such as x-ray examination, echocardiography, and lumbar puncture may account for inaccurate tracings. Various components of the electrocardiogram (ECG) pattern may be diagnostically helpful. The QRS complex should be monitored for baseline height and width. **A sudden decrease in QRS complex height that is not caused by artifact may be an indication of pneumothorax.** The QT interval is helpful in diagnosing hypocalcemia in some infants. Other portions of the strip may be evaluated for electrolyte imbalance and possible cardiac ischemia. Hyperkalemia can induce arrhythmias, including heart block, ventricular tachycardia and fibrillation, and asystole. Initially the ECG will

show peaked T waves with a narrow base. As the potassium level rises, the P dampens, the PR interval increases, and the QRS widens. Further increases in the potassium value lead to absent P waves, QRS merging with the T wave to form a sine wave, followed by fibrillation, and then asystole.[27]

Humans display variability in vital signs because of the constant adjustments by the sympathetic and parasympathetic nervous systems. Vital sign variability in the healthy infant is maintained near a baseline value. When stressful events such as late-onset sepsis, intraventricular hemorrhage, or severe chronic lung disease are present, there is a corresponding change in vital signs and diminution in variability. Infants developing late-onset infection may exhibit subtle, nonspecific signs in advance of a clinical diagnosis. To aid in detecting heart rate changes that may indicate developing infection, some NICUs now use the HeRO system (Medical Predictive Sciences, Charlottesville, VA). Heart rate changes over a 5-day period are tracked allowing health care personnel to follow patient trends. **Loss of beat-to-beat variability and rising heart rate warrant investigation.** As with any instrument, use of this device requires patient assessment and judgment.[19]

Blood Pressure Monitoring

Arterial pressure monitoring may be accomplished via the UAC attached to a transducer and monitor. Central venous pressure monitoring may be carried out in the same manner using the UVC. The same type of transducer may be used for either arterial or venous pressure recording.

Some research has indicated that the predictive value of peripheral blood pressure screening for CCHD is small and that oscillator blood pressure measurements are less accurate than pulse oximetry screening to detect CCHD.[5] This failure to detect CCHD is more pronounced in aortic arch obstructive defects.

Point-of-Care Testing

The Centers for Medicare and Medicaid Services regulates POCT through the Clinical Laboratory Improvement Act (CLIA).[9] **Federal regulations require initial education about POCT procedures, as well as annual reassessment of competency.** The quality of these tests is imperative to ensure proper diagnosis and treatment, and the CLIA regulations strive to ensure quality testing.

The accuracy of whole blood glucometers compared with laboratory values may vary depending on hypoxia, hematocrit, and elevated triglyceride values. Accuracy also depends on the product that is being measured, because some glucometers measure glucose only, whereas others measure total sugars, including glucose, galactose, maltose, and xylose. In addition, the clinician must remember that an **approximately 11% difference exists between plasma glucose (laboratory sample) and whole-blood glucose (POCT device). The POCT value should be multiplied by 1.11 to determine a more approximate plasma value.**[13] A variance of accuracy also exists with bedside electrolyte assessment devices. Transcutaneous neonatal bilirubin assessments require correlation between the serum bilirubin value and each device, institution, and patient population for which it is used.[11] As neonatal care advances, rapid availability of patient information will become more and more crucial. Expect continuous expansion of POCT.

Event Monitoring

The advancement of physiologic monitors with memory capability has enhanced the ability of the practitioner to **review the physiologic status of the infant as measured by multiple physiologic parameters for the past 24 to 48 hours**. In many NICUs, the monitor output is integrated into the electronic or computerized chart. This integration allows the care provider to retrieve the data from the monitors into the chart at preselected times, either prospectively or retrospectively. **When the monitors are programmed with critical value ranges, any deviation outside these ranges is noted as an event, which can then be reviewed, tallied, or otherwise annotated.** For care providers at the bedside, the challenge is to keep iatrogenic events (e.g., lead removal, excessive activity of the infant, a stopcock turned the wrong direction) minimized such that the infant's record is as valid a reflection of actual physiologic status as possible. Any circumstances noted at the time of the event that may produce false readings should be recorded so that when the infant's record is reviewed, these events can be placed in context of the circumstances at the time.

BOX 7.1 CRITICAL FINDINGS
COMPLICATIONS OF INDWELLING CATHETERS

- Umbilical artery catheters
  - Ischemia from thrombi, emboli, or arterial spasms
  - Hemorrhage caused by catheter dislodgement or loose connections
  - Infection
  - Malposition
- Umbilical vein catheters
  - Thrombus formation leading to pulmonary embolization
  - Thrombus formation in portal vessels
  - Hepatic necrosis
  - Intestinal ischemia
  - Hemorrhage caused by catheter dislodgement or loose connections
  - Cardiac complications: dysrhythmias, myocardial perforation, pericardial effusion
  - Infection
- Peripherally inserted central catheter lines
  - Occlusion
  - Clotting
  - Infection
  - Malposition
  - Cardiac complications: dysrhythmias, myocardial perforation, pericardial effusion
  - Breakage and leaking
  - Phlebitis
  - Peripheral edema
  - Vascular erosion into the pleural space[4]

COMPLICATIONS

UACs act as foreign bodies, causing fibrin deposition and thrombus formation around the catheter. Although most catheters are associated with thrombus formation, it is of clinical significance in less than 10% of patients (Box 7.1). **A common problem associated with major complications of UACs is ischemic disease resulting from emboli or arterial spasms. In such cases, the catheter should be removed immediately and antithrombin therapy should be considered.** Although vasospasm is common, usually it does not require immediate removal of the catheter. **Blue discoloration, commonly called "catheter toes," is seen, rather than blanching.** Obviously, **a hemorrhage may occur when the catheter slips out or when any of the various connections loosen.** For reasons such as these, **UACs require constant attention.** If the **lower extremities or buttocks blanch, the catheter should be removed immediately and antithrombin therapy considered.** The benefit of antithrombin therapy must be balanced against the increased risk for intracranial hemorrhage.

To prevent bleeding once the catheter is removed, immediately pinch the subumbilical area with sterile gauze for 5 minutes until hemostasis is achieved. **Avoid downward abdominal pressure that may compromise respiratory effort.** When the color has returned to the affected area and the infant is stable, replacement of the catheter can be considered. **If vasospasm occurs in one leg or foot, apply warm wraps (diapers wetted with warm water or chemical heel warmers) to the opposite leg, or apply wraps to the upper extremities, thereby producing a reflex vasodilation to the legs. However, inherent in this action is the hazard of obscuring recognition of compromise in that extremity. The wraps should be reheated every 10 to 15 minutes until the spasm has resolved. The skin temperature of the infant must be greater than 36°C (96.8°F) for wraps to be effective.**

UVCs may cause thrombus formation. Thrombi can result in pulmonary embolisms. Clots may form in the portal vessels, resulting in portal hypertension. Hepatic necrosis, gut ischemia, and hemorrhage have been associated with UVCs. Other complications include dysrhythmias, myocardial perforation, pericardial effusion, and endocarditis.

PICCs that are placed in central veins have complication rates lower than those placed in noncentral veins.[51] Complications include occlusion, clotting, infection, sepsis, phlebitis, leakage, extravasation, peripheral edema, malposition, catheter migration, cardiac tamponade, and catheter breakage.[52] **Bacteremia, always a major concern, will require the removal of the catheter if the blood culture remains positive for more than 24 hours. To prevent central line–associated bloodstream infection (CLABSI), establishment of and strict adherence to a care bundle is beneficial.[8]** Bundle items for insertion include a procedure cart with sterile perimeter,

skin disinfection, and strict sterile technique. Maintenance items include handwashing, use of gloves, attention to PICC access and fluid tubing changes, and daily CLABSI surveillance. Refer to a full discussion in Chapter 16. Occlusion sometimes may be treated with clot-dissolving agents. Establishment of a PICC team to insert and manage these devices, catheter tip placement in the superior or inferior vena cava, and heparinized solutions have been shown to reduce complications. In an emergent situation, evaluate catheter tip placement before administering medications or fluid boluses in case of catheter malposition and cardiac tamponade.

CONTROVERSIES

Clinicians continue to disagree on the optimal placement site for UACs. However, a Cochrane review and subsequent update determined that **high UACs resulted in fewer vascular complications than did low UACs and recommended the exclusive use of high placement for UACs.**[3] Prophylactic administration of antibiotic agents is not indicated.[33] Use of the UAC for infusion of antibiotic agents, calcium, hyperalimentation solutions, or blood varies, and no definitive studies are available. Blood cultures can be drawn from the UAC for up to 6 hours after insertion. The use of heparin in the infusate has been controversial because heparin decreases catheter occlusion but not thrombosis.[34] In addition, heparin use in a flush solution alone is not beneficial in preventing catheter occlusion.

Enteral feeding with an umbilical line in place lacks definitive studies; however, this practice is more common than was previously thought. A *Cochrane* review found that trophic enteral feedings were not detrimental.[30] Select NICUs provided trophic and more substantial enteral feedings with umbilical catheters in place.[21]

Routine monitoring of all infants receiving intermediate or intensive care is the standard of care. Indwelling catheters for blood pressure monitoring have the advantage of continuous readout, but external cuffs are less invasive. There is a continued need for research into the efficacy and safety of umbilical catheters. Box 7.2 cites new research into future possibilities for neonatal physiologic monitoring.

BOX 7.2 WHAT'S NEXT IN PHYSIOLOGIC MONITORING?

1. Intelligent monitoring systems. Rather than signal when a single parameter exceeds a preset threshold, these monitors would integrate multiple data, including patient medications and laboratory results, to provide a more complete view of the patient's status.[2]
2. Telemedicine has demonstrated success in examining and diagnosing retinopathy of prematurity and genetic and neurologic abnormalities.[51] It will now evolve to allow a remote neonatal intensive care unit model where a neonatologist can simultaneously monitor multiple infants continuously—visually and by the integration of multiple data. Virtual rounds as needed, as well as care direction, can occur.[47,50]
3. Telemedicine to provide follow-up care of newborns discharged from NICU, resulting in a decreased need for hospital visits.[37]
4. Use of nasogastric tubes to monitor intraabdominal pressure of VLBW preterm infants (<1500 g) to evaluate for feeding intolerance.[7]
5. Electrode-free, noninvasive wireless vital signs monitoring systems.[32,44]
6. Artificial womb for preterm infants <26 weeks of gestation.[15,35,49]

BOX 7.3 PARENT/CAREGIVER TEACHING PHYSIOLOGIC MONITORING

Physiologic Monitoring

1. Placement of umbilical lines is invasive. Educate parents about the following:
   - Placement is painless because the umbilical cord contains no nerves.
   - The point of catheter insertion and where the tip of the catheter is located.
   - The umbilical catheter can be used for numerous functions: administering IV fluid, medications, and blood products; monitoring; and obtaining laboratory specimens.
   - Care should be taken when holding or manipulating the infant to prevent catheter dislodgement and blood loss.
   - Holding the infant out of the incubator and wrapped in blankets obscures visualization of the catheter and connections.
2. The NICU environment can be frightening. Educate parents about the following:
   - The baby is being monitored by various methods, including cardiorespiratory, blood pressure, and transcutaneous monitors.
   - The purpose and a short description of each monitor.

PARENT TEACHING

Important elements of parent teaching are listed in Box 7.3. As with the many other invasive procedures in neonatology, the clinician obtains

permission from the parents for umbilical vessel catheterization and PICC placement. This may be the clinician's first contact with the family and thus sets the atmosphere for future contacts. Although parents initially are hesitant about umbilical catheter placement, generally they are comforted to learn that it will result in a painless way of drawing blood; there are no nerves in the umbilical cord to sense pain. Parents also appreciate that PICC placement will reduce the number of peripheral IV attempts. **Before parents visit the infant, providers need to inform parents about the technology that is being used to monitor the infant** (i.e., umbilical catheter, transcutaneous monitors, cardiorespiratory monitors, blood pressure monitors), including what the technology is registering. Often parents are confused about where the catheter goes once it enters the umbilicus and the purposes of other monitoring devices.

Parents need to be instructed on how to hold their infant while an umbilical catheter or PICC is in place because manipulating the infant may accidentally dislodge the catheter and result in blood loss and potential infection. When the infant is being held out of the incubator and wrapped in blankets, the integrity of the catheter and connections is not easily evaluated. The parents' vigilance around the technology used on their infant can potentially avoid these incidents.

8 ACID-BASE HOMEOSTASIS AND OXYGENATION

JAMES S. BARRY, JANE DEACON, CARMEN HERNANDEZ, AND M. DOUGLAS JONES, JR.

Accurate interpretation of blood gas values and an understanding of acid-base and oxygenation physiology are essential to the proper diagnosis or management of an ill neonate.[9,33,53] The measurement of arterial blood gases allows an analysis of two interrelated but separate processes: acid-base homeostasis and oxygen-carrying capacity.[1,32,44] This chapter considers the parameters that describe these processes, their measurements, and the effects of proposed treatment on homeostasis.[1,53] Common abbreviations and their meanings are listed in Box 8.1.

Components of arterial blood gases include (1) measured values (Pao_2, $Paco_2$, and pH) and (2) calculated values (oxygen saturation, bicarbonate concentration, and base excess). Some analyzer systems also estimate hemoglobin concentration. **The pH, $Paco_2$, base excess, and bicarbonate components are used to assess acid-base homeostasis,[32,44,56] whereas Pao_2, saturation (Sao_2), and hemoglobin concentration[1,9] are used to assess the adequacy of oxygen-carrying capacity** (Table 8.1).

PHYSIOLOGY

Acid-Base Homeostasis

To review basic chemistry, an acid is a hydrogen ion donor, and a base is a hydrogen ion acceptor. The pH refers to the concentration of hydrogen ions [H^+] in a liquid and reflects the acid-base balance in liquid.[56] The quantity of hydrogen ions is minute, approximately 0.0000001 mole/L. Therefore, the negative log of the hydrogen ion concentration is used to define pH and create a positive, workable number (pH = 7) (Equation 1). **A pH of 7 represents a neutral solution, a pH of less than 7 represents acidity, and a pH of greater than 7 represents alkalinity:**

$$\begin{aligned} pH &= -\log [H^+] \\ pH &= -\log [0.0000001] \\ pH &= -[-7] \\ pH &= 7 \end{aligned} \qquad (1)$$

The Henderson-Hasselbalch equation describes pH as equal to a constant (pK) plus the logarithm of the ratio of the base-to-acid concentration (Equation 2).[10,36] Thus, if there is an increase in the concentration of hydrogen ions (reflected in the denominator), the blood pH value decreases, and acidemia results. Conversely, if there is less acid or more base, the blood pH increases, and alkalemia results.[10]

$$pH = pK + \log \left({}^{base}/_{acid} \right) \qquad (2)$$

The first step in determining acid-base homeostasis is the measurement of pH. The normal human pH is between 7.35 and 7.45. *Acidemia* and *acidosis* are often used interchangeably, but strictly speaking, a pH of less than 7.35 is acidemia, and the process that caused it is acidosis; a pH of greater than 7.45 is alkalemia, and the process that caused it is alkalosis.[33] **Arterial carbon dioxide ($Paco_2$) and bicarbonate [HCO_3^-] values represent the two main components of acid-base homeostasis: (1) the respiratory contribution ($Paco_2$) controlled by alveolar ventilation[1,17,20] and (2) the nonrespiratory or metabolic contribution controlled primarily by renal excretion, retention, or production of HCO_3^-.[1,30,50]** Other factors that affect the nonrespiratory components of acid-base

BLUE type highlights content that is particularly applicable to clinical settings.

BOX 8.1 ABBREVIATIONS

A	Alveolar
a	Arterial
D	Difference
F	Fraction
I	Inhalation, inspired
P	Partial pressure (tension, driving force)
pH	Negative log of hydrogen ion concentration

Combined Abbreviations

Pao_2	Partial pressure of arterial oxygen
Fio_2	Fraction of inspired oxygen
Pio_2	Partial pressure of inspired oxygen
P_{50}	Partial pressure at which hemoglobin is 50% saturated

balance cause a change in $[HCO_3^-]$; thus, $[HCO_3^-]$ is an indicator of the nonrespiratory component.[30,35,50]

RESPIRATORY CONTRIBUTION

Carbon dioxide is produced from cellular metabolism.[1,46] As carbon dioxide is produced, it dissolves in intracellular fluid and can be measured as the partial pressure (P) of the dissolved gas (CO_2). As the pressure of the dissolved gas increases inside the cell, carbon dioxide moves out of the cell and into the blood. Blood transports dissolved carbon dioxide (some combined with hemoglobin as carboxyhemoglobin, most as bicarbonate) to the lung, where the partial pressure in the pulmonary capillary is greater than that in the alveoli,[43] causing carbon dioxide to move into the alveoli down a concentration gradient. **Ventilation is the only method of removing carbon dioxide. The amount of carbon dioxide in the blood is the net result of the body's metabolism (production) and alveolar ventilation (clearance).** Because metabolism does not change greatly and CO_2 diffuses easily across membranes, the only clinically important limitation to CO_2 removal is at the lungs. **Thus, $Paco_2$ reflects alveolar ventilation.**[10,17,20,33]

In the red blood cell, the enzyme *carbonic anhydrase* promotes the combination of a fraction of dissolved CO_2 with water to form carbonic acid (H_2CO_3), which then dissociates into a hydrogen ion $[H^+]$ and a bicarbonate ion $[HCO_3^-]$[1,46]

$$CO_2 + H_2O = H_2CO_3 = [H^+] + [HCO_3^-] \quad (3)$$

TABLE 8.1 NORMAL (ARTERIAL) BLOOD GAS VALUES

BLOOD GASES	VALUES
pH	7.35–7.45
$Paco_2$	35-45 mm Hg
HCO_3^-	18-26 mEq/L
Base excess	(–5) to (+5)
Pao_2	60–80 mm Hg
O_2 saturation	92%–94%

Therefore, an increase in $Paco_2$ (hypoventilation) causes pH to fall. This is called *respiratory acidosis*.[17] **A decrease in $Paco_2$ (hyperventilation) results in less acid formation in the blood and causes pH to rise. This pathophysiologic process is known as *respiratory alkalosis*.**

NONRESPIRATORY (METABOLIC) CONTRIBUTION

Nonrespiratory (metabolic) derangements can also disturb acid-base homeostasis. Normal metabolism produces hydrogen ions. **Blood pH is maintained within normal limits by renal mechanisms for excreting hydrogen ions. Increased production of $[H^+]$ may occur in conditions such as shock with poor peripheral tissue perfusion or genetically determined aberrations of metabolism.**[52] The hydrogen ions produced must be eliminated to avoid a fall in blood pH. Derangements also occur when hydrogen ions are lost (e.g., in gastric fluids) or when bicarbonate is lost (e.g., in diarrheal fluid or ileostomy drainage).[53]

Authorities differ as to the best way to describe nonrespiratory derangements in acid-base status. The traditional approach relies on the measurement of pH, Pco_2, and $[HCO_3^-]$. An alternative description is of acid-base status in terms of (1) strong ions (Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-), strong because they remain dissociated at normal human blood pH, and (2) weak acids (hemoglobin, albumin, inorganic phosphate), weak because they are partially dissociated at the normal human blood pH. Blood pH in this conceptualization is a function of the difference between strong cations and strong anions, the strong ion difference (SID). As an example, the alkalosis associated

with the loss of gastric fluid would be described exclusively in terms of the loss of [Cl^-], with the loss of [H^+] making no independent contribution to the resulting alkalemia. Advocates maintain that the measurement of SID leads to a greater understanding of the causes of nonrespiratory and mixed acid-base derangements.[16,24,29,46] Others favor staying with the traditional bicarbonate-centered model.[15,34] The present discussion focuses on the traditional bicarbonate-centered approach. Readers are referred to recent reviews for comparisons of the two methods.[29,34]

A fall in blood [HCO_3^-] might indicate that bicarbonate, a base and therefore a hydrogen ion acceptor, has been used up by the addition of [H^+]. As shown in Equation 3, a change in [HCO_3^-] might also reflect a change in Pco_2. This difficulty is overcome in blood gas analyzers by correcting the Pco_2 (graphically) to 40 mm Hg, yielding a "standard bicarbonate" concentration.[46] The standard bicarbonate concentration and the buffering properties of hemoglobin are combined in the concept of base excess (BE). **BE is strictly defined as the amount of base or acid that is needed to restore blood to a pH of 7.4 at a normal Pco_2 of 40 and temperature of 37°C.[2] A positive value suggests a deficit of fixed (i.e., not volatile as with H_2CO_3) acid or an excess of base; a negative value indicates an excess of fixed acid or a deficit of base.[46] An abnormality of the standard bicarbonate concentration or BE indicates a process of nonrespiratory (metabolic) alkalosis[30] or nonrespiratory (metabolic) acidosis.[49]** Caution is needed because various blood gas analyzers do not calculate BE in a similar manner and can vary by 3 to 9 mmol/L.[2] Additionally, BE is commonly calculated using assumptions from adult physiology with a normal bicarbonate of 26, which is significantly higher than what would be considered normal for a premature neonate.[39]

In the Henderson-Hasselbalch equation (see Equation 2), the pH is equal to a constant, pK, plus the logarithm of the base:acid ratio.[1,33,46] By substituting [HCO_3^-] for the base and dissolved CO_2 for the acid[17,46] and multiplying CO_2 by its solubility coefficient (0.03 mEq/L/mm Hg), the equation becomes the following:

$$pH = pK + \log [HCO_3^- / (Pco_2 \times 0.03)] \quad (4)$$

The value of pK is 6.1; the normal [HCO_3^-] is 24 mEq/L, and the normal $Paco_2$ is 40 mm Hg.

Substituting, we obtain the following:

$$pH - 6.1 + \log (20/1.2) \quad (5)$$

or

$$pH = 6.1 + 1.3 = 7.4$$

Changes in the 20:1.2 ratio have profound effects on the pH.[1,29] The following are two examples:

1. Hypoventilation of sufficient degree that $Paco_2$ is doubled from 40 to 80 (respiratory acidosis) results in a ratio of 24:2.4, or 10. The logarithm of 10 is 1, and the pH would be 6.1 + 1, or 7.1.
2. If a metabolic acidosis reduced [HCO_3^-] from 24 to 12 mEq/L, the ratio would be 12:1.2 or 10:1, and the pH would be 7.1.

MIXED CONTRIBUTIONS

The two most common reasons for acid-base disturbance in humans are the accumulation of carbon dioxide and the production of lactic acid through anaerobic metabolism as a consequence of tissue oxygen deprivation. Thus far, these derangements (Fig. 8.1) have been discussed as if they happened in isolation, but respiratory and nonrespiratory problems often occur simultaneously depending on pathologic processes in the body. **Besides the four single acid-base derangements, there are combined acid-base derangements: (1) respiratory acidosis and metabolic acidosis, (2) respiratory acidosis and metabolic alkalosis, (3) respiratory alkalosis and metabolic acidosis, and (4) respiratory alkalosis and metabolic alkalosis.** The combined acidoses or combined alkaloses have a cumulative effect on the pH, whereas a combination of acidosis and alkalosis tends to negate the effects of each on the pH value.[32,33,44,56]

COMPENSATION

Acid-base homeostasis maintains pH near the normal range. **The body attempts to maintain equilibrium by balancing a pathologic process with a physiologic process or predictable buffering response.**[10,33,53] Thus, if either the respiratory or nonrespiratory components of the acid-base system are deranged, the other system will compensate to counterbalance the primary process. For example, any respiratory process that leads to retention of carbon dioxide (respiratory acidosis) stimulates a nonrespiratory system, in this case the renal system, to

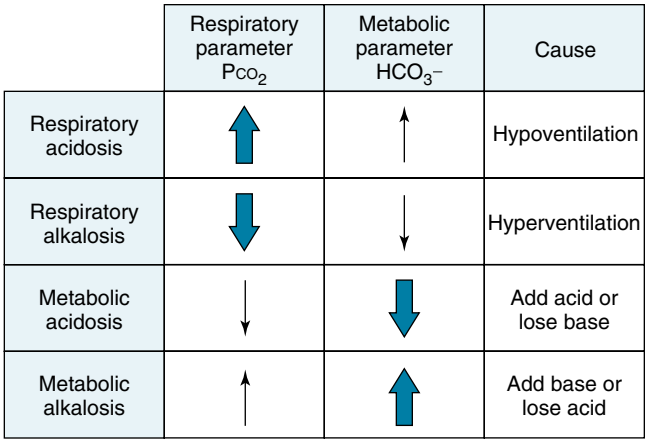

FIGURE 8.1 Acid-base derangements. *Large arrow* indicates primary process that produces change in pH. *Small arrow* indicates compensatory process.

return pH toward normal. **Retention of bicarbonate and corresponding excretion of hydrogen ions are the compensatory renal mechanisms that counterbalance respiratory acidosis.** Given sufficient time, this may increase blood bicarbonate by as much as 3 to 4 mEq/L for each increase of 10 mm Hg in carbon dioxide. Thus, a neonate with a chronically increased $Paco_2$ and a compensatory rise in bicarbonate may attain a near-normal pH.[33]

Metabolic compensations for deranged respiratory processes can go to remarkable extremes, but respiratory compensations for deranged metabolic processes are limited. Hyperventilation cannot lower the $Paco_2$ much below 10 mm Hg in compensation for metabolic acidosis. Similarly, hypoventilation is limited in compensation for metabolic alkalosis by the onset of hypoxemia.[53] Hypoxemia stimulates the respiratory drive, overriding compensatory hypoventilation and limiting the correction of alkalemia.[33]

CORRECTION

Correction of an acid-base disturbance occurs when the health care provider detects the pathophysiologic process and directs therapy at the primary pathologic process, rather than counterbalancing it with a second pathologic process.

For example, if respiratory acidosis is present, the clinician assesses the patient to discover the cause of the carbon dioxide retention and directs therapy at improving minute ventilation, the product of respiratory rate and tidal volume, rather than attempting to increase the retention of bicarbonate.

Oxygenation

The remaining components of the blood gas analysis are the Po_2, hemoglobin, and oxygen saturation.[44] Oxygenation is related to but also distinct from ventilation.[10] **The two main factors contributing to oxygenation at the tissue level are oxygen delivery and oxygen consumption.** Oxygen delivery is the product of the cardiac output and the oxygen-carrying capacity of the blood, whereas oxygen consumption is determined by the metabolic needs of the body's tissues. **Tissue hypoxia may be caused by many different factors that derange the balance between oxygen delivery and tissue needs. An inability of the lung to oxygenate the blood would decrease oxygen delivery because of arterial hypoxemia. Another cause of tissue hypoxia is interference with blood flow, as in heart failure.** The Pao_2 may be normal, but because of heart (pump) failure, oxygenated blood is not delivered in sufficient quantity. Treatment should be directed toward improving cardiac output and tissue perfusion (see Chapter 24). **A third cause of tissue hypoxia is decreased oxygen-carrying capacity of the blood, as with anemia. In this instance, the heart and lungs work adequately. Pao_2 is normal, but the quantity of hemoglobin available for oxygen transport is insufficient. Finally, tissue hypoxia may result from an abnormally high affinity of hemoglobin for oxygen, which leads to a decrease in tissue oxygen delivery. If oxyhemoglobin affinity is increased, oxygen will not dissociate from hemoglobin unless the**

venous, and therefore tissue, Po_2 falls to an unusually low level.[14]

Because Pao_2 measures only the partial pressure of oxygen in arterial blood (i.e., measures the amount of dissolved oxygen gas in the blood), it reflects lung function but not tissue oxygenation. Despite this, the measurement of Pao_2, together with the measurement of hemoglobin and a clinical assessment of tissue perfusion, is currently used as a surrogate of tissue oxygenation.[10]

Two situations merit special comment. First, in a **preterm infant whose retinal development is incomplete, high Pao_2 is associated with retinopathy of prematurity,** especially at a Pao_2 of greater than 100 mm Hg (see Chapter 23). Second, in **patients with cyanotic congenital heart disease, a right-to-left intracardiac shunt affects tissue oxygenation.** A portion of venous blood goes directly to the left side of the heart, then into the systemic circulation, bypassing the lungs. In such patients, the rise in Pao_2 with the administration of oxygen is limited. Low Pao_2 in these patients is not related to lung disease, although lung disease may complicate the picture, but results from blood bypassing gas exchange in the lungs.

Theoretically, **in a normal lung with perfectly matched ventilation and perfusion, the alveolar (Pao_2) and the arterial oxygen tension (Pao_2) should be equal.** This is not achieved. **A difference (gradient) exists between the Pao_2 and the Pao_2.** Minor mismatching of ventilation and perfusion leads to a functional intrapulmonary shunt. This creates an alveolar-arterial oxygen gradient ($D[A\text{-}a]O_2$).[10,17] However, a $D(A\text{-}a)O_2$ greater than 20 mm Hg indicates pulmonary disease.[10]

OXYHEMOGLOBIN SATURATION

Oxyhemoglobin saturation is the percentage of hemoglobin that is combined with oxygen. Oxygen binding with hemoglobin increases as the partial pressure of oxygen increases, but not linearly.[10,56] The oxygen dissociation curve is a measure of the affinity that hemoglobin has for oxygen (Fig. 8.2).

The "30-60-90 rule" is useful in remembering percent saturation and reconstructing the adult hemoglobin dissociation curve if necessary (see Fig. 8.2). At a Pao_2 of 30 mm Hg, the oxygen saturation is 60%; at a Pao_2 of 60 mm Hg, saturation is 90%; and at 90 mm Hg Pao_2, the hemoglobin is 95% saturated. At the normal venous oxygen tension of 40 mm Hg, the oxygen saturation is 75%. Factors that affect this affinity include temperature, pH, and hemoglobin structure. **Hypothermia, alkalemia, hypocapnia, and fetal hemoglobin increase the affinity of hemoglobin for oxygen (shift the curve to the left), whereas fever, acidemia, and hypercapnia decrease the affinity of hemoglobin for oxygen (shift the curve to the right).**

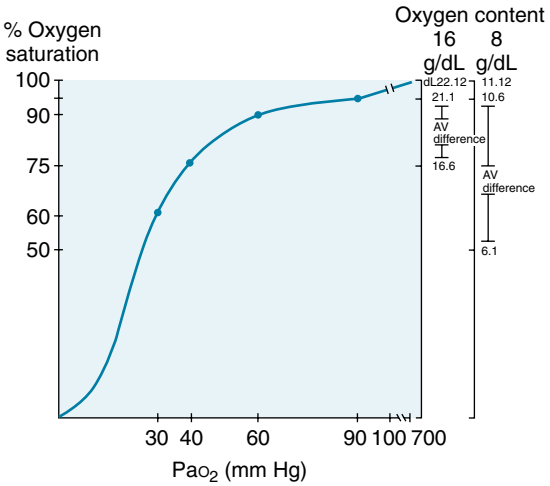

FIGURE 8.2 Oxygen-hemoglobin dissociation curve; the 30-60-90 rule is demonstrated. *Right,* The oxygen content for a hemoglobin concentration of 16 and 8 g/dL is given, demonstrating the effect of anemia on venous saturation and tissue oxygenation.

At a given tissue Po_2, an increased hemoglobin affinity for oxygen leads to less oxygen released at the tissue level, whereas a decreased affinity allows for more oxygen release to the tissues. Alternately, the Po_2 at which the oxygen-binding sites of hemoglobin are 50% saturated (the P_{50}) is low when the hemoglobin affinity is great and higher when the hemoglobin affinity is low.[10] **The affinity of fetal hemoglobin for oxygen is higher than adult hemoglobin (see Figure 7.1).** The P_{50} of fetal hemoglobin is 19 mm Hg compared with a P_{50} of 27 mm Hg for adult hemoglobin. **Approximately 70% of hemoglobin in term infants, and more in preterm infants, consists of fetal hemoglobin.**[14] As a result, hemoglobin in a term infant with a Pao_2 of 35 mm Hg will be 80% saturated, and a "pink" newborn infant may have a low Pao_2.

OXYGEN CONTENT

Oxygen content is calculated from the hemoglobin saturation and hemoglobin concentration. One gram of hemoglobin binds 1.39 mL of oxygen. The oxygen content in milliliters per deciliter is the product of the saturation percentage and the hemoglobin in grams per deciliter plus the amount of dissolved oxygen. For clinical purposes, we can neglect the amount of dissolved oxygen in the plasma because it is only 0.003 mL/dL/mm Hg.

Oxygen content becomes critical in anemia, which can decrease tissue oxygenation unless organ blood flow and cardiac output increase to maintain the delivery of oxygen.[10,55] The blood of an infant with a hemoglobin of 8 g/dL will have half the oxygen content compared to that of an infant with a hemoglobin of 16 g/dL at an equivalent oxygen saturation percentage. In Fig. 8.2, an infant with 16 g hemoglobin that is 95% saturated (Pao_2 = 90 mm Hg) carries 21.1 mL/dL oxygen, whereas the infant with 8 g hemoglobin carries 10.6 mL/dL oxygen. Tissues require approximately 4 to 5 mL/dL oxygen to maintain aerobic metabolism. With normal cardiac output, venous blood contains 4 to 5 mL of oxygen which is less than the arterial blood. The venous oxygen content in an infant with 16 g hemoglobin would be between 16 and 17 mL/dL, which corresponds to approximately 75% saturation, or a Pvo_2 of 40 mm Hg. However, unless cardiac output increases, the venous oxygen content in an infant with 8 g hemoglobin would be 6.1 mL/dL oxygen. The saturation is 55%, which corresponds to a Po_2 of less than 30.

BLOOD FLOW AND SHUNTS

The product of oxygen content and blood flow returning from the lungs determines the total amount of oxygen in arterial blood if no intra- or extracardiac shunting occurs. Total pulmonary blood flow can be divided into the amount of blood in the pulmonary capillaries and the amount that is shunted through or around the lungs.

A right-to-left shunt occurs when blood passes from the systemic venous to the systemic arterial circulation. This can occur because of anatomic defects in the heart (e.g., cyanotic congenital heart disease), with a persistently patent ductus arteriosus in the presence of pulmonary arterial pressures that are higher than systemic arterial pressures (pulmonary hypertension), or when pulmonary capillary blood perfuses poorly expanded alveoli (e.g., intrapulmonary shunts). **Shunts lower the final arterial oxygen saturation. The usual degree of shunting in a newborn is 15% to 20% of the cardiac output.**

Acid-Base and Oxygenation Disorders

Ventilation **is defined as the amount of gas leaving the lungs per unit of time (e.g., minute ventilation). Minute ventilation is equal to the product of the tidal volume and respiratory frequency in breaths per minute.** The tidal volume is composed of (1) gas in the airway and nonperfused alveoli *(physiologic dead space)* and (2) gas in the alveolar space.[10,17] ***Alveolar ventilation*** **is defined as the ratio of CO_2 production by the body to the $Paco_2$. Alveolar ventilation is inversely related to $Paco_2$.** When $Paco_2$ doubles, alveolar ventilation is approximately one half of the original value. If the $Paco_2$ triples, alveolar ventilation is approximately one third of the original value, and so forth.[1]

RESPIRATORY ACIDOSIS

When the lungs become less effective at removing carbon dioxide, $Paco_2$ increases, and respiratory acidemia ensues. The causes of respiratory acidosis can be separated into pulmonary and nonpulmonary causes.[17] The most common pulmonary cause of respiratory acidosis in term newborns is obstructive lung disease, such as meconium aspiration[48] and transient tachypnea[43] of the newborn. For newborns delivered prior to 34 weeks' estimated gestational age, surfactant deficiency and immature parenchymal lung and neuromuscular development are the most common reasons for respiratory acidosis. Obstructive lung disease occurs in the recovery phase of uncomplicated respiratory distress syndrome (RDS) and in bronchopulmonary dysplasia.[47] Also included in the pulmonary causes of hypoventilation are conditions that interfere with the expansion of the lungs, such as diaphragmatic hernia, phrenic nerve paralysis, a space-occupying mass, or pneumothorax. These limit the tidal volume.[17]

A nonpulmonary cause of carbon dioxide retention is poor respiratory effort. A decreased respiratory drive may be secondary to medications such as opioids, sepsis, intracranial hemorrhage (including intraventricular hemorrhage), prematurity, hypothermia, and metabolic disturbances, such as hypoglycemia.[17] Even if the respiratory drive is

appropriate, newborns may have an inadequate neuromuscular ability to ventilate. Ineffective respiratory mechanics may be related to prematurity, systemic illness with multiorgan dysfunction, and conditions that decrease muscular tone and strength such as those found in certain genetic syndromes (Prader-Willi), maternal conditions (Graves' disease), and medication side effects (magnesium sulfate for maternal preeclampsia).

RESPIRATORY ALKALOSIS

In respiratory alkalosis, carbon dioxide clearance is increased, and thus $Paco_2$ is below normal.[20] Respiratory alkalosis occurs as a result of hyperventilation, which may be caused by (1) excessive ventilatory support; (2) central nervous system (CNS) stimulation that increases the respiratory drive (e.g., hyperammonemia from a genetic abnormality of the urea cycle);[11] and (3) hypoxemia, which stimulates respiratory centers through chemoreceptors.[20]

NONRESPIRATORY (METABOLIC) ACIDOSIS

In nonrespiratory (metabolic) acidosis, the metabolic component results from either adding nonvolatile acid (an acid other than carbonic acid) or losing base (bicarbonate).[35,48,53] The underlying mechanisms of metabolic acidosis are (1) the loss of base in urine or stool, (2) exogenous acid that is unable to be effectively secreted by the kidneys (high levels of amino acid administration), and (3) abnormal metabolism that leads to an increase in nonvolatile acid levels. Nonvolatile acids originate from lactic acid in circulatory shock and hypoxia, organic acids in inborn errors of metabolism, and ketoacids in diabetic acidosis. Loss of bicarbonate occurs in renal tubular acidosis (inability of the renal tubules to reabsorb bicarbonate appropriately), with stool loss (diarrhea), or through urinary excretion.[50,52,54]

Measurement of the anion gap helps identify the mechanism of metabolic acidosis.[15,18,29,54] The anion gap is variably calculated as the serum sodium concentration minus the serum chloride concentration minus the serum bicarbonate concentration[33,54] or, alternatively, sodium plus potassium minus chloride minus bicarbonate.* The upper limit of the normal anion gap with the first method is given as 14 mEq/L[54] and with the second method as 15 mEq/L.[26] Addition of nonvolatile acids is associated with an increased anion gap. **Loss of base or excess chloride [Cl^-] is the likely mechanism of acidosis with a normal anion gap.**[46,54] The advantage of measuring the anion gap in understanding the effect of excessive chloride administration is clear. Given that there must be a balance between blood cations and anions to preserve electroneutrality, [Cl^-] in excess simply displaces [HCO_3^-], resulting in metabolic acidosis.[54] In normal anion gap acidosis, low serum potassium indicates loss of base (e.g., diarrhea), and high serum potassium points to a renal defect (e.g., renal tubular acidosis).[33]

Albumin is a major component of the anion gap. Hypoalbuminemia, common in critically ill neonates and children, may mask the presence of the anions of lactic and organic or other nonvolatile acids.[15,16,18,26,33] A "normal" anion gap in combination with low serum albumin indicates that a nonvolatile acid anion is making up the difference for "absent" anions that albumin would ordinarily provide. Correcting the anion gap for hypoalbuminemia is accomplished by adding 2.5 mEq/L to the anion gap for every g/dL that the concentration of serum albumin is reduced below the normal value of approximately 3.5 g/dL.[15,52]

NONRESPIRATORY (METABOLIC) ALKALOSIS

Nonrespiratory (metabolic) alkalosis is caused by either a loss of acid or an increase of base, principally bicarbonate.[30] Alkalosis occurs when excessive amounts of bicarbonate, acetate, citrate, or lactate are given; metabolism of the latter three anions in the liver generates bicarbonate. **Loss of acid occurs with gastric fluid removal or prolonged vomiting, as can be seen with pyloric stenosis. Acid loss by renal mechanisms can occur through the influence of diuretics, digitalis, or corticosteroids.**[20] Urine electrolytes, especially chloride, are useful in the differential diagnosis of metabolic alkaloses. Low urine Cl^- (<20 mEq/L) is associated with chloride (saline)–responsive metabolic alkalosis from acid loss (e.g., vomiting, nasogastric suction), whereas high urine Cl^- is associated with chloride (saline)–unresponsive metabolic alkalosis from renal acid loss (e.g., diuretics).[18,33]

*References 9, 15, 17, 21, 23, 40.

OXYGENATION

Inadequate cardiac output, anemia, an increased hemoglobin affinity for oxygen, and hypoxemia (decreased Pao_2) may cause tissue hypoxia. **Hypoxemia results from lung disease or cyanotic congenital heart disease. The most common lung abnormality is mismatched ventilation and perfusion.**[10] In newborns, there is always some degree of ventilation and perfusion mismatch. Two extreme examples are (1) ventilated and oxygenated alveoli without perfusion (e.g., pulmonary emboli) and (2) perfused but nonventilated alveoli (atelectasis). The former is an example of wasted ventilation, and the latter represents an intrapulmonary shunt. Either extreme is incompatible with life. Clinically relevant degrees of ventilation-perfusion mismatch lie somewhere between those extremes.[10]

Hypoxemia, resulting from ventilation-perfusion mismatch, can be overcome with supplemental inspired oxygen. An increased inspired oxygen concentration will eventually displace nitrogen from even the most poorly ventilated alveoli, and alveolar and then arterial oxygen tension will increase. **However, when an extrapulmonary shunt bypasses the lungs, Pao_2 does not increase.** This is important because clinicians can differentiate parenchymal lung disease from cyanotic congenital heart disease as a cause of hypoxemia: the latter will not have a significant increase in Pao_2 even with the administration of 100% oxygen.

To perform the *hyperoxia test,* the clinician should place the neonate in 100% oxygen for 10 to 15 minutes and obtain a right radial arterial blood sample. If the Pao_2 rises to more than 150 mm Hg, cyanotic congenital heart disease is very unlikely, and lung disease is the most common etiology.

Central hypoventilation from narcosis may cause hypoxemia. As alveolar carbon dioxide rises, PAo_2 falls, and Pao_2 decreases. This condition should be clinically evident and should not be confused with lung or congenital heart disease. Other causes of hypoxemia, such as decreased inspired oxygen tension with increasing altitude and oxygen diffusion limitation, are uncommon in the infant.

PREVENTION

Prevention of acid-base and oxygenation disturbances and maintenance of acid-base homeostasis require attention to detail. A clinician must have an understanding of the physiologic principles of acid-base homeostasis and oxygenation to identify the underlying mechanism and treat with the appropriate medical intervention(s).

With respiratory disturbances, immediate assessment and prompt therapy, including supplemental inspired oxygen and assisted ventilation, may help improve oxygenation and the respiratory component of acid-base disturbances (see Chapter 23). Careful monitoring of fluid and electrolyte intake and output, minimizing blood loss, and observing for sepsis help the clinician prevent the development of nonrespiratory acid-base disturbances (see Chapters 4 and 22).

DATA COLLECTION

Monitoring inspired oxygen concentrations and arterial oxygen tension and supplying appropriate concentrations of additional inspired oxygen will prevent hypoxemia and hyperoxemia (see Chapter 23). Monitoring may be accomplished intermittently through indwelling arterial catheters or continuously by transcutaneous oxygen monitors and pulse oxygen saturation devices (see Chapter 7). Monitoring hemoglobin concentrations and blood loss, with appropriate replacement, helps ensure adequate blood oxygen content.

Reviewing the patient's history, performing a physical examination, and evaluating laboratory data augment each other in the assessment of disturbances in acid-base homeostasis and oxygenation (Box 8.2).

History

An adequate obstetric and perinatal history may warn of potential acid-base and oxygenation disturbances in the newborn:

- Premature delivery predisposes the infant to infection and respiratory insufficiency.
- Meconium staining may portend infection, lung disease, and right-to-left shunting with associated pulmonary hypertension.
- Prolonged rupture of membranes, maternal diabetes, or abnormal maternal bleeding may be associated with either metabolic or respiratory acid-base disturbances and hypoxemia.
- A neonatal history of vomiting, diarrhea, or other gastrointestinal disturbances can cause acid-base disturbances.

BOX 8.2 EVALUATION OF ACID-BASE DISTURBANCES AND OXYGENATION PROBLEMS IN NEONATES

1. History
   a. Obstetric and perinatal
   b. Neonatal
   c. Family
2. Physical examination
   a. Vital signs
   b. General appearance
   c. Respiratory effort
   d. Pulmonary examination
   e. Cardiac examination
   f. Abdominal examination
   g. Neurologic examination
3. Laboratory
   a. Chest x-ray film
   b. Arterial blood gases
   c. Urinalysis
   d. In selected cases: sepsis evaluation, serum electrolytes, serum albumin, urine electrolytes, and urine osmolality

- The infant's general appearance, feeding habits, and activity level may indicate sepsis or CNS injury, both of which promote acid-base disturbances and hypoxemia.
- Nosocomial infections and pneumonia may significantly influence acid-base and oxygenation disturbances.
- A family history of inherited renal problems such as tubular acidosis may suggest an acid-base disturbance.
- A family history of salt-losing endocrinopathies may produce an acid-base disturbance.

Physical Examination

SIGNS AND SYMPTOMS

Signs of acid-base disturbance vary widely and often go undetected. Hypothermia, hypotension, tachycardia, bradycardia, or poor peripheral perfusion should alert caretakers to the possibility of metabolic acidosis. **An altered respiratory rate and pattern, grunting respirations, nasal flaring, and chest wall retractions raise the possibility of respiratory acidosis or respiratory compensation for metabolic acidosis.** Abnormalities on auscultation of the heart may point to congenital heart disease and resulting acid-base and oxygenation abnormalities. Lethargy, seizures, and abnormal neurologic signs increase concern for acid-base disturbances or hypoxemia.

LABORATORY DATA

Chest Radiograph: A chest x-ray examination may assist in identifying a respiratory or cardiac cause for an acid-base disturbance and hypoxemia.

Urinalysis: The routine urinalysis records urine specific gravity and complements monitoring of urine output. Urine electrolytes and pH are helpful in differentiating among the pathophysiologic mechanisms of metabolic derangements.

Arterial Blood Gases: **Interpretation of the arterial blood gases will point to the primary acid-base derangement and may reveal a secondary compensation and define the degree of hypoxemia.**[9,28,37,49] Presently, methods for monitoring the components of acid-base analysis comprise both invasive and noninvasive techniques. Intermittent arterial punctures or indwelling catheters in various vessels (often the umbilical artery or vein) supply data. However, we can continuously measure transcutaneous Po_2 or O_2 saturation. Monitors can continuously measure expired end-tidal CO_2, which corresponds to the alveolar CO_2. (Alveolar and arterial CO_2 are equivalent unless respirations are excessively rapid.) In addition, skin electrodes are available that measure Pao_2 and $Paco_2$ with varying success (see Chapter 7).

Although the pathophysiologic condition of the acid-base disturbance is determined through the analysis of arterial blood gases, further assessment of the infant is necessary, as follows:

- Respiratory alkalosis or acidosis can be suspected on the basis of obstetrical and family history, physical examination, and chest x-ray or diagnosed by arterial blood gas analysis.
- Metabolic acidosis often accompanies shock and septicemia. The anion gap and urine electrolytes may provide additional information to delineate causes. Blood pressure measurement, a complete blood cell count, an infectious work-up, serum and urine electrolytes and pH, serum albumin and glucose determinations, and assessment of intake and output of fluids are often needed to identify the source of metabolic acidosis.
- Oxygenation disturbances may be analyzed from the preceding laboratory tests and, when indicat-

TABLE 8.2 UMBILICAL VENOUS AND ARTERIAL CORD BLOOD GAS VALUES

	VENOUS	ARTERIAL
pH	7.25–7.45	7.18–7.38
Pco_2 (mm Hg)	26.8–49.2	32.2–65.8
Po_2 (mm Hg)	17.2–40.8	5.6–30.8
HCO_3^- (mmol/L)	15.8–24.2	17–27
Base deficit (BD) (mmol/L)	0–8	0–8

ed, an echocardiogram to evaluate for structural heart disease or pulmonary hypertension. If an echocardiogram is not readily available, performing a hyperoxia test to evaluate for the possibility of congenital heart disease may be necessary.

Another calculation, **the *oxygenation index (OI),* is used to assess critically ill neonates receiving ventilator therapy. The OI is (Fio_2 × 100 × mean airway pressure) divided by Pao_2 or, simply put, work/result.** In some centers, an OI of 25 or greater has been considered an indication for extraordinary ventilatory support, such as inhaled nitric oxide or extracorporeal membrane oxygenation (ECMO).[18]

CORD BLOOD GAS INTERPRETATION

Providers participating in delivery room stabilization, as well as subsequent care of at-risk newborns, benefit from a thorough understanding of cord gas interpretation, as well as familiarity with the perinatal conditions that may have an adverse effect on fetal outcome. Table 8.2 describes normal cord blood gas values.[38]

When reviewing **cord gas values, it is important to note that there is a broader range of normal values than with postnatal blood gas values, and the relationship between the venous and arterial norms is the opposite of that in conventional blood gases.[41] With fetal circulation, the umbilical vein transports oxygenated blood from the placenta (acting as the fetal lung) to the fetus. The umbilical arteries transport blood from the fetus back to the placenta for gas exchange. The most useful value of cord blood sampling for the clinician caring for the newborn is the umbilical arterial blood pH because it is indicative of the fetal metabolic condition just prior to birth and is most strongly associated with perinatal mortality and important morbidities.[22,37]**

UMBILICAL CORD BLOOD GAS SAMPLING

Controversy exists as to which perinatal circumstances warrant collection and review of umbilical cord blood gases. The American College of Obstetricians and Gynecologists' Committee on Obstetric Practice updated its opinion statement regarding cord blood gas analysis in 2012.[3] **Cord gas collection and review should occur in circumstances of cesarean delivery for fetal compromise, low 5-minute Apgar score, severe growth restriction, abnormal fetal heart rate tracing, maternal thyroid disease, intrapartum fever, or multiparous gestations.**

There are a few points to keep in mind when collecting and analyzing cord blood. Following delivery, immediate collection and analysis of cord blood ensure the greatest sampling accuracy. However, valid results can be obtained with samples collected and analyzed within 1 hour at room temperature or analyzed within 6 hours if the samples are refrigerated.[50] **The placenta continues to be metabolically active following delivery, and theoretically, if the blood being sampled is in close proximity to the placenta, there may be continued gas exchange, yielding cord gas results that reflect a dynamic state and not necessarily the prior fetal environment.**[5]

Over the past decade, **delayed cord clamping has become quite common and is now considered standard practice at the delivery of term and preterm newborns.** Umbilical blood vessel sampling is possible during delayed cord clamping,[4] but does delayed cord clamping, as compared to immediate cord clamping, affect the results and interpretation of arterial or venous cord blood samples? At the time of birth, dramatic physiologic changes occur as the fetus moves from a fluid-filled environment, which relies on the placenta for gas exchange, to an air-filled environment, whereby the newborn's cardiorespiratory system fulfills that role. **During delayed cord clamping, gas exchange may occur simultaneously through the placenta and the newborn's cardiorespiratory system, which has the potential to significantly alter sampled cord blood gas values such as pH, Po_2, Pco_2,** and **base deficit.** A recent study[51] compared paired samples of arterial and venous cord blood samples obtained immediately after

birth with those obtained after delayed cord clamping in term pregnancies. **Statistically significant differences were noted for pH, Pco_2, lactate, and base excess, but not Po_2. The mean differences noted between immediate cord clamping and delayed cord clamping were as follows: pH lower by 0.03, Pco_2 higher by 3 mm Hg, lactate higher by 3 mg/dL, bicarbonate lower by 0.3 mmol/L, and base deficit increased by 0.3 mmol/L.** In term deliveries, a significantly lower pH and higher Pco_2 have been found in cord blood samples obtained after vaginal delivery as compared to operative deliveries.[37] The results, although statistically significant, may not be clinically relevant; however, these differences should be considered when interpreting cord blood gas values obtained with delayed cord clamping after vaginal or operative deliveries.

CORD BLOOD GAS INTERPRETATION

Asphyxia results when there is an interruption of placental-fetal gas exchange. More specifically, asphyxia is defined as metabolic acidemia following birth measured by a pH of less than 7.00 and a base deficit of greater than 12 mmol/L.[41] General causes of intrapartum asphyxia are (1) impaired uteroplacental gas exchange (uteroplacental insufficiency), (2) inadequate umbilical blood flow (cord occlusion), and (3) impaired fetal cardiac output.

General principles of cord blood gas interpretation include the following:

1. Umbilical venous blood represents uteroplacental status.
2. Umbilical arterial blood represents fetal *and* uteroplacental status.
3. When interpreting an infant's paired cord gases, the cord venous gas will *always* have a higher pH, a lower Pco_2, and a higher Po_2 than the umbilical artery cord gas. If values do not align with these rules of interpretation, it is likely that the samples were from the same vessel or mislabeled.[8,40]

Uteroplacental Insufficiency. There are multiple perinatal and intrapartum factors that can lead to uteroplacental insufficiency. Some common clinical conditions include maternal hypotension or hypertension, maternal hypoxia, maternal medications, a hyperstimulated uterine contraction pattern, premature placental separation, and defects in placental development. On many occasions, uteroplacental insufficiency is mild in nature and has no lasting effect on neonatal outcome. However, if a critical threshold of uteroplacental insufficiency is reached, the fetus becomes hypoxic. **The degree and duration of the hypoxia will determine whether metabolic acidosis will occur.**[21] **When intrapartum asphyxia is the result of uteroplacental insufficiency, the umbilical venous and arterial blood gases will *both* reveal derangements in acid-base status. However, with fetal hypoxia, the arterial gas will demonstrate a lower pH, higher Pco_2, and lower Po_2 than the venous cord sample. On many occasions, the cord gases reveal a paired respiratory acidosis without a metabolic component, which indicates an acute (less than 30 minutes) event.**[8]

Cord Occlusion (see Chapter 2). Identification of true cord prolapse during labor is enough to raise even the calmest of clinician's heart rates. However, there are several less intuitive scenarios leading to functional cord occlusion that result from stretching or compression of the umbilical vessels. They include an anatomically short cord; breech presentation; occult cord prolapse; shoulder dystocia; nuchal cord; body cord; true knot in the cord; kinking of the cord; cord entanglement between monoamniotic/monochorionic twins; and following rupture of the membranes, any instance in which there is compression of the umbilical cord vessels.[41]

The most common cord occlusion scenario is compression of the umbilical vein and at least partial patency of the umbilical arteries due to the differences in the vessel wall structure. The vein is thin walled and more easily compressed as compared with the thicker, more muscular arterial wall, which is less prone to compression. Cord blood gas sampling in this scenario would yield a near-normal venous gas with an arterial sample demonstrating metabolic and respiratory acidosis to various degrees depending on the severity and duration of the vessel compression. **Overall, the hallmark cord gas findings in cord occlusion are a widened venoarterial pH, Pco_2, and at times, base deficit differences.**

Fetal Circulatory Failure. A myriad of causes can ultimately lead to fetal circulatory failure. Included

among these are fetal hemorrhage/anemia, structural heart disease, arrhythmias, cardiomyopathies, extracardiac malformations, and septic shock. For example, in progressive fetal anemia, as seen with Rh isoimmunization, the fetus compensates for the anemia by increasing cardiac output. As **the anemia worsens, oxygenation becomes inadequate to meet cellular metabolism, and heart failure occurs.** As cardiac output decreases and blood flow slows, there is increased oxygen extraction from the blood and increased production of CO_2. This phenomenon will create widened venoarterial pH, Pco_2, and Po_2 differences. **Cord gases following fetal circulatory failure have a similar appearance to gases obtained after cord occlusion.**[41]

PATHOLOGIC PREDICTIVE VALUE OF CORD BLOOD GASES

Cord blood gas data and analysis are useful for immediate management, but pH alone is poorly predictive of long-term outcomes. Infants who recover quickly with reassuring neurologic examinations tend to have good long-term outcomes regardless of cord blood pH.[25] Although low cord blood pH is clearly associated with poor outcome, association is not cause and effect. The underlying cause of both acidosis and organ damage is tissue hypoxia.[25,31] In **contrast, an arterial cord pH of less than 7.00 in combination with abnormal clinical signs and symptoms is strongly associated with adverse outcomes.**[57] Low et al. demonstrated that arterial base deficits of 12 to 16 mmol/L were associated with moderate or severe newborn sequelae in 10% of the neonates studied. That number increased to 40% of neonates once the base deficit reached greater than 16 mmol/L.[36] Conversely, mild acidosis is not usually associated with newborn complications. Although analysis of cord gases can at times be difficult, paired cord blood gases have a role in determining underlying etiologies, guiding further evaluation and appropriate treatment(s).

TREATMENT

In respiratory acidosis, the pathophysiologic mechanism is decreased alveolar ventilation. Treatment is directed at the underlying cause.[15] **Hypoxemia caused by ventilation-perfusion mismatch is treated with increased inspired oxygen concentration.** Techniques that may be of benefit to treat respiratory acidosis include continuous positive airway pressure (CPAP), standard ventilation, high-frequency ventilation, ECMO, inhaled nitric oxide, and others (see Chapter 23). **Treatment of respiratory alkalosis usually consists of reducing minute ventilation.** One of the causes of neonatal central hyperventilation that requires a high index of suspicion and urgent evaluation and treatment is hyperammonemia caused by an inborn error of urea cycle metabolism[11] (see Chapter 27).

Asphyxia often leads to a combined respiratory and metabolic acidosis. Ventilation will resolve the respiratory acidosis. Improved oxygen delivery and tissue perfusion usually resolve lactic acidosis without bicarbonate therapy. In narcosis, temporary ventilator support may be necessary. **Narcosis may be reversed with the administration of naloxone (Narcan) at a dose of 0.1 mg/kg if the possibility of chronic maternal opiate drug abuse has been ruled out.** With chronic intrauterine opioid exposure, neonatal Narcan administration may result in acute withdrawal and seizures (see Chapter 4).

With any acidosis and alkalosis, determining the underlying etiology is critical for effective management. If the cause of metabolic acidosis is septicemia, intestinal necrosis, or poor cardiac output severe enough to result in metabolic acidosis, successful treatment of the cause is of far more importance than buffer therapy for acidosis. Historically, sodium bicarbonate has been administered for neonatal metabolic acidosis. However, controversy exists on the true physiologic benefit from sodium bicarbonate administration.[7] **Sodium bicarbonate administration may conversely cause harm, especially with a bolus administration, because it is a hypertonic solution that may increase the risk of intraventricular hemorrhage.**[13,35,45] It should not be used if severe lung disease restricts carbon dioxide elimination (see Equation 3).

COMPLICATIONS

Unrecognized oxygenation disturbances may lead to increased mortality or morbidity rates in survivors. Unrecognized acid-base disorders are not as important in themselves as they are

because they serve as indicators of unrecognized serious, perhaps life-threatening pathology such as septicemia or poor cardiac output. For example, otherwise-normal newborn infants and trained athletes can be severely acidotic without consequences.[25,27] Everyday, clinical experience in neonatal intensive care confirms that chronic respiratory acidosis, even with extreme hypercapnia, can be tolerated for long periods. **It is not always appreciated that acute correction of chronic acid-base disorders can be more problematic than the disorder itself.** For example, **sudden correction of respiratory alkalosis results in potentially damaging acute increases in cerebral blood flow.**[23] Sudden correction of chronic hypercapnia was long ago shown to be problematic.[17,18,30,40,42] In short, **complications of the correction of the acid-base balance vary according to the disturbance and the treatment provided. The treatment of respiratory acidosis by assisted ventilation can produce all of the complications of assisted ventilation, including infection, trauma, oxygen toxicity, sepsis, air leak, and subglottic stenosis** (see Chapter 23).

Complications of oxygen therapy include hypoxemia and hyperoxemia. **Severe hypoxemia may cause pulmonary vasoconstriction, a change from aerobic to anaerobic metabolism (with eventual metabolic acidosis), bradycardia, hypotonia, and impaired CNS and cardiac function.** Prolonged high inspired oxygen concentrations can result in oxygen toxicity, which may be central to significant morbidities such as retinopathy of prematurity and bronchopulmonary dysplasia.[12,28]

EXAMPLE CASES

Case 1

You are caring for a 7-day-old, former 36-week female infant who has poor feeding, sleepiness, decreased urine output, and a new oxygen requirement with Fio_2 0.40 on 2-L/min nasal cannula. On exam, she is only mildly responsive to stimulation; has delayed capillary refill of 3 to 4 seconds throughout, with poorly palpable peripheral pulses, especially in her lower extremities; and has a respiratory rate in the 80s, with labored breathing and clear breath sounds. Blood pressure measured with a cuff on her right arm is 65/40, heart rate is regular in the 160s, and oxygen saturations range in the low 90s in the right upper extremity. You are concerned about her appearance and order a chest x-ray, complete blood count (CBC) with differential and platelets, electrolytes, blood culture, urine culture with Gram stain and microanalysis, C-reactive protein, and arterial blood gas. The first result that confirms your concerns is the arterial blood gas: pH 7.03, Pco_2 30, Po_2 55, calculated bicarbonate of 9, base excess of −16. Serum electrolyte results include the following: sodium of 134, potassium of 5.9, chloride of 95, and bicarbonate of 10. You calculate an anion gap of 35 (134 + 5.9 − 95 − 10). Your clinical suspicion is that this newborn has coarctation of the aorta that has become critical upon closure of her patent ductus arteriosus, which is confirmed by echocardiogram. The patient receives an administration of parenteral prostaglandin, establishment of arterial and central venous access, and a cardiology consultation. **In patients with metabolic acidosis, it is imperative to identify the cause of the acidosis,** which, in this case was due to decreased oxygen delivery to tissues below the level of the coarctation, resulting in a large anion gap metabolic acidosis from lactic acid production due to anaerobic metabolism.

Case 2

You attended the delivery of a 32-week, 1.6-kg infant after preterm labor with rupture of membranes and clear fluid 1 hour before delivery. The mother did not receive betamethasone or antibiotics before delivery. He was delivered vaginally, with Apgar scores of 5 and 7 at 1 and 5 minutes, respectively. He presented with poor respiratory effort and responded to drying, stimulation, and positive-pressure ventilation with 30% oxygen after color and oxygen saturation did not improve with free-flow oxygen. By 5 minutes, he was breathing spontaneously, with an oxygen saturation measured at 85%. He was admitted to the neonatal intensive care unit (NICU) and placed in a hood with 50% oxygen. On exam, he was grunting, with marked retractions; had decreased breath sounds with rales; and had a respiratory rate of 80 with an oxygen saturation of 82%. The rest of the examination was noncontributory. He was placed on continuous positive airway pressure (CPAP) of 5 cm H_2O and Fio_2 0.45, and oxygen saturations increased to the high 80s. Catheters were placed in the umbilical vein and artery. A chest x-ray revealed low lung volumes, a fine reticulogranular pattern, and prominent air bronchograms. The arterial blood gas at 2 hours of life shows a pH of 7.13, a Pco_2 of 66, a Po_2 of 51, a calculated bicarbonate of 14, and a base deficit of 5. You suspect the infant has respiratory distress syndrome based on symptoms beginning at birth, chest x-ray (CXR), and a blood gas revealing hypoxemia and, predominantly, respiratory acidosis. Additional supporting factors include prematurity, lack of antenatal steroids, and exam significant for retractions and poor air exchange. Your management includes surfactant replacement therapy and mechanical ventilation in addition to antibiotics and a follow-up blood gas. Respiratory acidosis is a classic finding in respiratory distress syndrome, especially in the preterm population. Treatment goals are aimed at normalizing both oxygenation and ventilation and treating for the possibility of infection.

9 DIAGNOSTIC IMAGING IN THE NEONATE

JASON P. WEINMAN, BRIDGET M. BRONSERT, AND JOHN D. STRAIN

Imaging is an important part of the diagnosis and treatment of medical problems in newborns. The ability to noninvasively screen for and diagnose disease, monitor the effects of therapy, and help define prognosis has made imaging an essential part of neonatal care. With refinements in diagnostic equipment and capabilities, the role of imaging has expanded significantly in recent years. There are many ways to assess any problem, and the vast potential of the new imaging modalities makes appropriate imaging a constant challenge (Table 9.1). New modalities have been introduced, and advancement in computer technology has added sophistication to established modalities. Nearly 60% of diagnostic imaging involves modalities that were not even available 30 years ago.

Many excellent reference books and textbooks on neonatal imaging address specific questions.* This chapter reviews the various imaging modalities available for diagnosis and intervention. A short summary of each imaging modality includes background information and the risks and benefits of each. For clarity, this thumbnail description of each modality provides a concise, tailored discussion of the physics of image acquisition. Each section addresses the most common usage of the modality in neonates, followed by a focused discussion of one or two aspects of image interpretation.

Because there is often more than one appropriate way to evaluate any given problem, it is essential to understand the inherent advantages and limitations of each modality to decide which might be most effective. Understanding some of the challenges associated with diagnostic imaging can lay the foundation for a focused problem-solving approach with appropriate collaboration between clinicians and radiology that will result in the best care for the patient.

RADIOGRAPHY

Background

The 1896 introduction of the roentgenogram was met with great enthusiasm, and x-ray examination quickly became an indispensable clinical diagnostic tool throughout the world. Until 35 years ago, the field of radiology was based almost exclusively on the use of the x-ray.

A beam of ionizing radiation from a source (x-ray tube) passes through the patient, and various structures within the body interact to attenuate the x-ray before it is received on the other side. The x-rays pass through the patient and then expose a film, just as light exposes a negative in black-and-white film photography. The film is developed, and the resultant image (radiograph) is a map that corresponds to the transmitted x-ray (that portion of the x-ray not attenuated by absorption or scattered as it passes through the patient). Somewhat analogous to the shadows that result from objects in the sun, the images from x-ray are a shadow of the object being radiographed.

Bone attenuates a greater amount of the x-ray (or allows the penetration of fewer x-rays) than lung tissue does, resulting in a film on which the rib is white and the lung is black. In some ways, this can be compared with the different shadows cast by the trunk of a tree and by its leaves. With radiography, the spatial resolution is exquisite,

BLUE type highlights content that is particularly applicable to clinical settings.

TABLE 9.1 COMPARATIVE ANALYSIS OF IMAGING MODALITIES

IMAGING MODALITY	IONIZING RADIATION	SPATIAL RESOLUTION	CONTRAST RESOLUTION	COST	SEDATION	MISCELLANEOUS
X-ray	Very low	Excellent	Fair	Low	Never	Very fast acquisition eliminates motion
Fluoroscopy	Low	Excellent	Fair	Moderate	Never	Evaluates motion in real time
Ultrasonography	None	Good	Fair	Moderate	Never	Portable; evaluates motion real-time
Computed tomography	Low	Good	Good	Moderate to high	Sometimes	Cross-sectional imaging
Magnetic resonance imaging	None	Good	Excellent	High	Frequent	Multiplanar (i.e., in multiple planes) imaging, flowing blood without contrast
Nuclear medicine	Very low	Poor	Excellent	Moderate to high	Sometimes	Physiologic imaging

although the contrast resolution is lacking. One can capture 10 to 20 line pairs per millimeter with film radiography, although **only five different densities can be routinely distinguished: air, fat, water (which includes all solid viscera—liver, spleen, kidney, pancreas, and heart), bone, and metal.**

More recent developments in x-ray technology include computed radiography (CR) and digital radiography (DR). Although the physics of x-ray generation is essentially the same, the receiver has changed. With CR, a phosphorescent plate replaces film, and the latent image is captured digitally. With DR, the image is directly captured by a digital detector. The introduction of these products was driven by the desire to capture, archive, distribute, and display digital images. Almost all medical imaging is now digital, and a *picture archiving and communication system (PACS)* has become an essential component of any imaging department.

Clinical Utility in the Neonatal Intensive Care Setting

Radiography is the simplest and most reliable way to define tube and line position. Radiopaque markers are incorporated into most of these devices. **From peripherally inserted central catheters (PICCs) to endotracheal, thoracostomy, and feeding tubes, a simple radiograph can quickly identify suboptimal line or tube placement, allowing for repositioning and helping to eliminate complications** (Table 9.2). **Chest radiographs are most commonly used to evaluate the heart and lungs. Abdominal imaging allows a limited assessment of the solid viscera (the liver, spleen, and kidneys), as well as the bowel gas pattern, which is useful in evaluating a neonate with a feeding intolerance** (Fig. 9.1). **The bones of the trunk and extremities are easily assessed with plain-film radiology.**

TABLE 9.2 POSITION OF LINES AND TUBES

LINE/TUBE	POSITION
Endotracheal tube	1 cm above the level of the carina
Umbilical artery catheter	Descending aorta between T8 and T10
Umbilical venous catheter	Junction inferior vena cava and right atrium
Central line	Junction superior vena cava and right atrium
PICC line	Junction superior vena cava and right atrium
Nasogastric tube	Antrum of the stomach

PICC, Peripherally inserted central catheter; *T8* and *T10*, thoracic vertebrae 8 and 10.

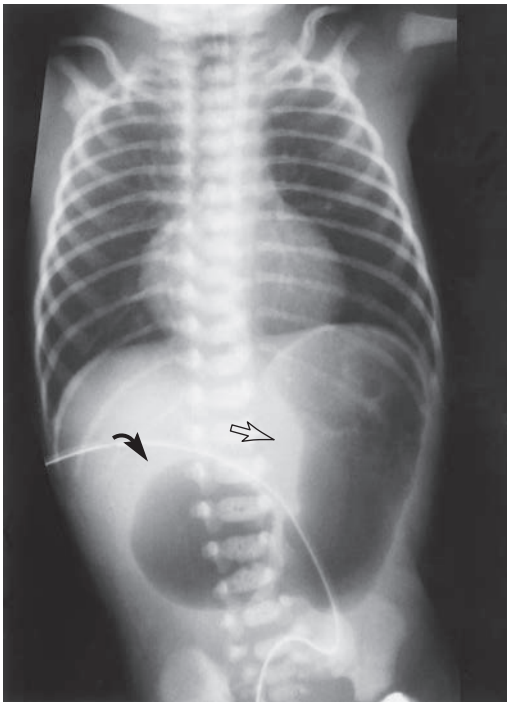

FIGURE 9.1 Frontal chest and abdomen show gaseous distention of the stomach *(open arrow)* and duodenal bulb *(curved arrow)*, the classic double bubble seen in duodenal atresia. Incidental note is made of 13 pairs of ribs in this patient with Down syndrome.

Focused Discussion: Chest Radiographs

The most common use of x-ray imaging in the neonatal unit is for evaluation of the chest to help define abnormalities that might contribute to respiratory distress. Respiratory distress in newborns can be divided into three categories: conditions that are managed medically, those that are managed surgically, and iatrogenic respiratory distress.

MEDICALLY MANAGED RESPIRATORY DISTRESS

Table 9.3 **summarizes plain-film diagnosis of respiratory distress in newborns.** The use of this approach takes advantage of the fact that only a limited number of changes can be identified radiographically, and a constellation of findings can define a specific group of etiologic factors. **A systematic analysis of these various characteristics helps determine a specific group that has a fairly limited differential diagnosis** (Box 9.1).

SURGICALLY MANAGED RESPIRATORY DISTRESS

Respiratory conditions that are managed surgically can be subdivided into three groups: (1)

TABLE 9.3 PLAIN-FILM DIAGNOSIS OF MEDICALLY MANAGED CAUSES OF RESPIRATORY DISTRESS IN THE NEWBORN (CHIMP DIFFERENTIAL)

		GESTATIONAL AGE	HEART SIZE	LUNG VOLUME	NATURE OF INFILTRATE	PROGRESSION	ANCILLARY FINDINGS
C	Congenital heart disease		Increased	Normal or increased	Increased pulmonary vascularity or edema	Stable or progressive	Abnormal situs, aortic discordance
H	Hyaline membrane disease*	<36 weeks		Decreased	Diffuse granularity with air bronchograms	Progressive over first 24 hours	No pleural effusions or body wall edema
I	Immature lung	<26 weeks	Normal	Decreased	Diffuse granularity	Progressive	Absent thymus from stress
M	Meconium aspiration	≥39 weeks	Normal	Increased	Streaky and patchy	Stable	Air leak (i.e., pneumothorax)
P	Neonatal pneumonia		Normal or increased		Either diffuse or focal		Pleural effusions and body wall edema

*Surfactant deficiency disease.

BOX 9.1 CHIMP DIFFERENTIAL DIAGNOSIS MODEL

Congenital heart disease
  Transient tachypnea of the newborn (resolves over first 24 hours)
  Extracardiac shunts
Hyaline membrane disease*
  Diffuse atelectasis
Immature lung
  Represents anectasis rather than atelectasis
Meconium aspiration
  Amniotic fluid aspiration
Pneumonia
  Diffuse
    Birth asphyxia
  Focal
    Pulmonary hemorrhage
Bronchopulmonary dysplasia represents the chronic lung disease that may result from any of the causes of respiratory distress.

*The use of exogenous surfactant modifies the picture of hyaline membrane disease (idiopathic respiratory distress syndrome [IRDS]) significantly. The irregular distribution after endotracheal administration causes a much less uniform infiltrate, and the patchy pattern that results has a look similar to that in meconium aspiration, which might be seen in a term or postterm infant.

those associated with aspiration, such as cleft palate, laryngeal cleft, or tracheoesophageal fistula (TEF); **(2) those that compromise functional lung volume,** including congenital diaphragmatic hernia (CDH), congenital lobar emphysema (Fig. 9.2), pulmonary sequestration, and congenital pulmonary airway malformation (CPAM); and **(3) those associated with tracheal or bronchial narrowing,** such as a double aortic arch and other vascular rings and slings, congenital tracheal stenosis, and bronchogenic cyst (Box 9.2).

IATROGENIC RESPIRATORY DISTRESS

Most iatrogenic respiratory distress results from either a misplaced catheter or tube or from barotrauma. An endotracheal tube (ETT) can be placed too deep and will preferentially ventilate only a single lung. An ETT may even be placed inadvertently into the esophagus, resulting in inadequate ventilation (Fig. 9.3), which is further compromised by distention of the esophagus and small bowel, limiting lung expansion.

Air leaks are often the result of barotrauma (Fig. 9.4). Although barotrauma occurs much less frequently because of the availability of exogenous surfactant, high-frequency ventilation, and nitric oxide therapy, air leaks continue to be a problem that causes significant concern. Appropriate ventilation management requires timely and accurate diagnosis. **One goal in the review of a chest x-ray is to define the location of any extrapulmonary gas. Abnormal extrapulmonary gas can include any one or a combination of the following: pulmonary interstitial emphysema, subcutaneous emphysema, pneumomediastinum, pneumothorax,**

FIGURE 9.2 Frontal view of the chest shows a hyperaerated lucent left upper lobe *(arrows)* associated with mediastinal shift from left to right and is characteristic of congenital lobar emphysema.

BOX 9.2 SURGICALLY MANAGED RESPIRATORY DISTRESS

1. Associated with aspiration
   a. Cleft palate
   b. Laryngeal cleft
   c. Tracheoesophageal fistula
2. Compromised functional lung volume involvement
   a. Congenital diaphragmatic hernia
   b. Congenital lobar emphysema
   c. Congenital cystic adenomatoid malformation
3. Cause tracheal or bronchial narrowing
   a. Double aortic arch
   b. Tracheal stenosis
   c. Bronchogenic cyst

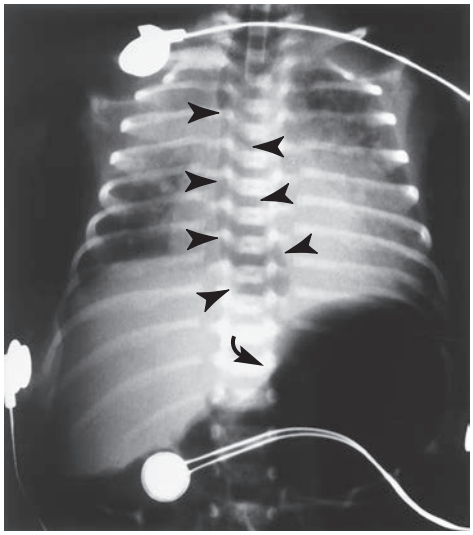

FIGURE 9.3 Frontal chest film. Although the endotracheal tube projects over the midline mediastinum near the thoracic inlet, the dilated esophagus *(arrowheads)* and distended stomach *(arrow)* associated with right upper lobe and left lower lobe atelectasis suggested esophageal intubation, which was diagnosed in this patient.

pneumopericardium, pneumocardia, and portal venous gas.

Focused Discussion: Skeletal Dysplasia

Skeletal dysplasias are a group of bone and cartilage disorders that, although rare individually, overall occur in approximately 1 in 5000 births. Today over 450 individual skeletal dysplasias are known and classified by their clinical, radiographic, and genetic findings. The accurate identification and classification of a patient with skeletal dysplasia can have important implications for the patient because some prove fatal in early life. **In patients for whom a complex skeletal dysplasia is suspected, a skeletal survey consisting of anteroposterior (AP) and lateral views of the skull, AP and lateral views of the spine, and AP views of the pelvis and all extremities (with separate AP views of the hands and feet) should be obtained.[21]**

The first step in assessing the radiographs in a patient with suspected skeletal dysplasia

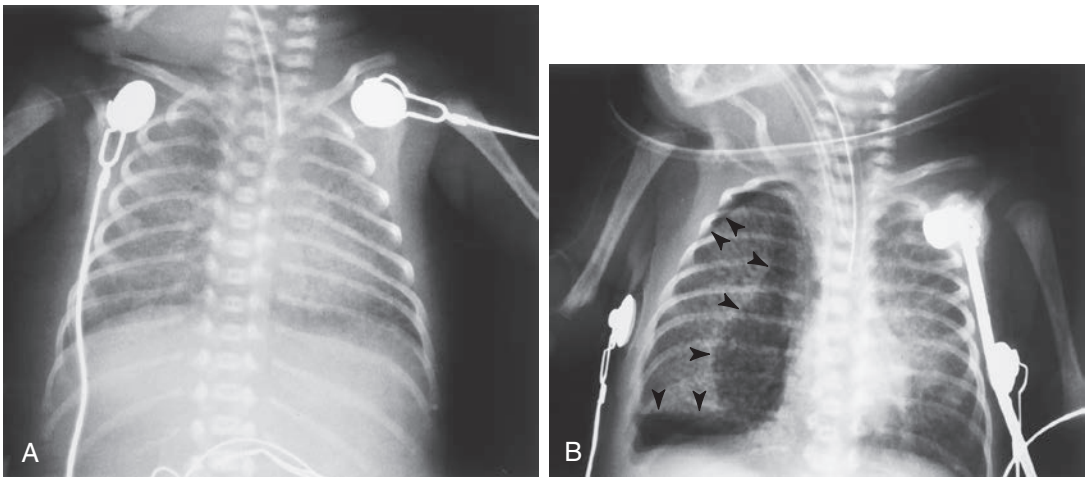

FIGURE 9.4 A, Frontal chest film. Surfactant deficiency disease (hyaline membrane disease) in this patient is defined by the diffuse symmetric granular infiltrates with low lung volumes. This patient required intubation, and the endotracheal tube tip projects in satisfactory position. B, Follow-up examination in the same patient demonstrates linear lucencies within the right lung resulting from pulmonary interstitial emphysema. A tension pneumothorax *(arrowheads)* is identified on the right with mild mediastinal shift from right to left. The lack of atelectasis on the right is the result of the extremely poor lung compliance that accompanies pulmonary interstitial emphysema. The endotracheal tube tip projects in a satisfactory position, but the nasogastric tube is in the midesophagus.

is to look for disproportion. A disproportionate appearance of the chest, such as a narrowed, elongated chest, can be an important diagnostic sign of dysplasia. Other signs include flattening of the vertebral bodies (platyspondyly), with short-trunk disproportion, and shortening of the extremities, such as rhizomelia (root or proximal limb shortening), mesomelia (middle limb), or acromelia (distal limb). **The next step is to evaluate epiphyseal, metaphyseal, and diaphyseal ossification.** Growth of long bones occurs at the ends, where the midshaft *(diaphysis)* is contiguous with the distal shaft *(metaphysis)* and separated by a radiolucent cartilaginous plate *(epiphyseal cartilage or physis)* from the distal end *(epiphysis)*. Ossification centers of the distal femur, proximal tibia, calcaneus, and cuboid are often present at birth. With these findings in mind, the patient can often be classified into a group of skeletal dysplasias. With the help of reference books on skeletal dysplasias, such as *Taybi and Lachman's Radiology of Syndromes, Metabolic Disorders and Skeletal Dysplasias,*[20] specific findings can lead to a diagnosis.

Achondroplasia is a relatively common dysplasia, with 2.8 cases per 100,000 births. **Achondroplasia is a disproportionate rhizomelic short-limbed skeletal dwarfism** (i.e., the proximal segment [humerus] is shorter than the middle [radius and ulna] and distal [wrist and hand] segments). Patients with achondroplasia also have a disproportionately large head, with a decreased size of the skull base and narrow foramen magnum. The lower lumbar spine demonstrates narrowing of the distance between the pedicles, which normally widen at the lower lumbar spine, and kyphosis (posterior angulation) at the thoracolumbar junction. Infants often suffer from respiratory difficulties due to adenoidal hypertrophy, narrow nasal passages, and a small thorax. Narrowing of the foramen magnum and cervicomedullary compression can lead to hydrocephalus and neurologic complications.

Thanatophoric dysplasia is also a disproportionate rhizomelic short-limbed dwarfism. Although the radiographic findings are qualitatively similar to achondroplasia, the severity of the manifestations helps differentiate the two. Classic findings in newborns with thanatophoric dysplasia include very short, bowed femurs with metaphyseal flaring (telephone receiver femurs); a narrow thorax; a large head with small facial bones; and flattened vertebral bodies with notched endplates. Thanatophoric dysplasia is frequently suggested on prenatal ultrasonography by shortened femurs and a narrow chest. This dysplasia has important implications in the neonatal intensive care unit (NICU) because infants will die within the first few days of life without respiratory support.

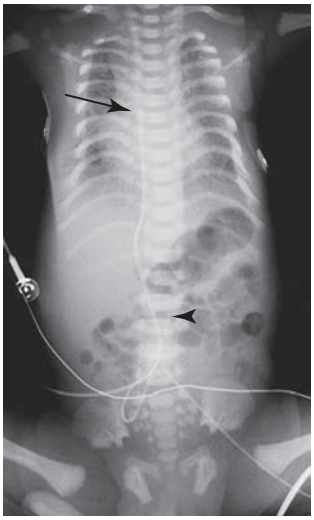

FIGURE 9.5 Anteroposterior film of the chest and abdomen of a patient with asphyxiating thoracic dystrophy (Jeune syndrome) demonstrates short broad ribs with a narrow thorax as well as shortened iliac wings with bony spurs. Also note the malpositioned umbilical venous catheter with its tip in the upper right atrium *(arrow)* and umbilical arterial catheter *(arrowhead)*.

In *asphyxiating thoracic dysplasia* (Jeune syndrome), presenting signs include a long, narrow thorax with short horizontal ribs and respiratory difficulties in infancy (Fig. 9.5). Shortening of the extremities, including the hands and feet, with occasional polydactyly (extra digits), also occurs and can present at birth or later in life. In the pelvis, the iliac wings are shortened in the craniocaudal direction, with bony spurs projecting from the acetabula. Complications of asphyxiating thoracic dysplasia in the neonate center on respiratory distress due to reduced lung volumes/small chest size. Later in life, respiratory infections become a problem, and progressive renal disease leading to renal failure may occur. Patients may also develop hepatic fibrosis, pancreatic fibrosis, and retinal degeneration.

FLUOROSCOPY

Background

Fluoroscopy employs an x-ray tube similar to that used for plain-film radiography. The x-ray is

generated in the same manner as in plain radiography, but it is received in most cases by a device that is similar to a TV camera or VCR. **Fluoroscopy allows real-time evaluation of a patient and can be performed with or without contrast material.** The spatial resolution in fluoroscopy is not as good as that in plain-film radiography, but it is still excellent. The contrast resolution is about the same: air, fat, water, bone, and contrast are the primary densities that can be separated. Contrast media can be given orally or per rectum, instilled into the urinary bladder, or given intravenously. The contrast attenuates the radiation beam to a variable extent related to physical properties and thickness of the attenuator. Most contrast agents are compounds that use either inert barium or iodine as the attenuator of the radiation beam. **The most important characteristic of fluoroscopic imaging is the ability to evaluate motion in real time. This is essential in the evaluation of swallowing function, gastrointestinal (GI) peristalsis, and diaphragmatic motion.**

Clinical Utility in the Neonatal Intensive Care Setting

The most common fluoroscopic examinations requested for neonates include the upper GI (UGI) series, contrast enema, and voiding cystourethrography. The UGI series (and modifications of it) is useful in the evaluation of swallowing, feeding intolerance, vomiting, and abdominal distention with possible bowel obstruction.

A contrast enema should be the initial diagnostic study of choice when low bowel obstruction is suggested clinically or on radiographs. A contrast enema can be diagnostic in many cases of low bowel obstruction, including distal small bowel atresia, meconium ileus, and small left colon syndrome. Findings suggestive of Hirschsprung disease can lead to further evaluation with punch biopsy and play an important role in surgical planning (Fig. 9.6). **In addition to a diagnostic role, a contrast enema can be therapeutic in small left colon syndrome and meconium ileus.**

A voiding cystourethrogram is used to evaluate the urinary bladder and the urethra and to look for vesicoureteral reflux (Fig. 9.7), which is associated with urinary tract infection. Vesicoureteral reflux is a common cause of hydronephrosis, which is now frequently identified during prenatal ultrasonography.

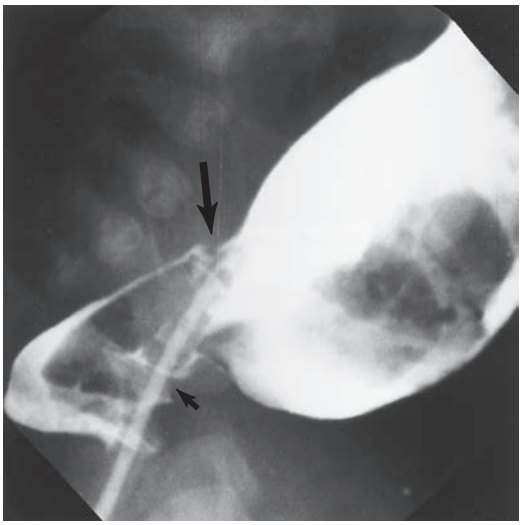

FIGURE 9.6 A lateral film from the early filling phase of a contrast enema demonstrates spasm of the distal rectal segment *(short arrow)* with a transition zone to dilated colon *(long arrow)*. These findings are characteristic of colonic Hirschsprung disease.

FIGURE 9.7 Frontal view from a voiding cystourethrogram demonstrates grade II vesicoureteral reflux on the left *(arrow)*.

Ureteroceles, periureteral diverticula, and posterior urethral valves all can be associated with hydronephrosis in the neonatal period and demonstrated with cystourethrography.

Air functions as a useful contrast agent, and the nasal and oral airway, as well as the trachea and proximal bronchus, can easily be evaluated fluoroscopically. Because the diaphragm is immediately adjacent to aerated lungs, diaphragmatic motion and its relationship to inspiratory effort help in the evaluation of phrenic nerve injury and diaphragmatic paralysis. Eventration of the diaphragm also can be evaluated fluoroscopically, but at times, it can be indistinguishable from diaphragmatic hernia.

Focused Discussion: Upper Gastrointestinal Series

Indications for performing a UGI fluoroscopic study include swallowing dysfunction, vomiting, choking, and apnea. An appropriately performed UGI series offers a systematic approach to the upper GI tract. Starting with the patient in a left-side-down recumbent position, deglutition, transport, aspiration, and laryngeal penetration all can be grossly assessed, with more detailed assessment reserved for a modified barium swallow using contrast material with varying thicknesses. The right-side-down position better separates the esophagus and the tracheal air column. However, if this position is used initially and the evaluation of the esophagus is prolonged, the stomach may empty, filling the proximal small bowel and obscuring the location of the ligament of Treitz. **The left-side-down position allows evaluation of swallowing and the esophagus without concern that the stomach may empty prematurely.**

Esophageal atresia **usually is diagnosed clinically;** plain-film observation of intraluminal bowel gas defines the most common form, which is associated with a distal tracheoesophageal fistula. **Often, an enteric tube that coils in the proximal esophageal pouch is the initial radiographic finding in patients with tracheoesophageal fistula.** The benefit of a proximal pouch study in esophageal atresia is controversial. There is a small incidence of fistula from the proximal pouch to the trachea; this incidence is independent of the presence or absence of a distal fistula. If the surgical approach to esophageal atresia repair includes direct visualization of the proximal pouch *(esophagoscopy),* the pouch contrast study is superfluous. If, on the other hand, esophagoscopy is not routinely performed, there is some value in evaluating the proximal pouch before surgery. In the absence of esophageal atresia, the location of the fistula (H type) is at the thoracic inlet. This is higher than the fistula that occurs at the level of the carina in the most common form of esophageal atresia.

The contour and caliber of the esophagus are evaluated next. Impressions on the posterior esophagus are suggestive of vascular rings and are correlated with side of the aortic arch to determine if further work-up for vascular ring is needed. Impressions on the anterior esophagus can be related to pulmonary artery slings. Esophageal contour, mucosal detail, and peristalsis are assessed. **The configuration of the gastroesophageal junction can indicate gastroesophageal reflux, and rare hiatal hernias can be diagnosed.**

Gastric emptying is evaluated, and gastric peristalsis is examined. Because the rotation and fixation of the bowel have important consequences in the newborn period, definition of the duodenal bulb, C-loop, and position of the ligament of Treitz is a critical part of a complete examination. Both the posteroanterior (PA) and lateral views are essential in localizing the ligament of Treitz. For proximal bowel rotation and fixation to be considered normal, the duodenal-jejunal junction (fixated by the ligament of Treitz) must be retroperitoneal (and therefore posterior), to the left of the spine, and at the level of the retroperitoneal portion of the second portion of the duodenum (just distal to the duodenal bulb).

The rotation of the proximal bowel may be independent of the rotation of the hindgut. **Therefore, if the clinical question is malrotation and possible volvulus, the UGI series is the examination of choice.** The caliber, contour, and fold pattern of the proximal bowel are evaluated, and the transit time is observed. This simple, systematic, yet comprehensive approach to the UGI series yields a tremendous amount of information.

ULTRASONOGRAPHY

Background

One of the most prominent mass-media introductions of ultrasound (US) technology came when Dr. Robert Ballard located the wreckage of the *Titanic*

using US to explore the ocean floor of the North Atlantic. Medical ultrasonography has its roots in sound navigation and ranging (sonar) developed during World War II.

In medical ultrasound, a transducer (essentially a piezoelectric crystal) converts electrons into a mechanical vibration that creates high-frequency sound waves within the body. The same transducer serves as both the transmitter of the sound wave and the receiver of the reflected sound. Within the body, these high-frequency sound waves propagate through the soft tissues until they meet a reflective surface that reflects some of those sound waves back to the transducer. The percentage of the sound beam reflected relates to the difference in the acoustic impedance of the material being evaluated. When the acoustic impedances of materials are similar, as is the case with the musculature of the abdominal wall (e.g., liver, kidney), most of the sound is transmitted, and a small percentage is reflected at each interface. As the sound wave travels through the abdominal wall to the liver, the abdominal wall–liver interface reflects a portion of the beam and transmits most of the sound through the liver to the liver–kidney interface. The small difference in acoustic impedance between the liver and kidney causes reflection of some of the beam and transmission of most of it to the posterior abdominal wall. This allows the visualization of multiple interfaces that are deeper than the first structure encountered. If the velocity of the sound beam in tissue is known, the distance to the reflective surface can be estimated by measuring the time it takes for the pulse to travel the distance to and from the object imaged.

Most of the tissues in the body have similar acoustic impedances; however, air has extremely low impedance, and bone has extremely high impedance. This means that there is a big difference in the acoustic impedance between these substances and the organs most commonly imaged. For this reason, both bone and air reflect nearly all of the sound that reaches them. This is why a coupling gel is used on the skin surface to eliminate the air gap between the transducer and the skin. This also explains why imaging through the liver gives a good acoustic window to deeper structures, but bowel gas obscures imaging lower in the abdomen. **For ultrasonographic imaging of the brain in a neonate, the anterior fontanel serves as the acoustic window because the bone of the skull acts as a reflective surface that limits through-transmission of US to deeper structures.** The mastoid fontanel serves as a window to the posterior fossa. Bulk fluids within the body, such as urine in the urinary bladder, bile in the gallbladder, or cerebrospinal fluid in the ventricles, have no internal interfaces and therefore are seen as solid black on conventional ultrasonography. Cysts have a sharp posterior wall and have increased through-transmission because the sound wave penetrates the fluid without any reflections to block transmission of the sound.

Doppler ultrasonography takes advantage of the physical principle that the US reflection from a moving object distorts the wavelength, with the distortion related to the velocity of the object being measured. This is the principle that causes the pitch of a train's whistle to change from high to low as the train passes an observer. It is the same principle used by radar guns to monitor the speed of a car or to measure the velocity of a pitcher's fastball. In fact, this same principle is responsible for the "red shift" observed by astronomers in determining that we live in an expanding universe. The Doppler evaluation in medical ultrasonography uses the distortion of the wavelength caused by moving red cells to identify flowing blood.

One of the major advantages of US imaging is the lack of ionizing radiation. Although most diagnostic imaging utilizes low doses of ionizing radiation, any radiation exposure is a concern and should be avoided when possible. The portability of US equipment has made it a valuable adjunct to diagnostic imaging in the neonatal intensive care setting.

Clinical Utility in the Neonatal Intensive Care Setting

Ultrasonography has had a major effect on the evaluation of the neonatal brain. Most of the early work focused on intracranial hemorrhage, which was a common occurrence in preterm neonates. **Even though the incidence has decreased, intracranial hemorrhage remains an issue for which US imaging is extremely well suited.** Ultrasound equipment has improved tremendously, and with the addition of color and pulse Doppler technology, great strides have been made in the refinement and sophistication of intracranial imaging. Numerous complex structural abnormalities can be recognized, and screening for developmental

abnormalities can largely be accommodated with cranial ultrasonography. Because bone reflects most of the sound, limiting through-transmission, the open fontanel is the window to the brain. As the fontanel closes over time, ultrasonography becomes less and less useful for intracranial imaging.

Renal imaging offers another major role for ultrasonography in the neonatal unit. The kidneys are well visualized ultrasonographically, either through a posterior approach or, more commonly, by using the liver or spleen as soft-tissue acoustic windows to the kidneys. **US is an excellent way to evaluate hydronephrosis**, which is now frequently picked up on routine prenatal evaluations. **US has a role in the evaluation of a jaundiced patient because it is ideal for evaluating cystic structures,** such as the gallbladder, and can readily identify dilated biliary ducts. Jaundice caused by biliary obstruction from a choledochal cyst, for instance, can be diagnosed readily with US. Because of the reflectivity of bone and bowel gas, US imaging is much more effective in the upper abdomen, in which the liver and spleen serve as the acoustic windows, or in the pelvis, in which the urinary bladder can function as the window.

Although US is limited by bone, **it has a significant role in the evaluation of the hips in the neonate.** Because the capital femoral epiphysis of the newborn is cartilage, the hip can be well imaged in a neonate. Maternal estrogen causes ligamentous laxity. This changes significantly during the first weeks of life; **therefore, the accuracy of hip ultrasound examinations improves after the first 3 to 4 weeks of life.** Ultrasonography is very good for the detection of developmental dysplasia of the hip and can be used to evaluate the degree of femoral head coverage, the acetabular angle, and any instability of the hip.

The use of US to provide the localization of central lines is becoming common practice. The types of lines frequently used for infants in the NICU include umbilical venous catheters (UVCs), umbilical arterial catheters (UACs), and PICCs. **Many complications can occur if the tips of these lines are not in the correct position, including pleural effusions, cardiac arrhythmias, cardiac tamponade, thrombosis, liver hematoma, liver injury, and portal hypertension.** The gold standard for assessing the position of lines and tubes has been radiographs of the chest, abdomen, or both. **The use of US has many advantages over radiography, including real-time assessment of the line; no radiation exposure; the ability to place and manipulate the catheter under US guidance; reduced insertion time; and fewer malpositions, manipulations, and complications.**[*] Bedside US can be accomplished with appropriate training. Numerous recent studies have suggested that the use of US for line placement has good sensitivity and specificity compared with radiographs.[†]

Focused Discussion: Cranial Ultrasonography

Ultrasonography is an ideal tool for evaluating the brain in a newborn. In general, an ultrasonographic examination is the first step in the imaging evaluation for any neurologic question. **A routine screening US is recommended at between 7 and 14 days of age in all premature infants born under 32 weeks' gestation and should be repeated at 36 to 40 weeks of gestational age.**[32] Structural abnormalities, intracranial hemorrhage, sequelae of anoxic or ischemic events, and infection are all well assessed via ultrasound. The most common approach is through the anterior fontanel, but additional information can be gained with axial imaging through the squamosa of the temporal bone. The posterior fossa can be evaluated through the posterior lateral fontanel. Familiarity with the normal anatomy is essential. Coronal and parasagittal views are obtained. **Normal structures can be easily recognized; their absence or deformity can define developmental abnormalities of the brain.** The ventricular size and configuration are assessed. Characteristic ventricular configurations can define lobar or semilobar holoprosencephaly. In addition, the ventricular configuration can suggest septo-optic dysplasia or agenesis of the corpus callosum. The corpus callosum can be visualized directly; abnormalities of the corpus callosum are commonly associated with *Chiari malformation* and other structural abnormalities of the brain, such as *Dandy-Walker malformation*. **Dilation of one or more of the ventricles can be an indication of a pathologic condition.** An obstruction of the flow of cerebrospinal fluid (CSF) in the region of the Sylvian aqueduct manifests with a disparity in ventricular size. The lateral and third ventricles are enlarged, whereas the fourth ventricle remains normal in size. Dilation of

[*] References 2, 10, 12, 16, 17, 18, 19, 23.
[†] References 2, 12, 16, 17, 18, 19, 24, 28.

one of the lateral ventricles, especially when associated with an area of *porencephaly,* is indicative of an in utero destructive event. **Seizures or apnea may indicate an anoxic or ischemic event in a neonate.** Certain structural abnormalities can suggest a specific diagnosis; for instance, periventricular nodules and cortical tubers define tuberous sclerosis. US examination is less sensitive than computed tomography (CT) and magnetic resonance imaging (MRI) in defining subtle areas of gray-matter heterotopia or focal pachygyria, examples of developmental abnormalities associated with seizures. **US imaging is very sensitive to intracranial hemorrhage, and areas of increased echogenicity can be demonstrated in areas of edema.** Intracranial hemorrhage is an important concern in a premature neonate (Fig. 9.8) and is classified into four grades; each grade is prognostically significant.[34] Grade I hemorrhage usually has a good outcome, whereas the prognosis with grade IV hemorrhage is frequently poor. **Grade I hemorrhage is confined to the germinal matrix in the caudothalamic groove. This is the last fetal germinal matrix to mature and is prone to hemorrhage in preterm babies. Grade II intracranial hemorrhage has intraventricular blood. Grade III hemorrhage is associated with ventricular dilation as the intraventricular clot enlarges the lateral ventricles. Grade IV hemorrhage is defined by parenchymal extension.** It has been hypothesized that grade IV hemorrhage may be the result of venous infarction that occurs from obstruction of the septal veins by the swollen germinal matrix hemorrhage. **White-matter injury of prematurity (periventricular leukomalacia) is a consequence of anoxic or ischemic injury to the brain that manifests as increased echogenicity in the deep periventricular white matter of the centrum semiovale. This may progress to cavitation and is then called *cystic leukoencephalomalacia*.** US can detect changes of leukoencephalomalacia, which is usually apparent within 2 weeks of birth.[33]

COMPUTED TOMOGRAPHY

CT was initially developed in 1972 in Middlesex, England, by Electric and Musical Industries (EMI), an industrial research company. After signing the Beatles in 1962, the company sold its computer business; however, it kept a researcher named Godfrey Hounsfield and funded his independent research through the revenue generated by the Beatles' success. Hounsfield imagined that he could determine what was inside a box by taking x-rays of the box at all angles. He then worked to build a computer that could reconstruct a slice of an object from the data of these x-rays acquired at various angles. He shared the Nobel Prize in Physiology and Medicine with Allan Cormack, who developed the theoretical mathematics for the invention of CT.

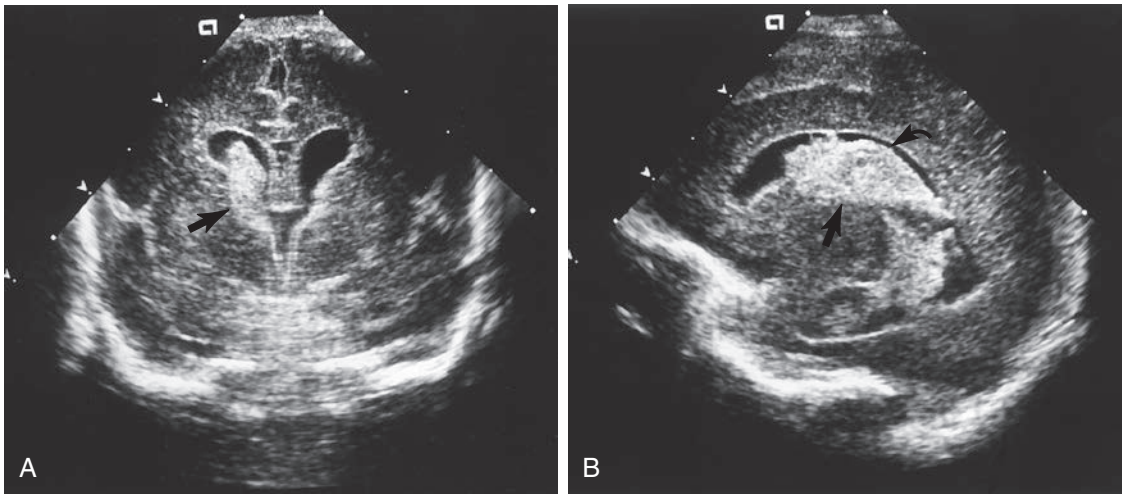

FIGURE 9.8 Coronal **(A)** and parasagittal **(B)** ultrasound images from a cranial ultrasound study demonstrate an echogenic clot *(arrows)* within the dilated right ventricle. The intraventricular clot with ventricular dilation defines a grade III hemorrhage.

Early CT scanners produced images by acquiring x-ray data in multiple positions in an axial plane, moving to a different level between acquiring slices. The initial EMI scanner solved mathematical equations representing the attenuation of the different x-ray beams, like a giant Sudoku puzzle. The complexity of mathematics involved as well as limitations in computers at the time contributed to the limited speed of the scanner; it took approximately 10 minutes to acquire and reconstruct each slice, and the resolution was limited to an 80 × 80 matrix. For comparison, today's fastest dual-source CT scanners can acquire 64 slices in about 0.07 second in the fastest scanning mode with a matrix of 1024 × 1024.

On modern multidetector helical CT scanners, image acquisition takes place as the patient is carried on a mobile table through a rotating gantry containing an x-ray source on the opposite side of the gantry from x-ray detectors. A ring of data is acquired as the patient is moved through the gantry; the path of image acquisition is in effect a helix, resembling a coiled spring, hence the term *helical* or *spiral* CT. Multidetector arrays of 4, 8, 16, 64, and even 320 elements allow rapid acquisition of multiple slices in a single rotation of the tube. This renders high-resolution isovoxel data sets (each volume element has the same width, height, and depth). Because the data are acquired in a continuous helix in an isovoxel data set, as if peeling an apple from top to bottom in one peel, the data can be reconstructed in any plane as well as rendered in three-dimensional (3D) format, just as you could imagine putting an apple peel back together to look like an intact apple. Reconstruction of the acquired data has undergone and continues to undergo revisions. In the most commonly employed method, filtered back-projection lines of gray representing the attenuation of the patient are layered on top of each other to create images, with different filters applied to accentuate different aspects of the image. This renders a cross-sectional slice that can show all of the structures within that slice. For instance, a slice through the upper abdomen may show the liver, spleen, pancreas, both kidneys, and the spine, each separated by a plane of fat and each with a subtly different density.

New technologies on recently introduced CT scanners include volumetric scanning, dual-source and dual-energy CT scanners, and technology designed to reduce the radiation dose to patients by limiting the patient's exposure during the scan or allowing for improved reconstruction of scans obtained at lower radiation doses. Volumetric scanning achieved with up to 320 detectors can allow for an area up to 16 cm to be scanned in a single rotation of the scanner gantry. Dual-source, dual-energy scanners can leverage two tubes and two detector arrays, either for an increased scanning speed of up to 0.07 second for 64 slices with both tubes at the same energy or improved tissue differentiation using different energies. **Given the recent attention to radiation effects from CT in both the medical literature and the lay press, there has been a renewed focus on technology to reduce the dose in CT scans.** This includes both improving the mechanics of the CT scanners themselves as well as developing more advanced reconstruction algorithms that allow scans obtained at lower doses to produce excellent-quality images.

These recent advances in CT technology have resulted in spectacular images and an explosion in CT utilization. The radiation dose in CT, however, is significantly higher than that in routine radiography. CT now accounts for more than 60% of the radiation exposure from medical imaging in the United States. Trailing this growth in the utilization of CT has been greater understanding of and concern for the effects of ionizing radiation in medical imaging. Evaluation of the risk associated with the low doses of ionizing radiation used in medical imaging is a complex and evolving topic. The majority of studies estimating risk from low doses of radiation have been based on models in which survivors of large known doses of radiation, such as from the atomic bombs in Japan, have been followed longitudinally to assess the risk of developing cancer. These models assume that by extrapolating the effects of large radiation doses to low doses, the risk for low doses can be assessed in what is called a linear no-threshold model. Although the accuracy and assumptions in this type of model have been questioned, with some investigators claiming that there is in fact no risk, or even benefit, with low doses of radiation, **more recent studies have suggested that there is a small increased risk of cancer associated with clinical medical imaging.**[5,6,13] **A retrospective cohort study that looked at the incidence of leukemia and brain tumors in pediatric patients who had undergone CT demonstrated an association between the radiation received from**

CT scans and leukemia and brain tumors.[25] Although there was a significant increase in relative risk suggested in this study, the absolute risk remained low.

Medical research suggests that the radiation dose currently used in diagnostic CT is associated with an increase in the risk for radiation-induced malignancy. Neonates, infants, and children are more susceptible to the effects of radiation than adults. This stems from the fact that for a given exposure to radiation, the smaller the patient, the greater is the effective dose because more of the radiation penetrates the patient. Also, longer life expectancy puts younger patients at an increased risk because there is a longer period of time for a radiation-induced complication to develop.

Ionizing Radiation in Perinatal Medicine

The effects of ionizing radiation on the fetus of a pregnant patient also present complex and important concerns. Although the use of ionizing radiation generally should be avoided in patients who are pregnant, there still exist indications for which the benefit of performing the examination may outweigh the risk to the fetus. Additionally, on rare occasions, a CT may have been performed on a patient who was not known to be pregnant before the examination. Although a comprehensive analysis of the risk and radiation exposure of a pregnant patient undergoing CT should be considered in consultation with a medical physicist, general guidelines have been provided by the American College of Radiology in conjunction with the Society for Pediatric Radiology, as briefly described in the following paragraphs:[1]

Before conception, there has been no documented genetically heritable risk in the human population. ***In the first 2 weeks*** after conception, the only potential risk is felt to be the loss of pregnancy. Doses associated with radiographic procedures have not been clearly associated with increased risk, although this is difficult to determine because approximately half of all conceptions are lost in this period, often without recognition of the loss by the woman.

Radiation exposure ***between 2 and 15 weeks*** after conception has more complex risk implications. In general, radiologic procedures outside of the abdomen and pelvis, including the head, neck, and chest, should result in only a very low dose to the fetus from scatter radiation. In a patient who is known to be pregnant, the study should be optimized to limit the dose to the fetus even further. When imaging of the abdomen and pelvis is indicated or has been performed, consideration of the risk to the fetus takes on greater importance. In centers that carefully manage their CT radiation dose, as do most children's hospitals, the dose to the fetus is thought to be below the level associated with any developmental abnormality. However, before counseling takes place, verification of the dose by a qualified medical physicist is recommended. If the dose is determined to be low, the majority of the risk associated with radiation exposure to the fetus is a small increased risk of cancer in later life, and termination of pregnancy would not be indicated. Doses associated with increased developmental disorders are uncommon in routine practice and usually occur in circumstances that have important implications for the pregnancy, such as in patients who require complex cardiology or interventional radiology procedures.

The effects of radiation exposure to the ***fetus more than 15 weeks*** after conception are even smaller, with risk to the developing nervous system occurring only at very high doses, usually beyond what would be typically encountered even with multiple radiology procedures. Therefore, after 2 weeks' gestation, the predominant concern with low-dose diagnostic imaging is the small increase of developing cancer over a lifetime.

Although concern for the deleterious effects of radiation is important, it should always be viewed in the context of the patient as a whole. CT can be a powerful tool in evaluating the pediatric patient. Caution is the key: (1) image only when indicated; (2) limit the scan to the region of concern; and (3) be cognizant of dose and use as low peak kilovoltage (kVp) and milliampere-second (mAs) as possible, and use dose-reduction technologies while maintaining diagnostic-quality examinations.

Clinical Utility in the Neonatal Intensive Care Setting

Cranial imaging is the most common use of CT in most neonatal intensive care settings. CT adds significant specificity to the abnormalities

recognized with ultrasonography. Concern about ionizing radiation and the fact that CT equipment is generally not portable makes obtaining a CT more difficult than obtaining a sonogram. **CT is more accurate in assessing the nature of extra-axial fluid collections and is very helpful in further defining structural abnormalities of the brain, particularly those associated with the abnormal distribution of gray or white matter.** It is also very good for evaluating intracranial hemorrhage and infection. Exquisite bone detail defines craniofacial anomalies, choanal atresia and stenosis, and abnormalities of the petrous bone associated with hearing loss.

Focused Discussion: Computed Tomography Angiography of the Chest

Chest CT angiography (CTA) is becoming much more frequent in the NICU. CTA is often used to evaluate abnormalities detected during intrauterine US, chest x-ray, and echocardiogram examinations, such as congenital lung lesions and potential surgical lesions such as vascular rings identified on chest x-ray films.[7,11]

Through carefully controlled administration of intravenous (IV) contrast, CTA can supplement, and in many cases replace, the need for traditional catheter angiography.[15] Uses include describing the vascular supply to congenital lung lesions such as bronchopulmonary sequestrations, defining vascular and airway anatomy for surgical planning in patients with vascular rings, and surgical planning in patients with complex cardiac disease.

Congenital lung lesions are a spectrum of developmental abnormalities of the lung that include bronchial atresia, congenital pulmonary airway malformations, and bronchopulmonary sequestration, among others. Often suggested on prenatal sonography and, in some cases, characterized on fetal MRI, **CTA is often used in the postnatal period to further characterize the lesion and plan surgical intervention.**[11] Bronchial atresia can be diagnosed on CTA when an atretic bronchus is identified, often in association with a dilated, mucus-filled segment or "bronchocele/mucocele" distal to the atretic airway. Although often found in isolation, studies have identified bronchial atresia in up to 77% of other congenital lung lesions.[20] Cystic pulmonary airway malformations (CPAMs) have been traditionally defined by the size of the cysts within the lesion, with type 1 having cysts greater than 2 cm, type 2 with cysts less than 2 cm, and type 3 appearing solid; more recent alternative classification systems have been proposed, and the pathology of type 3 has been disputed. CPAMs can have a multilobar and rarely bilateral distribution. **CTA can define the cyst size and distribution as well as provide a roadmap for surgical planning.** Rare malignant potential for type 1 CPAMs has been reported, as has recurrent infection. Bronchopulmonary sequestrations were traditionally defined as portions of the lung with a systemic arterial supply and then further characterized as either extralobar or intralobar. Extralobar sequestrations most often appear as a wedge-shaped mass with systemic arterial supply with a pleural margin, often on the left and below the otherwise normally formed lung. Intralobar sequestrations are thought to be developmental abnormalities of the lung composed of isolated nonfunctional lung tissue, sometimes accompanied by cystic change within an otherwise-normal lobe. CTA provides excellent identification and characterization of both the vascular supply and associated parenchymal change in these lesions.

Although vascular rings are often initially suggested on chest x-ray or upper GI, CTA and MR angiography have largely replaced other techniques in the characterization of vascular rings.[7,14] CTA has the advantages of easy availability, improved depiction of the airway and lung parenchyma, and short scanning times, which in some cases can eliminate the need for sedation. Disadvantages include the use of ionizing radiation and iodinated contrast. MR angiography is a viable alternative in some cases in which the need for a detailed evaluation of the airway and lung parenchyma justifies the need for sedation.

In embryonic development, the ventral and dorsal aorta are connected by six pairs of aortic arches. Normally there is regression of some of these arches to result in the normal left-sided aortic arch. The sixth arch forms the ductus arteriosus and proximal right and left pulmonary arteries. Failure of regression or inappropriate development of these primitive vascular structures leads to the development of vascular rings and slings.

Vascular rings are formed when vessels, either patent or atretic, encircle the trachea and esophagus, with the potential to result in esophageal or tracheal compression. The most common

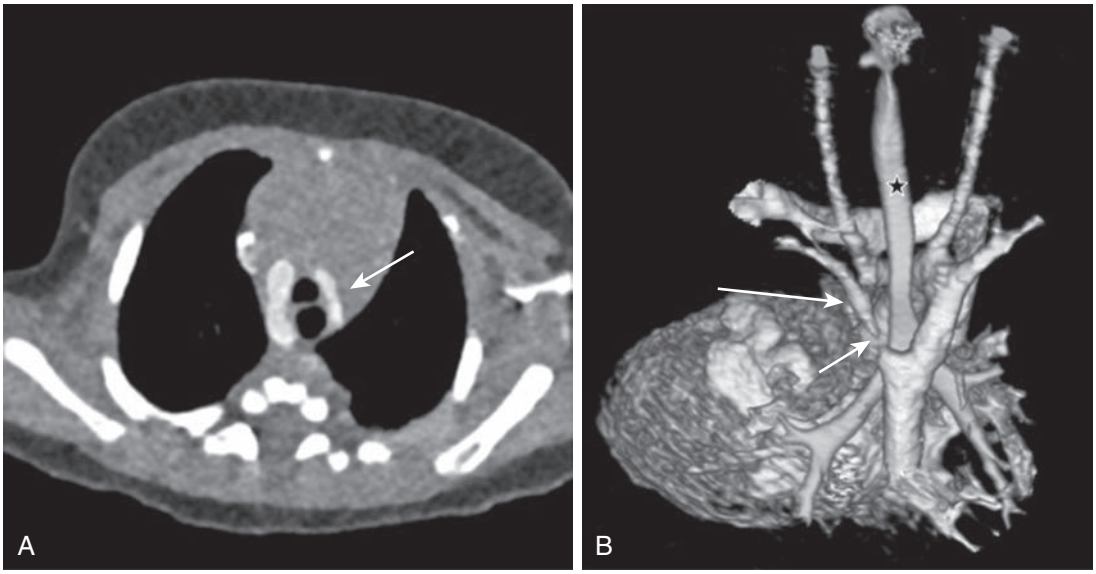

FIGURE 9.9 Axial **(A)** and volume-rendered three-dimensional **(B)** images of a computed tomography angiogram of the chest demonstrate a double aortic arch with hypoplastic left arch (*long arrow,* **A** and **B**) with atresia of the posterior aspect of the left arch (*short arrow,* **B**). The volume-rendered image (viewed from behind) better demonstrates the spatial relationships of the arches to each other as well as to the encircled trachea *(star)*.

symptomatic vascular ring is a double aortic arch (Fig. 9.9).[14] In most cases the right arch is dominant and higher than the left, although the arches can be the same size and one arch can be atretic. The second most common vascular ring is a right-sided aortic arch with aberrant left subclavian artery and left-sided ligamentum arteriosum. Less common vascular rings include left-sided aortic arch with aberrant right subclavian artery and right-sided ligamentum arteriosum and right-sided aortic arch with mirror-image branching and left-sided ligamentum arteriosus as well as circumflex aortas. In several of these conditions, the sidedness of the ligamentum arteriosus or other atretic structures determines if a complete vascular ring is present. The atretic structure itself usually cannot be visualized. Instead, the presence of a *dimple* on the aorta or pulmonary artery, *diverticulum* of the subclavian artery, or position of the *descending* aorta on the side opposite the arch (also referred to as the three "Ds") determines the position of the atretic segment.

Ultrasonography remains the first-line diagnostic tool for the evaluation of the kidneys, liver, and spleen, but when a pathologic condition of the abdomen is a concern and a good acoustic window for US imaging is not available, CT is frequently the examination of choice. CT can be performed with significantly less sedation than that necessary for MRI. CT eliminates many of the artifacts, including those of vascular flow, respiratory motion, and even bowel peristalsis, that limit the utility of MRI. **Skeletal lesions are well visualized with CT. Ultrasonography is the method of choice in the evaluation of congenital hip dysplasia, but CT can be very helpful in evaluating the position of the femoral heads after reduction and treatment of congenital hip dysplasia when the patient is immobilized in a plaster cast.**

CT can be very helpful in identifying the organ of origin of a specific pathologic condition.[14] This is, of course, the first step in narrowing a differential diagnosis. The addition of IV contrast can define the presence and extent of tumor and infection or abscess. CT can also evaluate for adenopathy, as well as the presence of tumor thrombus in renal arteries and the inferior vena cava, which may affect the surgical approach to renal and hepatic neoplasms. The findings on CT often lead to a specific diagnosis. The multiplanar, cross-sectional rendition of anatomy, which allows structures to be distinguished from one another, and the improved

contrast resolution make CT a useful tool when clinically indicated.

Focused Discussion: Intracranial Blood

Noncontrast CT is extremely sensitive and specific for the detection and localization of intracranial blood (Fig. 9.10). Blood from acute hemorrhage has a density on noncontrast CT (measured in Hounsfield numbers) higher than any normal structure except bone and calcium. The increased contrast resolution of CT allows the differentiation of gray matter from white matter and lends itself to a detailed structural evaluation of the brain. The ventricles are low in density (0 Hounsfield units, equal to water), the white matter is denser, and the gray matter is even more dense still, followed by blood from acute hemorrhage and, finally, calcium and bone. **Blood from acute hemorrhage is visualized as white as soon as a clot is formed, and this high density will slowly decrease over time.** For instance, the blood in a subdural hematoma after 2 to 3 weeks will become lower and lower in density until it is indistinguishable from water and CSF. **MRI can differentiate blood from a chronic subdural hematoma for a longer time than CT because the protein within a chronic subdural hematoma modifies the signal on MRI for an extended period.** Although all intracranial blood does change density over time, the compartment in which the blood is found affects the rate of change to some extent. **Therefore, the timing of an event responsible for the blood cannot be precisely determined based on density alone.**

The location of the blood is the next issue. **CT is the most accurate imaging method for detection of subarachnoid blood.** The presence of subarachnoid blood postpartum is common, even after a relatively nontraumatic birth. Unfortunately, on rare occasions, subarachnoid blood can cause vasospasm of vessels near the skull base, which can result in relative ischemia or hypoperfusion of the peripheral cortex. Areas of edema can be detected by looking for the loss of the normal gray–white differentiation or by finding a focal area of brain edema characterized by relatively low density resulting from the addition of low-density water to an otherwise-normal area of the brain.

The shape of a collection of blood is important in evaluating intracranial hemorrhage. Subarachnoid blood assumes a configuration that follows the arachnoid space. Therefore, it is most frequently seen in the suprasellar cistern, the ambient cistern, the Sylvian fissure, or the interhemispheric fissure, or layering on the tentorium. The most sensitive locations for identifying subarachnoid blood are in the region of the quadrigeminal plate cistern, the posterior aspect of the third ventricle, and the interpeduncular cistern. Subdural hematomas occur most frequently over the convexities or along the interhemispheric fissure. Those over the convexity can be differentiated from epidural hematomas by their crescentic configuration as opposed to the lenticular configuration of an epidural hematoma. The dura is the periosteum of the inner table of the skull; therefore, an epidural hematoma is limited by the adhesion of the periosteum to the skull and hence the lenticular configuration. This also explains why epidural hematomas are most often associated with higher-pressure arterial bleeding and why subdural hematomas frequently are associated with venous bleeding. Another key to differentiating the compartment is the relationship to cranial sutures. **An epidural hematoma will not cross a suture line because of the anatomic limitation of the dura by the suture. A similar limitation by the dural attachment at suture lines helps distinguish a cephalohematoma from a caput succedaneum.** The direct sagittal imaging of MRI has revealed the high prevalence of subdural blood in the posterior fossa.

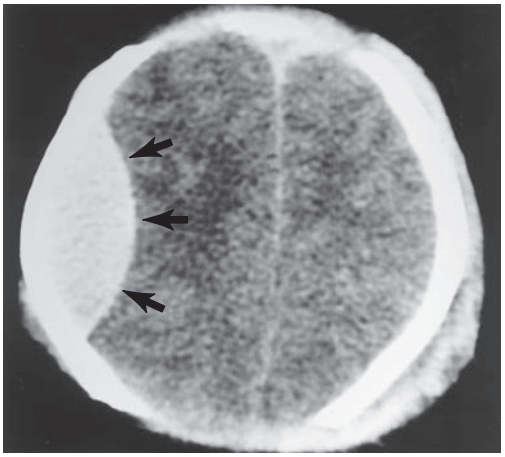

FIGURE 9.10 A single axial image near the vertex demonstrates a high-density lenticular mass *(arrows)* in the extra-axial space over the right cerebral cortex. The lenticular configuration is that of an epidural fluid collection and the high-density characteristic of blood from a chronic hematoma.

MAGNETIC RESONANCE IMAGING

Background

MRI is a modality that images protons or hydrogen ions within the body. The rapid development of magnetic resonance was a result of, in part, the transfer of sophisticated reconstruction algorithms used in CT and the computer power developed in other fields, such as the 3D graphics used in animation, cartography, and seismology. These technologic advances allow tremendous amounts of information to be manipulated quickly enough to make image reconstruction a reality. **MRI is essentially hydrogen imaging, and because the human body is 98% water, much hydrogen is available to image.**

MRI is performed by placing a patient in a strong magnetic field, which varies slightly from the head to the foot. Each proton acts as a small magnet, and just as the needle on a compass orients itself in one direction when placed next to a magnet, the protons in the body align when placed into a strong magnetic field. This alignment of protons is essential to create an environment that has a net electromagnetic field. Without the alignment of protons by the magnetic field, the random orientation of protons would have no measurable net field effect when stimulated and therefore would create no signal to image.

Once the patient is in the magnetic field, a radiofrequency (RF) pulse is delivered. In current imaging systems, the pulse wave has the frequency of an FM radio wave. Less than 1 in 1 million hydrogen ions will absorb any energy, and only certain RFs will allow the transfer of energy from the RF pulse to a hydrogen ion.

An analogy of this energy transfer can be seen on a schoolyard playground. Visualize a child on a swing. When pushing the swing in rhythm or resonance with the natural frequency of the motion of that swing, the swing will absorb the energy, and the child will swing higher and higher with each push. This natural rate of harmonic motion depends on the length of the rope on the swing and the mass of the swing and the child. If you were to push at a rate that was not synchronous with the swing's natural rhythm, pushing would not allow the energy to assist in propelling the swing higher and higher, and in fact, you would disrupt the normal rhythm of the swing.

In a famous TV commercial for Memorex in the 1970s, the playback of Ella Fitzgerald's voice caused a goblet to break, demonstrating the absorption of resonance frequency by the crystal in the goblet. The absorbed energy caused the goblet to shatter. In MRI, the FM RF energy is used to stimulate hydrogen ions or protons in the body.

Because the field strength of the magnet used for imaging varies slightly from one end of the patient to the other and the resonance frequency depends on the field strength of the magnet, one can selectively stimulate various locations within the patient. By changing the RF slightly, a different specific group of protons is stimulated. Protons stimulated by an RF pulse absorb energy and move to an unstable higher-energy state. They give up the absorbed energy as an RF pulse or "echo" of the pulse they received. The echo is received by an antenna, just as with a radio receiver, and converted to an image. The signals or echoes received are the result of T1 and T2 relaxation times, which are simply physical parameters that describe the environmental interactions that influence the signal released from a proton. Such spin-echo pulse sequences are frequently used sequences in routine MRI.

An analogy of a spinning top can help to explain the T1 and T2 relaxation times that result in spin-echo imaging. Each hydrogen ion has a dipole moment (a positive pole and a negative pole) and therefore acts like a small magnet within the powerful magnetic field of the imaging magnet. These protons spin or precess with a precessional frequency that is related to the field strength of the magnet. Electromagnetic energy can be transferred to these protons if the energy is delivered at the resonance frequency. Once an RF pulse of resonance frequency is delivered, a small number of protons will absorb this energy and move to a higher-energy state. The T1 relaxation time reflects the time it takes for these excited protons to give up their higher energy and return to baseline.

T2 relaxation times relate to a second parameter of physical interactions. Although the protons are rotating at a frequency proportionate to the magnetic field in which they exist, they are not in phase. In other words, there is no net direction of polarity from all of these spinning magnets. Once the RF pulse perturbs or stimulates these protons, they begin to spin synchronously and therefore create a net magnetic field. This spinning net magnetic field generates an electromagnetic wave that can be

picked up by the RF antenna of the imaging system as an "echo" of the original RF pulse delivered. (The principle of a spinning magnet inducing an electromagnetic pulse is the basis for the turbines of hydroelectric generators.)

Because its immediate electromagnetic environment affects each proton differently, these protons will remain synchronous in their precession for a very short period. As they move out of phase or synchrony, the net magnetic field that was created dissipates; therefore, the signal received by the RF antenna diminishes. The T2 relaxation time indicates the time it takes the protons to go from a state of synchronous rotation, when maximal signal is created, to random, out-of-phase precession, with zero net magnetic field and hence no signal. The requirement of a net magnetic field to create a signal is used to evaluate flowing blood without the need for contrast. An RF pulse saturates the protons in the field being imaged. The saturated blood within the vessels of that field flow out of the field and are replaced with nonsaturated blood from an adjacent slice. Consequently, there is no signal from the vessel containing the blood flowing perpendicular to the slab being imaged.

Diffusion-weighted sequences have proven to be very sensitive in defining neonatal pathology. Diffusion weighting is the most sensitive technique in the identification of early anoxic-ischemic injury. Diffusion weighting takes advantage of the random Brownian motion of molecules in fluid and the restriction of Brownian motion by anatomic barriers or edema. Water within the ventricular system will diffuse homogeneously in all directions (i.e., no restricted diffusion) and will be a low signal on a diffusion-weighted sequence and high signal (white) on an apparent diffusion coefficient (ADC) map. An acute or subacute infarction, for instance, will cause restricted diffusion in the affected region as fluid rushes into cells due to failure of the cells' homeostatic mechanisms, such as ion pumps. The restricted diffusion caused by acute cell death will be a high signal on the diffusion sequence and a low signal on the ADC map. Late findings after infarction will demonstrate facilitated diffusion with a high signal on both the diffusion and ADC map as the infarcted cells burst and therefore no longer restrict the movement of water molecules. Diffusion tensor imaging measures diffusion in at least six planes simultaneously. From that data, a map of the magnitude and direction of water movement can be generated. The axons within white-matter tracts will allow diffusion in the direction of the axon but will restrict diffusion in any direction other than the course of the axon. This allows one to map the white-matter tracts and has been studied in relation to developmental abnormalities in the brain, the relationship of intracranial neoplasm to white-matter tracts, and the plasticity of the developing brain in response to injury.

The key feature of the physics of MRI is that images are acquired without ionizing radiation, which is particularly important in pediatrics. No known harmful effect of either magnetic exposure or RF exposure at the levels used in MRI has been observed. **However, MRI is still relatively new, and one should be cautious in using MRI for fetal and newborn imaging. Energy deposition is a concern, and protocols have been established that limit patient exposure.** Another concern is the effect a magnetic field might have on electronic instrumentation, such as pacing devices and metallic surgical clips. The torque on metallic implants can be quite high, but this is rarely of clinical significance. However, the artifact caused by the disturbance of the magnetic field can be significant. The most important and real safety concern is that of the magnetic-field attraction of ferromagnetic material. Pens, stethoscopes, or even oxygen canisters can act as projectiles when inadvertently brought too close to a magnetic field.

The main drawback of current MRI technology is the time it takes to acquire an image. Motion-free imaging is necessary for optimal image quality, and because image acquisition in MRI takes minutes, sedation frequently is necessary. Respiratory and cardiac gating can help for physiologic motion, but even physiologic motion can be problematic.

Focused Discussion: Practical Considerations

The physics of MRI is complex, and multiple variables influence the signal received (Fig. 9.11). These influences variably affect the T1 and T2 relaxation times in spin-echo imaging. Imaging sequences tend to be called *T1* or *T2 sequences,* depending on which physical parameter has the most influence on the appearance of the image. A helpful simplification of spin-echo imaging is that in T1-weighted spin-echo sequences, fluid is black,

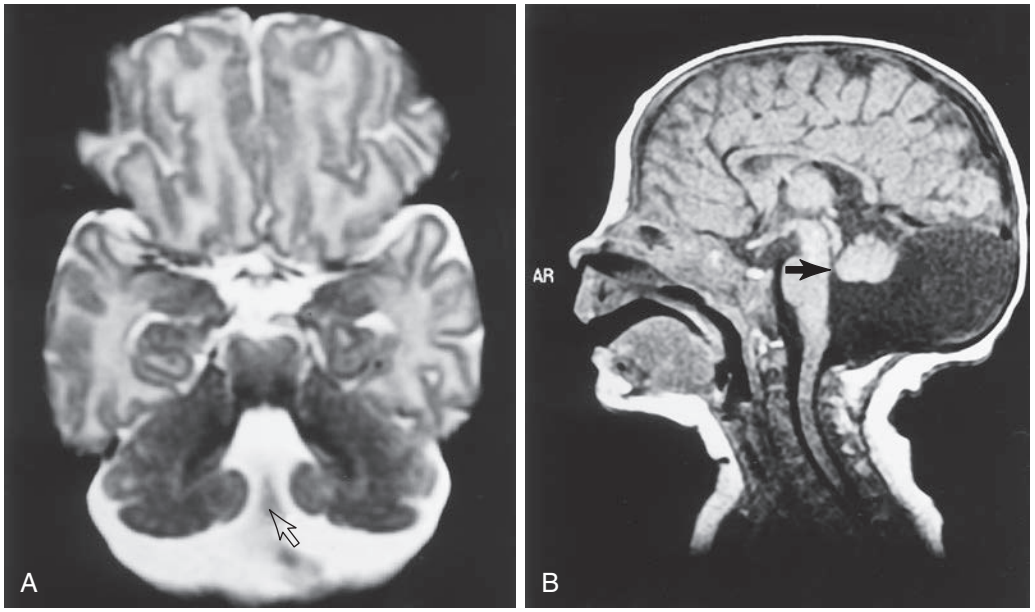

FIGURE 9.11 Axial T2-weighted image through the posterior fossa **(A)** demonstrates the high-signal cerebrospinal fluid in the posterior fossa cyst, which communicates with the fourth ventricle more anteriorly *(open arrow)*. Midsagittal T1-weighted image **(B)** demonstrates a Dandy-Walker variant in this patient. The partial formation of the vermis seen best on the sagittal image defines a Dandy-Walker variant *(black arrow)*.

whereas in T2-weighted imaging, fluid is white. **Most pathologic conditions are characterized either by the distortion of the normal anatomy or by edema, which is manifested as increased fluid in an otherwise normal structure or within the particular lesion.** Therefore, if one looks for a fluid collection (e.g., CSF in the ventricles of the brain, such as CSF in the subdural space around the cord; orbital fluid of the aqueous humor; or fluid in the heart or urinary bladder), one usually can determine whether the imaging sequence is T1 weighted, in which the fluid appears black, or T2 weighted, in which the fluid appears white. On T1-weighted sequences, a pathologic condition is seen as a black or lower signal because a pathologic state is associated with increased water in the area of abnormality. In T2-weighted sequences, the pathologic lesion tends to be white.

Focused Discussion: Fetal MRI

Historically, US has been the most effective and informative imaging modality in fetal medicine. However, as the field of maternal-fetal medicine evolves, fetal MRI is becoming an essential part of the imaging armamentarium (Fig. 9.12). The explosion in fetal MRI is the result of advanced instrumentation, imaging sequence development, and expertise in interpretation. The newer equipment and modified sequences shorten acquisition time and therefore minimize artifact, yielding better-quality images.

US continues to offer the advantage of availability, portability, and real-time acquisition. MRI, like US, is performed without ionizing radiation. Although fetal US continues to be the screening modality of choice, MRI as an additional modality can clarify US findings. **Literature also has demonstrated that fetal MRI can identify additional abnormalities not seen by fetal US, particularly in the central nervous and genitourinary systems.** A fetal MRI examination takes much longer to perform than an US study, and in general, the imaging is not real-time. However, **MRI offers a number of advantages. Tissue characterization with MRI is superior to that of US.** This is particularly helpful when evaluating the fetus for developmental anomalies of the

FIGURE 9.12 Sagittal T2-weighted fetal magnetic resonance imaging demonstrates a defect within the lumbosacral spine with associated cystic structure consistent with a lumbosacral myelomeningocele. The associated findings of a small posterior image with dilatation of the lateral ventricles, consistent with a Chiari II malformation, are also partially visible.

central nervous system. Cerebral sulcation, cortical and white-matter development, and ventricular size and configuration can be readily displayed with fetal MRI. **MRI can clarify spinal abnormalities suggested by screening US.** MRI is an essential part of the Management of Myelomeningocele Study (MOMS Trial) comparing the results of prenatal versus postnatal repair of myelomeningocele. **Another important role of fetal MRI relates to imaging of the airway and lungs.** Valuable information concerning the degree, location, and nature of bronchial obstruction can have a significant effect on ex utero intrapartum treatment (EXIT) procedures to deal with complex anatomy that could result in fatal airway compromise after birth.

NUCLEAR SCINTIGRAPHY

Nuclear scintigraphy is the most physiologic of the tools commonly used in neonatal imaging. A pharmaceutical is tagged with a radiotracer, which is a radioactive isotope that can be detected by a nuclear medicine camera. The pharmaceutical may be injected intravenously, given orally, or delivered directly into the urinary bladder. The pharmaceutical is distributed in the body based on the parent compound to which the radioisotope is chelated or bound. The patient then is imaged using a detector that maps the distribution of the tagged isotope in the body.

The radiation dose in scintigraphy is small. With the doses used for diagnostic purposes, there is little risk to the individual and no risk to anyone who is in immediate contact with the patient. The pharmaceutical agents have both a biologic half-life related to the natural elimination of the parent compound from the body and a radioactive half-life determined by the isotope used to label the pharmaceutical. The spatial resolution is poor, but the contrast resolution is exquisite because the radiopharmaceutical is distributed so specifically within the body.

Clinical Utility in the Neonatal Intensive Care Setting

Three common investigations for which nuclear medicine is well suited are renal scintigraphy, hepatobiliary imaging, and splenic imaging. In patients with the syndrome defined by vertebral, anal, cardiac, tracheal, esophageal, renal, and limb (VACTERL) anomalies, renal scans can be helpful in determining the number and location of the kidneys. Renal scintigraphy can be used to quantify relative renal function. **Scintigraphy is a functional way to evaluate the degree of obstruction in hydronephrosis.** Nuclear cystography has a very low radiation dose; therefore, it is a good method for following vesicoureteral reflux. Fluoroscopic cystography usually is performed for the initial evaluation because the excellent spatial resolution can assist in defining anatomic abnormalities that may be responsible for reflux (e.g., that might be missed with the poor spatial resolution of nuclear imaging).

Hepatobiliary imaging can assist in the evaluation of the jaundiced patient. The radiopharmaceutical is extracted from the blood pool by the liver and excreted like bile, allowing one to determine transit time and flow of the bile from the liver into the gallbladder, through the common bile duct, and into the duodenum. **Hepatobiliary imaging can help distinguish neonatal hepatitis from biliary atresia. In neonatal hepatitis, there is limited clearance of the pharmaceutical agent from the blood by the liver;** therefore, the liver shows little activity compared with the background, but a small amount of activity is excreted into the bowel. **In**

biliary atresia, the clearance or extraction of the radiopharmaceutical agent from the blood is closer to normal, but the isotope never leaves the liver, and therefore no activity is seen in the duodenum and small bowel, even on delayed images. A choledochal cyst accumulates radiotracer and is diagnosed by an intense area of focal activity and a dilated biliary system more proximally.

Splenic imaging can be performed with technetium sulfur colloid, which is taken up in the Kupffer cells in the liver and spleen. Alternatively, radiolabeling of red blood cells can be used for splenic images because damaged cells are sequestered in the spleen. Splenic imaging frequently is helpful in patients with complex congenital heart disease and situs abnormalities to diagnose asplenia or polysplenia.

Focused Discussion: Renal Scintigraphy

The radiopharmaceutical choices for renal imaging are either cortical agents that bind in the renal cortex, filtered agents that transit the cortex and then are excreted into the collecting system, or a combination of both cortical and filtered agents. Cortical agents are useful in defining the size, number, location, and relative function of the kidneys (when there are two kidneys). The US characteristics of multicystic dysplastic kidney (MDK) usually are diagnostic; however, renal scintigraphy (Fig. 9.13) occasionally can help differentiate the hydronephrotic form of MDK from severe ureteropelvic junction (UPJ) obstruction. A combination agent, such as mercaptoacetyltriglycine (MAG3), is useful in the evaluation of hydronephrosis because one can determine the relative function of each kidney and evaluate the degree of obstruction. Addition of the furosemide (Lasix) washout study augments the evaluation of hydronephrosis by rendering a washout curve that is indicative of the severity of obstruction. In evaluating hydronephrosis, it is generally helpful to place a catheter in the urinary bladder to prevent possible vesicoureteral reflux from confounding the examination results. Although all of these tests can be performed in the newborn period, the concentrating ability of the newborn kidney is marginal. Therefore, the tests often are reserved until the patient is 3 to 6 months of age to improve their accuracy and prognostic capability.

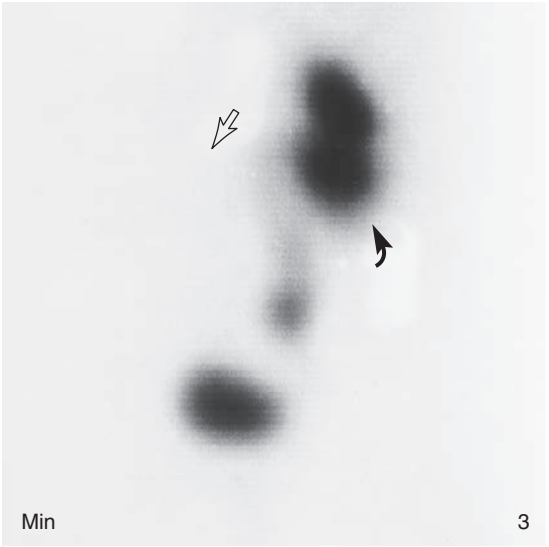

FIGURE 9.13 This posterior image from a diethylenetriaminepentaacetic acid (DTPA) renal scan demonstrates the collecting system, ureter, and urinary bladder associated with the functioning right kidney *(black arrow)*. The multicystic dysplastic kidney on the left shows no functional renal tissue *(open arrow)*.

POSITRON EMISSION TOMOGRAPHY

Background

Clinical utilization of positron emission tomography (PET) in neonates and young infants has been limited because the radiation dose is significant. Nonetheless, the recent growth of and interest in PET for specialized applications argue for its understanding.

The concept of PET was initially proposed in the early 1950s, and medical PET was first attempted in the mid-1970s. The physics of PET involves the introduction of a positron-emitting radiopharmaceutical combined with a biologically active substance. These short–half-life radiopharmaceuticals require a cyclotron to produce and are therefore less available than the pharmaceuticals most commonly used in routine nuclear scintigraphy. A positron is a particle with the opposite charge of an electron that travels only a very short distance within the body until it hits an electron. The collision of the positron with an electron results in two annihilation electrons (gamma rays) of the specific energy 511 keV being emitted in opposite directions at equal velocity. The location in space of the point source of the electrons can be calculated from the

fractional difference in the time it takes for the electron to reach the detector. The positron-emitting tracer attached to a metabolically active substance is introduced into the body intravenously, and the radiotracer is distributed throughout the body with the active metabolite. After 30 to 60 minutes of redistribution within the body, a scintillation scanning device detects the nearly coincident paired gamma rays. In the body, bones and other attenuators block some of the electrons from reaching the detector. Therefore, a means of identifying the blockers is needed.

CT happens to be a very efficient means of locating bones and other blockers but has the added benefit of rendering anatomic images. This allows for more precise localization of signal and its relationship to internal structures. Because of the ability to acquire both anatomic and metabolic information simultaneously, the combination of PET and CT (PET/CT) has been responsible for the rapid growth of PET in recent years. Not only can one identify regions of high metabolic activity, but also the location can be more precisely correlated with the internal anatomy, with significant improvement in diagnostic accuracy. In humans, the most common pharmaceutical used is fluorodeoxyglucose (FDG), which is a glucose analog. FDG is distributed like glucose throughout the body. Regions of abnormal metabolic activity can be identified and, with CT, localized to a specific structure in the body. A metabolically active tumor, for instance, would demonstrate a focus of increased activity in a PET image. For example, if it were localized in the anterior mediastinum, it would be consistent with the diagnosis of lymphoma.

Clinical Utility in the Neonatal Intensive Care Setting

The relatively high radiation dose associated with PET has limited its use, but it has been effectively utilized in staging neonatal neoplasm. The role PET will play in the evaluation of hypoxic-ischemic injury and the evaluation of neonatal seizures is yet to be determined.

INTERVENTIONAL RADIOLOGY

Intervention is one of the newest but most rapidly growing subspecialty areas in medical imaging. Interventional radiology has assumed an important role as a minimally invasive way to treat disease. Imaging can also direct the surgical approach. From a practical standpoint, **there are four major areas of radiology intervention: (1) vascular access; (2) tissue sampling for minimally invasive diagnosis of neoplasm or infection; (3) catheter or needle drainage of fluid collections or abscesses; and (4) directed delivery of cells, chemotherapy, or embolic material, which may be used to diminish flow to a vascular lesion.**

Any of the imaging modalities may be used to guide the intervention, but the most commonly used are fluoroscopy, ultrasound, and CT.

Clinical Utility in the Neonatal Intensive Care Setting

Vascular access is the most commonly requested radiologic intervention in most pediatric institutions. Ultrasound or fluoroscopy can be used to visualize veins for venous access. Although bedside catheter placement with confirmation of placement by ultrasound or radiography is often possible, placement in interventional radiology is sometimes necessary in difficult cases, such as patients with aberrant anatomy, vascular narrowing, or occlusion.

***Tissue sampling* is often performed to diagnose neoplasm.** In general, utilizing ultrasound, fluoroscopy, or CT, a needle is placed into an area of abnormal tissue to obtain either a fine-needle aspirate or, often in solid tumors, a core needle biopsy. The advantage of a core needle biopsy is that the tissue obtained is frequently large enough to complete many of the pathologic studies necessary in the pretreatment evaluation of the neoplasm. This can be particularly helpful in patients in whom a neoplasm, once defined, can be pretreated before definitive surgical resection is performed.

***Cysts or abscesses can be drained,* obviating the need for an open surgical procedure and thus minimizing morbidity and shortening recovery time.**

A *gastrostomy or gastrojejunostomy tube* also can be placed in a minimally invasive manner, rather than a more invasive surgical procedure. This can be an ideal approach for the placement of a temporary feeding tube.

***Directed delivery of chemotherapy* has been used in neonatal units for the treatment of hepatoblastoma.** Chemotherapy can be directed through the hepatic artery into the involved lobe and the tumor reduced in size before excision. By reducing the size of the tumor preoperatively, a previously nonresectable tumor can sometimes be removed.

Another example of directed delivery is the *embolization* of infantile hepatic hemangioma. Infantile hepatic hemangioma is a rare cause of congestive heart failure resulting from an extracardiac shunt in the neonatal period. It is possible to embolize the benign neoplasm, thereby diminishing the shunt and correcting the heart's failure. Vein of Galen malformation is another extracardiac vascular shunt that frequently predisposes the patient to high-flow cardiac failure. A spectrum of vein of Galen malformations exists, and the success of embolization is highly dependent on the degree of vascular insufficiency resulting from the steal associated with a high-flow lesion. In patients who present early and in florid heart failure, the outcomes are predictably worse than in patients who present later with an abnormality discovered during a routine physical examination, in which an intracranial bruit might be identified.

Finally, directed delivery for cell implantation and genetic engineering shows great promise. These areas are early in their development, but the ability to direct a catheter to a specific organ for cell implantation or gene therapy will clearly have a role in future applications of interventional radiology.

Focused Discussion: Vascular Access

The availability of ultrasonographic equipment can allow placement of PICCs or central venous catheters in vessels as small as 2 mm. With US imaging, the vessel is visualized directly. Fluoroscopic guidance requires limited venography by injecting contrast through a peripheral IV line. After visualization with either ultrasonography or fluoroscopy, a 21-gauge needle is placed into the selected vessel. Once good blood return confirms the intraluminal position of the needle tip, a 0.18-wire is passed through the needle. The needle is removed, and the tract is dilated. Next, a peel-away sheath is placed over the wire. The catheter is sized and then passed through the peel-away sheath. The location of the catheter tip is confirmed fluoroscopically.

PICTURE ARCHIVING AND COMMUNICATION SYSTEMS

The widespread use of picture archiving and communication systems (PACSs) has had a significant effect on diagnostic imaging and medicine throughout the United States and the world. Simply put, a PACS is the process of image display, distribution, and archive as it relates to radiology (Box 9.3). **PACS allows images obtained by CT, MRI, ultrasound, nuclear imaging, and plain radiography to be distributed to any location for simultaneous access by any number of caregivers and specialists.** Images can be distributed via a local network within a hospital, over a regional network to a group of providers, or over the Internet for viewing anywhere in the world. Systems have been developed that offer resources never before possible with film. Archives are protected for patient privacy and safety.

BOX 9.3 PICTURE ARCHIVING AND COMMUNICATION SYSTEM

- Acquires, displays, distributes, and archives patient images
- Displays digital images on computer monitors (soft copy)
- Enables manipulation of images to enhance visualization
- Provides brightness, contrast, magnification
- Makes simultaneous viewing at multiple sites possible
- Improves efficiency and accelerates results reporting
- Enhances decision support, which improves patient management

For a number of years, CT, MRI, and US images have been acquired digitally or, at a minimum, were handled digitally after an analog-to-digital conversion. Before computerized radiography (CR) and digital radiography (DR), x-ray images obtained on film could be converted into a digital format by scanning the film in a laser scanner. Fluoroscopic and x-ray images are now captured digitally with CR or DR and thereby become immediately available for soft-copy reading from a computer monitor as opposed to viewing a radiograph on film at a view box, known as *hard-copy reading.* CR is very similar to conventional radiography except that it replaces film with a phosphorescent imaging plate that transfers the latent image into a digital format when developed. DR provides for direct conversion of the x-ray into an electronic digital format that requires no processing of the imaging plate.

The flexibility provided by digital imaging permits extensive manipulation of images. The contrast and brightness (window and level) can be adjusted to optimize visualization of selected images or even portions of an image. These parameters can be changed when viewing an image to enhance a particular structure or finding. The window and

level can be changed when viewing a chest x-ray image, for example, to accentuate the lung, bones, a central catheter, an endotracheal tube, or a gastrostomy button. Images can be magnified, rotated, inverted (black to white and white to black), and even screened by sophisticated computer programs to improve the detection of pathology. Radiology reports can be transcribed with voice-recognition software, allowing the radiologist to edit and sign a report within minutes of acquisition. The reports then are associated with images from the examination. **It is now common to have images and interpretations available on a computer monitor in the NICU by the time the patient returns from radiology.** Reports and images then are assimilated into the patient's electronic medical record. PACS is a powerful tool that improves medical management by translating bits of data into clinically relevant information. It enhances medical care and decision support by making images and interpretations available simultaneously in numerous locations, including in the NICU and often at the bedside, in a fraction of the time previously necessary.

FAMILY EDUCATION AND INVOLVEMENT

The NICU team can have a positive effect on imaging by helping educate the parent. When parents understand a procedure and know what to expect, they can be very helpful. Not only is the quality of the imaging better, but also the experience of the parent and patient is improved. **An informed parent can effectively assist in the imaging process when included in the treatment plan.**

An optimal study requires motion-free imaging. Even with fluoroscopy and ultrasonography in which motion is recorded, the actual acquisition of the image must be free of extraneous motion. With x-ray and CT studies, shortening the acquisition time helps to accomplish this. Respiratory motion can be limited by taking the image at the end of inspiration. Some modalities cannot acquire the image data fast enough to eliminate motion. These examinations frequently require sedation. **The most common modalities to require sedation are MRI, nuclear scintigraphy, and CT.**

Sedation protocols vary from institution to institution, but certain aspects of sedation are universal. **The patient must be given nothing by mouth (NPO) for a period of time before sedation.** It is simply unsafe to sedate a patient who has eaten recently. Failure to keep a patient NPO is one of the most common reasons that a scheduled examination has to be canceled and rescheduled. **Parents generally are informed of the need for sedation and asked for consent (verbal or written).** The choice of sedation depends on many factors. These include the length of the examination, the fragility of the patient, and the experience and training of the individual responsible for sedation. The route of administration also is variable and includes IV, intramuscular (IM), oral (PO), rectal, and inhalation. **The sedated patient is monitored throughout the procedure and recovery. Recovery can occur in the imaging suite, a recovery area, or newborn center, but the patient must be monitored until fully recovered.**

Some unique aspects of newborn care require special attention in the imaging suite that might not be as important in older patients. These important issues are of even more concern in the sedated patient. Thermoregulation is always of concern in the neonate. Imaging suites frequently are cold. **Maintaining body heat is especially problematic in studies that require prolonged imaging times and in those in which the patient could get wet, such as cystography and fluoroscopic GI procedures. Blankets and overhead warmers can mitigate the problem, but providers must anticipate the issue.**

Fluid administration also can be problematic in the neonate. **Newborns need dextrose in their IV lines, especially if they are not feeding. Therefore, it is important in these patients to keep IV lines open and functioning. Most IV pumps are not compatible with MRI, and many cause interference that degrades image quality. However, it is not appropriate to suspend fluid administration for the duration of the study.** The issue should be anticipated and addressed in a timely fashion.

Care of a critical newborn in the imaging suite can be challenging. It requires cooperation between the NICU staff (nursing and medical) and the imaging staff. Parental education enables the parents to participate in the care of

their newborn and has a positive effect on the newborn's imaging experience.

Numerous imaging alternatives are available for the evaluation of any patient condition. The best imaging choice varies depending on local expertise and availability. A clear understanding of the clinical question, patient condition and comorbidities, and the differential diagnosis being considered is essential for optimal imaging and interpretation. **The clinician should consider the pros and cons of each modality and consult with a radiologist if there is any uncertainty as to the best method of imaging.**

10 PHARMACOLOGY IN NEONATAL CARE

LAWRENCE C. KU, CHI HORNIK, AND DEANNE BUSCHBACH

Optimal pharmacotherapy involves dosing drugs to deliver the maximum intended beneficial effects with the minimum toxicities. Determining the optimal pharmacotherapy for neonates is problematic in that much of the data have been extrapolated from research in adults, children, and laboratory animals. **Neonates show significant differences in processing and responding to drugs compared with older children and adults.[39,46] There is also great variability in the response to pharmacotherapies among neonates. Gestational age, chronologic age, and disease state alter a neonate's ability to metabolize medications and affect the response to the drug.[46,72]**

This chapter discusses neonatal pharmacology, illustrating how rational decisions can be made for pharmacotherapies used in neonatal intensive care unit (NICU) patients. The chapter also includes discussions on strategies to avoid medication errors, strategies for drug delivery, information on how therapeutic hypothermia affects pharmacokinetics, and a summary of recent pharmacokinetic studies in NICU patients.

PHYSIOLOGY

Pharmacodynamics and Pharmacokinetics

The drug-receptor theory states that the amount and duration of exposure of a drug to a receptor determine its effectiveness. ***Pharmacokinetics* describes what the body does to the drug (exposure over time),** which then determines how a drug is available to the receptors and for what length of time (Fig. 10.1).[37,78] ***Pharmacodynamics* describes what the drug (or its active metabolite, such as caffeine for theophylline or morphine-3 and morphine-6 glucuronide for morphine) does to the body at certain concentrations (effect over exposure).** The drug's effectiveness also depends on receptor availability, the affinity of the drug for the receptor, and cellular functions in response to the drug–receptor interaction.

***Antagonist* drugs block a receptor's cellular and physiologic activity (e.g., naloxone), whereas *agonist* drugs elicit the receptor's action (e.g., cardiovascular agents such as dopamine and epinephrine).** Some drugs act with receptors to increase or decrease gene expression (e.g., antenatal steroids such as betamethasone), whereas others affect cell membrane permeability. Some drugs, such as methylxanthines, increase or decrease the amount or activity of second-messenger molecules within cells. Antibiotics and antiviral agents act through some of these mechanisms to reduce the viability of pathogenic organisms by changing vital characteristics and functions. Readers should note that most drugs have more than one effect, so although the desired therapeutic effect may occur, the drug's other effects can limit its usefulness. *Side effects,* which can vary from minor to prohibitive, occur within the therapeutic range of concentration. *Toxic effects* result from a drug overdose or serum concentrations higher than the recommended therapeutic range.

Individual infants may have *idiosyncratic responses* to medications, which are rare and unpredictable reactions, as well as expected responses. Different,

BLUE type highlights content that is particularly applicable to clinical settings.

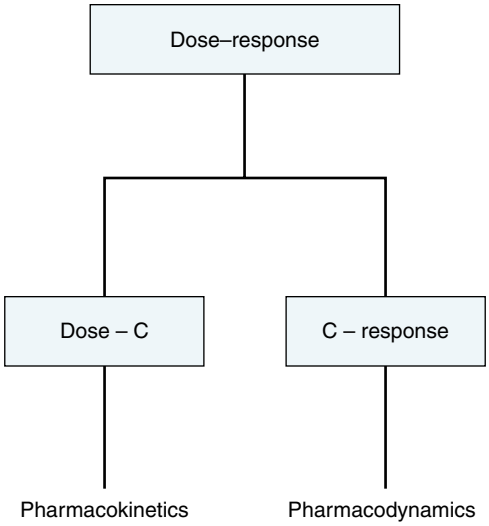

FIGURE 10.1 Variability in dose–response relationship can be the result of differences in pharmacokinetics or pharmacodynamics. *C,* Drug concentration (plasma or serum).

competing mechanisms related to postmenstrual age (PMA) in weeks, postnatal age (PNA) in days, disease, genetics, and drug interactions can lead to infants who exhibit a drug response less than that expected for a usual dose and other infants who exceed the expected response for a given dose and drug level. Unpredictable adverse reactions differ from expected responses. Patients may become tolerant to a given drug dosage, as is commonly seen with opioids. ***Tachyphylaxis*, a rapid decrease in drug response without a dosage change,** may be related to limited receptors or other intracellular mechanisms.[14,33]

Developmental differences related to infant physiology are responsible for significantly different pharmacokinetics in infants compared with adults and older children. Characteristics affecting drug disposition in infants include total serum protein available for binding to drugs, body water composition, kidney function, and skin thickness affecting the intradermal absorption of drugs; these characteristics change drastically over a period of days, weeks, and months after birth.[16,40,85] Many enzymes responsible for the metabolism of drugs prescribed to infants also undergo significant changes in levels of expression and activity with age.[13] In many cases, these enzymes will have significantly reduced activity at birth that slowly increases with postnatal age. As a result, drugs that are predominantly metabolized by these enzymes will demonstrate different rates of elimination among infants of different ages.

Developmental differences in the number and function of receptors and intracellular mechanisms are also critical to estimating drug actions.[77] For example, neonates may have increased sensitivity to morphine compared with adults due to higher levels of expression of the *mu* opioid receptor in neonates.[54] **Changes in alpha- and beta-adrenergic receptors also occur with gestational and chronologic age and must be considered in determining dosages with vasopressors and inotropes.**[8]

A clinician determines a drug regimen and dosage largely on the likelihood of achieving the desired therapeutic response with minimal toxic effects in the "average" patient. In concept, the clinician does this by targeting a drug concentration in the body compartment where the desired effect is wanted.

Plasma concentration is often used as a surrogate for effect when the relationship between concentration (C) and effect has been demonstrated in similar patients. The *minimum effective concentration (MEC)* **is the concentration at which 50% of patients exhibit the desired response** (Table 10.1). The maximum safe concentration (MSC) **is that at which 50% of patients exhibit a toxic response** (Fig. 10.2). The *therapeutic index* is calculated as the ratio of MEC to MSC. Drugs with a **narrow therapeutic index (i.e., where the MEC is close to the MSC) will require careful considerations during patient care, such as drug-level assessments or close monitoring for signs of toxicities.**

To elicit the desired therapeutic effect, the drug must be delivered to the receptor and remain available for an appropriate amount of time.[88] If a clinician aims **to continue the therapy beyond a single dose, then plasma concentration at steady state (Css) is targeted within the MEC and the MSC, where most patients exhibit the desired effect and few suffer toxic effects. With ideal maintenance therapy, the drug administered should equal the drug elimination. The time-dependent variability around the Css depends on the dose, dosage interval, and drug disposition. Even before clinicians consider the age-related changes in drug metabolism when prescribing maintenance therapy for neonates,**

TABLE 10.1 ABBREVIATIONS

ABBREVIATION	ABBREVIATION DEFINED	UNIT OF MEASUREMENT
C	Drug concentration (plasma or serum)	mg/L
Css	Steady-state concentration (average)	mg/L
MEC	Minimum effective concentration	mg/L
MSC	Maximum safe concentration	mg/L
F	Extent of drug availability (0-1): how much active drug gets to the systemic circulation	Unitless
Vd	Volume of distribution: relates to loading dose	L/kg
Cl	Clearance: relates to maintenance dose	L/kg/h
$t_{1/2}$	Drug elimination half-life: relates to the time course of changes in drug concentration	Hours

L, Liter = 1000 milliliters; *mg,* milligram = 1000 micrograms.

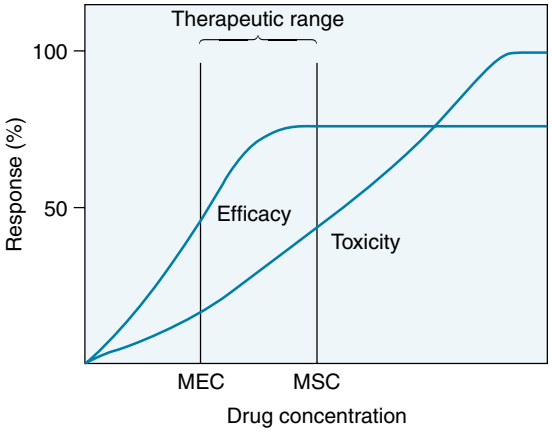

FIGURE 10.2 Percentage of patients with desired and toxic responses as a function of drug concentration. Therapeutic range is bounded by minimum effective and maximum safe concentrations. *MEC,* Minimum effective concentration; *MSC,* maximum safe concentration.

clinicians should anticipate the need to adjust dosages regularly for changes in infant body weight and composition. There is a 10-fold variation in weight range among NICU patients (0.5 to 5 kg). For term newborns, the weight is expected to double in the first 3 to 4 postnatal months, whereas in premature infants, the rate of weight gain can be more rapid.[87]

The target Css is influenced by the amount of drug bound to plasma protein. It is only the free, unbound drug that exerts its effect on receptors and is subject to elimination in the body. In a newborn, **unconjugated bilirubin can displace numerous drugs of lower protein affinity,** including ampicillin, penicillin, phenobarbital, and phenytoin,[80] whereas **other drugs can displace unconjugated bilirubin, which can worsen hyperbilirubinemia and its potential for toxicity,** as observed with ceftriaxone, ibuprofen, benzyl alcohol, and sulfisoxazole.[3,5] **Intravenous (IV) lipid infusions also can affect the protein binding of both bilirubin and some drugs,** such as nafcillin and ceftriaxone. The drug concentration measured in most available assays is usually the total drug concentration, which includes both protein-bound and free forms; therefore, the available concentration at the receptor (i.e., free drug) usually is somewhat less than the total serum concentration. This changes over time for NICU patients with changes in bilirubin production and changes in the amount and types of plasma proteins that come with age. The **lower affinity of fetal albumin to weak acids and the displacement of drugs from binding to albumin by bilirubin can lead to higher levels of freely circulating active drugs** (e.g., protein binding of ampicillin, phenytoin, and phenobarbital in neonates is about half of that noted in adults).[40,77]

The effect of differences in protein binding on drug pharmacokinetics can be illustrated using micafungin as an example. Micafungin is an antifungal agent that disrupts fungal cell walls. It is highly protein bound and highly metabolized by several enzymes known to have lower expression in neonates compared with adults. It would be expected that, based on decreased metabolizing enzyme activity in neonates, the elimination of micafungin would be slower, and lower doses would therefore be needed in neonates compared with adults. However, pharmacokinetic studies in premature infants demonstrated that premature infants had 1.7- to 2.6-fold-greater

micafungin clearance compared with older patients and required a threefold-higher dose than adults to achieve similar drug exposures.[34,77] **Decreased protein-bound micafungin in neonates could explain why neonates have higher clearance rates compared with adults.** Neonates demonstrate a lower fraction of protein-bound micafungin compared with adults (96.7% vs. 99.6%). Because there is a greater amount of unbound micafungin in neonates, more of the drug is available to the elimination mechanisms, resulting in much faster elimination in the younger population. Due to these differences in neonatal physiology, the micafungin doses needed for treating neonates (10 to 12 mg/kg IV daily in extremely low-birth-weight infants) differ greatly from the doses used to treat adults (100 to 150 mg IV daily, which would be 1.5 to 2 mg/kg/dose based on a 70-kg average adult patient).

DOSE–CONCENTRATION–TIME CONSIDERATIONS RELATED TO AGE

In the NICU, doses and intervals must be adjusted based on changes in the dose–concentration and the concentration–response relationships. Measurements of total drug concentrations using therapeutic drug monitoring (TDM) enable a more accurate and precise response to changes in dose–concentration effects. Unfortunately, not all drugs have TDM assays readily available for clinicians. As with the micafungin case, clinicians must observe for clinical effects and assess the influences of other factors that can affect free drug concentrations to estimate drug efficacy and the responsiveness of receptors and cellular processes to the drug.

As noted earlier, pharmacokinetics describes the delivery and removal of a drug to and from the body. **Four major processes can affect a drug's disposition: drug entry (absorption), distribution, biotransformation (metabolism), and elimination.** Doses and dose intervals are expressed mathematically by pharmacokinetic parameters related to absorption, distribution, biotransformation, and elimination, such as the time to reach maximum drug concentrations, volume of distribution, clearance, and half-life. There are many factors unique to newborns that can alter the dose–concentration relationships seen in this population.

Absorption

The process of *absorption* defines the rate and amount of a drug that enters the bloodstream. In the NICU, various routes are used for drug administration. Drugs are frequently given directly into the bloodstream by IV injection. When a drug is given through IV injection, it is said to have **100% bioavailability, meaning that all of the drug given reach the circulatory system.** Drugs are also frequently given by other means that do not introduce drugs directly into the bloodstream, including intramuscularly, via inhalation, intranasally, intrarectally, topically, and subcutaneously. When extravascular administration methods are used, the drug must overcome physical, chemical, mechanical, and biologic variables to enter the circulation. Oftentimes, these obstacles can result in a bioavailability that is less than 100%, meaning that not all of the drug administered will reach the bloodstream. When considering **extravascular administration, clinicians must keep in mind the clinical and developmental stage of the patient.** For example, in extremely premature infants, transdermal absorption is much greater than in term infants due to a thinner stratum corneum and less adipose tissue, but intestinal absorption in the extremely premature infant may be less due to slower transit time and delayed gastric emptying.[40,77]

Bioavailability is represented by the parameter *F*, indicating the percentage of administered drug that becomes available in the systemic circulation, with *F* = 1 indicating the drug is 100% available. Systematic studies of absorption in critically ill newborns are lacking, and differences in absorptive processes are expected but generally remain unmeasured. Some differences in newborns that potentially affect bioavailability include developmental changes in the surface area and permeability of gastrointestinal (GI) mucosa, age-dependent changes in acid secretion in the stomach (neonates have higher gastric pH than in older children and adults in the first postnatal days), changes in gastric emptying time and total GI transit time, and the composition of intestinal microflora. Drugs such as ranitidine and metoclopramide also affect the absorption of other medications by altering gastric and intestinal pH and gastric emptying time and intestinal motility (faster transit time results in less absorption).[77]

First-pass elimination occurs when a drug is eliminated after administration but prior to reaching the systemic circulation. Common sites of first-pass metabolism for orally administered drugs include the liver and the gastrointestinal tract. Other sites of first-pass elimination include the

vascular endothelium and lungs.[64] **Different drugs are absorbed at different rates, and different formulations of the same drug may be protected from first-pass metabolism.**[37] The first-pass phenomenon is why many drugs (e.g., furosemide, propranolol, morphine) require larger doses when given orally compared with intravenously.

Distribution

Medications rely on many factors for distribution to their sites of action, including blood flow, organ size, presence of drug transporters, and drug permeability. The *volume of distribution* (Vd) for a drug is a parameter that relates the total amount of drug distributed throughout the body to the serum or plasma concentration.[14] It is an attempt to quantify the space in which the drug can go. Strictly defined, the volume of distribution is the hypothetical volume of body fluid necessary to dissolve the total amount of drug as found in the serum. The ***volume of distribution* must be used to estimate the amount of a loading dose or a change in plasma concentration with any bolus dose.**

The *volume of distribution* usually is expressed as a function of body weight, with units of volume per kilogram. **Major factors that affect the volume of distribution include plasma protein binding and body composition.**[8] Changes in body composition happen throughout fetal and newborn life. **Total body water as a percentage of body weight decreases with increasing age: 85% in extremely preterm infants; 70% in term infants; and 55% in most adults.** Total body water may increase with conditions such as the syndrome of inappropriate antidiuretic hormone (SIADH) excretion. About half of the total body water is found in the extracellular space in a healthy term neonate, where large, water-soluble drugs will tend to accumulate. **Intravascular water makes up only about 10% of the body weight; protein-bound medications are trapped in this smaller compartment.** Preterm infants have more total body water as a percentage of body weight compared with term infants, and water-soluble drugs such as penicillins, aminoglycosides, and cephalosporins have greater volumes of distribution in preterm infants than in older infants. Preterm infants also have greater volumes of distribution for these water-soluble drugs and require a higher dose per kilogram than term infants to achieve the same exposure.[51,77]

Plasma protein amounts and binding capacities also differ with gestational and chronologic age. Protein binding is decreased in newborns due to lower total amounts of albumin. Additionally, fetal albumin has less capacity to bind certain drugs. Acidic drugs such as ampicillin, phenytoin, and phenobarbital bind less to fetal albumin, thus increasing the unbound fraction of the drug, thereby increasing the amount of free drug available to exert the drug's effect. **Changes in pH also can affect a drug's affinity for albumin.**

Fat content varies with gestational age and degree of illness. For fat-soluble drugs, increased adipose tissue increases the volume of distribution for lipophilic drugs such as propofol and fentanyl. [40,77]

As described previously, the interaction of circulating unconjugated bilirubin and protein-bound drugs is particularly concerning in neonates. **Several anionic drugs, like ceftriaxone, bind to albumin and can displace bilirubin, increasing free bilirubin and increasing its potential for neurotoxicity.** For other drugs, bilirubin can have a higher affinity for albumin than the drug; it may displace these drugs from albumin, increasing the concentration of unbound drug and, therefore, the potential to reach toxic levels.[3,5]

Biotransformation

***Biotransformation*, or *drug metabolism*, occurs most commonly in the liver. Drug metabolism results in the modification of the structure of drugs in the body, leading to their eventual elimination from the body.** Phase I metabolism describes the nonsynthetic metabolism of medications and includes oxidation, reduction, and hydrolysis reactions. Phase I metabolism does not always inactivate the drug; in some cases, the metabolite formed can retain active properties sometimes more potent than the parent drug. Phase II, also known as conjugation, is synthetic metabolism, in which small molecular moieties are added to the drug in the body to aid in its elimination; examples of phase II metabolism include glucuronidation, sulfation, and acetylation. **The enzymes responsible for these reactions change with age, disease states, and interactions with certain drugs.** For example, many enzymes responsible for the **oxidation**

and glucuronidation of drugs are decreased in newborns.

Drugs that rely on these reactions for elimination, such as acetaminophen, phenobarbital, and phenytoin, will be eliminated more slowly and result in higher exposures in the neonate compared with the adult. The possibility of prolonged peak concentrations of available drug or active metabolites for many pharmaceuticals mandates careful monitoring of drug levels and clinical conditions to titrate doses. Additionally, a decrease in plasma protein binding (or any other change in the volume of distribution) may increase the hepatic metabolism and subsequent clearance of a drug, as seen with the micafungin example.

Clearance (Elimination)

***Drug clearance* or *elimination* occurs by excretion of the active drug or biotransformation to an inactive metabolite.** Most drug-elimination pathways can become saturated if the dose is too high or if the dose intervals are too frequent. Most drugs used in the NICU have therapeutic doses less than those necessary to saturate the elimination system. When clearance mechanisms are not saturated, the Css in plasma is proportional to the dose. **Clearance equals the rate of drug elimination divided by the drug concentration.**[37] Just as the volume of distribution relates to the loading dose and initial concentration, **clearance relates to a maintenance dose that keeps a drug's concentration at steady state.** The appropriate dose rate can be calculated if the clinician can specify the desired steady-state plasma concentration and knows the clearance and bioavailability of a drug (from peak and trough levels in a particular patient).

RENAL EXCRETION

The kidney is the primary route of excretion for many drugs commonly used in the NICU. The kidney clears drugs through glomerular filtration and tubular secretion. Examples of medications eliminated through the kidney are aminoglycosides, digoxin, diuretics, and penicillins. Doses and dose intervals of drugs that have renal excretion must be adjusted for age and disease state. **The glomerular filtration rate (GFR; the amount of blood filtered by the kidney in a unit of time) is low at birth and gradually increases over the first few weeks. In preterm infants, the GFR starts even lower than in term infants, with a significant increase occurring around 34 weeks' PMA.** Nephrogenesis begins at 5 to 6 weeks of gestational age, with over 60% of nephrons being formed during the last trimester.[68] Preterm infants born before 36 weeks' gestational age are at risk of having a decreased nephrogenic potential.[1] Tubular secretion also matures with increasing gestational age and depends on tubular function. In adults, aminoglycosides may be dosed based on creatinine clearance, but in neonates less than 1 week old, serum creatinine may reflect maternal levels, as well as renal impairment. Acidosis and a history of hypoxia or ischemia also may modify an infant's renal function, slowing excretion and altering pharmacokinetics. Again, measuring levels through TDM in cases of suspected renal impairment, whether from suspicious history or laboratory values, is important in determining an appropriate dosage strategy.

Half-Life

A drug's *half-life* ($t_{1/2}$) is the time necessary for the drug concentration to decrease by 50%. The half-life is used to predict and interpret the time course of changes in plasma drug concentrations and is related to both the volume of distribution (Vd) and clearance (CL). For example, the time to reach Css with repeated dosing is 4 to 5 half-lives. The half-life is useful in selecting dosing intervals and determining whether a loading dose is necessary. This concept is illustrated in Fig. 10.3.

Loading doses help expedite the attainment of the desired therapeutic concentrations, especially for drugs with long half-lives, in which a desired effect is needed immediately. For example, caffeine is a drug used to treat apnea of prematurity in premature infants. In this patient population, the half-life of caffeine can be as long as 3 to 4 days. Given that the time to reach Css is 4 to 5 half-lives, administering just the maintenance dose will require 12 to 20 days to reach the target concentration and presumably achieve a therapeutic response. For this reason, a loading dose is given to reach the target concentration immediately to achieve a rapid therapeutic response. For drugs with one-compartment distribution that stay in the circulation and are not stored in cells or tissue, the loading dose may be given as a single dose. Drugs that are fat soluble or stored intracellularly are more

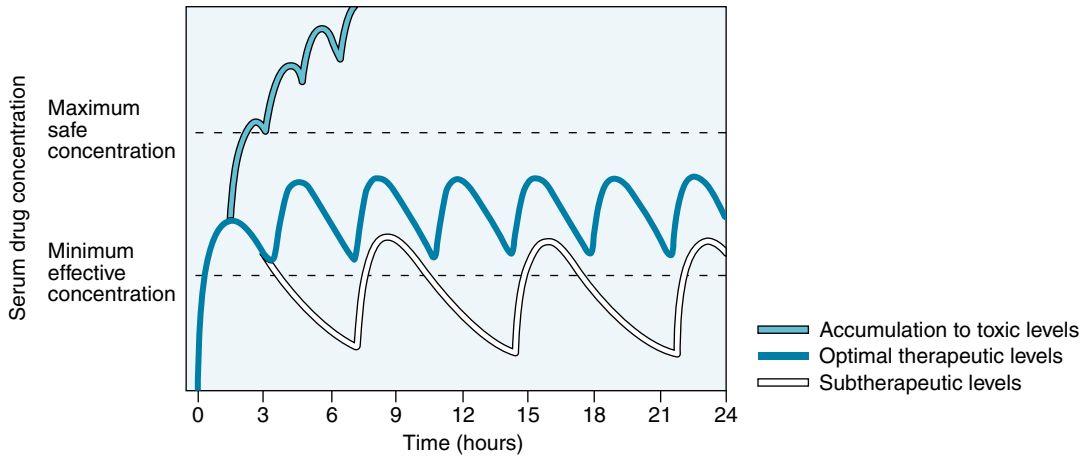

FIGURE 10.3 Effect on serum drug concentration of multiple dosages along with different time intervals between doses. (From Roberts RJ. *Drug Therapy in Infants*. Philadelphia: WB Saunders; 1984.)

difficult to assess, and the volume of distribution of those drugs must be included in the loading-dose assessment.

If the volume of distribution for caffeine in preterm infants is 0.8 L/kg, 20 mg/L is the desired concentration, and *F* for an IV dose is assumed to be 1, a loading dose can be calculated as follows:

$$LD = (Vd \times C) / F = 0.8\ L/kg \times 20 mg/L$$
$$= 16\ mg\ of\ caffeine/kg$$

In certain clinical conditions, such as a birth-depressed **newborn undergoing therapeutic hypothermia, the prolonged half-life of medications is due to significantly reduced metabolism and clearance.** For example, studies have shown that phenobarbital has a prolonged half-life of 8 to 22 days in these patients.[23,74] Similarly, the decreased clearance and longer half-life of gentamicin in cooling infants mandates spacing out the dosing intervals to every 36 hours versus the standard dosing of every 24 hours to prevent accumulation.[26]

Pharmacogenetics and Pharmacogenomics

In the 30,000-plus known genes, there are over 4 million "common" variants (occurring in more than 1% of the population), many of which directly affect the function of the coded proteins. **In certain cases, these genetic differences can result in changes in the expression and function of proteins involved in the absorption, distribution, metabolism, and elimination of certain drugs.** These changes can lead to significant clinical consequences. *Pharmacogenetics* **is the study of the role of inheritance in the individual variation in drug response.** *Pharmacogenomics* **is the study of the influence of multiple genes, and their interaction with each other and the environment, on drug effects.**[15,68,77]

Genetic variations affecting the ability of patients to metabolize drugs have been well described. Over 40 years ago, one of the first reports of a genetically caused variation in drug metabolism focused on *butyrylcholinesterase*, the enzyme responsible for the hydrolysis of succinylcholine. One in 3500 people is homozygous for the gene encoding an atypical form of butyrylcholinesterase. Patients with the atypical form of the enzyme are poor metabolizers of succinylcholine and thus eliminate succinylcholine much more slowly than people with the normal enzyme variant. Because metabolism is significantly hindered in patients with the atypical enzyme form, succinylcholine levels in patients with the atypical variant are more likely to accumulate to levels that can lead to prolonged muscle paralysis.

The cytochrome P-450 (CYP) enzymes are a group of enzymes responsible for the metabolism and subsequent elimination of many of the drugs used to treat patients. CYP2D6 is an example of a CYP enzyme with genetic variations resulting in clinically significant consequences. Codeine is an opioid used in the treatment of pain. For codeine

to achieve its clinical effect of pain relief, it must first be converted by CYP2D6 to its active form, which is morphine. Certain patients have genetic variants of this enzyme that result in decreased function of CYP2D6, thus making these patients poor codeine metabolizers and, therefore, poor responders to codeine. There are also patients who have genetic variants that result in increased function of CYP2D6, thus making these patients ultra-rapid metabolizers of codeine. These patients can metabolize codeine into morphine much faster than the normal patient, resulting in faster formation and accumulation of morphine and increased risk for toxicity. This can have especially important consequences in breastfeeding women. **A breastfeeding woman who is an ultra-rapid metabolizer of codeine can develop morphine levels high enough to transfer to her infant through the breast milk and lead to signs of opioid toxicity in the infant,** such as sleepiness, poor feeding, and even respiratory depression. In the worst cases, this has resulted in infant death due to morphine toxicity.[47] In 2007, the U.S. Food and Drug Administration (FDA) issued a public health advisory on life-threatening side effects in nursing babies of some women who were prescribed and taking codeine. Since then, the FDA (and the European Medicines Agency)[21] issued a strengthened warning in 2017 for codeine and a new warning for tramadol in breastfeeding mothers due to the same concern with ultra-rapid metabolizers.[83]

A genetic variant in mitochondrial DNA, the A1555G mutation, has been linked to a risk of hearing loss associated with aminoglycoside toxicity. The frequency of this mutation in the general population is estimated to be between 1% and 3%, but among deaf subjects tested, the concurrence of deafness with the aminoglycoside treatment associated with this mutation is more common. This suggests that in the future, testing for the mutation before the use of aminoglycosides might be warranted. However, it is currently unknown whether tighter control of aminoglycoside levels in these patients would reduce the risk of hearing loss. No recommendations can be made until more extensive, population-based studies are done. Such studies must include controlling for drug levels and duration and genotypes in the assessment of the risk of hearing loss.[56]

In addition to drug metabolism, genetic variants can also affect the expression and function of drug targets. These include adrenergic and dopamine receptors and enzymes, such as acetylcholinesterase, and are likely to have effects on the response to drugs targeting these proteins, such as bronchodilators, vasopressors, and inotropes, and angiotensin-converting enzyme (ACE) inhibitors such as enalapril and captopril.

There have been few studies focused on pharmacogenomics in neonates, particularly those who are premature. However, genetic differences with clinically important consequences have been described in premature infants.[4] For example, polymorphisms in the enzyme UGT2B7, which is responsible for the metabolism of morphine, have resulted in pharmacokinetic differences in infants treated with morphine.[48] Also, polymorphisms affecting the expression of the opioid receptors upon which morphine exerts its effects have resulted in differences in the need for rescue doses of morphine among premature infants on mechanical ventilators.[49] Still, very little is known about the clinical effects of many genetic polymorphisms among infants; pharmacogenetics and pharmacogenomics are areas deserving more study in infants.

DATA COLLECTION

Monitoring Safety and Efficacy of Pharmacotherapies in the Clinical Setting

Clinicians must be aware of a medication's desired therapeutic effects, side effects, and toxicities; know when these are expected to occur; and continuously monitor for these effects. Whether or not a dose effect occurs requires documentation. **The exact time when therapeutic drug monitoring is conducted should be recorded in order to accurately evaluate the dose–plasma concentration.** If the drug's serum concentration relates to clinical response, the plasma concentration should be monitored in addition to clinical signs. To optimally assess drug serum levels, the expected plasma concentration is calculated from the dosage history, and patient variables that may affect pharmacokinetics and the timing of blood samples are considered. A comparison of expected values with measured values allows rational adjustment of future dosages.[15] Potential explanations for differences

BOX 10.1 POTENTIAL EXPLANATIONS FOR DISCREPANCIES BETWEEN MEASURED AND EXPECTED DRUG CONCENTRATIONS

- Inadequate compliance
- Inadequate medication delivery
- Inappropriate timing of samples
- Laboratory error
- Revision in initial estimates of necessary pK required

pK, Pharmacokinetics.

between measured and expected concentrations are listed in Box 10.1.

Even if predictable pharmacokinetic and pharmacodynamic changes are considered, other factors may influence a drug's effect. Clinical end points must be followed and recorded, with dosage regimens adjusted accordingly. One example is the monitoring of renal function with indomethacin dosage; an indication for using IV indomethacin is for treatment of hemodynamically significant patent ductus arteriosus (PDA). Some of these infants may exhibit compromised perfusion to their kidneys because of the PDA steal phenomenon. However, **if clinical signs of renal dysfunction (a potential side effect of indomethacin) are noted, the drug is not administered. A pharmacist on the caregiving team can clarify the dose and disposition parameters for individual neonates with a variety of conditions.**

If a suboptimal clinical response is noted in conjunction with a subtherapeutic plasma concentration, revised estimates of clearance require adjustments with one or two available plasma concentrations. If a single level is drawn after drug absorption and distribution are complete or concentrations are near steady state, then the maintenance-dose formula can be rearranged to calculate the revised clearance. The commonsense approach suggests that if a patient has half the expected concentration of a drug, then perhaps the clearance is twice the initial estimate. If the patient has twice the expected concentration, the clearance likely is half the initial estimate. However, this technique is misleading if a steady state has not been reached. **If a drug's level is higher than expected and higher than what is considered safe, or if toxicity is noted, the drug should be discontinued until the concentration decreases to the appropriate target range.**

Examples

The following examples illustrate the need to pay close attention to issues of dose and clinical effects. The following examples are for caffeine citrate in neonates. The half-life of caffeine citrate in premature neonates is 3 to 4 days, the *Vd* is *0.8 to 0.9 L/kg,* and clearance is *0.008 L/kg/h*.

EXAMPLE 1: A 15-day-old, 1-kg preterm infant receives oral caffeine for apnea of prematurity. After the loading dose of 20 mg/kg, the infant has received 5 mg every 24 hours of caffeine for 5 days. At 8 AM on the fifth day, 4 hours after the last dose, the baby's heart rate is more than 180 beats/min, but apnea has not been a problem. Clinical and laboratory evaluation of tachycardia includes consideration of caffeine toxicity. A blood sample for caffeine is sent to the laboratory. To estimate the concentration of caffeine, use the following formula:

Necessary data (assume $F = 1$):

$$\text{Total body weight} : 1\,\text{kg}$$
$$\text{Vd} = 0.8\,\text{L/kg} = 0.8\,\text{L in this patient}$$
$$\text{Cl} = 0.008\,\text{L/kg/hr} = 0.008\,\text{L/hr in this patient}$$
$$t_{1/2} = 0.7 \times \text{Vd} / \text{Cl} = 0.7 \times 0.8\,\text{L} / (0.008\,\text{L/hr})$$
$$= 70\,\text{h}$$
$$\text{Time to steady state (Tss)} = 4t_{1/2} = 280\,\text{h}$$

Therefore:

$$\text{Css} = F \times \text{Dose} / (\text{Dose interval} \times \text{Cl})$$
$$= 1 \times 5\,\text{mg} / (24\,\text{hr} \times 0.008\,\text{L/hr})$$
$$= 26\,\text{mg/L}$$

The Css was estimated using average Vd and Cl values reported in similar infants, adjusted for this infant's weight. If this infant has diminished clearance relative to the "average" infant, toxicity may result from the standard dose. Toxicity may not have been noted until day 5 because of the estimated time to steady state (Tss) of 115 hours.

EXAMPLE 2: When the next dose of caffeine is due at 4 AM, 24 hours after the last dose, a caffeine concentration of 27 mg/L is reported. This is within the therapeutic range for caffeine in neonates, but this infant is exhibiting tachycardia, a side effect of the

drug, at this level. His heart rate is now consistently >190 beats/min. The patient is stable on room air, with no occurrence of apnea. Because of the slightly higher-than-expected level, it is most likely the result of decreased clearance. Using this concentration, estimate the time when the concentration will decline to 20 mg/L, and determine a 24-hour dosage schedule to maintain that concentration. The 4 AM dose is held, and the tachycardia resolves 24 hours later.

$$\begin{aligned}\text{Clearance revised} &= F \times \text{Dose} / (\text{Interval} \times \text{Css}) \\ &= 1 \times 5\,\text{mg}/(24\,\text{h} \times 27\,\text{mg/L}) \\ &= 0.008\,\text{L/h}\end{aligned}$$

$$\begin{aligned}\text{Revised } t_{½} &= 0.7 \times \text{Vd}/\text{C1}_{\text{revised}} \\ &= 0.7 \times 0.7\text{L}/0.008\,\text{L/h} = 70\,\text{h}\end{aligned}$$

Therefore, the concentration 70 hours later should be one half of the measured 27 mg/L, or about 13.5 mg/L. To maintain a concentration of 20 mg/L:

$$\begin{aligned}\text{Dose} &= (\text{Interval} \times \text{C1}_{\text{revised}} \times \text{Css}) / F \\ &= (24\,\text{hours} \times 0.008\,\text{L/h} \times 20\,\text{mg/L})/1 \\ &= 3.8\,\text{mg caffeine PO q 24 h}\end{aligned}$$

EXAMPLE 3: Before the new oral regimen is initiated, another blood specimen is drawn 70 hours after the first and is found to be 14 mg/L. Because tachycardia has resolved, an oral regimen based on the last two levels is resumed to maintain a caffeine concentration of 20 mg/L. Estimate the necessary maintenance dose: The concentration fell 50%, from 27 to 13.5 mg/L in 70 hours, which confirmed our original estimate of half-life. Although caffeine has a wide therapeutic index, clinicians can use TDM and pharmacokinetic calculations to help individualize dosing regimens to provide optimal clinical responses while minimizing side effects.

PHARMACOLOGY AND BREASTFEEDING CATEGORIES

Breastfeeding mothers may require treatment with medications for acute or chronic conditions, resulting in concerns for safety with exposures to drugs excreted in breast milk. In all cases, **the benefits of breastfeeding must be weighed against the risk of drug exposures to the infant.** When possible, certain considerations may be taken to lessen the risk of unintended drug exposures to the infant through breast milk, including the following: avoidance of long-acting medication formulations, timing medications with breastfeeding to achieve minimum concentrations at the time of feedings, choosing medications that will accumulate the least in breast milk, providing a therapeutic interchange with another medication that has a safer profile in neonates, and monitoring the infant closely for abnormal signs and symptoms related to the medications being taken by the mother.[66,67,71]

Although most medications are safe for mothers and the nursing infant, some drugs are known to potentially cause harm to the nursing infant and are contraindicated during breastfeeding, such as anticancer drugs and drugs with radioactivity.[87] Lactation risk categories can be assigned to drugs based on available information.[32] Categories range from safest, designated as L1, to hazardous, designated as L5. Only drugs categorized as L5 are contraindicated during breastfeeding. Other categories require balancing of risk versus benefit to the mother and the infant in the decision on whether to allow breastfeeding in conjunction with the medication being questioned. **Table 18.7 provides information about specific maternal drugs excreted in breast milk.**

DRUG CATEGORIES

Antimicrobial Agents

Antimicrobial agents inhibit microbial growth or kill microorganisms; they include antibacterial, antiviral, and antifungal agents. *Bacteriostatic* agents limit microbial growth, allowing host defenses to control spread; this will not reliably eliminate a pathogen but can prevent its proliferation. *Bactericidal* agents kill the pathogen. Bactericidal agents at low concentrations may be bacteriostatic. The *minimum inhibitory concentration (MIC)* is the lowest concentration of an antimicrobial that stops the spread of an organism in laboratory culture media. This cannot be directly measured in an infected neonate and depends on tissue concentration and the number of bacteria present. The *minimum bactericidal concentration (MBC)* is the lowest concentration of antimicrobial that reduces the microbial number in laboratory media by 99.9%. Pathogens can develop *resistance* to antimicrobials by changing their cellular structures or producing enzymes that reduce antimicrobial activity.

For effective antimicrobial action, the drug must reach an adequate concentration in the infected tissue. The ideal concentration elicits a maximum effect on the pathogen with minimum effects on the patient. Selection criteria for antimicrobials include the microorganism's sensitivity, the availability of the drug to the target tissue (e.g., when treating central nervous system (CNS) infections, it is important to note that some antibiotics do not cross the blood–brain barrier), the bioactivity of the antimicrobial in the target tissue, the known MIC and MBC relative to side-effect and toxic-effect levels for the medication, and the infant's biologic state—that is, whether the systems of absorbance (e.g., intestinal integrity) and elimination (e.g., kidney and liver function) are working adequately for effective and safe drug delivery and removal. **When the use of antimicrobial agents is planned in an infant, as with other drugs, consideration must be given to clinical status and PMA and PNA in order to appropriately select the right drug at the right dose for the right indication for the right duration.**

In particular, the pharmacokinetics of antifungal drugs in neonates have been studied, and these data have guided optimal dosing in the neonatal population for an infection associated with high morbidity and mortality rates.[6,20,44] For example, one cited study on the use of fluconazole, a synthetic triazole, suggested that a loading dose (25 mg/kg) prior to starting maintenance dosing achieved the therapeutic target more rapidly than without a loading dose in infants.[63] When treating *Candida* infections in neonates, immediate attainment of the target level of fluconazole (area under the concentration curve/MIC) is paramount. As more pharmacokinetic studies of commonly used antimicrobials in critically ill neonates are completed, such as with clindamycin, metronidazole, piperacillin-tazobactam, and meropenem, dosing regimens based on PMA and PNA continue to be updated and improved in the NICU.[17,18,29,52,76]

Diuretics

Diuretics are used in the NICU to remove excessive extracellular fluid. Diuretics commonly cause a loss of electrolytes along with water. **Response to any diuretic depends on renal function and the drug's ability to reach its target in adequate amounts. Most diuretics work within the tubule, but any drug that increases GFR can increase water loss.** Drugs that increase cardiac output without decreasing renal perfusion, and others that specifically increase renal blood flow, can also cause diuresis.

In infants, renal tubular function improves with increasing chronologic and gestational age. Poor absorption and response to aldosterone (especially in extremely preterm infants) and electrolyte losses can be clinically significant with the addition of a loop diuretic such as furosemide or bumetanide. The ongoing losses may lead to hypochloremic metabolic alkalosis and less response to the diuretic.

Delivery of diuretics to the kidney loop increases with increasing chronologic and gestational age. Most diuretics rely on secretion from the proximal tubule and filtration through the glomerulus to reach their site of action. Both these functions improve with age. Enteral absorption of some diuretics is limited, so clinical effectiveness and electrolyte stability must be monitored closely to help determine safe and effective dosage regimens. The kidney also is responsible for diuretic excretion, again through tubular secretion and glomerular filtration. These functions are age dependent; the clinician must ensure that the clearance time is adequate to avoid toxic levels.

Cardiovascular Drugs

Medicines used to improve cardiovascular function include digitalis and the sympathomimetic amines, which include drugs such as dopamine, dobutamine, and epinephrine. ***Antiarrhythmics,* including digoxin, act to control the electrical conduction within the myocardium.**

The sympathomimetic amines bind to β and G receptors; the number and availability of receptors determine response. A β_1 receptor response leads to constriction of vascular smooth muscle. β_2 receptors cause a decrease in GI motility. Stimulation of the G1 receptor stimulates cardiac contractility, and the G2 response includes vascular and bronchial smooth muscle relaxation. The response in any individual, and in any individual's specific organ system, depends on the relative amount of these receptors. Receptor numbers and their linked response elements within cells vary with gestation and clinical condition, and the response must be monitored to aid in dosage decisions. Prolonged administration of sympathomimetic amines can lead to a decreased response—an example of tachyphylaxis.

***Antihypertensive* agents occasionally are used in neonates for essential hypertension and occasionally to decrease afterload in infants with heart failure.** These include volume reducers such as diuretics, inhibitors of physiologic regulators of blood pressure like enalapril, and drugs that decrease vascular resistance through β and G receptors. ACE inhibitors, such as enalapril, should be avoided in preterm infants because they are at significant risk of acute renal failure after exposure to this class of drugs.[41,43,45]

The pathophysiology of neonatal disease should direct the choice of cardiovascular agent. Extremely close monitoring of physiologic effects helps determine the safety and efficacy of therapy. Monitoring must include very frequent, if not continuous, monitoring of blood pressure, heart rate, perfusion, and oxygen saturation (preductal and postductal in some cases). **Other drugs are often given concomitantly while a neonate is receiving cardiovascular medicines; thus, thorough knowledge of possible drug interactions is mandatory.** The absorption of cardiovascular drugs is unpredictable. **The sympathomimetic amines, such as epinephrine, must be given by the IV route unless used in an emergency situation in which endotracheal (ET) administration is indicated.** Once dosed, the drug must be delivered to the target organ system. Infants in shock may not have the circulatory wherewithal to deliver the medication to elicit the desired therapeutic response. Due to the variability in β- and G-receptor development and distribution, undesired side effects in various organ systems may accompany desired responses. **Rapid metabolism of the sympathomimetic amines demands continuous IV infusion, and infiltration of IV fluids may lead to significant tissue damage.** Along with the physiologic effects, these IV lines must be carefully monitored to prevent adverse effects as well as to ensure the infant receives the drug.[46,72]

Also related to the cardiovascular system are drugs used to treat patent ductus arteriosus (PDA) in neonates. The ductus arteriosus is a vascular connection between the aorta and the pulmonary artery. In utero, the ductus arteriosus serves the important function of bypassing blood flow away from the nonfunctioning fetal lungs and back into the systemic circulation through the aorta, where the blood can then travel to the placenta. The ductus arteriosus typically closes spontaneously after birth. If the ductus arteriosus fails to close after birth, the resulting PDA can result in shunting of blood away from the body and back to the lungs and cause significant problems to the infant, including pulmonary overcirculation and decreased perfusion to vital organs such as the kidneys. The presence of prostaglandins is known to keep the ductus arteriosus patent, which can be produced endogenously by the infant at the ductus arteriosus or be administered as a drug for certain congenital heart defects.

Pharmacotherapies are used to treat a PDA when more conservative treatments, including volume restriction and diuretics, have failed. These pharmacotherapies are directed at inhibiting the formation of prostaglandins at the ductus arteriosus. Indomethacin, a nonsteroidal anti-inflammatory drug (NSAID), is often used to treat a PDA in these cases. Indomethacin works by inhibiting the enzyme cyclooxygenase, which prevents the formation of prostaglandins, allowing the PDA to close.[50] **When indomethacin is used, close monitoring is necessary for several important side effects, including decreased kidney function and thrombocytopenia. Contraindications against the use of indomethacin include extremely elevated serum creatinine levels, severe oliguria or anuria, and severe thrombocytopenia. Studies have also demonstrated an increased risk in the development of spontaneous intestinal perforations among premature infants treated with indomethacin and hydrocortisone concomitantly; the use of indomethacin with hydrocortisone, and likely other corticosteroids, in this population should be avoided if possible.**[86]

More recently, there has been increased use of acetaminophen/paracetamol for the treatment of PDA in infants. Acetaminophen may cause PDA closure through the inhibition of prostaglandins, although the exact mechanism of how acetaminophen results in PDA closure is still unknown. A recent Cochrane review evaluating eight studies that included a total of 916 preterm infants demonstrated that **acetaminophen performed similarly to ibuprofen or indomethacin and better than placebo for successfully treating PDAs.**[59] Furthermore, acetaminophen may be safer than ibuprofen or indomethacin, without the adverse effects related to NSAIDs, including decreased renal and mesenteric blood flow. However, the authors of the review concluded that further studies, including long-term neurodevelopment

outcome studies, must be conducted before acetaminophen can be recommended as a standard treatment for PDAs.[59]

Central and Peripheral Nervous System Drugs

Nervous system drugs include **analgesics, which decrease pain sensations; *anesthetics,* which control pain peripherally or in the CNS; *sedatives/hypnotics,* including barbiturates (phenobarbital) and nonbarbiturates (lorazepam), which do not control pain and can control some seizures; and *antiepileptic* agents, which are designed to control seizures (phenytoin, fosphenytoin).** These drugs are associated with problems of addiction, tolerance, dependence, and withdrawal.

Neonates are incapable of developing addiction but are able to develop tolerance, dependence, and withdrawal to these medications. *Addiction* is a complex lifestyle change that involves drug-seeking behavior, which is not applicable to neonates. Tolerance occurs with many drug types. *Tolerance* exists when increasing doses and serum concentrations of a medicine are necessary to achieve a desired effect. A patient is *dependent* on a medication when regular drug administration is necessary for physical well-being. *Withdrawal* is a collection of physiologic and behavioral signs attributed to the absence of a medication in a dependent individual. There are two distinct types of withdrawal in neonatal patients. **Neonatal abstinence syndrome is secondary to in utero exposure to illicit substances,** such as heroin, or prescribed medications, such as methadone or buprenorphine, taken by mothers during pregnancy. **Iatrogenic withdrawal is induced by prolonged exposure to opioids, benzodiazepines, and other sedatives used in sick infants who often require prolonged mechanical ventilation.** Withdrawal has been identified for many medications, but it has been classified and described, along with weaning protocols, for opioid analgesics and benzodiazepines[22] (see Chapter 11).

The mechanism of most CNS medications is not clearly known. Again, careful monitoring of therapeutic effects relative to dose, duration, and serum concentrations is extremely important. **Significant respiratory depression can occur with most CNS medications, so appropriate resuscitation equipment must be available.** Variations in hepatic metabolism and the volume of distribution are important in the ongoing assessment of dose response. Some medications are highly fat bound and are slowly released into the circulatory system, causing prolonged effects, both therapeutic and undesired (e.g., respiratory depression, poor gastric motility, and abnormal neurologic function such as feeding difficulties).

If therapeutic hypothermia is used for infants with hypoxic-ischemic encephalopathy (HIE), evidence suggests that opioids accumulate in the circulation in excess of the accumulation in similar infants with HIE who are not cooled. Therefore, when using opioids in cooled infants with HIE, opioid levels are likely to be higher than expected for a given dose, and the expectations for the neurologic examination must be modified given the accumulation of high levels and delayed neurologic findings.[68]

Pharmacokinetics During Hypothermia

In recent years, **therapeutic hypothermia has become the standard approach in NICUs for term newborns with neonatal HIE.[72] (see Chapter 26) Therapeutic hypothermia entails lowering the core body temperature below 34°C for the first 72 postnatal hours, followed by gradual rewarming.**[73] Neonatal HIE is often accompanied by metabolic acidemia in the first postnatal hours to days, along with kidney and liver injury. This complex combination of end-organ injury and cooling below the usual physiologic core body temperature influences the pharmacokinetics of commonly used medications in the NICU.[89]

Antiepileptics, opioids, and antibiotics are among the more commonly used medications for infants with HIE. In adults, the systemic clearance of drugs metabolized by cytochrome P-450 is decreased between approximately 7% and 22% per degree Celsius below 37°C during cooling. Several studies have assessed specific medications often used for term neonates with HIE.

Hypoxic newborns are at high risk of seizures. Clinicians who are treating these infants with HIE should understand the antiepileptic agents and their dosing and pharmacokinetic profiles. **Phenobarbital (PB) administered to newborns under whole-body hypothermia results in higher plasma concentrations and longer half-lives**

than expected in normothermic newborns. In the report on phenobarbital pharmacokinetics for neonates cooled for HIE, C_{max}, C_{min}, and C_{avg} were higher, and half-lives were longer, than reported in normothermic newborns in earlier studies. **Clinicians using PB to treat seizures in such newborns should be aware of the risks of elevated serum PB concentrations with doses of 40 mg/kg or higher.[23]** Other antiepileptics with a better safety profile, such as levetiracetam, may be used adjunctively to treat refractory seizures in infants who have been administered PB.[84] This may decrease the need to push PB doses to suprathera-peutic levels in this cohort.

Even in noncooling infants, morphine should be used judiciously in neonatal patients due to its many known adverse effects. In the Total Body Hypothermia Study (TOBY), one center measured and reported morphine pharmacokinetics for the infants enrolled in the study.[69] All of the infants were treated with a continuous infusion of morphine, with the rate adjusted according to clinical status. Serum morphine concentrations reached a steady state after 24 hours in normothermic infants with HIE but continued to increase throughout the assessment period in the hypothermia group. The authors concluded that **infants with HIE have reduced morphine clearance and elevated serum morphine concentrations when morphine infusion rates are based on the clinical state. Potentially toxic serum concentrations of morphine are more likely with the combination of HIE, moderate hypothermia, and infusion rates greater than 10 micrograms/kg per hour** than with HIE not treated with hypothermia.[69] To reduce the accumulation of morphine, a loading dose of 50 mcg/kg followed by 5 mcg/kg/hour was predicted to achieve target serum concentrations in neonates with HIE receiving therapeutic hypothermia.[25]

Gentamicin is a common antibiotic used to treat early-onset sepsis in infants. In a study of 29 infants treated with hypothermia for HIE, **gentamicin clearance was decreased in neonates with HIE treated with hypothermia** compared with previous reports in nonasphyxiated, normothermic full-term neonates. At a 36-hour dosage interval, a dose of 4 to 5 mg/kg was predicted to achieve target gentamicin peak and trough concentrations in more than 90% of neonates.[27] In a subsequent study, this group demonstrated that a gentamicin dosage strategy of 5 mg/kg every 36 hours in neonates with HIE receiving therapeutic hypothermia improved the achievement of the target trough concentration of less than 2 mg l(–1) compared with dosage every 24 hours while still providing high peak concentration exposure.[26]

From these few examples, **the effect of hypothermia on the pharmacokinetics of important drugs in a very vulnerable population is evident.[19]** An ongoing, multicenter study in the Netherlands is investigating how therapeutic hypothermia influences the pharmacokinetic and pharmacodynamic time profiles of analgesics, sedatives, antibiotics, and antiepileptic drugs in infants with HIE.[19] So far, these studies have demonstrated that therapeutic hypothermia results in significantly decreased clearance rates for the antibiotics gentamicin, amoxicillin, and benzylpenicillin, resulting in the need to adjust to lower dosing for all three drugs during therapeutic hypothermia and rewarming.[9-11]

PREVENTION OF THERAPEUTIC MISHAPS

The Institute of Medicine (IOM) estimates that more individuals die each year in the United States from medical error than from motor vehicle accidents, breast cancer, or AIDS-related illness.[35] **Many medical errors are medication errors. Neonatal patients are at a higher risk for errors given the narrow margin of safety in very small, fragile patients with an immature organ system and clinical illness.[64]** For example, a decimal point error in dosing that may not cause adverse effects in an adult could cause significant harm to a preterm neonate. **Between 20% and 50% of neonates in the NICU experience medication errors, with the youngest, smallest, and sickest neonates being the most affected.[69]**

Medication errors can occur at any stage in the medication-use process: (1) prescription/transcription, (2) preparation/dispensing, (3) administration, and (4) monitoring.[70]

Prescription and Transcription

A recent descriptive study of common medication errors in the NICU found that the majority (98.5%) occurred in the prescribing phase, with 58.7% due to calculation errors.[62]Additionally, wrong-patient orders are more common in the NICU than in

non-NICU pediatric settings.[2] Dosing references; administration guidelines, such as IV compatibility and infusion rate guidelines; and other drug resources should be made available to all clinicians in the NICU.[12,70] Building dosing recommendations and clinical guidelines into order sets within a computerized order-entry system (CPOE), even the use of a "preselected prescription" concept, reduces errors in prescribing and assists in standardizing and optimizing clinical outcomes.[30] Designing the ordering system to reduce complexity and provide rule-based order screening and double-checking of calculations and developing effective information delivery may be more effective than traditional education or process-improvement efforts that target interventions after an error occurs.[22,28]

The use of a CPOE system with an approved neonatal formulary, prompts, and clinical decision support decreases errors by making the prescribing legible, guides the prescriber in the safest and most cost-effective medications, and enables the prescriber to become proficient with a selected number of drugs.[70] CPOE systems can be customized to a specific NICU and use only "acceptable" or no abbreviations, write out or use capital letters for "look-alike/sound-alike" drugs, and use both generic and brand names of the drugs in the neonatal formulary. **Electronic generation of medication administration records (MARs) by pharmacists after checking the medication order improves accuracy in the transcription process and ensures legibility compared with handwritten MARs.** Pharmacist participation in NICU patient rounds enables multidisciplinary communication and clarification of new medications to be ordered and any therapeutic drug monitoring that needs to be done. **Neonatal clinical pharmacist participation in NICU rounds and clinical care has been shown to decrease errors by 80%.[74]**

Preparation and Dispensing Medications

Even after making a correct choice of medication, one must pay attention to the appropriate dose and interval based on factors that affect a drug's pharmacokinetics and pharmacodynamics.

Investigators estimate that 8% of drug doses calculated and administered by competent NICU nurses are at least 10 times greater or less than the ordered dose.[71] A system in which unit doses are prepared in the pharmacy, labeled, and delivered to the NICU is a safer system than having stock medications in the NICU that are reconstituted and/or diluted by the bedside nurse. **Pharmacist interventions can reduce medication errors and adverse drug events.[12,59,81,82]** In the pharmacy, unit doses are checked by two pharmacists[12,36,81,82] to ensure accuracy, scanned using barcode technology, and placed in the automated dispensing system (ADS). Emergency medications are available in the ADS, which is accessed by the nurse for dispensing; the drug is then prepared by the nurse (reconstituting or diluting), and the appropriate dose is measured and double-checked with a second nurse before administration.[36,57,82,81] When unit-dose patient labels are integrated with the CPOE system, labels contain the dose, volume, concentration, route, preparation instructions, and time of administration.[70]

BOX 10.2 THE "SIX RIGHTS" OF DRUG ADMINISTRATION

Right drug
Right patient
Right route
Right dose
Right time
Right response

Administration of Medications

Completing the "six rights" of medication administration (Box 10.2) **in the NICU is essential and may be complicated by the small doses and dosage adjustments based on infant weight or body surface area.** Many drugs used in neonatal care must be diluted because they are ordered in amounts that are not commercially available. The rate of drug entry, or absorption, also varies, depending on the route of administration. Even with unit dosing, the **calculation of the medication dose received must be double-checked by two nurses at the bedside before administration. This redundancy of independent double-checking in the pharmacy and at the bedside is a strategy for reducing medication errors.[12,36,57,80,81]** Drug delivery must be ensured; this includes **appropriately prescribed**

orders or transcribed orders, appropriate dose calculations, appropriate mixing with diluents, and appropriate method of administration. The *Rule of Six* was developed originally for use with vasopressor agents in code situations, and its use has extended beyond that. The rule, which allows nurses to estimate a pediatric dose by using a factor of 6, is prone to error (Fig. 10.4).

Standardized drug concentrations are less error prone and safer for patients than the *Rule of Six*.[2] Because of medication errors, The Joint Commission (TJC) requires the use of standardized IV drug concentrations for pediatric patients prescribed medications for which the *Rule of Six* was routinely used.

The use of smart IV pumps reduces IV medication errors by 73%.[42] Smart pumps are used for both continuous and intermittent IV administrations. Smart pumps are programmed with each IV medication from the neonatal formulary and are separate from adult medication pumps. Proper training on use of medication pumps is crucial. Errors occur from poor training on pumps. (https://www.ncbi.nlm.nih.gov/pmc/articles/PMC6318721/). In addition to **barcode scanning, visual verification of the medication label to ensure that the medication, dose, concentration, and route match the electronic order and the MAR information also prevents errors and increases patient safety.[42,70]** Access to medication references with administration guidelines, compatibilities, dilution guidelines, diluent information, and administration time is essential for all NICU staff.[70]

Monitoring Medication Effects

After medications are administered, all care providers must evaluate the neonate for drug interactions, incompatibilities, and untoward and adverse effects. The effects of therapy at the chosen dose and systematic monitoring for therapeutic and toxic effects must be included in NICU care when medications are used.

TDM is necessary for some medications to measure whether pharmacokinetic and pharmacodynamics goals are being met.[69] Blood is drawn at peak, trough, or random times, and medication doses are adjusted as necessary. Therapeutic ranges are specified for each drug, and doses are adjusted for maximum efficacy and the prevention of toxicity. **NICU staff must be educated in how and when to accurately and consistently monitor drug levels, as well as the appropriate interventions that are to be expected given laboratory values that are outside of therapeutic ranges.** When clinical pharmacists participate in patient rounds, they promote safety by effective monitoring with laboratory values as well as with education of the NICU staff.[42,70,75,79] Additionally, the **bedside nurse who is constantly with the sick neonate must be familiar with the adverse effects of all medications that are given so that the nurse is able to advocate for the patient who is showing symptoms of toxicity.** For example, a very low-birth-weight (VLBW) infant on caffeine therapy who has a resting heart rate of 180 beats/ minute and is vomiting after gavage feeding is symptomatic of caffeine toxicity and needs a caffeine level drawn; the next dose of caffeine should be withheld until results of the caffeine level are known.

A recent national survey found that of the 164 respondent NICUs, 85% adhered to practices designed to decrease and eliminate medication errors, yet some safety practices were not used.[31] The American Society of Health-System Pharmacists has published guidelines for preventing medication errors in hospitals.[12] These such include hospital-wide actions as the establishment of a clearly defined system for drug ordering, dispensing, and administration, with review of the original drug order before dispensing *and* administration. Confirmations of patient weight, drug dosage, and strength are also recommended. **Avoiding the use of the terminal zero to the right of the decimal point (e.g., writing *5* instead of *5.0*) and using a zero to the left of a dose less than 1 (e.g., using *0.1* rather than *.1*) will help reduce medication errors. Avoid abbreviations of drug names** (e.g., *MS* may mean either morphine sulfate or magnesium sulfate), **spell out dosage units rather than using abbreviations** (e.g., *units* rather than *U,* or *mcg* for microgram rather than *μg*), **and use generic medication names rather than trade names.** Avoid verbal orders whenever possible; verbal orders should only be used in emergency situations.[81] **See Table 10.2 for other interventions to reduce medication errors. For neonatal/pediatric nurses, recommendations include the following:[12,36,57,69,81]**

TABLE 10.2 INTERVENTIONS TO REDUCE MEDICATION ERRORS

STRATEGY	EXAMPLES
Establish an institutional and NICU culture of safety[12]: • Safety is valued • Medication safety leader • Structure for safe medication practices • Strategic plan	Medication safety is a priority that is supported by a system of safety that makes it easy to prevent an error and difficult to make an error[12]: • "Just" culture that evaluates systems flaws as well as human errors; a support system for second victims: care for health care providers traumatized by being involved in medication error(s) • Nonpunitive event-reporting system that includes "misses" and "near-misses" that undergo RCA to identify causes and devise strategies to prevent a recurrence • Interdisciplinary medication safety team to proactively assess risk, as well as systematically and collaboratively address medication safety within the NICU • Continuous quality improvement process regarding evaluation of errors/harm: use of technology that reduces risk and prevents patient harm. • Strong designs that assess and reduce risk and patient harm • reduce risk and patient harm • Use of electronic barcode scanning systems that reduce preventable adverse drug events by 50% to 80%[39,53]
Multidisciplinary staff education and teamwork training to establish, enhance, and/or sustain a culture of safety in the NICU	Administer the AHRQ's Survey on Patient Safety Culture before and after compulsory, multidisciplinary teamwork and communication training; compare unit data to AHRQ's national survey data[55]
QI projects	Collect data before and after QI interventions related to medication safety, such as double-checking and signing for all neonatal medications; use of barcode scanning
Random safety audits: safety tool to prevent adverse events	Collect data from smart (IV) pumps to assess the frequency of appropriate use of infusion pump safety systems[7]
Multidisciplinary team develops a neonatal/pediatric formulary	Neonatal/pediatric drugs to be used in NICU, age-specific dosage guidelines along with dilutions of common drugs. Use of standardized drug preparation and dosage, standardized nomenclature and CPOEs with alerts for unusual drug doses[70]
Develop written protocols and procedures that are easily accessible to all NICU staff	Use of smart pumps, insulin, skin care; monitoring of IV infusions and therapeutic drug levels; intervention for IV extravasation
Provide up-to-date references easily accessible to all NICU staff	Neonatal/ pediatric drug dosage handbooks, intranet resources, 24-hour access to pharmacist[70]
Use CPOE system with neonatal dosing regimens and order sets	Build national and local guidelines into admission order sets, disease-state order sets, and all commonly used neonatal medications

AHRQ, Agency for Healthcare Research and Quality; *CPOE*, computerized provider order entry; *IV*, intravenous; *NICU*, neonatal intensive care unit; *QI*, quality improvement; *RCA*, root cause analysis.

- Familiarizing oneself with the system for medication ordering and documentation
- Accepting only medication orders that specify not only the amount to be given but also the intended amount per kilogram so that intended dosing can be recalculated by the dispenser (pharmacist) and the administrator (nurse) of the medication
- Clarifying medication orders before the prescriber leaves the NICU
- Verifying drug orders before administration
- Confirming patient identity by two forms of identification before each dose
- Using electronic barcode scanning system to verify patient and medication before administration

- Verifying calculations, IV pump programming, and medication concentrations by using independent double checks with a second individual
- Verifying any unusually large volumes or dosage units for a single patient dose
- Verifying verbal orders by "reading back" the complete order to the prescriber
- Familiarizing oneself with the methods of drug administration: oral syringes that are unable to be connected to IV ports, smart pumps, unit dosing, oral measuring devices in metric system
- Listening to the patient, parent, or other caregiver
- Asking questions as to whether a drug should be administered—for example, discontinuing antibiotics after negative laboratory findings, including cultures in an asymptomatic neonate
- Maintaining familiarity with the operation of administration devices and the potential for errors with such devices

METHODS OF ADMINISTRATION

Once a clinician orders a medication and the drug and dose are found to be appropriate for that particular infant, the nurse's challenge is to administer the medication correctly. The following section addresses methods that help improve the accuracy of drug delivery.

Oral Administration

It must be noted that **all oral medications should be prepared and administered using only oral syringes and oral orogastric (OG) or nasogastric (NG) tubing. These oral syringes and tubing do not allow oral medications to be given inadvertently through an IV line.**[80] Variations in oral bioavailability and unanticipated and unmeasurable loss of the drug complicate the administration of oral medications to newborns. Loss of medication occurs when infants regurgitate or require gastric suctioning and lose residual fluid that may include medication. **If an infant is receiving OG or NG feedings, the medication should be placed into the center of the barrel of a syringe containing a small portion of the feeding to dilute the medication, thereby decreasing the osmolality of the medication and, subsequently, increasing the tolerance.** The nurse should document drug administration attempts and any possible loss of drug, with an estimate of the amount lost. **For infants receiving oral medications, documenting the color of the emesis or residual material helps determine the presence of medications that have a distinctive color.**

If an infant is bottle-fed, it is not recommended to put the medication in the full bottle. The concern is that if the infant fails to take the whole volume, he or she has not received the full dose. One option is to gently introduce very small portions of a dose into the cheek pouch and wait for the infant to swallow. **Another method is to put 5 to 10 mL of a feeding, with the medication, in a small bottle and let the infant take that amount, then continue with the remainder of the feeding. The medication also may be placed into a nipple with a small volume of feedings and then offered to the infant.** For breastfeeding infants, medications may be administered into the mouth as described previously, with or without a small volume of expressed breast milk.

Intramuscular Administration

A newborn infant has relatively little muscle mass to receive injections. **When IM injections are necessary, as with vitamin K, the anterior thigh is the site of choice. Comfort measures should be given before and after the injection** (see **Chapter 12**). For an infant weighing less than 1500 grams, the volume injected into one leg should not exceed 0.5 mL. The final step is to document the administration.

Intravenous Administration

IV medications can be given by push or pump infusion. Although drugs directly enter the bloodstream, the time necessary to complete drug delivery to receptors is a function of dosage volume, IV flow rate, and injection site (depending on particular IV methods).[87] Failure to recognize these potential time lags could result in inappropriate expectations of the timing of physiologic responses and peak and trough concentrations. **Certain drugs should either be avoided or cautiously administered into the umbilical vein or artery, and drug incompatibilities should be recognized before setting up multiple medications through the same IV line.** Appropriate flushing is necessary, especially in between intermittent medications that are incompatible. Careful monitoring for infiltrates and knowledge of drug-specific treatments for this complication are essential to safe IV drug

administration. **Some medications require central venous access to safely administer medications, and stable access may be required before administration.** Continuous IV infusion of vasopressors is common in the NICU, and because of their rapid clearance and physiologic importance, these infusions should never be interrupted or given by bolus **without orders.** A sudden influx of potent medication and flushes to clear lines with continuous infusions of sympathomimetic amines should be avoided.

PUSH INJECTION

IV push medications must be mixed in appropriate volumes, delivered through appropriately sized syringes, and followed with an appropriate flush solution.

The IV port closest to the patient should be used to administer an IV push injection. Administer a small volume of the appropriate flush solution, and then administer the medication over 1 to 2 minutes. Slow IV push rates must be specified by the ordering clinician. **A post-medication flush is given at the same rate as the medication to clear the line of remaining medication. IV push administration of many medications used in the NICU is *contraindicated* because of the possibility of immediate adverse reactions associated with rapid bolus injections. Opioids and sedatives should be given with great care and constant attention to respiratory and cardiovascular parameters. Check a pharmacology reference for any uncertainty.**

INTRAVENOUS INFUSION ON THE PUMP

To avoid delay of drug delivery, two methods of pump infusion using a mechanical infusion device allow control of drug amount and delivery rate. These devices consist of a pump that can be set to deliver a specific volume over a specific time, a syringe or other container that holds the medication or fluid to be delivered, and connecting tubing to connect the pump to a port for drug delivery. Because pumps vary by manufacturer and some may be used in a variety of ways, **each NICU should have a policy to ensure that each staff member carries out pump infusions in the same manner.**

INTRANASAL ADMINISTRATION

Some medications, such as midazolam or fentanyl, can be given through the intranasal route. **Although the intranasal route of delivery for these medications has not been approved by the FDA in neonates, this drug delivery route has been shown to be useful as a rapid and less invasive method of administering certain drugs,** especially in neonates who have limited IV access. The nasal mucosa has a rich vascular bed that allows rapid absorption of these drugs into the bloodstream.

OTHER CONSIDERATIONS REGARDING IV ACCESS AND ADMINISTRATION

Access via Peripherally Inserted Catheters (PICCs) or Peripheral Intravenous Lines (PIVs). PICCs have been used in the neonatal world for more than 30 years. PICC use has decreased mortality and morbidity and optimized care for infants requiring prolonged stable access for parenteral nutrition or IV pharmacotherapies. PICCs have proven to be **a reliable, safe method to deliver medications and fluids with high osmolarity.**[60] Training for PICC placement is accomplished through specialized courses that adhere to strict sterile techniques. IVs may be placed by a bedside nurse without the specific training course that is needed to place a PICC. **Common sites for IV placement in neonates include the hands, feet, arms, legs, or scalp veins. A trans-illuminator or ultrasound machine**[36] **may help locate vessels in extremities.** Always use nonpharmacologic comfort measures and consider local anesthetic or analgesia prior to attempting access (see Chapter 12).

Some vessels do not provide blood return. Babies in hemodynamic shock also may not have blood return. If the needle is thought to be in the vessel but no blood return is seen, then a small amount of flushing solution may be injected. If the needle is not in the vessel, the tissue will swell. **If it blanches, the vessel is most likely an artery.**

When securing a line, leave adequate visual access to the insertion site and allow monitoring for changes in color or edema that indicate complications such as infiltrates, phlebitis, or hematomas.

If a medication is to be administered intermittently and the line is not otherwise used, it may be heparin or saline locked and flushed per unit protocol with your unit's standard flush solution. Alternatively, a continuous heparinized fluid can be infused at a low rate of 0.5 to 1 mL/h to keep the access patent and can be used as a medication carrier fluid.

COMPLICATIONS OF INTRAVENOUS THERAPY

Complications of IV therapy include phlebitis, infiltration, hematomas, chemical burns, compartment syndrome, and emboli.[46] Long-term complications include disfigurement, contractions, and the need for surgical repair or amputation. Frequent *(at least hourly)* assessment of IV sites helps reduce, but does not absolutely prevent, all IV complications (Box 10.3).

Footdrop[24] and *compartment syndrome,* in which nerves and vessels are damaged by swelling of tissue within a limited space, have been associated with positioning a footboard along the lateral aspect of the fibula, with or without an IV infiltration. The use of rolled washcloths as footboards or extensive padding of IV boards with cotton or gauze may prevent excessive pressure. **Unnoticed infiltrations may result in significant tissue loss. Warm soaks are *contraindicated* because, when warmed, extravasated fluid may exacerbate the burn, maceration, and necrosis**. In addition, **heat increases oxygen demand in the already-compromised tissues.**

Elevating the infiltrated area increases venous and lymphatic drainage, helping to decrease the edema. Hyaluronidase[58] destroys extracellular barriers, allowing rapid diffusion and absorption of the infiltrated medication, such as calcium. For vasoconstrictive substances that extravasate, such as epinephrine infusion, local use of vasodilators like phentolamine can aid in reperfusion. Table 10.3 lists treatment approaches for extravasation.

Clinicians must remain attuned to additional concerns when administering IV medications. **Medications may require filters or protection from light sources or may have significant specific gravity osmolarity. A 0.22-micron filter may provide "cold sterilization"** (i.e., remove particulate matter and bacterial contamination). **Some medications cannot be administered through a filter because the filter removes the active ingredient.** Medications with a specific gravity less than that of the IV fluid have a tendency to accumulate at high points in the IV tubing, whereas those with a higher specific gravity settle into low tubing loops, in both cases resulting in delayed and inaccurate drug delivery.

BOX 10.3 CRITICAL ASSESSMENT
Intravenous Extravasation

- Check all indwelling lines hourly for signs of extravasation.
- Look for phlebitis, edema, burns, adequacy of perfusion to site, hardness of tissue, or inflammation at needle site.
- For scalp veins, check dependent side of head for trauma.

PARENT TEACHING/ COMMUNICATION

IV lines in newborns often frighten the newborn's parents, especially lines placed in a scalp vein. (Box 10.4). **Family members may need reassurance that an IV catheter/needle**, IV fluids, and possibly medications are going into large veins and not directly into the infant's brain. Parents may need

TABLE 10.3 TREATMENT APPROACH FOR EXTRAVASATION

DRUG SUPPLIED	DOSAGE/ADMINISTRATION	COMMENTS
Hyaluronidase (Amphadase) 150 units (mL)	1 mL (150 units) given as 4 or 5 intradermal 0.2-mL injections with a 25-gauge needle around the periphery of the IV extravasation site	Use with extravasation of hyperosmolar or extreme pH drugs. Administer within 1 hour of event. Not for use with vasoactive drugs.
Phentolamine (Regitine) 5 mg/mL in 1-mL vial	0.5 mg/ml given as 4 or 5 intradermal 0.2-mL injections with a 25-gauge needle around the periphery of the IV extravasation site	Prepare a dilution. Use with vasoactive drugs. May be given up to 12 hours after an event.

Modified from Roberts RJ: Intravenous administration of medication in pediatric patients: problems and solutions. *Pediatr Clin North Am.* 1981;28:23-34.

encouragement to touch and hold infants when IVs are in place.

Parents will need assurance that pain assessment and control are part of the caregiver's ongoing efforts and are always addressed during IV placement and maintenance.

Parents need to be aware that venous fragility, combined with the types of solutions used, can make the need to restart IV lines and or the need for multiple sticks per line relatively commonplace. **The potential for infiltration also should be addressed, and parents should be included in the effort to monitor the appearance of IV sites (see Chapter 12).**

As for an infant's treatment, the parents should be included in conversations regarding pharmacotherapy and nonpharmacotherapy choices in the NICU. Parents need not know the details of medication dosage and significant medications within their infant's treatment regimen. **At discharge, parents need to know the names, uses, dosages, frequency of administration, and side effects of each of their infant's medications and how to obtain refills.** Some medications for infants are not readily available. Caregivers must teach parents to administer prescribed medicines, and parents must demonstrate the parent's ability to safely and reliably draw up liquid medications using syringes and administer the prescribed doses to the infant. **The parents need to receive written drug information instructions, which may be developed by the unit for their families or may be commercially available. Instructions must include the name of the medication, treatment indications, dose, route of administration, dosage schedule, and potential side effects.**

BOX 10.4 PARENT/CAREGIVER TEACHING
Indwelling Lines for Parents

Talk with parent about indwelling lines. Discuss the following:

- Type of line, purpose, and any limitations on holding, handling, or feeding the infant
- Pain control measures for the placement of lines
- Need for restarting lines
- At discharge: The name of the medications, the dosages, purpose, routes, and any potential side effects
- At discharge: Medication administration and what to do if the infant does not receive the full dose of medication

NEONATAL RESUSCITATION MEDICATIONS

Name: _____ Weight: _____ Suction depth: _____

Date of birth: _____ ET tube size: _____

Drug	Strength	Dose	Route	Amount to administer
Epinephrine	1:10,000	0.1 mL/kg	IV, ET	_____
Atropine	0.1 mg/mL	0.1 mL/kg	IV	_____
Volume expanders		10 mL/kg	IV	_____

11 DRUG WITHDRAWAL IN THE NEONATE

JODI JACKSON, BETSY KNAPPEN, AND STEVEN L. OLSEN

When a neonate shows signs of withdrawal from a medication or drug taken by the mother during pregnancy, this does not necessarily imply that the mother was addicted or an "addict." Medications may be needed for maternal health reasons that pose a risk for withdrawal in the baby following birth. These risks and benefits must be known and discussed between the health care provider and patient before being used. Nonetheless, **the rising prevalence of illicit and prescription maternal substance use and abuse has affected pregnant women of all demographic backgrounds.**[25,103] The extent of drug use during pregnancy is often underestimated, as are the effects on the fetus and neonate. **Estimated illicit drug use suggests an annual prevalence of approximately 6% of pregnant women, with the highest use at 18.3% in women 15 to 17 years of age.** Illicit use decreases to 9% in those 18 to 25 years of age and 3.4% in those 26 to 44 years of age.[115] The Centers for Disease Control and Prevention (CDC) reported from 2011 to 2013 an average of 10.3% of all pregnant women 18 to 44 years of age voiced current alcohol use, with 3.1% engaging in binge drinking. Cigarette smoking, while decreased overall, has remained unchanged in the pregnant woman.[115] The National Survey on Drug Use and Health in 2013 showed that 15.4% of pregnant women 15 to 44 years of age smoked cigarettes in the previous month.[113]

Neonatal abstinence syndrome (NAS) parallels the national opioid epidemic. While the CDC's press report in 2018 shows opioid use disorder increased from 1.5 per 1000 hospital deliveries in 1999 to 6.5 in 2014, NAS escalated accordingly.[19] **NAS has increased from 1.2 to 5.8 per 1000 hospital births per year from 2004 to 2012.**[92] **Many infants are exposed to poly-substances that compound NAS.**[95] The national average length of stay for an infant requiring treatment for NAS has increased from 16 days to 19 days.[119] In turn, aggregate hospital charges for NAS increased from 732 million to 15 billion, 81% attributed to state Medicaid programs.[92,95,119] The National Institute of Drug Abuse 2017 "Monitoring the Future" study showed that past-year misuse of prescription opioids over the last 15 years (2002 to 2017) among 12th graders is declining (Vicodin dropped from 9.6% to 2%).[82] Across all grades, past-year use in 2017 of heroin, methamphetamine, synthetic cannabinoids, and cigarettes are at their lowest.[19,82]

Providers must recognize these data as a snapshot of these young people and that these behaviors can change. **The sequelae of both licit and illicit substance use by the mother during pregnancy must be recognized and addressed to provide optimal medical care of the neonate.** Stereotypic biases should not interfere with the diagnosis or treatment. Therefore, **health care providers must consider drug exposure in any neonate who is exhibiting symptoms at birth suggestive of withdrawal from or exposure to illicit or prescribed drugs.**

Opioid use by a mother during pregnancy has been studied in detail for decades in terms of its effects on the woman, the fetus, and the developing child.[27,33,46,51,65] **An *opioid* is defined as any natural or synthetic drug that has pharmacologic properties similar to those of opium.**[27,32,46] An opiate is derived from opium or contains opium. The diagnosis of "opioid use disorder" was introduced in the *Diagnostic and Statistical Manual of Mental Disorders*

BLUE type highlights content that is particularly applicable to clinical settings.

(DSM 5) in 2013 and combined the two previous diagnoses: opioid dependence and opioid abuse. The diagnosis incorporates a wide range of illicit and prescribed drugs of the opioid class. Because time, circumstances, and knowledge have changed, other factors now should be considered in treating neonates. **Diagnostic data can no longer be gathered on the assumption that one drug or substance was used. Poly-drug use (the concurrent use of two or more drugs) is now the norm and not the exception. Poly-drug use also can be the combination of illicit substances with those that are legal or found over the counter. The effect on the fetus and neonate is not necessarily minimized by the legality of the substance.** Patterns of abuse, purity of the illicit drug, and sometimes potent or poisonous additions to them also may cause catastrophic sequelae in newborns.

Iatrogenic physical dependence has been documented in infants given intravenous fentanyl or morphine to maintain continuous analgesia and/or sedation during extracorporeal membrane oxygenation (ECMO) and mechanical ventilation.[118] The signs of withdrawal are much like those reported in infants born to opioid-dependent mothers. Fifty percent to 84% of neonates removed from fentanyl within a 24-hour period exhibited withdrawal symptoms, and 48% exhibited signs and symptoms with morphine withdrawal.[118] **Regardless of the agent(s) used for sedation, once the decision is made to start weaning the medication, careful observation of the infant is crucial to monitor for signs and symptoms of withdrawal.**[14,118] A review of the literature points out the importance of initiatives for adequate analgesia in neonates, the development of formal policies concerning intensive care sedation, and the treatment of the withdrawal.[8,114,118]

Several authors have described the use of specific tools for documentation of the manifestations of withdrawal including: the Lipsitz Tool (1975), the Finnegan Scoring System (1975), and the Neonatal Withdrawal Inventory by Zahorodny (1998).[74,80,88] The literature cites various pharmacologic agents that have been used to alleviate the symptoms of opioid withdrawal with methadone, buprenorphine, oral morphine sulfate, and others.[33,45,58,64,68]

Advances in neonatology have continued to broaden the period of viability as many more premature infants are surviving. **What appears to be decreased severity of abstinence in preterm infants may be related to developmental immaturity of the central nervous system (CNS) or to differences in total drug exposure.** This proves to be a problem in evaluating the severity of abstinence signs in a smaller preterm infant because scoring tools were developed largely for use with term or near-term infants.[5,46,78]

This chapter presents current information about treatment issues surrounding drug-exposed neonates, with the main focus on opioid withdrawal. The effects of other substances such as stimulants, hallucinogens, selective serotonin reuptake inhibitors (SSRIs), nonopioid CNS depressants, tobacco, methamphetamines, and alcohol are addressed when symptoms deviate from those of NAS.

PHYSIOLOGY

Because of their low molecular weight and lipid solubility, all drugs of abuse reach the fetal circulation by crossing the placenta, causing direct toxic effects on the fetus.[15,24,48,56]

Although certain drugs may produce specific effects, many abused drugs produce similar manifestations of fetal and neonatal disease. In addition, the effects of legal drugs such as tobacco, caffeine, and alcohol may confound simple drug-effect relationships.[5,13,46,75,93] **A hostile intrauterine environment may also be caused by adverse effects of the mother's drug use and must be considered when diagnosing the neonate's problems.** Examples of factors that could affect neonatal outcome include lifestyle, homelessness, physical or sexual abuse, prostitution, poverty, poor or no prenatal care, poly-drug abuse, intravenous drug abuse, binge and withdrawal cycles, anorexia, poor maternal nutrition, pica, dehydration, alcoholism, sexually transmitted diseases, dental abscesses, preexisting medical conditions requiring pharmacologic therapy, human immunodeficiency virus (HIV)–positive status or acquired immunodeficiency syndrome (AIDS), and hepatitis B and hepatitis C.[5,24,52]

ETIOLOGY OF NEONATAL ABSTINENCE SYNDROME

Neonatal abstinence is described as a generalized disorder characterized by CNS hyperirritability, gastrointestinal dysfunction, respiratory distress,

and autonomic dysfunction manifesting as vague symptoms such as yawning, hiccups, sneezing, mottled skin color, and fever.[27,33,46,64,65,122] NAS occurs in two ways as listed in Box 11.1. Infants exposed in utero and born to mothers using potent narcotics; morphine derivatives, heroin, methadone, or buprenorphine have a high incidence of NAS (60% to 90%).[30] Less potent opioids or opioid-like agents have also been implicated in the development of NAS. Box 11.2 **gives a complete list of drugs associated with NAS.**

When narcotics cross the placenta, equilibrium is established between maternal and fetal circulations. Before birth, the drug is cleared from the fetal circulation primarily by the placenta and maternal excretory and metabolic mechanisms.[46] Multiple investigators have described the potential genetic contributors to variability in fetal opiate exposure, NAS severity, and response to treatment.[21,67] A multicenter cohort study examined the association of *OPRMI* and *COMT* single-nucleotide polymorphisms on NAS, the infant's length of stay, and need for pharmacologic treatment. This study concluded that infants with the *OPRMI* gene had a length of stay 8.5 days less than those without the variation and a better chance of not needing pharmacologic treatment. Neonates with the *COMT* gene variation were in the hospital 10.8 fewer days and had less treatment.[121]

The onset of withdrawal symptoms varies from hours after birth to 2 weeks of age, but the majority of symptoms appear within 72 hours. Many factors influence the onset of NAS (Boxes 11.3 and 11.4).

Once the umbilical cord has been cut, the **neonate is no longer exposed to the drug, and monitoring of symptoms of withdrawal should commence within 2 to 4 hours. Any symptoms occurring before this point are likely "drug effect" (symptoms of the drug expressing themselves in the newborn, which is the drug toxic profile or toxidrome). These symptoms will**

BOX 11.1 ETIOLOGY OF NEONATAL ABSTINENCE SYNDROME

- Passive exposure to opiates/opioids in utero
  - Use of illegal drugs (e.g., heroin) or use of legal medications that are not prescribed to the user (e.g., "off the street" codeine, hydrocodone, oxycodone, methadone, buprenorphine)
  - Use of medications that are prescribed, but not as part of a structured treatment program (e.g., short-acting narcotics for pain)
  - Use of medications that are prescribed as part of a structured treatment program (methadone or buprenorphine).
- Iatrogenically, by the administration of opiates/opioids such as fentanyl, morphine, hydromorphone, or methadone to the neonate for analgesia and sedation.

BOX 11.2 DRUGS ASSOCIATED WITH NEONATAL ABSTINENCE SYNDROME

Opioids
- Heroin
- Fentanyl
- Methadone/buprenorphine
- Morphine
- Meperidine (Demerol)

Less Potent Opioids and Opioid-like Agents
- Propoxyphene hydrochloride
- Codeine
- Pentazocine (Talwin)
- Tramadol
- Dextropropoxyphene

BOX 11.3 FACTORS INFLUENCING THE ONSET OF IN-UTERO ACQUIRED NEONATAL ABSTINENCE SYNDROME

- Drugs used by the mother (mono- or poly-medication/drug use, nicotine exposure)
- Possible gene variations of the *OPRM1* gene or *COMT* gene (currently under investigation)

BOX 11.4 FACTORS INFLUENCING THE ONSET OF IATROGENIC NEONATAL ABSTINENCE SYNDROME

- Prolonged opiate sedation for mechanical ventilation
- Duration of opioid analgesia use during extracorporeal membrane oxygenation
- Type of opiate used
- Maturity and presence of intrinsic disease in the neonate

decrease as the drug is cleared from the newborn's system as opposed to worsening as is seen with true withdrawal.[46]

Neonatal withdrawal from psychoactive substances that the fetus is exposed to occurs in varying degrees. Because most opioids are short-acting and not stored by the fetus in appreciable amounts, **neonatal abstinence is usually apparent within the first 24 to 72 hours of life. The onset of clinical NAS symptoms depends on which opioids the pregnant woman used.** For example, with heroin, NAS may occur in the first 24 hours, whereas with methadone, it may not develop until after 2 to 5 days.[27,46,61,74] **Symptoms of NAS in heroin-exposed infants occur earlier than in infants of methadone-maintained mothers because of heroin's shorter half-life.**

Withdrawal may be mild, transient, and delayed in onset, or it may increase stepwise in severity. **Symptoms may be present intermittently or follow a biphasic course characterized by acute NAS signs, followed by improvement, and then the onset of a subacute withdrawal reaction.**[33,46]

Whether drug dose and period of exposure influence the degree of withdrawal seen in affected neonates is unclear. While some researchers report that NAS is more severe in infants whose mothers have taken large amounts of drugs for an extended period, other researchers have not confirmed this finding.[46,74,122]

Usually the origin of NAS lies in the abnormal intrauterine environment. A series of steps appear to be necessary for the onset of NAS and thus the recovery of the infant. The growth and ongoing survival of the fetus are threatened by the continuing or episodic transfer of noxious substances from the maternal to the fetal circulation. During this time, the fetus goes through a biochemical adaptation to the abnormal element. **At delivery, abrupt removal of the drug is the catalyst needed to start the onset of symptoms.** The newborn continues to metabolize and excrete the substance, so that withdrawal signs occur when critically low tissue levels have been reached. **Recovery from NAS is gradual and occurs as the infant's metabolism is reorganized to adjust to the absence of the offending drug.**[33,46]

Studies of the relationship between maternal dose of methadone and severity of NAS have yielded inconsistent results: 50% of the studies find a relationship, whereas 50% find no relationship.[11,30,33,46,108] Use of adequate maternal methadone for therapeutic effect may decrease concomitant drug use and fetal risk; there is no compelling evidence to reduce maternal dosing to avoid NAS.[4,30] **Box 11.5 outlines the effect of maternal methadone maintenance on mother and newborn.**

Neonates experience a physiologic tolerance and withdrawal from medications and drugs they are exposed to in utero, but do not experience "addiction," and cannot be classified as "addicts." Addiction implies a psychological component of dependence that is not part of the newborn experience.

BOX 11.5 EFFECT OF MATERNAL METHADONE MAINTENANCE ON THE MOTHER AND CHILD

- Reduces illegal opiate use and use of other drugs, diminishing the risk for hepatitis, HIV/AIDS, and other sexually transmitted diseases
- Helps remove the opiate-dependent woman from the drug-seeking environment
- Eliminates illegal behavior, including prostitution
- Prevents fluctuation of the maternal drug level that may occur throughout the day
- Decreases mortality and severe maternal morbidity
- Permits a more stable intrauterine environment for the fetus, decreasing chances of hypoxia; increases birth weight
- Increases retention in substance abuse treatment
- Stabilized mothers on methadone more likely to retain custody of their children
- Children can be monitored by methadone clinic staff
- Provides opportunity for parenting education and other life skills
- No association between neonatal abstinence syndrome severity and the following:
  - Maternal methadone dose
  - Trimester of methadone initiation
  - Duration and amount of methadone exposure
  - Duration of maternal drug use before pregnancy

Modified from Substance Abuse and Mental Health Services Administration (SAMHSA). Pregnant, Substance-Using Women (TIP2) BKD127 Guideline 4. U.S. Department of Health and Human Services; 1995.

Maternal Exposure to Opioid Substances

When drugs such as heroin, methadone, morphine, buprenorphine, and meperidine cross the placenta, the fetus may become passively dependent.

Morphine, the major metabolite of heroin, methadone, as well as buprenorphine and its metabolite have been identified and measured in amniotic fluid, cord blood, breast milk,[1,35,38] neonatal urine, and meconium.[46,55,68,79] Non-opioid CNS depressants (e.g., benzodiazepines, barbiturates) and the other opiates/opioids (e.g., codeine, hydrocodone, oxycodone, hydromorphone, pentazocine, propoxyphene) all have been identified in neonatal urine and meconium.[46,73] Ethanol and its primary metabolite, acetaldehyde, have been identified in placental tissue and amniotic fluid.[22,46,74]

Human and animal studies have shown that **use of opioids during pregnancy directly affects fetal growth.** Heroin is associated with intrauterine growth restriction (IUGR), with only a slight reduction in gestational length, although the mechanism through which heroin inhibits growth is not known.[29] Early speculation reported that maternal heroin use during pregnancy accelerated fetal lung maturity, but this has not been borne out when formally studied. Additionally, no plausible mechanism through which heroin exposure resulted in this has been elucidated, although the associated growth restriction and chronic stress has been suggested.[43]

Older studies comparing methadone-exposed with non-exposed infants have found that methadone-exposed infants had lower birth weights. However, **infants born to methadone-maintained women have been reported to have higher birth weights than those born to women using heroin,** while decreased head circumference has been an inconsistent finding. A meta-analysis of illicit drug use and neonatal outcomes found birth weights of newborns born to mothers using heroin were lower than those of newborns whose mothers used methadone alone, and those of newborns whose mothers used both heroin and methadone during their pregnancy.[106] A mean reduction of 483 g (about 1 pound) in birth weight and a relative risk for low birth weight were associated with any opiate use during pregnancy. **Uncertainty remains regarding the teratogenicity of opioids. One systematic review found some association with oral clefts, ventricular septal defects/atrial septal defects, and clubfoot with prenatal opioid use.**[68]

Methadone maintenance had been an accepted treatment strategy for opioid dependence for more than 40 years. Beginning in 2010, reports were published using buprenorphine for the treatment of maternal opioid use and opioid use disorder as well the effect on NAS.*

Buprenorphine in Comparison to Methadone

Buprenorphine and methadone both act on the μ-opioid receptor; however, each has a unique pharmacology. **Whereas methadone has approximately 90% oral bioavailability, buprenorphine has approximately 50% oral bioavailability.** This is because methadone is a full μ-agonist and buprenorphine is a partial μ-agonist and κ-agonist. Buprenorphine has higher receptor affinity and a longer duration of action than methadone.[51,53]

The MOTHER Study, an eight-site, international, double-blind, double-dummy, flexible-dosing trial compared buprenorphine and methadone in a comprehensive care environment, enrolling 175 opioid-dependent pregnant women, of whom 131 delivered while on the study. Among the women who completed the study, there were **no significant differences between the buprenorphine and methadone groups with respect to any baseline characteristics.** There also were no significant differences between the groups in primary outcomes (i.e., percentage of neonates requiring NAS treatment, peak NAS scores, and head circumference). **However, there were significant differences in two primary outcome measures: (1) the total amount of morphine needed for NAS treatment (mean dose 1.1 mg vs. 10.4 mg) and (2) the length of hospital stay (4.1 days vs. 9.9 days). On average, the buprenorphine-exposed neonates required 89% less morphine and spent 43% less time in the hospital than those exposed to methadone.**[51,53]

Table 11.1 compares methadone and buprenorphine **for the management of women with opioid use and opioid use disorder in pregnancy**. Since the MOTHER study, investigators continue to compare the effects of methadone versus buprenorphine for maternal treatment in regard to infant outcomes. In a study environment, or retrospective review, methadone and buprenorphine are likely comparable, but there are some possible advantages to buprenorphine.[59,83,89,124] However, concerns remain regarding confounders in these evaluations, as well as the structure in which buprenorphine is used in the natural environment.[18,50,66,89]

TABLE 11.1 A COMPARISON OF METHADONE AND BUPRENORPHINE FOR THE MANAGEMENT OF WOMEN WITH OPIOID USE AND OPIOID USE DISORDER IN PREGNANCY

	METHADONE	BUPRENORPHINE
Issue	**Only available through tightly regulated programs**	**Available through registered individual providers**
Risks	Stigma attached to the program. Limited number of programs, many exclude pregnancy, difficult for women to access on short notice because of waiting lists	Not carefully regulated[50]
Benefits	Carefully regulated with psychosocial supports and wraparound services; higher rates of retention in some populations	More easily available to more people More private and less stigma
Issue	**Dose given either daily or at tightly regulated time only through the program**	**Prescription given, often for months at a time with multiple doses dispensed**
Risks	Difficult for low-resource or gainfully employed women to get to the clinic daily	Patients can vary their dosing as desired (which may contribute to increased NAS). Patients can share or sell dosing and take less or more as desired.
Benefits	Dosing controlled; patient unable to vary dosing. Unable to sell doses and/or take more or less than prescribed	Patients do not have to make a trip for medication at regular intervals
Issue	**Mandated regular drug screening**	**No required drug screening**
Risks	Inability to obtain an accurate specimen. Women fail to come for dosing if worried about other medications/drugs appearing in the drug screen	Patients can use other legal or illegal substances without understanding the consequences of an increase in NAS
Benefits	If patient uses other drugs, her supports can be adjusted to help her maintenance on the program	Less expensive program
Issue	**Psychosocial supports mandated**	**Psychosocial supports often not available**
Risks	Some patients may fail to enroll because of their aversion to group or individual therapy	Addiction not treated as a multifaceted disease; only treats physiologic dependence on drugs/medications. Greater risk of relapse postpartally because the underlying disease is not treated.
Benefits	Addiction is treated as a multifaceted disease, not just a physiologic dependence on drugs/medications	Patients who would not enroll in a methadone program will seek a provider for buprenorphine and regulate the exposure of the substance to the fetus, which has the potential to increase the risk of NAS (from erratic dosing of other substances) if taken as prescribed without continued use of other drugs/medications.
Issue	**Payment for program: some are state subsidized, in over one-half of the states. Medicaid or private insurance provides coverage. More likely to receive the medication covered by insurance because it is dispensed as part of the program.**[87,89,93,112]	**Payment for program and medication: often not paid for by private insurance or Medicaid because the drug is dispensed by an "outside pharmacy." Many providers have a "cash-and-carry" model and will not bill insurance.**

Maternal Exposure to Nonopioid Substances

COCAINE

Although still controversial, the neonatal effects of maternal cocaine use, especially on fetal growth, is consistently observed. Researchers hypothesize that **cocaine reduces fetal growth through maternal vasoconstriction, reduced uteroplacental transfer, and direct effect on fetal metabolism interfering with fat deposition.**[105] Cocaine crosses the placenta by simple diffusion. This occurs because of its high lipid solubility, low molecular weight, and low ionization at physiologic pH. In addition, the low level of plasma esterases in the fetus and the relatively low pH of fetal blood (cocaine is a weak base) enhance the accumulation of cocaine in fetal compartments.[79] Taking advantage of the fact that cocaine and its metabolite *benzoylecgonine (BE)* accumulate and can be detected months after exposure in maternal and neonatal hair, an analytic test for cocaine and BE has been developed. The investigators looked at the characteristics of maternal and neonatal hair cocaine as biomarkers of fetal exposure.[37] Cocaine in hair and BE concentrations are not normally distributed, and there was no correlation between maternal hair cocaine concentration and the baby-to-mother cocaine ratio, which ruled out a dose-dependent mechanism. **However, the positive correlation between cocaine concentrations in maternal and neonates' hair corroborates previous reports showing transplacental transfer of cocaine.[37,79] Cocaine has a significant vasoconstrictive property, which decreases blood flow to the placenta and fetus, contributing to IUGR and hypoxia.**[37]

Accumulated evidence from well-designed prospective investigations has revealed less severe sequelae in the majority of infants exposed to cocaine than originally anticipated. Unlike opioids, which may produce NAS and neurobehavioral deficits, **cocaine exposure appears to be associated with significant but subtle decrements in neurobehavioral, cognitive, and language function.**[8]

Maternal cocaine abuse has been shown to produce infants of lower birth weight and birth length, and infants who were significantly more likely to require medical support or resuscitation.[34] Another study revealed children with intrauterine exposure to cocaine had lower mean cortical gray matter, lower total parenchymal brain volumes, and smaller mean head circumferences than comparison children.[100] The most important central action of cocaine is its stimulation of the CNS by inhibiting the reuptake of norepinephrine, serotonin, and dopamine. In the neonatal period, cocaine, unlike opiates, does not produce an abstinence syndrome.

As part of the Maternal Lifestyle Study, Bada et al. used multivariate regression models with more than 11,000 mother-infant dyads to try to estimate the effects of cocaine exposure on intrauterine growth and to investigate when fetal growth deviation would manifest itself in the woman's gestation.[7] After controlling for confounders, at 40 weeks of gestation, cocaine exposure was estimated to be associated with decreases of 151 g in birth weight, 0.71 cm in length, and 0.43 cm in head circumference. **Investigators concluded that in utero cocaine exposure was associated with growth deceleration that becomes more pronounced as gestation advances.**[7]

ALCOHOL

Alcohol is the most common teratogen that fetuses are exposed to in Western societies, and unlike other teratogens, ethanol has no receptor but affects cellular activity.[110] In both recent prospective and retrospective studies of animals and mammals, ethanol has been shown to cause multiple problems during gastrulation and organogenesis that includes cellular growth, differentiation, and migration.[110,120] These cellular effects can be seen with both ethanol and acetaldehyde and are instrumental in inducing fetal malformations.

Early exposure to alcohol, whose effects are globally referred to as fetal alcohol spectrum disorders (FASD) are well-known causes of mental deficit.[120] *FASD* is an umbrella term describing the range of effects that can occur in an individual who was prenatally exposed to alcohol. These effects may include physical, mental, behavioral, and/or learning disabilities with lifelong implications. FASD is not a diagnostic term. It refers to specific conditions, such as fetal alcohol syndrome (FAS), alcohol-related neurodevelopmental disorder (ARND), and alcohol-related birth defects (ARBDs).[111] **Research documenting deleterious outcomes for children prenatally exposed to even small amounts of alcohol (0.5 drink per day) has led to a realization that a threshold (or critical dose effect) has not been identified.**

Current research has also found a genomic effect that is different in all individuals.[110] When ethanol exposure is held constant, genetic factors modulate the risk for cardiac, craniofacial, skeletal, and central nervous system defects in the developing fetus.[110] In light of these facts, **health care professionals should counsel all women not to drink any alcohol while pregnant.**[97,98]

When women consume cocaine and alcohol together, they compound the danger. Researchers have found that the human liver combines cocaine and alcohol to produce a unique metabolite, cocaethylene, which intensifies cocaine's euphoric effects. Cocaethylene is associated with a greater risk for sudden death than cocaine alone.[81] **Discussions in the 1990s surrounding the use of cocaine and alcohol together suggested that cocaethylene was reported to be 10 times more potent than cocaine alone and more toxic to the growing fetus.** No current studies further our understanding of this toxic metabolite.

AMPHETAMINES

Amphetamines and methamphetamines known as *crystal, ice,* or *crank* are abused by pregnant women in many geographic areas in the United States with the same frequency as cocaine. Like cocaine and "crack," the amphetamines are potent stimulants, and effects on the fetus and neonate are similar; also like cocaine the preponderance of available data would suggest little or no effect of amphetamine on organogenesis.[44] Early research has shown how in utero amphetamine exposure can lead to congenital brain lesions, including hemorrhage, infarction, or cavitary lesions. Investigators also described the sites of these lesions as frontal lobes, basal ganglia, posterior fossa, or generalized atrophy; the effects of the lesions are not exhibited until the child is older. In the neonatal period, neurologic abnormalities including decreased arousal, poor state control, difficulty with habituation, tremors, hyperactive neonatal reflexes, abnormal cry, increased stress, drowsiness, poor feeding, and seizures have been reported.[109] Outcome effects of prenatal exposure to amphetamines have yet to be isolated from the effects of alcohol and nicotine, the two drugs most often used with the methamphetamines.[81]

A review of the literature documents lack of prenatal care as the hallmark of maternal cocaine and amphetamine use with an increase in maternal morbidity and mortality as its consequence.[46,106] **The use of these stimulants is reported to be toxic to the fetal brain, and there may be an increase in sudden infant death syndrome (SIDS). Stimulants (amphetamines and cocaine) have been found in breast milk in extremely high levels, and may produce an acute neurotoxic syndrome with hypertonia, tremors, apnea, and seizures.**[7,37,46,105,109]

MARIJUANA

Marijuana, one of the most popular illicit drugs used by pregnant women,[33] has been studied for many years with conflicting data. Accumulating evidence in animals and humans indicate that prenatal exposure may result in harm to the developing fetus. Cannabinoids mediate their effects through the endocannabinoid receptors, which form very early in fetal life and have critical function in fetal and postnatal brain development, neuronal connectivity, and glial cell differentiation.[16,49,102] In a prospective cross-sectional study that included full-term infants born to adolescent mothers who used marijuana, de Moraes et al. found that marijuana was detected in both the mother's and the infant's hair and that the exposure during pregnancy altered the neurobehavioral performance of the term newborns when assessed with the neonatal intensive care unit (NICU) Network Neurobehavioral Scale (NNNS).[24,46] Other recent studies have highlighted the long-term effects of marijuana use in pregnancy on the neonate and child and reveal conflicting data. While **some studies show a correlation with prenatal marijuana use and increased hyperactivity, impulsivity, inattention symptoms, and delinquency,**[81] **other studies have reported minimal effects on cognition, language, and motor development.**[16,76] There are also conflicting data in regard to fetal growth and birth complications, with few studies citing lower birth weight, others concluding an increase in NICU admissions, and still others reporting an increased risk of neonatal morbidity.[16,76] The only finding that seems consistent across studies is that **marijuana does not cause structural anatomic defects in humans.**[16] In summary, there are no randomized controlled trials on the effect of marijuana use by pregnant and lactating women, and the available longitudinal studies must be viewed with caution given the potential confounding of the effect of marijuana during pregnancy by other licit and illicit substances, as well as

sociodemographic and environmental risk factors. Given that the evidence about the effects of marijuana use during pregnancy and fetal-related complications and child development is inconclusive, **continued counseling to abstain from marijuana use during pregnancy needs to be conveyed.**[102] Further research is critical to understand the specific risks to the developing fetus and growing child.[123]

BENZODIAZEPINES

Benzodiazepines have hypnotic, muscle-relaxant, and anticonvulsant properties. They can be used to treat anxiety, insomnia, panic disorder, seizures, and agitation, and for sedation.

The data regarding the use of the benzodiazepines (including clonazepam, alprazolam, lorazepam, and diazepam) during pregnancy are insufficient. There is some suggestion that there may be an **increased risk of cleft lip and palate associated with first-trimester exposure to these medications.**[85] Risk does not seem to be influenced by the dosage of medication taken by the mother.

There is further concern regarding drug effect (toxidrome) and withdrawal for the baby exposed to benzodiazepines in utero. **Symptoms of toxicity have been reported in newborns, and these include sedation, hypotonia, and breathing problems**, as could be seen in anyone exposed to these medications. **Withdrawal symptoms include irritability, sleep disruption, and, less commonly, seizure.** Onset ranges from 12 hours to days.[3,6,71,115]

BARBITURATES

Barbiturates, a type of sedative-hypnotic, are used to treat anxiety, seizures, and insomnia. **Barbiturates are no longer routinely prescribed for pregnant women because of concern for birth defects, but remain a substance of abuse.** The drug effect or toxidrome of barbiturates is similar to those of benzodiazepines described earlier. **Withdrawal symptoms include irritability, tremors, hyperacusis, excessive crying, vasomotor instability, diarrhea, restlessness, increased tone, hyperphagia, vomiting, and disturbed sleep.** Onset can occur during the first 24 hours, but as late as 10 to 14 days of life.[3,6,115]

INHALANTS

No well-controlled, prospective studies have been done on maternal inhalant use (huffing)—often substances of abuse in poor and underprivileged communities because they are widely available (e.g. acetone), legal, and relatively inexpensive. Organic solvents are chemical compounds used to dissolve substances, and although their chemical structures widely differ, they share some common features: low molecular weight, lipophilia, and volatility at room temperature.[73,107] Inhalants are classified into four groups: volatile solvents, aerosols, gases, and nitrites.[73,75,107]

Inhalants may produce a variety of rapid neuropsychiatric effects with euphoria or drowsiness occurring within seconds to minutes. Case reports and follow-up studies of children of inhalant/solvent-abusing mothers are available. **Inhalant/solvent-abusing mothers give birth to babies who are small for gestational age (SGA) and who have developmental delays, craniofacial deformities, and an alcohol-like withdrawal syndrome.**

ANTIDEPRESSANT USE IN PREGNANT WOMEN AND OCCURRENCE OF NEONATAL ABSTINENCE SYNDROME

Psychopharmacology for pregnant women with coexisting mental health diagnoses are also of concern.[42] **As many as 70% of pregnant women experience some symptoms of depression, with 10% to 16% of pregnant women meeting diagnostic criteria for a major depressive disorder.**[116] The typical or atypical antipsychotic drugs all pass the maternal blood–placenta barrier, with significant difference among compounds.[99] Continuing treatment throughout pregnancy, at the lowest effective dose, may be necessary to prevent relapse and to prevent potential harmful effects on the mother-fetal dyad. Case reports, adverse drug reaction reports, and prospective studies have linked third-trimester use of SSRIs in pregnant women to a **constellation of neonatal signs indicating an altered neonatal adaptation to extrauterine life. These include continuous crying, irritability, jitteriness, and/or restlessness; shivering; fever; tremors; hypertonia or rigidity; tachypnea or respiratory distress; feeding difficulty; sleep disturbance; hypoglycemia; and seizures.** The onset of these signs ranged from several hours to several days after birth and usually resolved within 1 to 2 weeks. **Biochemical studies that correlate serial serum SSRI concentrations and markers of CNS serotonin activity support a drug toxicity phenomena rather than a drug withdrawal state as the cause of the clinical signs.**[46,57,58] A mother on treatment with an

SSRI who desires to breastfeed her infant should be counseled about the benefits of breastfeeding as well as the potential risk that her infant may continue to be exposed to a measurable level of the SSRI with unknown long-term effects.[46] There has been some suggestion of possible link of SSRIs with congenital malformations.[85]

*PREVENTION

Neonatal drug withdrawal is preventable if women do not use dependence-producing substances, licit or illicit, during pregnancy. Through intense educational efforts, the desirability and availability of drugs may be thwarted. Unfortunately, the psychosocial and socioeconomic milieu of modern society continues to propagate dysfunctional families, victimization of women, and an intergenerational cycle of substance abuse.

Therefore, our goals must be to provide prenatal care for the pregnant drug-dependent woman and her fetus to diminish or eliminate the sequelae of NAS. The health care community is challenged to become more astute in its assessment and intervention for the problems of drug-dependent parturients. More treatment options are necessary for women with opioid use disorder and their neonates through inpatient residential care and outpatient interdisciplinary clinics that focus on the elimination, as well as the consequences, of addiction. Despite recent discussion in the press and some literature regarding medically supervised withdrawal during pregnancy, studies continue to demonstrate, and the American College of Obstetricians and Gynecologists (ACOG) states, **"that for women with an opioid use disorder, opioid agonist pharmacotherapy is the recommended therapy."** The ACOG document also states that pharmocotherapy is preferable to medically supervised withdrawal because withdrawal is associated with high relapse rates, which lead to unfavorable outcomes.[4,10,16,40,117] **Additionally, it is now recognized that to achieve lasting results from treatment of opioid use disorder in any population, treatment must be family centered and trauma informed.**[70,90]

For iatrogenic NAS, there is a need for guidelines for effective weaning of neonates from opiate analgesics and sedatives.[8] **Investigators encourage dose reductions of 10% to 20% per day.** For the prevention of iatrogenic NAS, discussions in recent literature include limiting total doses of fentanyl during ECMO therapy by administering morphine boluses or using continuous morphine infusions to replace fentanyl, substituting enteral methadone for morphine, or using sublingual buprenorphine.[64,77]

DIAGNOSIS

History

A comprehensive prenatal medical and drug history, especially with respect to poly-drug abuse, is of prime importance. All pregnant patients who are substance abusers, regardless of the drug used, are considered high risk because of the effects of the drug, as well as complications arising from concomitant infections and lifestyle.[26] Fear of referral to child welfare agencies or the legal system in recent years has prompted women to conceal their drug abuse and/or pregnancy. This fear and denial may prevent the pregnant woman from seeking prenatal care. Thus, she may appear in the emergency department of the hospital either in crisis or ready to deliver. In this instance, a prenatal history is absent, making neonatal assessment more difficult.[4]

Signs and Symptoms of Neonatal Abstinence Syndrome

At birth, most infants exposed to opioids appear physically and behaviorally normal with **symptoms of withdrawal beginning shortly after birth and up to 2 weeks of age, but the majority are exhibited within 72 hours.**[33,46,61] **Acute symptoms may persist for several weeks, whereas subacute symptoms (e.g., irritability, sleep problems, hyperactivity, feeding problems, hypertonia) may persist for 4 to 6 months.**[15]

The most common signs and symptoms of NAS are listed in Box 11.6. A standardized NAS scoring system is recommended for assessing infants.[46] Caregivers should have extensive training on this scoring system with ongoing competencies and second-scorer validation for high scores to ensure as objective a measure as possible. For the convenience of referencing, the signs and symptoms discussed here are in the order in which they appear on the assessment sheet reviewed within this chapter, as shown in Fig. 11.2.

BOX 11.6 CRITICAL FINDINGS[29,32] NEONATAL ABSTINENCE SYNDROME

- Signs and symptoms of neonatal abstinence syndrome may not be exhibited for up to 72 hours.
- Most common signs and symptoms of neonatal abstinence syndrome are central nervous system hyperirritability, gastrointestinal dysfunction, respiratory distress, and autonomic instability.
  - Acute signs and symptoms that may persist for several weeks:
  - Restlessness
  - Tremors (disturbed at first to undisturbed)
  - High-pitched cry
  - Increased muscle tone
  - Irritability and inconsolability
  - Increased deep tendon reflexes
  - Exaggerated Moro reflex
  - Seizures in approximately 1% to 2% of heroin-exposed neonates and approximately 7% of methadone-exposed neonates
- Subacute signs and symptoms that may persist for 4 to 6 months:
  - Irritability
  - Sleep pattern disturbance
  - Hyperactivity
  - Feeding problems
  - Hypertonia

Initially, the infants appear only to be restless. **Tremors develop, which are mild and occur only when the infant is disturbed, but these progress until they occur spontaneously without external stimulation of the infant.** One of the most serious but rare consequences of neonatal opioid abstinence is the development of seizures. No relationship between maternal methadone dosage and the frequency or severity of neonatal seizures has been established. In addition, no significant differences have been found between neonates with seizures and those without seizures in birth weight, gestational age, occurrence of their withdrawal symptoms, day of onset of withdrawal symptoms, or the need for specific pharmacologic treatment.[46] **The short-term prognosis for abstinence-associated seizures is favorable compared with the prognosis after seizures associated with other causes.** This observed improvement in neurologic function may be based on the replenishment of neurotransmitters after transient depletion in the neonatal period.[72,109]

The risk for SIDS should be considered when the neonate has an especially difficult course of NAS, when the mother uses multiple agents (poly-pharmacy: opioids and stimulants such as cocaine or amphetamine, nicotine), and when a combination of therapeutic agents is used for treatment. The rate of SIDS in these infants has been demonstrated to be 5 to 10 times over that in the general population. Research reports that the risk for SIDS is increased in opiate-exposed infants and varies from 2.5% to 4%.[47] Wingkun and other investigators studied carbon dioxide sensitivity in infants of substance-abusing mothers and found that these infants have abnormal sleep ventilatory patterns and "an impaired repertoire" of protective responses to hypoxia and hypercapnia during sleep cycles.[125]

In addition to having disturbed sleep patterns, infants undergoing withdrawal from narcotics exhibit excessive spontaneous generalized sweating. Other autonomic nervous system signs include yawning, elevation of temperature, sneezing, and skin mottling. **The rooting reflex is exaggerated, and these infants frequently suck their fists or thumbs; yet when fed, their suck-and-swallow reflexes are uncoordinated and ineffectual.** Therefore they tend to regurgitate or vomit in a projectile manner. The infant also may develop loose stools and is susceptible to dehydration and electrolyte imbalance.[5,33,46] These symptoms are exhibited as a result of exposure to opioids, as well as to nonopioid CNS depressants. However, with **nonopioid CNS depressant exposure, symptoms tend to begin at a later age, with malnourishment at birth an unusual feature.** Because barbiturate withdrawal may not develop until an infant has been discharged from the nursery, it may not be treated unless suspicion has been aroused by the mother's symptoms or actions. **Furthermore, there is a greater risk for seizure activity in neonates withdrawing from barbiturates than in those withdrawing from opioids.**[5,30,46]

Symptoms exhibited by stimulant-exposed newborns are manifestation of drug toxicity (drug effect or toxidrome) rather than withdrawal.[46] **The symptoms usually decrease with time rather than increase as is seen with true withdrawal.** The literature describes cocaine-exposed infants as tremulous, irritable, lethargic, unable to respond appropriately to stimuli, and having abnormal state control and cry patterns.[5,7,46,61,106]

Also described are abnormalities in orientation, motor ability, state regulation, muscular hypertonia, and abnormal reflexes. Infants may show symptoms of lethargy intermittently with irritability, poor sucking patterns, and sleep disturbances. When cocaine has been the primary drug of abuse, most clinicians have not seen symptoms severe enough to treat the infant pharmacologically.[31,46,61]

Laboratory Data and Differential Diagnosis

Before initiating medication for treatment of NAS, common neonatal metabolic alterations that can mimic or compound withdrawal, such as hypocalcemia, hypomagnesemia, hypoglycemia, and hypothermia must be ruled out. Serum glucose and calcium tests may be indicated. If the mother has had no prenatal care, it would be prudent to thoroughly assess the infant at birth, including testing for occult disease, sepsis, and intracranial bleeding. A urine and meconium test for toxicology should also be obtained. Meconium is more accurate and can detect a longer period of drug exposure. Umbilical cord testing has the benefit of being obtained even before drug exposure is suspected, but may not be as sensitive a test as meconium, and can be logistically more difficult.[20,28,74,121]

TREATMENT AND INTERVENTION

Infants at risk for NAS should be monitored closely for signs and symptoms of withdrawal. The appropriate duration of observation should be dependent on careful assessment of maternal substance history. **Infants born to mothers requiring or taking an opiate with a short half-life (hydrocodone) may be discharged after 72 hours if without signs of withdrawal. Infants exposed to maternal opiates with a long half-life (methadone, buprenorphine) should be monitored for 5 to 7 days.**[46] Fifty-five percent to 94% of infants with maternal opiate exposure will have some signs or symptoms of withdrawal. While there is **clear literature to support nonpharmacologic management as the initial treatment for infants at risk for NAS or experiencing symptoms of NAS, there is no literature-based standard for pharmacologic treatment.**[46] A randomized control trial showed that implementation and adherence to a formalized NAS protocol with set initiation, escalation, and weaning parameters was key to improving pediatric outcomes.[42] **Nonpharmacologic care should be implemented after birth to help abate symptoms of withdrawal and to help control symptoms if pharmacologic treatment becomes necessary.**[41,42,46,121]

To best monitor an infant, each nursery should adopt a protocol for the evaluation and management of NAS. Staff should be trained on the use of an abstinence assessment tool.[46] Institutions may increase the reliability of NAS assessment through competency requirements and second-scorer validation of elevated scores. The most predominantly used assessment tool is the Finnegan Neonatal Abstinence Scoring System (FNASS). The Lipsitz Tool, initially endorsed by the American Academy of Pediatrics in 1998, is still in use in some institutions.[74]

With the increased focus on NAS monitoring and treatment, many centers have moved attention to not only modifying the Finnegan Scoring System, but also creating whole new systems that emphasize physiologic behaviors, comfort care, and team-approach scoring.[39] For example, **the *Eat, Sleep, Console model* is a comprehensive nonpharmacologic approach on which infants are assessed on three key aspects: how well the infant is eating, how well the infant is sleeping, and consolability of the infant.** Pharmacologic treatment is based on infant function and comfort versus reducing all signs of opioid withdrawal. **Medication treatment is initiated only when an infant fails to eat, sleep, or console because of symptoms from NAS after assuring nonpharmacologic treatment has been maximized.** Although this model of care has not been validated, the initial study showed a decreased length of hospitalization in infants with NAS from 22.5 to 5.9 days with the initiation of the Eat, Sleep, Console model's launch in 2011.[39] Presently, further validation and evaluation of this system is taking place.

The FNASS, developed in 1975, is used in 95% of US hospitals, although the tool has been modified frequently. **Centers now allow for comfort care, clustering of care, assessing after feedings, and not waking an infant simply for scoring.**[39]

This system allows for assessment of the onset, progression, and resolution of symptoms, as well as the infant's clinical response to pharmacotherapy for the control of NAS symptoms. Titration of therapeutic agents is thus based on the degree of withdrawal symptoms that correspond to a specific score (Fig. 11.1). **Although a number of scoring tools have been used in both clinical and research settings, the modified 21-item Finnegan neonatal abstinence score has remained useful.** The nurse and multidisciplinary team are vital in the assessment of withdrawal in an infant. It is vital that interrater reliability be developed among all nursing staff and anyone responsible for scoring and assessment of the infant.

The ***Finnegan Abstinence Score*** sheet (see Fig. 11.2) uses a weighted scoring of 21 actual items that are most commonly observed in an opioid-exposed neonate.[31,46,74] **Signs and symptoms are recorded as single entities, or in several categories if they occur in varying degrees of severity.** Each symptom, with its associated degree of severity, has been assigned a score. **Higher scores are assigned to symptoms found in infants with more severe withdrawal. The total score is determined by adding the scores assigned to each symptom observed throughout the entire scoring interval. The scoring system is dynamic rather than static;** all signs and symptoms observed during the 3- to 4-hour intervals at which infant symptoms are monitored are point-totaled for that interval. Most institutions now use intervals from one feeding to the next to ensure the implementation of nonpharmacologic comfort care.

Fig. 11.2 shows the NAS scoring system. Symptoms are listed on the left and scores on the right. Times of each evaluation are listed at the top, and the total score is listed for each evaluation. A new sheet should be started at the beginning of each day. A "Comments" column is provided for nursing and medical staff to record important notes about the infant's progress.

The first score should be recorded approximately 2 to 4 hours after the neonate's admission. This score reflects all infant behaviors from admission to the first point in time when the scoring interval is complete. The times designating the end of the scoring intervals have been left blank to permit the health care team or nursing staff to choose appropriate times for scoring. **Most institutions now center scoring around or after feedings.**

The need for medication is indicated when the total score is 8 or higher for three consecutive scorings (e.g., 9, 8, 10). Medication treatment is also warranted when the infant's total is 12 or higher for two consecutive intervals.

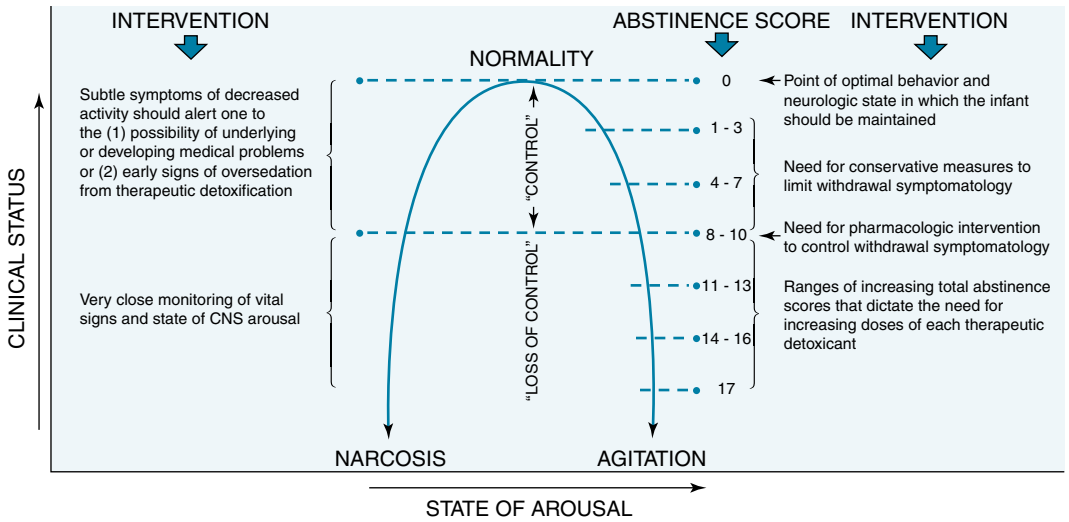

FIGURE 11.1 Management of neonatal abstinence syndrome. *CNS,* Central nervous system. (From Finnegan LP. Neonatal abstinence syndrome. In: Nelson N, ed. *Current Therapy in Neonatal-Perinatal Medicine.* 2nd ed. Ontario: Decker; 1990.)

NEONATAL ABSTINENCE SCORE

Date:_____ Weight: _____

System	Signs and Symptoms	Score	Time AM / PM	Comments
Central nervous system disturbances	Excessive high-pitched cry	2		
	Continuous high-pitched cry	3		
	Sleeps <1 hour after feeding	3		
	Sleeps <2 hours after feeding	2		
	Sleeps <3 hours after feeding	1		
	Hyperactive Moro reflex	2		
	Markedly hyperactive Moro reflex	3		
	Mild tremors when disturbed	1		
	Moderate - severe tremors disturbed	2		
	Mild tremors when undisturbed	3		
	Moderate - severe tremors undisturbed	4		
	Increased muscle tone	2		
	Excoriation (specific area)	1		
	Myoclonic jerks	3		
	Generalized convulsions	5		
Metabolic/vasomotor/ respiratory disturbances	Sweating	1		
	Fever <101° F (37.2° - 38.2° C)	1		
	Fever 38.4° C and higher	2		
	Frequent yawning (>3 - 4 times/interval)	1		
	Mottling	1		
	Nasal stuffiness	1		
	Sneezing (>3 - 4 times/interval)	1		
	Nasal flaring	2		
	Respiratory rate >60/min	1		
	Respiratory rate >60/min with retractions	2		
Gastrointestinal disturbances	Excessive sucking	1		
	Poor feeding	2		
	Regurgitation	2		
	Projectile vomiting	3		
	Loose stools	2		
	Watery stools	3		
	TOTAL SCORE			
	Initials of Scorer			

FIGURE 11.2 Neonatal abstinence score sheet. Check sign or symptom observed at various time intervals, and add scores for a total at each evaluation. (Modified from Finnegan LP, Kaltenbach K. The assessment and management of neonatal abstinence syndrome. In Hoekelman RA, Nelson N, eds. *Primary Pediatric Care*. 3rd ed. St Louis, MO: Mosby; 1992.)

Some simply refer to the threshold for medical treatment as the "rule of 24." **When two to three consecutive scores add up to 24 or greater, then pharmacologic treatment should be considered. Once an infant's score is 8 or higher, one must ensure nonpharmacologic measures (comfort measures) are maximized, and scoring intervals should be changed to hourly to closely monitor the infant's symptoms, the efficacy of the comfort measures employed, and the potential need for pharmacologic treatment.** Many centers now use a second scorer to validate ("second-scorer validation") scores greater than 8 to allow more objectivity in scoring. This is important because the decision to treat medically relies on this measure. Table 11.2 describes the symptoms of withdrawal, appropriate observations, and nonpharmacologic interventions (comfort care).

Pharmacologic Treatment of Neonatal Abstinence Syndrome

Even though there is a plethora of evidence to support nonpharmacologic (comfort) approaches for NAS, no single evidence-based best practice concerning pharmacologic treatment exists.[45,46,94,121] Many pharmacologic approaches, all varying in choice of drug and dose, as well as approaches to escalation of dosing and weaning have been suggested.[46,60,61,74,121] **In the past decade and in the latest study of 199 US NICUs in the Vermont Oxford Network,**[96] **morphine is the most commonly used medication for pharmacologic treatment of NAS. However, in recent years there is increasing research about the use of methadone or buprenorphine.**[23,46,61,96,121] Table 11.3 lists

TABLE 11.2 CREATING A SUPPORTIVE ENVIRONMENT FOR THE DRUG-EXPOSED NEONATE

INFANT BEHAVIOR	OBSERVATIONS	INTERVENTIONS (COMFORT CARE)
High-pitched cry	Note onset. Note length of time the cry persists: Is it continuous? Is it high pitched and piercing as though infant were in pain?	Nonnutritive sucking Swaddle infant Soothe with slow, rhythmic swaying Skin-to-skin contact with parent Feed on demand Decrease environmental stimuli (low noise, low light, limit visitors) Organize care to minimize handling
Inability to sleep	Note how long infant sleeps after feeding. Note general sleep-wake patterns. If drug therapy has been initiated, note changes in sleep patterns, ability to rest, and any decreased activity indicative of drug overdose.	Decrease environmental stimuli (low noise, low light, limit visitors) Feed on demand, or small amounts at frequent intervals Organize care to minimize handling Swaddle infant Skin-to-skin contact with parent Soothe with slow, rhythmic swaying
Frantic sucking of fists	Note onset and amount of fist sucking.	Use infant shirts with sewn-in sleeves for mitts to prevent skin trauma Offer pacifier for nonnutritive sucking
Yawning	Note onset and frequency.	None
Sneezing	Note onset and frequency.	Wipe secretions with cloth
Nasal stuffiness	Note severity of nasal stuffiness, and determine whether it hinders breathing and feeding.	Allow more time for feeding with rest between sucking Check rate and character of respirations frequently
Poor feeding	Note sucking pattern: Is infant uncoordinated in attempt to suck, swallow, and breathe?	Weigh daily Decrease environmental stimuli (low lights, low noise, limit visitors) Feed small amounts at close intervals Swaddle infant Maintain fluid and caloric intake required for infant's weight Feed on demand Use alternative feeding methods (e.g., gavage) Consider higher-calorie formula Organize care to minimize handling to ensure adequate rest between feedings
Regurgitation	Note when regurgitation or vomiting occurs: Is there a precipitating factor (e.g., medication, handling, manipulation, position)?	Measure intake and output closely Burp infant each time he or she has a long pause in sucking during a feeding Hold infant upright for 15–20 minutes after feeding Monitor weight closely Feed small amounts at close intervals
Hyperactive Moro reflex	Is reflex moderately or markedly exaggerated? If drug therapy has been started, is Moro reflex diminished or absent?	None

Continued

TABLE 11.2 CREATING A SUPPORTIVE ENVIRONMENT FOR THE DRUG-EXPOSED NEONATE—CONT'D

INFANT BEHAVIOR	OBSERVATIONS	INTERVENTIONS (COMFORT CARE)
Hypertonicity	Note degree (mild, moderate, or severe) of increased muscle tone by: • Attempting to straighten arms and legs and recording degree of resistance • Picking up infant by hands and noting body rigidity with degree of head lag (a withdrawing infant often exhibits trunk rigidity and holds the head on a plane with the body for a prolonged time) • Raising infant by arms and letting baby stand (a withdrawing neonate exhibits marked leg rigidity and can support body weight for considerable periods)	Swaddle infant Skin-to-skin contact with parent Decrease environmental stimuli (low lights, low noise, limit visitors) Organize care to minimize handling Avoid overdressing or overswaddling because of the risk for increased body temperature with hypertonicity
Tremors	Note whether tremors occur when infant is disturbed or undisturbed. Note location of tremors: • Note whether degree of tremors is mild, moderate, or severe.	Decrease environmental stimuli (low lights, low noise, limit visitors) Organize care to decrease handling Support movements during caregiving Swaddle infant as much as possible during caregiving Swaddle when sleeping in crib
Seizures	Observe for seizures; if they occur, note onset, length, origin, body involvement, type (tonic, clonic, or both), eye deviation, and infant's color.	Monitor respiratory rate, heart rate (sign of apnea or bradycardia) Initiate resuscitation as indicated

Modified from Finnegan LP, MacNew BA. Care of the addicted infant. *Am J Nurs.* 1974;74:685.

first-line and adjunctive pharmacologic treatment for NAS. Although preliminary data suggest methadone and buprenorphine are both viable options in the pharmacologic treatment of NAS, there are presently no neonatal formulations of these medications commercially available for use, and studies have used formulations specifically designed for the study.[23] Additionally, in former eras of NAS care, the longer-acting opioid choices had fallen out of favor because of a prolonged half-life and difficultly weaning effectively in a short period. **Both phenobarbital and clonidine are used for adjunct therapy when first-line treatment does not control symptoms.**[46,96,121] Although continued data are needed to support a specific treatment drug choice or protocol, standardized, evidence-based practice is essential. Within a specific unit or system, the following must be clearly defined: (1) medication to be used, (2) initial dosing (can be symptom based, weight based, or both), (3) parameters for escalation of dosing, (4) parameters for weaning of dosing, and (5) second-line therapy with all of the previously mentioned specifications. The development and use of a standardized NAS treatment protocol has been shown to improve neonatal response and decrease length of stay.[17,41] **Although a standard pharmacologic approach to NAS is important, expert clinical judgment is also necessary to individualize care when necessary.** If there are some unappreciated clinical findings that seem to confound scoring, this must be fully examined before starting treatment "per protocol." Likewise, if an infant becomes excessively sleepy or less responsive, the dosing protocol must be put on hold while the infant is thoroughly assessed by the provider. Although the standard medication dosing dictated by a protocol may be appropriate for most infants, there may be cases in which the starting dose is in excess of that required by an individual infant so that care individualization is necessary.

TABLE 11.3 PHARMACOLOGIC TREATMENT FOR NEONATAL ABSTINENCE SYNDROME

DRUG	DOSAGE	COMMENTS
Oral buprenorphine[62–64]	Initial dose: 5.3 mcg/kg every 8 hours sublingually; give pacifier and administer under tongue while neonate sucks on pacifier Total dose per day: 15.9 mcg/kg/day divided in three doses	Three RCTs comparing oral buprenorphine and morphine found advantages to buprenorphine use.[62–64] The most recent RCT found fewer days of treatment (15 days vs. 28 days), shorter LOS (21 days vs. 33 days), and fewer babies requiring adjunctive phenobarbital in the buprenorphine-treated group.[62] Longer duration of action than methadone
Oral methadone: used in 20% of participating VON US NICUs[96]	Initial dose: 0.05–0.1mg/kg every 6 hours Increment: 0.05 mg/kg/dose Maximum dose: to effect	Long half-life of 8–59 hours[101]
Oral morphine: used in 80% of participating VON US NICUs[96]	Initial dose: 0.04 mg/kg every 3–4 hours Increment: 0.04 mg/kg/dose Maximum dose: 0.2 mg/kg/dose[46] Use a 0.4-mg/mL dilution: 1 mL of the 4 mg/mL injectable solution added to 9 mL preservative-free normal saline solution. Protect from light; stable for 7 days, refrigerated.	Control is evidenced by an NAS average score <8, rhythmic feeding/sleep cycles, optimal weight gain, same opium dose for 72 hours, and pharmacologic weaning. Continue to score for NAS. Scores must remain <8. Advantages: Diminishes bowel motility and loose stools; 20% to 40% bioavailability when administered orally; lower doses and shorter dosing interval are associated with shorter hospital stay in infants with NAS resulting from maternal methadone treatment. Disadvantages: Respiratory depression, hypotension, delayed gastric emptying, ileus, urine retention.
Adjunctive Pharmacologic Therapy		
Oral clonidine[46]: used in less than 10% of participating VON US NICUs[96]	Initial dose: 0.5–1 mcg/kg every 6 hours Increment: not studied Maximum dose: 1 mcg/kg every 3 hours	Reduces CNS sympathetic outflow and palliates symptoms of autonomic overactivity, such a tachycardia, hypertension, diaphoresis, restlessness, and diarrhea. Cessation of clonidine treatment can result in a rebound of autonomic activity. Reported experience with clonidine as a primary or adjunctive treatment of NAS is limited but promising.[46]
Phenobarbital: used in 24% of participating VON US NICUs[96]	Loading dose: 20 mg/kg to achieve an expected therapeutic level in a single dose. If score is ≥8, give 10 mg/kg every 12 hours until control or signs of toxicity appear. Maintenance dose (once under control): 2–6 mg/kg/day for 3–4 days. Decrease dose to 3 mg/kg/day. Discontinue: serum levels <15 mcg/mL.	Daily serum levels can be obtained. Advantages: Drug of choice for poly-drug use; especially effective in controlling irritability and insomnia; controls symptoms in 50% of infants. Disadvantages: Does not prevent loose stools. Infant should be in a nursery where he or she can be monitored closely.

LOS, Length of stay; *NAS*, neonatal abstinence syndrome; *PO*, by mouth; *RCT*, randomized controlled trial; *VON*, Vermont Oxford Network.

Complications of excessive pharmacologic treatment are listed in Box 11.7. Alternatively, these neonatal symptoms may represent another underlying issue (e.g., hypoglycemia, sepsis, meningitis) unrelated to NAS that requires investigation and treatment. Detection of underlying medical problems may be difficult, because poorly controlled abstinence may mimic and/or disguise many common neonatal conditions.

Breastfeeding the Infant With Neonatal Abstinence Syndrome

All drugs of abuse pass through the breast milk. However, breastfeeding for women in medically supervised treatment programs with nontoxic agents need not be discouraged.[1,30,46,61,84] In contrast, women using stimulants and other potentially toxic drugs, as well as those who are infected with HIV, should be discouraged from breastfeeding because of the potential toxic and negative effects on the neonate.

Both methadone and buprenorphine are found in breast milk. Methadone appears in low levels in breast milk, but absolute levels depends on maternal dosing.[30] **Buprenorphine is excreted into breast milk approximately 2 hours after maternal ingestion.** The concentrations of buprenorphine and norbuprenorphine in breast milk are highly variable because of differences in breast milk protein and fat. However, neither concentrations of buprenorphine and norbuprenorphine exceed plasma concentrations.[51] One study comparing breastfeeding rates and the relationship between breastfeeding and NAS in buprenorphine-exposed neonates found the following:[51]

- 76% or (65 of 85 participants) in the study chose to breastfeed.
- 66% were still breastfeeding at 6 to 8 weeks postpartum.
- **NAS was less severe with the breastfeeding group** (mean peak NAS scores of 8.83 vs. 9.65 on the Finnegan scoring system).
- **Breastfed infants were less likely to require pharmacologic treatment** (23.1% vs. 30%) than infants who were not breastfed.

The Norwegian National Cohort Study of 124 women treated with either methadone or buprenorphine found that 77% of the women chose to breastfeed. **Methadone-exposed infants had a lower incidence of NAS requiring pharmacologic treatment (53% vs. 80%). Breastfed infants exposed to both methadone and buprenorphine needed less medication for a shorter period.**[69]

In summary, the limited published research (barring other complications and contraindications, such as an HIV-positive mother) support **current guidelines that recommend breastfeeding for mothers who are stabilized on either methadone or buprenorphine.**[2,51] **Likewise, it is recommended that women who are stable on any medically supervised opioid agonist treatment program are supported in their breastfeeding efforts.**[4] **Marijuana is the most commonly used recreational drug among breastfeeding women.** Authors of case reports have documented the presence of marijuana metabolites in human milk. Recently, one study measured variable quantities of the primary psychoactive ingredient in marijuana, Δ-9-tetrahydrocannabinol, in human milk up to approximately 6 days after marijuana use.[12] Similar to marijuana use during pregnancy, there are insufficient data to evaluate the effects of marijuana use on infants during lactation and breastfeeding, and in the absence of such data, marijuana use is discouraged.[16]

BOX 11.7 COMPLICATIONS OF EXCESSIVE PHARMACOLOGIC TREATMENT

- Diminished or absent reflexes: Moro, sucking, swallowing, Galant, Perez, tonic neck, corneal, grasp (palmar, plantar)
- Truncal (central) or circumoral cyanosis or persistent mottling not associated with ambient temperature decreases
- Decreased muscle tone with passive resistance to extension of extremities, or decreased neck or trunk tone
- Altered state of arousal (e.g., obtunded, comatose)
- Diminished response to painful stimuli
- Failure of visual following
- Hypothermia
- Altered respirations: irregular (periodic breathing in full-term infants), shallow (decreased air entry), decreased respiratory rate (<20/min), apnea
- Cardiac alterations: irregular rate, distant heart sounds with weak peripheral pulses, heart rate of 80 to 100 beats/min, poor peripheral perfusion (pale, gray, mottled skin), cardiac arrest

Complications

Kocherlakota nicely summarized in a 2014 publication the recommendations for discharge and

follow-up of babies who have exhibited signs and symptoms of NAS[61]:

- **Neurodevelopmental assessments** to identify motor deficits, cognitive delays, or relative microcephaly
- **Psychobehavioral assessments** to identify hyperactivity, impulsivity, and attention-deficit/hyperactivity disorder in preschool-age children, as well as school absences, school failure, and other behavioral problems in school-age children
- **Ophthalmologic assessment** to identify nystagmus, strabismus, refractive errors, and other visual defects
- **Growth and nutritional assessment** to identify failure to thrive and short stature
- **Family support assessments** to exclude continuous maternal substance abuse and child abuse

Depending on the substance to which the fetus was exposed some expected long term effects may include alterations in growth, behavior, cognition/ executive function, language and school achievement.[9] An empiric evaluation of in utero drug exposure and school performance also demonstrated poor and deteriorating school performance in children who were diagnosed with NAS during the neonatal period.[86]

PARENT TEACHING

As soon as it is identified that an infant may be at risk for NAS through maternal use of illicit or prescription drugs, whether in a structured program or prescribed by an individual caregiver, education for the family must begin. The education is best delivered by health care providers who have been educated and are well versed in the issues of NAS. **Best practice is to supply written material that is supportive and nonjudgmental, describing the symptoms of NAS; what families can do before, during, and after birth; comfort measures; expectations regarding time of observation; and details of scoring.** Also essential is a discussion regarding the potential need for treatment and what to expect regarding length of stay and location of care (family room vs. separate location). **When families are prepared with knowledge and expectations before the birth, they are better able to partner in the care of their infant and comply with recommendations.**[46]

It is important for primary caretakers to understand that infants exposed to narcotics through maternal drug use have been found to be more irritable and less cuddly, exhibit more tremors, and have increased tone (Box 11.8). These infants are also less responsive to visual stimulation and are less likely to maintain an alert state. **Some symptoms of withdrawal may persist for 2 to 6 months, and the health care professional should discuss this possibility with the family caregivers well before discharge so they can begin building the skills they will need under the watchful eye of supportive staff.** The infant may continue to feed poorly and regurgitate, yet vigorously suck fists and hands. Mothers and families frequently misread this continued, exaggerated rooting reflex as hunger and therefore may overfeed the infant, contributing to emesis and continued loose stool.

These infants may have hyperacusis or are easily disturbed by normal household sounds and do not sleep well. They sweat more than other infants and, when crying, continue to have a high-pitched cry. They may have poor tolerance of being held or to abrupt changes in position. This, along with

BOX 11.8 PARENT/CAREGIVER TEACHING

CARING FOR AN INFANT EXPOSED TO OPIOIDS

Some symptoms may persist for 2 to 6 months.

- Infants exposed to narcotics in utero are more irritable, less cuddly, and tremulous and have increased tone: Parent(s) may interpret these behaviors as signs of rejection; the infant may not want to be held or cuddled as other babies do.
- Less responsive to visual stimulation
- Less likely to maintain a quiet-alert state: Let parent know symptoms are time-limited.
- Poor feeding habits: Continues to regurgitate yet shows vigorous sucking of fists or pacifier: Constant sucking and exaggerated rooting reflex may lead to overfeeding the infant.
- Continuation of loose stools: Important to stress good diaper hygiene to prevent infection from excoriated skin.
- Infants easily disturbed by sounds: Parent may decrease stimuli in house.
- Sweat more than other newborns: Dress infant appropriately to avoid overheating.
- High-pitched cry: Not easily consoled, parents need someone to share infant care and give them some rest from an irritable infant to prevent neglect or abuse.
- Hypertonia
- Less eye-to-eye contact, which decreases social interaction

hypertonia, may continue, and the mother may interpret this as a sign of rejection. Clinician support (doctors, nurses, and all in contact with the family), including a thorough description of potential symptoms and their management and the fact that they are time-limited, is vital if maternal-infant attachment is to occur and potential neglect and abuse are to be avoided. **Studies continue to demonstrate that drug-dependent mothers and their newborns demonstrated poor performance on a measure of social engagement.** The drug-dependent mothers demonstrated significantly less positive affect and greater detachment, and the drug-exposed infants presented fewer behaviors promoting social involvement. Drug-exposed infants and their mothers experience a difficult early period during which both are less available, less likely to initiate, and less responsive to social involvement.[61]

Therefore, parents of the drug-exposed infant may need assistance in recognizing important symptoms that signal problems and cues necessary for caregiving. A frank discussion must be had regarding the infant's exposure to secondary crack smoke, crystal methamphetamine smoke, marijuana smoke, and tobacco smoke. These can be detrimental to the health of the newborn; therefore, parents should be warned of the consequences of using these substances around their infant.

Parents also need to be educated about sudden infant death syndrome (SIDS) and complications from any perinatal infections. The complexity and challenging nature of the home atmosphere should never be underestimated in these situations. The importance of an optimal home environment for the global development of these children should be emphasized to all parents.[61]

Although much has been learned over the past several decades from research in the field of perinatal substance exposure and abuse, there remains a need for continued evidence-based studies to better determine the intricacies of NAS, effective treatment, and overall immediate and long-term effects.

12 PAIN AND PAIN RELIEF

SANDRA L. GARDNER, MARY ENZMAN-HINES, AND RITA AGARWAL

Neonatal pain is a complex phenomenon and at times elusive. **Extremely fragile premature infants experience multiple painful procedures** (e.g., heel sticks, intravenous sticks, intubation, lumbar punctures, introduction of chest tubes, placement of nasogastric tubes) during their stay in the neonatal intensive care unit (NICU). **The number of exposures to these procedural events varies from 0 to 53 per day, and approximately 30% of these neonates fail to receive analgesia.**[21,272] **Rationalization for inadequate treatment of pain has resulted in unnecessary suffering for these fragile infants and the suffering of the neonatal nurses who care for them.**[170] Research has shown that the "unchecked release of stress hormones by untreated pain may exacerbate injury, prevent wound healing, lead to infection, prolong hospitalization, and even [lead] to death."[348] **These fragile neonates are simply too sick to *not* have their pain treated. Health care professionals are responsible for influencing positive change in clinical practice about neonatal pain.***

Several decades ago, neonates did not receive analgesia and/or anesthesia agents for surgery because of the controversy as to whether they feel pain and whether they are physiologically stable enough to tolerate the effects of these drugs. **The rationale for withholding analgesia and/or anesthesia agents included the following beliefs:**

- Neonates have an immature central nervous system (CNS) with nonmyelinated pain fibers and are thus incapable of perceiving pain.
- Neonates have no memory of pain.
- Pain is a highly subjective experience that is difficult to objectively assess in nonverbal neonates.
- Anesthetics and analgesics are dangerous when administered to neonates, and neonates are safer if they are not medicated.

There is increasing evidence from more than 30 years of research that neonates, including preterm infants, have a CNS that is much more mature than previously thought.[11,29] **Pain pathways are myelinated in the fetus during the second and third trimesters and are completely myelinated by 30 to 37 weeks of gestation.** Even thinly myelinated or nonmyelinated fibers carry pain stimuli. Incomplete myelination implies only a slower transmission, which is offset in the neonate by the shorter distance the impulse must travel.[29]

Even though pain is not expressed verbally in semiconscious patients, nonverbal adults (e.g., intubated, mute), or infants, this does not negate their experience of pain. In response to the question of whether the neonate's responses are reflexive or express a perception of pain, research has focused on measuring the infant's pain experience. **The infant's capacity for memory is far greater than was previously thought,**[11,20,21] **and a neuropsychologic complex of altered pain threshold and pain-related behavior has been identified.***

Concern has been expressed that giving potent medications to an already critically ill infant might be dangerous. Local and systemic drugs that are now available, as well as new techniques and devices for monitoring, enable all neonates to be safely anesthetized and provide safe and effective analgesia while maintaining a stable condition.[29]

Neonates exhibit (1) physiologic, (2) hormonal, (3) metabolic, and (4) behavioral responses to invasive procedures that are

*References 2, 11–16, 111, 112, 222, 345, 417.

BLUE type highlights content that is particularly applicable to clinical settings.

similar to, but more intense than, adult responses.[17,18,22,29,96] Exposure to multiple painful procedures may increase the vulnerability of preterm infants to gross neurologic damage (intraventricular hemorrhage, periventricular leukomalacia).[19,21,61,172] **Pain relief benefits the neonate by decreasing physiologic instability, hormonal and metabolic stress, and the behavioral reactions accompanying painful procedures.**★

The Committee on Fetus and Newborn of the **American Academy of Pediatrics (AAP) has recommended the administration of local or systemic drugs for anesthesia or analgesia to neonates undergoing surgical procedures.**[12] The committee further states that any decision to withhold these drugs should not be based solely on the infant's age or perceived degree of cortical maturity but should be based on the same criteria used in older patients.[12,22] The latest version of the AAP guidelines cites that **prolonged exposure to untreated pain increases morbidity and alters subsequent behavioral and physiologic responses to pain.**[13] **National and international associations have promulgated standard-of-care guidelines or position statements about neonatal pain management.**† **The focus of these documents is on the proactive assessment and management of pain in the neonate.** The National Association of Neonatal Nurses (NANN) guidelines outline the following recommendations.[412]

- Parents must be informed of pain relief as an important part of the neonate's health care plan, must be educated by staff about nonpharmacologic measures they can use,[243,323] and should be encouraged to actively participate in their neonate's assessment and management of pain.[40]
- *Every* institution must mandate clinical practice guidelines that ensure access and safe administration of pain control to the neonate. Institutions also should develop guidelines for assessing and monitoring pain management practices that include parental input[40] with the goal of measuring the adequacy of pain relief and control in the neonate.
- Institutions must support interdisciplinary research and ongoing education that includes a description of neonatal pain, accurate pain assessment, interventions to improve patient care and reduce morbidity, and guidelines to ensure adequate use of nonpharmacologic measures,[243] administration of analgesics and sedatives for the neonate, and quality improvement programs to monitor use of guidelines.[76,309]

A national study of experienced, highly educated neonatal nurses who were members of NANN was recently published.[96] **Only 50% of the surveyed nurses felt knowledgeable about pain; some disagreed about the neonate's capacity to feel pain or that there were long-term consequences of unrelieved pain.** Other findings of the survey include the following: (1) 81% used a pain assessment tool; only 65% thought the tool was appropriate for neonates, and 60% thought it was an accurate measure; (2) 83% felt confident in the use of pharmacologic interventions; and (3) 79% felt confident in the use of nonpharmacologic interventions.[96] Only 44% of the respondents reported that neonatal pain was well managed, and only 43% thought that their pain protocols were evidence-based. Barriers to relief of neonatal pain were identified as (1) professional (both nurses and doctors) resistance to change (44%); (2) lack of knowledge (23%); (3) fear of side effects of pain medications and incorrect evaluation of pain symptoms (15%); (4) time delay from pain assessment to receipt of medications (13%); and (5) lack of trust in the assessment tool (13%).[96] In this study, 147 of the total 237 respondents identified the following strategies to improve pain management: (1) education about pain (45%), (2) reading and using research (15%), and (3) more interdisciplinary communication.[96]

All neonatal health care providers have an ethical and legal obligation to practice the standard of care in assessing and intervening to relieve the neonate's pain, and to re-evaluate the safety and efficacy of the pharmacologic and comfort interventions used to treat pain.★

PHYSIOLOGY AND PATHOPHYSIOLOGY

"Pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[210] The neonate's expression of pain

★References 17, 18, 30, 31, 179, 303, 423.

†References 2, 11, 16, 246, 345, 417.

★References 2, 11–16, 23, 144, 195, 222, 231, 279, 317, 345.

does not fit the self-report aspect of this definition, which often results in the health care provider's failure to recognize and treat pain. Self-report is absent in the preverbal neonate, therefore, nonverbal behavioral information needs to be assessed and used to determine the treatment options for neonates. **The definition of pain has been amended. "The inability to communicate in no way negates the possibility that an individual is experiencing pain, and is in need of appropriate pain-relieving treatment."**[210] Although we cannot assess the emotional experience associated with pain in these babies, the necessary sensory pathways are now better understood. **Neonates have a developing, incompletely myelinated nervous system at birth; however, all the components of the nociceptive (pain)** pathways are present.[137,182] As background for an understanding of neonatal responses and their differences from adult responses, the basic mechanisms of adult pain transmission are presented in Fig. 12.1.

Types of pain experienced by the neonate have been identified as (1) *physiologic,* caused by tissue injury; (2) *inflammatory,* caused by inflammation of tissues; (3) *neuropathic,* caused by nerve injury/damage; and (4) *visceral,* caused by distention, inflammation, and contraction of viscera.[24,25] The common types of pain experienced by the newborn along with proposed definitions are shown in Table 12.1. **Pain in the neonate needs to be viewed as an *adverse event* and *traumatic event*.**[110,263]

NEUROANATOMY

Peripheral Nervous System

Peripheral nerves can be classified into three broad categories based on fiber diameter and velocity (Table 12.2). Pain receptors (nociceptors) are the A-delta fibers (A-δ) and C fibers that are widely spread in the superficial layers of the skin, periosteum, fascia, peritoneum, joints, muscle, pleura, dura, and tooth pulp. Most visceral tissues have fewer nociceptors, and these transmit to the spinal cord through the sympathetic, parasympathetic, and splanchnic nerves. **Tissue damage and inflammation cause the release of arachidonic acid and**

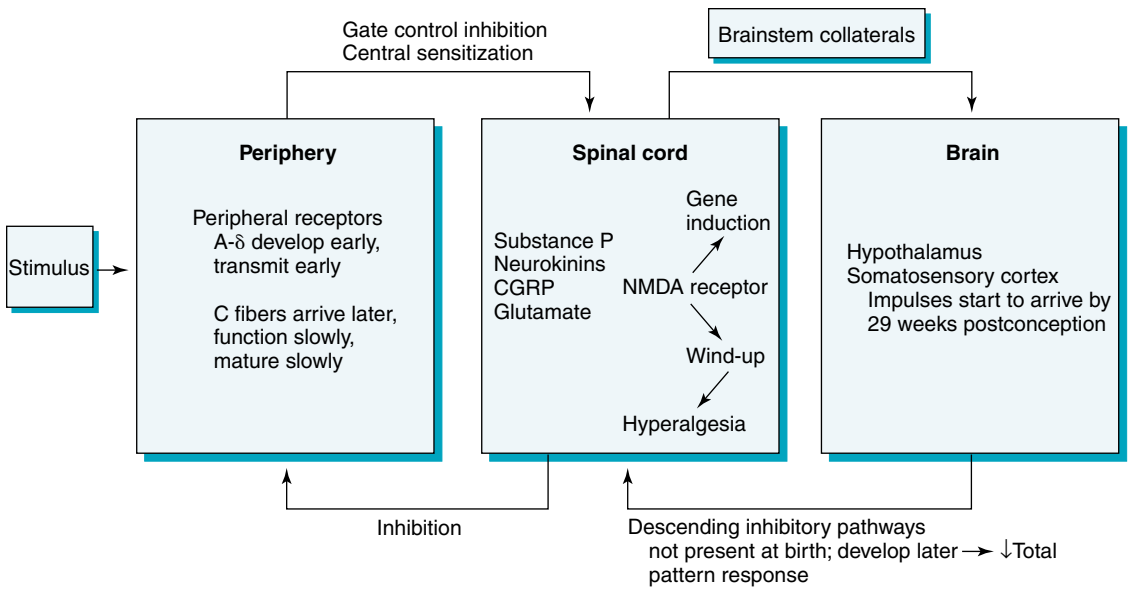

FIGURE 12.1 Schematic representation of transmission of noxious stimuli from the periphery to the brain. *CGRP,* Calcitonin gene–related peptide; *NMDA, N*-methyl-D-aspartate.

TABLE 12.1 SUGGESTED STARTING POINT FOR DEFINING THE PAIN TERMS USED FOR NEONATAL PAIN

PAIN TERM	ONSET	DURATION	CHARACTER *	PRIMARY HYPERALGESIA
Acute episodic	Immediate	0–120† minutes	Sharp, well-located	Present, mild, short-lasting
Acute recurrent	Immediate	Variable	Sharp, well-located	Present, moderate or severe
Prolonged‡	Rapid, may be gradual	1–24 hours†	Sharp, diffusely localized	Present, moderate or severe
Persistent‡	Rapid or gradual, cumulative	1–7 days	Dull/sharp, diffusely localized	Present, moderate or severe
Chronic	Usually gradual	8 days or longer	Dull, diffusely localized	May be present or absent, mild if present

PAIN TERM	SECONDARY HYPERALGESIA	ALLODYNIA	BEHAVIORAL PHENOTYPE	PHYSIOLOGICAL PHENOTYPE
Acute episodic	Probably absent	Probably absent	Strongly reactive and reflexive	High peak, sympathetic activation
Acute recurrent	Present, mild or moderate	Probably absent	Weakly reactive or reflexive	Prolonged peak, sympathetic activation
Prolonged‡	Mild or absent	Probably absent	Strongly reactive on stimulation	High plateau, sympathetic activation
Persistent‡	Present, mild or moderate	May be present, mild/moderate	Hyperactive initially, later hyporeactive	Normal or low sympathetic activation
Chronic	Present, mild or moderate	May be present, moderate/severe	Hyporeactive more often, could also be hyperreactive	Normal or suppressed sympathetic drive

*Based on descriptions in adult patients, but may be discerned by careful physical examination.
†Some infants with increased sensitivity to pain may have a slower decay of the acute pain following an invasive procedure, thus justifying some overlap in the duration of acute episodic pain and prolonged pain.
‡Continuous pain may be characterized as either "prolonged" or "persistent."

other chemicals that can sensitize nerve endings and cause vasodilation and plasma extravasation. This causes pain, swelling, and hyperalgesia.[121]

Aδ fibers are myelinated and therefore capable of fast impulse conduction. These nerves are responsible for "fast" or "first" pain. They are also known as *high-threshold mechanoreceptors (HTMs)* because they respond to strong pressure or tissue injury. The C fibers (polymodal nociceptors) are unmyelinated, conduct impulses more slowly, and are the main nociceptors for transmitting chemical, thermal, and mechanical noxious stimuli to the spinal cord.[281] The Aδ fibers develop ahead of the C fibers in the skin and the spinal cord. Aδ fibers are involved in the cutaneous flexion reflex. This reflex is exaggerated in the preterm infant. Thresholds to mechanical skin stimulation (which may or may not be perceived as pain in a newborn) are lower, and responses last longer. **Complete myelination occurs during the second and third trimesters. Lack of myelination had been thought to indicate the inability of a neonate to perceive pain; however, incomplete myelination leads only to slower conduction, which is offset by the shorter distances traversed in the infant.**[29,182]

Reflex responses to somatic stimuli begin at 7.5 weeks postconceptual age (PCA) in the perioral skin and continue to develop in the palms of the hands before finally reaching the hind limbs by 13 to 14 weeks. **Peripheral pain receptors are in place throughout the body by 20 weeks of gestation.**[373] It is likely that both Aδ fibers (touching) and Aδ fibers (pinching) transmit painful stimuli in the human fetus. In rat pups, the C fibers reach the

TABLE 12.2 CLASSIFICATION AND CHARACTERISTICS OF PERIPHERAL NERVES

NAME/CHARACTERISTICS	FUNCTION
A-alpha (A-α) d: 10–20 μ v: 70–120 m/sec myelinated	Innervate skeletal muscle
A-beta (A-β) d: 12–20 μ v: 30–70 m/sec myelinated	Light touch or pressure may be involved in peripheral sensitization and allodynia; in the premature and newborn infant, may be involved in the transmission of noxious stimuli
A-gamma (A-γ) d: 3–6 μ v: 15–30 m/sec myelinated	Muscle tone
A-delta (A-δ) d: 2–5 μ v: 12–30 m/sec myelinated	Fast, well-localized pain; high threshold mechanoreceptors
B d: 3 μ v: 3–15 m/sec myelinated	Preganglionic autonomic fibers may be involved in sensory or sympathetic coupling
C d: 0.4–1.2 μ v: 0.5–2 m/sec unmyelinated	Slow pain, touch, temperature, postganglionic sympathetic fibers, polymodal nociceptors

d, Nerve diameter; *v*, nerve velocity.

spinal cord but do not start to stimulate dorsal horn cells until the end of the first postnatal week. They subsequently continue to mature for several weeks. This slow maturation in rats may be caused by low levels of neuropeptides such as substance P (SP), neurotransmitters, or immature receptor sites. These changes in rat pups appear to correlate with the third trimester and the early neonatal period in humans.[137]

Spinal Cord

The pain transmission system begins with the peripheral pain receptors (nociceptors). Once a noxious stimulus is detected by the nociceptors, the signal is transmitted via the primary afferents to the dorsal root ganglia and from there to the dorsal horn of the spinal cord.[44,80] **Neurotransmitters and their receptors amplify or attenuate the signal in the dorsal horn before sending the signal to the brain.**

Excitatory neurotransmitters such as SP and other neurokinins are increased after acute inflammation and may be necessary for the transmission of painful stimuli to the brain.[215] Glutamate and aspartate are amino acids that appear to be involved in central hypersensitivity and wind-up.[28] ***Wind-up* is a phenomenon in which repetition of the same noxious stimulus leads to an exaggerated response. This response continues even after the noxious stimulus ceases.** Wind-up also may be responsible for converting a low-level, pain-related activity to a high-level, pain-related activity.[44,121,392] **The preterm infant experiences increased stress and activity in the nociceptive pathways after prolonged periods of exposure to painful stimuli.** A recent study showed that neonates with high levels of physiologic stress have larger amplitude of cortical nociceptive responses not reflected in their behavior.[222] During a heel lance, brain activity in infants with underlying stress is enhanced but not reflected in their behavioral response to the noxious stimuli. **After prolonged exposure, the preterm infant exhibits similar pain responses when exposed to other caregiving activities** (e.g., handling, suctioning the endotracheal tube, positioning).[132]

An additional factor in the development of **hypersensitivity (e.g., decreased pain threshold) and hyperalgesia** is the presence of nociceptive-specific receptors,[182] which respond only to pain. In the presence of peripheral inflammation, the threshold of these receptors is decreased so that they are capable of responding to other nonnoxious stimuli.[121] **For example, an infant whose heel has been repeatedly stuck for blood samples may demonstrate pain behavior, even when the heel is merely touched. Many of these responses can be blocked by low doses of opioids. However, once these responses are established, a 10-fold increased dose of opioids may be necessary to reverse them.**[138,418]

The spinal cord also contains inhibitory neurotransmitters (γ-aminobutyric acid [GABA], glycine), which are activated by descending neural pathways (from the brain to the spinal cord) and decrease the intensity of pain transmission. This results in modulation of pain transmission from the spinal cord to the cortex. Descending inhibition is necessary to modulate the pain response and yet allow for specific pain responses (e.g., withdrawal from a needle stick). **Delayed maturation of the**

descending inhibitory fibers results in a *higher pain threshold* in the upper extremities and a lower threshold in the lower extremities, resulting in more pain sensitivity in the lower extremities.[23] Lack of inhibition produces exaggerated, generalized, but definite responses to pain such as body wriggling, facial grimacing, and excessive crying. These pathways, in contrast with the excitatory ones, are not fully developed at birth in "rat pups and probably in preterm infants"[182] therefore, the neonatal spinal cord is more excitable.[137] **The pain transmission system of the premature infant (<36 weeks) is more developed than the pain modulation system; therefore preterm infants are *more* sensitive to pain than are term or older infants.**[182,373]

Neurotransmitters in the developing nervous system may be expressed early but are not necessarily located in areas normally found in an adult. This is particularly true of SP and glutamate, which may contribute to the unorganized responses noted with pain stimuli in the newborn (e.g., the whole body moves when an intravenous [IV] line is started).

Brain

Much less is known about the development of the pathways to the higher brain centers, such as the hypothalamus and cortex. **Once again, there is evidence of immaturity of the inhibitory pathways.**[137] Development in the human cortex continues for many years after birth. **Contrary to previous beliefs that newborns do not feel pain, it appears that, in fact, cutaneous responses are exaggerated and occur at much lower thresholds, and reflex muscle contractions last longer in newborns than in mature individuals.** Using real-time near-infrared spectroscopy (NIRS) in 18 preterm infants (25 to 45 weeks' postmenstrual age [PMA]), an increase in cerebral oxygenation over the contralateral somatosensory cortex was measured in response to heel stick blood draws[367] and in response to venipuncture in another study.[45] From these findings, researchers concluded that **pain is transmitted to the cerebral cortex of preterm infants from 25 weeks' PMA.**[367] Other recent research has found that low biobehavioral responsiveness to pain at 32 weeks' PCA is associated with poorer quality of motor function at 8 months' PCA; therefore pain reactivity in the NICU may be a marker of neuromotor development in later infancy.[180] In summary, **the newborn's nervous system, although still developing, is fully capable of transmitting, perceiving, responding to, and probably remembering noxious stimuli.**

PHYSIOLOGIC RESPONSES

Acute pain in adults is associated with increased sympathetic stimulation, heart rate, respiratory rate, blood pressure, cardiac output, myocardial oxygen consumption, peripheral resistance, anxiety, emotional distress, and hormonal imbalance, and greater morbidity and mortality. **Numerous studies have shown that both premature and full-term infants express the same physiologic responses to pain and noxious stimuli (e.g., intubation) as adults do (Box 12.1).**[12,29,96,420] Despite research on infants' pain response to circumcision and recommendations to use anesthetics or analgesics during circumcision, a survey in a large academic medical center showed that only 30% of infants being circumcised by obstetricians received any pain relief, and there was no documentation of discussion with parents about pain management.[236]

Pain reactivity varies by prior experience with pain.[96,351,386] Studies on pain reactivity in very-low-birth-weight (VLBW) infants at 32 weeks' PCA found that **younger gestational ages (GAs) and increased number of invasive procedures at birth resulted in a "dampening" of normal pain reactions** (e.g., delayed or fewer facial changes; lower pain scale scores)[96,220] and cortisol response.[174] These infants had higher baseline heart rates, which may have indicated that they were in a perpetual state of stress or pain. Previous exposure to morphine was associated with a "normalization" of responses to painful stimuli. More recent studies of the pain response in extremely low-birth-weight (ELBW) preterm infants (<27 weeks' GA) found (1) similar responses to older infants but also "dampened" responses[154,155,420] (i.e. discrete reactions such as eye movements, changes in respiratory pattern, and slight increase in pulse oximetry oxygenation value)[269] and (2) lower cortisol levels representing downregulation of the hypothalamic-pituitary-adrenal axis that is not counteracted by morphine use.[174] **These lower salivary levels are directly related to the number of painful procedures and have recently**

BOX 12.1 CRITICAL FINDINGS
NEONATAL PAIN RESPONSE*

Physiologic

- Increase in
  - Heart rate
  - Blood pressure (also fluctuations)
  - Intracranial pressure/cerebral blood flow,[266] which leads to higher risk for intraventricular hemorrhage
  - Respiratory rate
  - Mean airway pressure
  - Muscle tension
  - Carbon dioxide (↑$TcPco_2$; Pco_2)
  - Pulmonary vascular tone
  - Oxygen consumption
- Decrease in
  - Depth of respiration (shallow)
  - Oxygenation (↓Po_2; Sao_2), which leads to apnea or bradycardia
  - Vagal tone and peripheral blood flow
  - Cerebral oxygenation with vigorous crying
- Pallor or flushing
- Diaphoresis or palmar sweating
- Dilated pupils
- Nausea, vomiting, gagging, and hiccoughing

Behavioral

- Vocalizations
  - Crying (higher pitched, tense, and harsh)
  - Inaudible crying
  - Whimpering
  - Moaning
- Facial expressions
  - Grimacing
  - Furrowing or bulging of the brow
  - Quivering chin
  - Eye squeeze
  - Nasal flaring
  - Curling/curving of the tongue
  - Facial twitching
  - Lips open and pursed
- Body movements
  - General diffuse body activity (flexing/extending extremities; extending legs; finger splay, fisting, hand on face)
  - Limb withdrawal, swiping, thrashing
- Changes in tone
  - Hypertonicity, rigidity, fist clenching
  - Hypotonicity, flaccidity
- Touch aversion
- States
  - Sleep-wake cycle changes, wakefulness
  - Activity level changes: increased fussiness, irritability, listlessness, lethargy
  - Feeding difficulties
  - More difficult to comfort, soothe, quiet
  - Disruption of interactive ability with parents

Hormonal/Catabolic Stress Response

- Increase in
  - Plasma rennin activity
  - Catecholamine levels (epinephrine and norepinephrine)
  - Cortisol levels (serum and hair)
  - Nitrogen excretion/protein catabolism
  - Release of
    - Growth hormone
    - Glucagons
    - Aldosterone
  - Biomarkers of oxidative stress: Advanced oxidation protein products and total hydroperoxides[317]
  - Serum levels of
    - Glucose
    - Lactate
    - Pyruvate
    - Ketones
    - Nonesterified fatty acids
- Decrease in
  - Insulin secretion
  - Prolactin
  - Immune responses

* References 17, 18, 30, 97, 99, 159, 177, 181, 195, 293, 302, 381, 387, 418, 421.

been shown to still be present in 3-month-old (former) very preterm infants when reacting to a socioemotional stressor.[328] Two other studies have compared the biobehavioral pain responses of ELBW infants with term controls. The studies found that (1) at 4 months' corrected age, behavioral and cardiac autonomic responses were similar, with less parasympathetic withdrawal and more sustained sympathetic response during recovery in the ELBW group,[300] and (2) at 8 months' corrected age, behavioral response was similar to that in term infants but less sustained (i.e., faster dampening); baseline heart

rate was significantly higher in ELBW neonates.[178] **The number of previous painful experiences in the NICU was significantly related to subsequent pain reactivity in the ELBW infants,** and the ELBW infants who were exposed to higher doses of morphine had heart rate recovery more similar to that of the term infants.[178] **Higher numbers of invasive procedures are significantly associated with brain structure alterations, specifically reduced white matter and subcortical gray matter maturation in preterm infants.**[61]

ETIOLOGY

Invasive Procedures

Pain is produced with any invasive procedure (**Box 12.2**).[22,363] Two studies of the first 14 days in the NICU found (1) an average of 196 procedures per neonate with 14 invasive procedures per day per infant[363] and (2) a median of 115 procedures per neonate with 16 invasive procedures per day per infant.[74] In a more recent study, one-third of the

BOX 12.2 SELECTED COMMON CAUSES OF PAIN IN NEONATES

INVASIVE PROCEDURES	SURGICAL PROCEDURES	OTHERS
Intravenous cannulation	Central line placement	Clavicle, rib fracture
Venipuncture	PDA ligation	Extremity fracture
Heel stick	TEF repair	Chest pain
Intramuscular injection	Gastroschisis repair	Central pain syndrome (i.e., pain derived from CNS damage)
Arterial line, blood gas	Omphalocele repair	Echocardiogram[3]
Umbilical catheterization	CDH repair	Spasticity
Chest tube insertion or removal	Inguinal hernia repair	Abdominal pain resulting from short gut syndrome, multiple abdominal surgeries; visceral hyperalgesia[38]
Bone marrow aspiration	Cardiac surgery	Necrotizing enterocolitis
Lumbar puncture	Circumcision	Bowel obstruction
Paracentesis	Broviac catheter insertion or removal	Prolonged and/or improper positioning
Endotracheal intubation/removal	ECMO catheter insertion or removal	Position changes
Endotracheal or nasal288 suction		NG tube placement
Laryngoscopy for less invasive surfactant administration[56]		Flushing lines
Mechanical ventilation		Dressing changes
NCPAP		Eye examination for ROP
Bladder catheterization		IV administration of medications
Suprapubic aspiration		Addition/withdrawal of fluid from umbilical catheter
Ventricular tap		Transient mechanical birth trauma (e.g., cephalic hematoma, molding, bruising, forceps marks, petechiae)
Endoscopy		Cryo/laser surgery for ROP
Bronchoscopy		Chest physiotherapy
PICC line insertion/removal		Changing tape/suture removal
Cutdown (arterial/venous) for access		Therapeutic hypothermia[195]

Pain behaviors in LBW infants accompany some "nonpainful" caregiving procedures. *Neonatal Netw.* 1997;16:33.

infants received treatment for painful procedures, which included the following[74]:

1. Pharmacologic-only therapy (2.1%)
2. Nonpharmacologic-only therapy (18.2%)
3. Combination therapy (both No. 1 and No. 2) (20.8%)
4. No specific analgesia (79.2%)
5. Concurrent analgesia/anesthesia for other purposes (34.2%)

A recent systematic analysis of 18 observational studies found an average of 7.5 to 17.3 painful procedures per NICU infant per day, with the most frequent procedures being heel lance, suctioning, venipuncture, and peripheral intravenous (PIV) line insertion.[108] Another study showed that neonates in their first 7 days in the NICU underwent a mean of 6.6 invasive procedures per day, with only 32.5 % of them receiving pharmacologic or nonpharmacologic interventions for pain.[372] The Epidemiology of Procedural Pain in Neonates (EPIPPAIN) study looked at pain and pain management (for heel stick and venipuncture) in 16 NICUs in Paris, France[106,107] from birth to the first 2 weeks of life. The mean number of heel sticks per neonate was 16,[107] and the mean number of venipunctures per neonate was 3.8 for infants with a mean gestational age of 33.3 weeks and 4.1 for neonates less than 33 weeks.[107] Although 75.2% of heel sticks were performed with either continuous analgesia or specific pre-procedural analgesia, the use of analgesia was not systematic.[106] In this study, 76% of venipunctures were performed with pre-procedural analgesia, and 23.2% were done while the infant was receiving continuous analgesia.[106] These researchers recommend strategies to decrease the number of PIV attempts (38.3% required more than one attempt) and promotion of parental presence—both associated with lower pain scores.[106]

A study of neonates at increased risk for neurologic impairment found that these infants had the highest number of invasive procedures but received the least amount of analgesic on the first day of life.[378] Despite how these studies indicate an improvement in the use of pain relief for invasive procedures, **considerable work is needed to educate practitioners about the safety, efficacy, and benefits of appropriate pain management in neonates. Use of "better practices" strategies, clinical practice guidelines, and proven quality improvement methods has resulted in better pain management for neonates in the NICU.**[116,241,244,251]

Endotracheal intubation is associated with hypoxia, bradycardia, catabolism, increased intracranial pressure, increased systemic and pulmonary hypertension, and release of stress hormones.[236] **Recent research has shown that use of premedication for elective, nonurgent intubations is safer and more effective than awake intubations (see the Endotracheal Intubation section in** Chapter 23**). Unmedicated endotracheal intubation in the neonate should be reserved for emergency resuscitation in the delivery room.**[236] There is currently no validated scoring system to assess the level of sedation before elective intubation.[115]

No consensus exists about pain relief in the mechanically ventilated neonate, and clinical practice varies widely.[71,184,226,277,424] A recent survey of the use of sedatives and analgesics among a large group of ventilated preterm infants found that the use of opioids increased from 5% to 32%, and the use of sedatives increased from 5% to 24% from 1997 to 2012.[424] **Benefits of pain management in the ventilated neonate include (1) improved ventilator synchrony; (2) improved pulmonary function; (3) less neuroendocrine (cortisol, beta-endorphins, catecholamine) response; (4) better oxygenation; and (5) potentially ameliorated adverse effects of mechanical ventilation (Fig. 12.2) in the preterm infant.**[184,277] Two approaches to pain management in ventilated neonates are commonly used: (1) preemptive, continuous opioid infusion and (2) as-needed (PRN) intermittent bolus administration of opioids.[34,109,226,278] The NOPAIN pilot study found poor neurologic outcomes in only 4% of the ventilated preterm infants receiving continuous morphine sulfate (MS) for pain compared with 24% in the placebo group and 32% in the midazolam group.[27] In this study, the MS-treated preterm infants were the only group with significantly lower pain scores.[27]

The European Pain Audit in Neonates (EUROPAIN) study evaluated the use of sedatives and analgesics in the NICUs of 18 European countries.[71] **Tracheal ventilation and noninvasive ventilation resulted in administration of sedatives (midazolam) and analgesics (opiates) in 82% and 18% of the neonates, respectively, given by a continuous IV dose, intermittent doses, or both. Use of sedatives and analgesics**

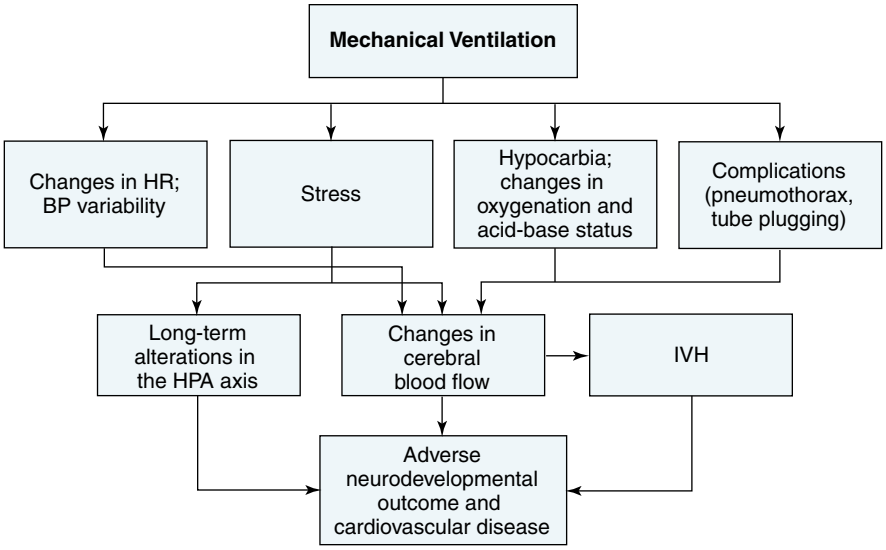

FIGURE 12.2 Potential mechanisms leading to adverse effects from mechanical ventilation in preterm neonates. *BP,* Blood pressure; *HPA,* hypothalamic-pituitary-adrenal; *HR,* heart rate; *IVH,* intraventricular hemorrhage. (Modified from Hall RW, Boyle E, Young T. Do ventilated neonates require pain management? *Semin Perinatol.* 2007;31:289.)

in the intubated neonates resulted in longer mechanical ventilation.[71] Using the same database, assessment for continuous pain only occurred in less than one-third of NICU admissions and daily in only 10% of neonates. The presence of pain guidelines, preterm infants less than 32 weeks of gestation, nursing champions, surgical admissions, mechanical ventilation, and use of opiates, sedatives, and general anesthesia resulted in more frequent assessments for continuous pain.[33] An analysis of the Italian data from the EUROPAIN study also found wide variation in the use of analgesia and sedatives and pain assessment among Italian NICUs.[242]

The NEOPAIN double-blind, randomized controlled trial (RCT), conducted in 12 American and 4 European NICUs, studied whether preemptive morphine analgesia would decrease early neurologic injury in 898 ventilated preterm infants less than 32 weeks of gestation.[28] There was a higher incidence of severe intraventricular hemorrhage (IVH) in the morphine-treated group of 27 to 29 weeks of gestation, possibly resulting from higher MS infusion rates or less MS clearance in hypotensive infants.[28] Further analysis of cohorts from the NEOPAIN study found the following: (1) MS-treated preterm infants had significantly longer ventilation, as well as more air leaks and supplemental oxygen use in preterm infants who received additional intermittent boluses of MS[53]; (2) MS delays the start of and the full attainment of enteral feedings but does not increase gastrointestinal complications[280]; (3) both preemptive and additional MS and lower GA are associated with hypotension[185]; (4) IVH (i.e., any and severe) and death are associated with preexisting hypotension, but morphine therapy did not contribute to these outcomes[185]; and (5) although MS infusions cause hypotension, they can safely be used for most preterm neonates.[185] **Use MS cautiously for 23- to 26-week preterm infants and those with preexisting hypotension.**[185] Another randomized, double-blind, placebo-controlled trial of morphine infusion for ventilated preterm infants showed that (1) the analgesic effect was similar between the treated and placebo group, (2) routine morphine infusion decreased the incidence of IVH but did not influence poor neurologic outcome, (3) routine use of MS infusions is not supported by the lack of analgesic effect and the absence of any beneficial effect, and (4) the long-term effects of MS on the neurologic outcomes of preterm infants need study.[364]

Studies have also compared fentanyl with morphine and fentanyl with sufentanil for analgesia during mechanical ventilation in neonates.[345,350] Fentanyl was equianalgesic with morphine, sufentanil

was equianalgesic to fentanyl, and sufentanil did not reduce the weaning period for ventilated (term) infants.[345,350] Continuous fentanyl infusion (plus open-label PRN boluses of fentanyl) for very preterm ventilated infants has been shown to reduce acute, but not prolonged, pain with more side effects (longer ventilation and delayed meconium passage) than use of PRN fentanyl boluses alone.[34] A recent follow-up of very preterm ventilated infants who received continuous fentanyl and open-label boluses found significantly poorer eye-hand coordination at 24 months' corrected age in the IV infusion group.[35] **Morphine, fentanyl, and sufentanil reduce the pain and stress of preterm infants being mechanically ventilated but may prolong the duration of ventilation.**[34] Only two studies have investigated the effect of fentanyl analgesia on acute brain outcomes, and no difference was found in the incidence of IVH, PVL, or mortality.[240,345]

Dexmedetomidine hydrochloride, an α-adrenergic receptor agonist, provides analgesia, anesthesia, and sedation for mechanically ventilated neonates.[277,302] Advantages include (1) less adjunctive sedation needed, compared with fentanyl; (2) minimal effect on blood pressure, heart and respiratory rates, oxygen saturation, and gastric motility; and (3) its safety and effectiveness for short-term pain relief during invasive procedures in ventilated and nonventilated neonates.[277,302] Only one study of the effect of dexmedetomidine on brain injury has been conducted. In a comparison of dexmedetomidine versus fentanyl used for sedation in mechanically ventilated preterm infants, there was no difference in the incidence of severe IVH or PVL between the two groups.[397] An RCT of the safety and efficacy of dexmedetomidine hydrochloride and the short- and long-term neurologic outcomes are needed.[88]

Although use of analgesia in ventilated infants is recommended,[13,21] **a meta-analysis concludes that there is insufficient evidence for "routine use" of opioids during mechanical ventilation.**[51] **The meta-analysis states that opioids should be selectively used for individual neonates based on clinical judgment and pain assessment.**[51] Long-term neurologic outcomes of MS analgesia for ventilated preterm infants are being studied. A recent pilot study of 5- to 7-year-olds from the NEOPAIN cohort of ventilated preterm infants who had received preemptive MS found that they were 7% smaller in head circumference; were 4% less in body weight; took longer and completed fewer (27%) short-term memory tasks; and had more social problems, specifically with creating and maintaining friendships.[136] This same cohort was again studied at 8 to 9 years of age and found to have significantly better executive function as evaluated by parents and teachers.[114] The method of pharmacologic pain relief, the appropriate drug to use, the use of preemptive or bolus infusion based on pain scores, and minimizing long-term adverse outcomes remain clinical and research challenges.

Surgery

Painful stimuli, surgery, and traumatic injuries have been shown in adults to trigger the "stress response," which causes the release of a variety of hormones, including epinephrine, norepinephrine, corticosteroids, glucagon, and growth hormones. These hormones prepare the body for a *fight-or-flight response* and cause, among other things, an increase in heart rate, respiratory rate, glucose production, and muscle and fat breakdown. This response allows the body to deal with an insult in the short term. **If the insult continues or is untreated, the ongoing catabolic stress response may become deleterious to the body's well-being by promoting more tissue breakdown and preventing growth and tissue repair. During the period of rapid brain growth and development, the immature brain of the preterm infant has heightened vulnerability to pain.** The first study to link cumulative neonatal pain stress to alteration in brain function in extremely low-gestation (≤28 weeks) preterm infants has recently been published. This study found **an association between cumulative neonatal pain-related stress and alteration in cortical function resulting in visual-perceptual difficulties at school age in this vulnerable population.**[124]

Both premature and full-term infants have a decreased stress response with the use of appropriate analgesia both during and immediately after surgery. Physiologic indicators (e.g., heart/respiratory rate, blood pressure) of postoperative pain may be unreliable or confounded by illness severity and use of analgesics and neuromuscular blocking agents★. **Use of adequate operative anesthesia**[12,13] **and postoperative analgesia is mandatory, even if its use might prolong postoperative ventilatory support.**

★References 16, 18, 23, 28, 30, 31, 67, 142.

A special example of untreated operative pain is newborn circumcision. In addition to the previously mentioned short-term effects of not treating the pain associated with circumcision, **male infants who have undergone circumcision without analgesia have an increased pain response to vaccination** at 4 to 6 months of age.[385,387] When these infants were pretreated for their immunizations with a topical anesthetic, their pain response was lessened.[387] Another study of 14- and 45-month-old children who had major surgery with appropriate analgesia (in their first 3 months of life) found that their biobehavioral pain response to immunizations was not altered compared with a matched group of toddlers who had not had surgery.[318] However, **prolonged exposure to early hospitalization did contribute to an altered pain response (in areas of prior tissue damage)** that "recovered" over time.[318,319] **Although early painful memories may not be consciously recalled, experiences of pain are "remembered" by the developing nervous system.**[19,20,32,319] Newborns have a much greater capacity for memory than was previously thought.

Other Causes

Rib, clavicular, and extremity fractures are not uncommon and should be considered in the presence of prolonged crying and failure to move the affected extremity.

Bronchopulmonary dysplasia (BPD) is a common problem in infants who were premature and may cause chest pain, a syndrome known to occur in some older patients with chronic lung disease. Neurologic dysfunction can leave patients with ongoing pain from central pain syndrome or excessive spasticity. One study showed that 27% of former ELBW infants who were now teenagers had neurosensory impairment, and 9% reported moderate or severe pain.[346]

PREVENTION

Prevention of pain in the neonate and preterm infant begins with a proactive plan of care aimed at preventing the pain cycle. The key approaches in this plan include (1) anticipation; (2) comprehensive and ongoing assessment of the variables; (3) distinguishing agitation and irritability from pain expressions and responses of the preterm infant; (4) ongoing communication among health care providers, using input from the parents; (5) advocating and implementing timely and effective treatment for irritability, agitation, and pain (e.g., pharmacologic and comfort measures); (6) reducing the number of painful procedures[74,123,291,410]; and (7) ongoing reevaluation of this proactive plan of care.[2] **Different types of common procedures in the NICU can be anticipated to be painful.** *Diagnostic procedures* include arterial puncture, heel stick, lumbar puncture, and retinopathy of prematurity (ROP) examination. *Therapeutic procedures* include tracheal intubation and extubation, tracheal suctioning,[118] surfactant administration with laryngoscopy,[56] chest tube insertion, mechanical ventilation, suture removal, therapeutic hypothermia,[195] and removal of adhesive tape. Some of the *common surgical procedures* are circumcision, patent ductus arteriosus (PDA) ligation, insertion of central venous catheters, and laser therapy for ROP. **Anticipation and prevention of pain during such procedures can markedly affect the success of the procedure and the condition of the infant. Preventing, reducing, and relieving neonatal pain constitute an essential health care provider goal to maintain the sick neonate's behavioral, physiologic, and biochemical homeostasis.**[22,349]

Individualized behavioral and developmental care is another important area in preventing stress and sensory overload, which often contribute to an ongoing pain cycle.[105,287,349,365] These approaches help prevent disorganization in the neonate. Several studies have shown that clustering care, a common practice in the NICU (see Chapter 13), actually results in an increase in behavioral responses and cortisol secretion for preterm infants of younger GA when exposed to a painful procedure.[197,198,201] **To facilitate stability and self-regulation before and during an invasive painful procedure, (1) do not cluster care, and provide a period of rest before the procedure; (2) assess the infant's state, and facilitate a change to an alert state; (3) contain extremities (see Chapter 13); (4) provide a pacifier and an opportunity to grasp (a finger, hand, or blanket); and (5) use another person (e.g., parent, caregiver) to support, contain, and observe for stress. After the procedure, provide support, comfort, and slow withdrawal so that the infant remains calm.**

The suffering of neonates can be avoided. Needless suffering is prevented by an established plan of care for assessment, management, and evaluation of pain and attempts to relieve pain. **Neonates depend on the skilled observations, assessments, and interventions of care providers for *prompt, safe,* and *effective* relief. A cooperative effort among health care providers and parents in the form of pain management teams[273] and well-established pain protocols[116,349] prevents unnecessary suffering of both neonates and their families.[230]** Controlling environmental stimuli (e.g., dimming lights, controlling noise level, speaking softly, performing rounds outside of the unit), although often difficult in the NICU, is crucial for decreasing stress and preventing unnecessary agitation. **Use of an individualized, developmentally appropriate plan of care reduces the need for sedation in severely ill, VLBW neonates.[17,365] Quieting techniques are also a useful way to help control pain response in the neonate; these include nonnutritive sucking (NNS), containment interventions, and rocking** (see Chapter 13).

DATA COLLECTION

History

Neonates experiencing procedural, surgical, and/or chronic pain must be provided measures to alleviate pain. Neonatal irritability and agitation (Box 12.3) secondary to chronic conditions (e.g., BPD, necrotizing enterocolitis, short bowel syndrome, neurologic deficits) **and/or environmental overstimulation may also require a combination of environmental interventions and sedation.[13]**

Assessment of pain in neonates is often challenging because they cannot verbalize their subjective

BOX 12.3 CRITICAL FINDINGS
INDICATORS OF IRRITABILITY AND AGITATION

Physiologic

- Increase in
  - Heart rate and blood pressure only with activity
  - Oxygenation ($\uparrow TcPco_2$; Po_2; Sao_2)
  - Respiratory rate and effort
- Decrease in
  - Oxygenation ($\downarrow Po_2$; Sao_2) after prolonged agitation
  - Heart rate (bradycardia)
  - Respirations (apnea)
- Alterations in skin color: cyanosis, mottling, duskiness, pallor
- Diaphoresis
- Vomiting
- Poor pattern of weight gain

Behavioral

- Vocalizations
  - Whining cry
  - Intense, urgent cry
  - High-pitched cry
  - Resumes fussiness when consolation ceases
- Facial expressions
  - Frowning
  - Worried facies
  - Gaze aversion
  - Closes eyes to tune out
- Body movements
  - Random movements of head and body
  - Hypertonic, rigid posturing; arching; hyperextended neck
  - Flailing, thrashing, frantic activity of extremities during fuss or cry
  - Decreased activity
  - Tremulousness
- States
  - Hyperalert—easily aroused from sleep; startles easily
  - Rapid and frequent state changes to fuss or cry
  - Unpredictable sleep-wake cycles
  - Feeding difficulties
  - Difficult to console, soothe
  - High level of persistence
  - Needs environmental structure to fall asleep; takes a long time to fall asleep
  - Ineffective self-consoling; requires vestibular stimulation or body containment to console; responds inconsistently to consolation
  - Noncuddly

Modified from Broome ME, Tanzillo H. Differentiating between pain and agitation in premature neonates. *J Perinat Neonat Nurs.* 1990;4:53; Burdeau G, Kleiber C. Clinical indicators of infant irritability. *Neonat Netw.* 1991;9:23; Franck LS. A national survey of the assessment and treatment of pain and agitation in the NICU. *J Obstet Gynecol Neonat Nurs.* 1987;16:387.

BOX 12.4 GUIDELINES FOR ASSESSING PAIN

- Assess and document pain, with vital signs every 4 to 6 hours or as indicated by pain scores and/or the clinical condition of the neonate.
- Use standardized pain assessment tools and methods with evidence of validity, reliability, and clinical utility.
- Use pain assessment tools that are sensitive and specific for infants of different gestational ages and/or with acute, chronic, or continuous pain (e.g., postoperative pain, inflammatory conditions).
- Use pain assessment tools that are comprehensive and multidimensional (e.g., measure behavioral, physiologic, and hormonal/biochemical indicators of pain) within the context of pain experience.
- Assess the neonate's pain after each potentially painful clinical intervention.
- Reassess and re-evaluate the neonate's pain to assess the efficacy of pharmacologic, behavioral, and environmental interventions.

Modified from Anand KJ and the International Evidence-Based Group for Neonatal Pain. Consensus statement for the prevention and management of pain in the newborn. *Arch Pediatr Adolesc Med.* 2001;155:173; Prince W, Horns K, Latta T, et al. Treatment of neonatal pain without a gold standard: the case for caregiving interventions and sucrose administration. *Neonatal Netw.* 2004;23:33.

experience.[21] The four objectives in the assessment of pain are (1) detecting the presence of pain, (2) assessing its effect, (3) providing pain-relieving interventions, and (4) evaluating the effectiveness of interventions.[97] **Guidelines for the assessment of pain are listed in** Box 12.4. **Expression of pain through behavior is one of the neonate's only means of communicating about pain.** Behavioral cues may include diffuse or localized motor activity, facial grimacing, crying, agitation, and change in level of activity (see Box 12.3). Female infants, both preterm and term, show more facial expressions of pain compared with male infants.[374] In an analysis of the responses of 149 infants to a painful event, facial actions were found 40% of the time to account for pain indicators in vulnerable neonates.[374]

Assessment of pain in the neonate is complicated by the infant's level of neural development and maturation.★ Infants of younger GA have limited autonomic and self-regulatory abilities. **Developmental immaturity also results in disorganized, ineffective responses to stimuli and makes it more difficult for these immature preterm infants to communicate pain.** Fewer facial changes related to painful stimuli have been observed in young preterm infants.[155] However, **crying, change in arousal state, and facial grimacing have been found to be the most robust pain behaviors.**[420] Another study showed a change in facial expression with heel lance in preterm infants as young as 25 weeks of gestation.[368] However, in this study, preterm infants less than 32 weeks' PMA took a significantly longer time to change their facial expression than did older infants.★

A more immature, fragile neonate may manifest alterations in sleep-wake cycles and habituate to the overwhelming stimuli of the NICU (see Chapter 13) and thus cannot exhibit any response to pain. Illness severity as an influence on pain response has shown contradictory findings in research studies. Some studies show altered pain response in more severely ill neonates, whereas others show no alteration in the most severely ill.[96,376]

Behavioral expressions of pain by the neonate are further hampered by intubation, use of restraints, and neuromuscular blockers.[299] Similarly, **chronically ill infants who have been exposed to repeated painful procedures have difficulty generating a pain response and exhibit a "dampened" pain response.**[98,154,155,174] Recent research shows that several body movements (e.g., fisting, flexing/extending extremities, finger splay, hand on the face) commonly assessed in the Newborn Individualized Care and Assessment Program (NIDCAP) for developmental care (see Chapter 13) are associated with acute pain response in preterm infants[290] (see Box 12.1). Preterm infants who have experienced more invasive procedures, who are lower in GA at birth, and who have spent more days on ventilators have a diminished behavioral and cardiac autonomic pain response to acute pain at 32 weeks' PCA.[172,175] Another study indicates that both term and preterm neonates who undergo handling and immobilization may exhibit exaggerated behavioral and physiologic response to later painful procedures.[184] Other studies have demonstrated no difference in biobehavioral response to pain in preterm infants with neurologic injury.[298,368,420]

Physiologic parameters also may indicate pain (e.g., increased heart and respiratory rates, elevated blood pressure, desaturation, apnea, palmar sweating). These symptoms are the result of sympathetic nervous system activation (see Box 12.1). One study found that some physiologic responses to pain (e.g., facial activity and state) moderately correlated to

★References 180, 199, 221, 272, 293, 336, 425.

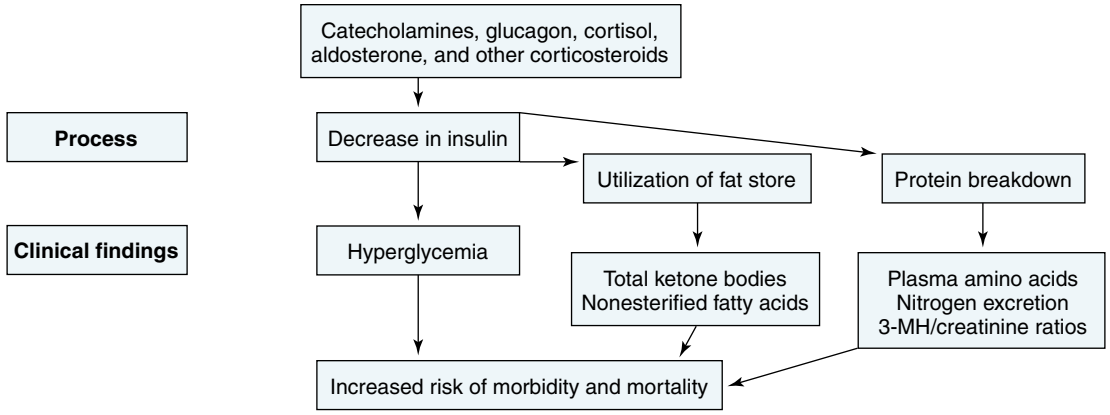

FIGURE 12.3 Hormonal response to pain in infants. *3-MH,* 3-Methylhistidine. (From Johnston C, Stevens B. Pain in infants. In: Watt-Watson J, Donovan M, eds. *Pain Management: Nursing Perspective.* St Louis, MO: Mosby; 1992.)

heart rate changes, whereas other behavioral expressions (e.g., finger splay) did not correlate with any autonomic changes.[289] However, in the same study, specific measures of cardiac autonomic modulation did not correlate with behavioral changes, suggesting that cardiac alterations are influenced by a multitude of factors[299] and may be independent measures of pain in the preterm infant.[289] A more recent study found higher physiologic reactivity (i.e., heart rate changes) in male preterm infants, but the evidence was insufficient to confirm a gender difference in pain responsivity.[400] **Some preterm infants respond to pain with more behavioral changes, whereas others respond with more physiologic changes.[377] In the first week of life, all infants of different GAs (e.g., <28 to 36 weeks) can differentiate between mild and more invasive procedures.[325]** At 36 weeks, these same infants exhibited differing physiologic pain responses based on their GA at birth. (e.g., infants born closer to term had lower increases in heart rate than those born at a younger GA).[325,420]

When pain is repetitive or persists for hours or days, there is a *decompensatory* response, resulting in hormonal and metabolic alterations (Fig. 12.3; see Box 12.1). The fight-or-flight mechanism of the sympathetic nervous system can no longer compensate, so **an adaptation syndrome begins with a return to baseline physiologic parameters.** The return of the heart rate, respirations, and blood pressure to baseline parameters makes assessment of the infant's pain more difficult and does not mean that the infant has "adjusted" to or is no longer experiencing pain.[66]

The lack of an expression of pain through physiologic and behavioral responses also does not mean that the neonate is not experiencing pain.[210] Pain responses may be delayed, cumulative, or absent. In the preterm infant, sustained elevations in vital signs and decreased oxygenation confirm the persistence of physiologic alterations after painful stimuli.[376] **Critically ill neonates and immature preterm infants may be so weak and overwhelmed that they have completely exhausted their energy and cannot respond.[177]** A recent study showed that only 65% of healthy newborns (>37 weeks and <42 weeks of gestation) cried after heel stick, although 100% of them showed a cortical peak response measured by electroencephalography (EEG) to the heel stick.[267] **The incidence of crying in response to painful or noxious stimuli is less than 50% in the preterm infant.[376]** Depending on GA, a preterm infant's behavioral responses to pain are similar to those of the term infant.[19,177,376] **A prospective cohort study comparing full-term infants (e.g., of diabetic mothers who were exposed to repeated heel sticks in the first 1 to 2 days of life) showed that these infants learned by conditioning to anticipate pain after their heel was swabbed with alcohol and exhibited a more intense pain response to a later venipuncture than infants who had not been exposed to repeated painful procedures.[393]**

Pain responses of the neonate are also influenced by the number and timing of painful procedures, the technique used, and the degree

of professional expertise.[13,98,393] Lack of a response to a painful stimulus occurs more frequently in younger newborns (both GA and PCA) who are asleep and who have recently undergone another painful procedure.[220,299,325] **Pain scores may be lower in preterm infants with higher severity of illness and higher number of previous invasive procedures,**[165] **whereas there is a larger heart rate response to repeated pain.**[322] **Mechanical lancets are preferred over manual devices for capillary blood draws.** A recent comparison of five automatic lancets found that the Tenderfoot device (Accriva Diagnostics, San Diego, CA) evoked the least pain and was most effective in obtaining adequate blood with a single lance.[371] **Venipuncture has been shown to be associated with less pain in the neonate than heel stick,**[303,356] and a new blood glucose device using the forearm has been found to be less painful for term infants than heel sticks.[347]

Assessment of neonatal pain is influenced by the attitudes and beliefs of care providers; amount of time spent observing for and having knowledge of pain responses; discrepancy between attitudes and practice, knowledge, and education of parents and professionals about pain; prioritization of pain recognition and relief in the NICU; interdisciplinary communication and collaboration; and the social community. If professionals (1) deny that newborns experience pain, (2) become desensitized to newborns' pain experience, (3) rationalize reasons for not assessing or treating pain, and (4) do not take responsibility for inflicting pain, there can be no improvement in neonatal pain management.[21,249,276]

A qualitative study of the responses of neonatal nurses to "inflicting pain" on extremely premature neonates found three subthemes: (1) "when caring and torture are the same thing," (2) "why are we doing this!" and (3) "comfort for baby and nurse."[170] In this study, the Australian neonatal nurses are passionate about the need for pain relief for neonates. **When these nurses inflicted pain on extremely premature infants, they experienced a profound sense of distress, manifested as existential suffering. Instead of relieving pain, the necessity of inflicting pain results in neonatal nurses questioning their role as compassionate caregivers: "It's agony for us as well."**[170]

Numerous other social factors influencing pain recognition and relief include the following: (1) appearance, behavior, and responsiveness of a sick neonate who varies markedly from the usual expectations about newborns; (2) lack of knowledge about analgesia and belief that pain is secondary in importance to the focus on survival; and (3) lack of knowledge about the effect on morbidity, mortality, and long-term consequences.*

Researchers have examined the beliefs and management techniques of 374 clinicians (both physicians and nurses) about procedural pain in newborn infants. Although the majority of clinicians believe that infants experience pain in the same or greater degree than adults, of 12 commonly performed bedside procedures (e.g., intubation, chest tube insertion, arterial or venous catheter insertion, heel sticks) were rated as "moderately to very painful." Neither pharmacologic nor comfort measures were frequently used.[325] More recent surveys and studies of professional attitudes have found the following: (1) assessment for neonatal pain is based on instinct rather than tested pain tools[4,67,91,104]; (2) there is inadequate staff knowledge and lack of evidence-based guidelines[4,67,91]; (3) level of empathy, secondary trauma, and burnout of the professional caregiver influences caregiving[248]; (4) there is difficulty translating knowledge to clinical practice[4,104,249]; and (5) nurse-physician collaboration is a strong predictor of evidence-based procedural pain control.[22,249,276] A recent qualitative study revealed NICU staff attitudes concerning neonatal pain. **Pain causes unnecessary suffering, and staff members realized how multiple and repeated procedures result in long-term consequences from previous pain experiences.** Second, health care providers realized how approaches to pain relief are based on feeling rather than facts. Furthermore, while comforting the neonate and when suffering is detected, health care providers have doubts and concerns about the use and side effects of drugs for pain relief. Lastly, **staff members felt that the parent's presence and caretaking in the NICU had the potential to decrease the neonate's response to painful stimuli.**[147] **Despite over 40 years of research focusing on pain and pain control in neonates, "clinical use of pain-control measures in neonates undergoing invasive procedures remains sporadic and suboptimal."**[31]

IRRITABILITY AND AGITATION

Differentiation between pain and irritability or agitation is a challenge (Fig. 12.4). **Agitation is a**

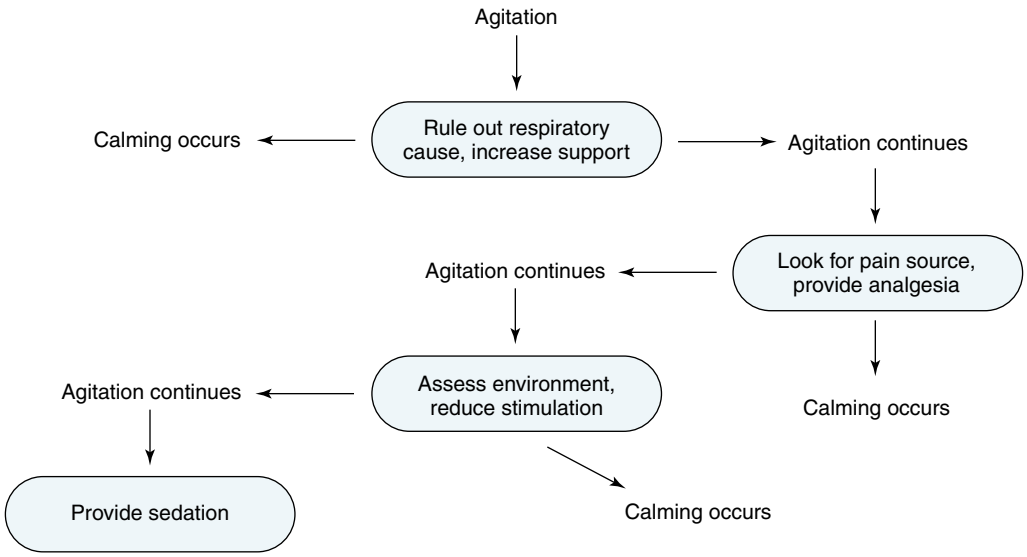

FIGURE 12.4 Decision tree for assessing and managing pain and/or agitation. (From Gordin P. Assessing and managing agitation in the critically ill infant. *Matern Child Nurs.* 1990;15:26.)

behavioral symptom of many problems, including environmental overstimulation, respiratory insufficiency, neurologic irritability, and pain. Factors influencing chronic irritability and agitation in neonates in the NICU are shown in Fig. 12.5. **Causes of agitation other than pain should be eliminated before pain management and/or sedation is initiated.** Assessment of environmental stimuli should be a routine part of the neonate's care. The neonate may associate certain stimuli with unpleasant events over time, and repeated exposure (e.g., ventilator alarms, placement of heel warmer, the odor of an alcohol wipe) may trigger agitation. Although these stimuli are inevitable, identifying, avoiding, or limiting them will help prevent anticipatory decompensation in these fragile infants.[411]

Strategies to prevent and intervene with irritable or agitated infants include the following:

- Minimize caregivers, and provide consistency in care by staff and family.
- Determine whether there is a "locus of pain" (e.g., pain-related irritability).
- Determine whether physiologic instability (e.g., needs suction/position change; hypoxemia) is the cause or the result of irritable behaviors.
- Use developmental care (see Chapter 13).
- Use sedatives judiciously.[411]
- Use individualized, developmental care to significantly reduce the need for sedatives in VLBW infants.[411]

Pain-related irritability must be treated by alleviating pain with the use of opioids and comfort measures. Use of sedatives *alone* for pain-related irritability suppresses behavioral expression of pain, has no analgesic effects, and may *increase* pain. Sedatives should be used only when pain has been ruled out as the source of the irritability or agitation. Although no research documents the safety or efficacy of combining sedatives and analgesics for the treatment of neonatal pain, sedatives are used with opioids to wean infants who have developed tolerance from prolonged opioid therapy.[411]

Assessment Tools

To quantify and objectify a neonate's pain experience and to facilitate health care professionals' recognition of the presence and severity of pain in neonates, research has resulted in the development of over 40 infant pain assessment tools.[98] Both the AAP[13] and the International Evidence-Based Group for Neonatal Pain strongly recommend use of neonatal pain assessment tools.[12,23] **The Joint Commission requires the selection and use of**

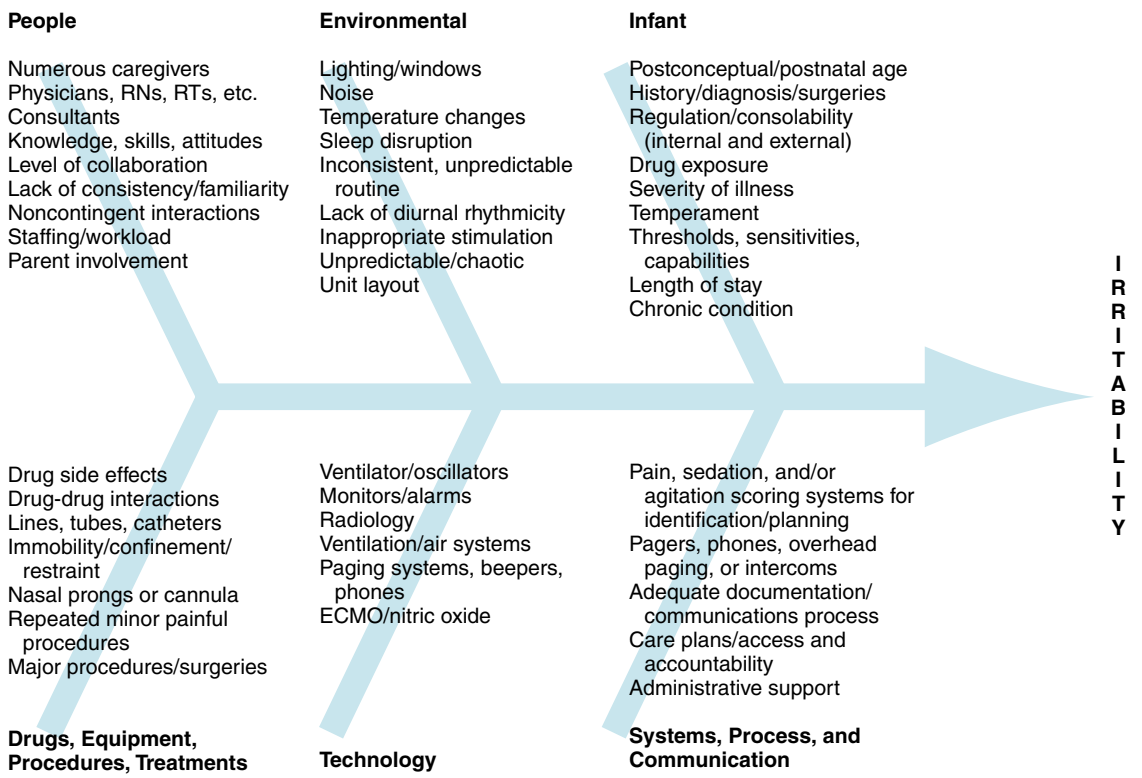

FIGURE 12.5 Fishbone diagram of factors influencing irritability. *ECMO,* Extracorporeal membrane oxygenation; *RNs,* registered nurses; *RT,* respiratory therapist. (From Walden M, Carrier C. Sleeping beauties: the impact of sedation on neonatal development, *J Obstet Gynecol Neonatal Nurs.* 2003;32:393.)

a valid, reliable pain assessment tool; however, there is no "gold standard" neonatal pain assessment tool.[23,98,221]

Of the myriad neonatal pain assessment tools, the Premature Infant Pain Profile (PIPP); and Neonatal Pain, Agitation, and Sedation Scale (N-PASS), Neonatal Facial Coding System, the Behavioral Infant Pain Profile, and the Echelle Douleur Inconfort Nouveau-Ne (EDIN) scale have been extensively tested and their validity and reliability established.[13]

The PIPP (Table 12.3) **is a multidimensional (physiologic and behavioral) assessment tool intended for use within clinical practice.**[377] The PIPP is a seven-item, four-point scale; its maximum score depends on the infant's GA and behavioral state of the premature infant at baseline. The PIPP has been validated with both full-term and preterm neonates and can distinguish between procedural and postoperative pain and nonpain (e.g., noxious) events. The revised PIPP (PIPP-R) has recently been validated in full-term neonates and preterm infants greater than 26 weeks' GA, it is easy to use, and higher pain scores require effective interventions.[156] Lower pain scores in the PIPP-R indicate that pain intervention strategy is efficacious.[156] The PIPP has not been validated for assessment of the efficacy of analgesia nor for its usefulness in the assessment of continuous pain.

The N-PASS (Table 12.4) **is an easily used clinical scale to assess, document, and manage pain and sedation.**[117,119,204,207–205] NICU infants being mechanically ventilated or in the immediate postoperative period were assessed with the N-PASS before and after pharmacologic intervention. **N-PASS measures acute, prolonged, and chronic pain, as well as the level of sedation.**[98,117,119,208] The N-PASS is a reliable and valid assessment tool for

TABLE 12.3 PREMATURE INFANT PAIN PROFILE (PIPP)

Infant Study Number: _____

Date/Time: _____

Event: _____

PROCESS	INDICATOR	0	1	2	3	SCORE
Chart	Gestational age	36 wk and more	32–35 wk, 6 days	28–31 wk, 6 days	Less than 28 wk	
Observe infant 15 seconds	Behavioral state	Active/awake; eyes open; facial movements	Quiet/awake; eyes closed; no facial movement	Active/asleep; eyes closed; facial movement	Quiet/asleep; eyes closed; no facial movements	
Observe baseline heart rate oxygen saturation						
Observe infant 30 seconds	Heart rate (max)	0–4 beats/min increase	5–14 beats/min increase	5–24 beats/min increase	25 beats/min or more increase	
	Oxygen saturation (min)	0%–2.4% decrease	2.5%–4.9% decrease	5.0%–7.4% decrease	7.5% or more decrease	
	Brow bulge	None 0%–9% of time	Minimum 10%–39% of time	Moderate 40%–69% of time	Maximum 70% of time or more	
	Eye squeeze	None 0%–9% of time	Minimum 10%–39% of time	Moderate 40%–69% of time	Maximum 70% of time or more	
	Nasolabial	None 0%–9% of time	Minimum 10%–39% of time	Moderate 40%–69% of time	Maximum 70% of time or more	

Scoring method for the PIPP:

1 Familiarize yourself with each indicator and how it is to be scored by looking at the measure.
2 Score gestational age (from the chart) before you begin.
3 Score behavioral state by observing the infant for 15 seconds immediately before the event.
4 Record baseline heart rate and oxygen saturation.
5 Observe the infant for 30 seconds immediately after the event. You will have to look back and forth from the monitor to the infant's face. Score physiologic and facial action changes seen during that time, and record immediately after the observation period.
6 Calculate the final score.

min, Minimum; *max,* maximum; *wk,* weeks.

pain/agitation and sedation in postoperative and/or ventilated neonates (0 to 100 days of age) at 23 or more weeks of gestation.[119,204,207,209]

The Neonatal Facial Coding System (Table 12.5) is an assessment tool based on nine facial expressions of term newborns in four sleep-wake states while experiencing the discomfort of heel rub and the pain of heel lance. Quiet, awake neonates demonstrate the most facial activity, whereas those in quiet sleep demonstrate the

TABLE 12.4 NEONATAL PAIN, AGITATION, AND SEDATION SCALE (N-PASS)

ASSESSMENT CRITERIA	SEDATION		SEDATION/PAIN	PAIN/AGITATION	
	–2	–1	0/0	+1	+2
Crying Irritability	No cry with painful stimuli	Moans or cries minimally with painful stimuli	No sedation/No pain signs	Irritable or crying at intervals Consolable	High-pitched or silent, continuous cry Inconsolable
Behavior state	No arousal to any stimuli No spontaneous movement	Arouses minimally to stimuli Little spontaneous movement	No sedation/No pain signs	Restless, squirming Awakens frequently	Arching, kicking Constantly awake *or* Arouses minimally/ no movement (not sedated)
Facial expression	Mouth is lax No expression	Minimal expression with stimuli	No sedation/No pain signs	Any pain expression intermittent	Any pain expression continual
Extremities Tone	No grasp reflex Flaccid tone	Weak grasp reflex ↓ muscle tone	No sedation/No pain signs	Intermittent clenching toes, fists, or finger splay Body is not tense	Continual clenched toes, fists, or finger splay Body is tense
Vital signs: HR, RR, BP, Sao_2	No variability with stimuli Hypoventilation or apnea	<10% variability from baseline with stimuli	No sedation/No pain signs	↑↓ 10%–20% from baseline Sao_2 76%–85% with stimulation, quick recovery	↑↓ >20% from baseline Sao_2 ≤75% with stimulation, slow recovery Out of sync with vent

ASSESSMENT OF SEDATION

- Sedation is scored in addition to pain for each behavioral and physiologic criterion to assess the infant's response to stimuli.
- Sedation does not need to be assessed/scored with every pain assessment/score.
- Sedation is scored 0 → –2 for each behavioral and physiologic criterion, then summed and noted as a negative score (0 → –10).
  - A score of 0 is given if the infant has no signs of sedation, does not underreact.
- Desired levels of sedation vary according to the situation:
  - "Deep sedation" → goal score of –10 to –5
  - "Light sedation" → goal score of –5 to –2
  - Deep sedation is not recommended unless an infant is receiving ventilatory support, related to the high potential for hypoventilation and apnea.
- A negative score without the administration of opioids/sedatives may indicate the following:
  - The premature infant's response to prolonged or persistent pain/stress
  - Neurologic depression, sepsis, or other pathology

ASSESSMENT OF PAIN/AGITATION

- Pain assessment is the fifth vital sign. Assessment for pain should be included in every vital sign assessment.
- Pain is scored from 0 → +2 for each behavioral and physiologic criterion and then summed:
  - Points are added to the premature infant's pain score based on his or her gestational age to compensate for his or her limited ability to behaviorally communicate pain.
  - Total pain score is documented as a positive number (0 → +11).
- Treatment/interventions are indicated for scores >3.
  - Interventions for known pain/painful stimuli are indicated before the score reaches 3.
- The goal of pain treatment/intervention is a score ≤3.
- More frequent pain assessment indications:
  - Indwelling tubes or lines that may cause pain, especially with movement (e.g., chest tubes) → at least every 2–4 hours
  - Receiving analgesics and/or sedatives → at least every 2–4 hours
  - 30–60 minutes after an analgesic is given for pain behaviors to assess response to medication
  - Postoperative → at least every 2 hours for 24–48 hours and then every 4 hours until off medications

TABLE 12.4 NEONATAL PAIN, AGITATION, AND SEDATION SCALE (N-PASS)—CONT'D

PARALYSIS/NEUROMUSCULAR BLOCKADE

- It is impossible to behaviorally evaluate a paralyzed infant for pain.
- Increases in heart rate and blood pressure at rest or with stimulation may be the only indicator of a need for more analgesia.
- Analgesics should be administered continuously by drip or around-the-clock dosing.
  - Higher, more frequent doses may be required if the infant is postoperative, has a chest tube, or has other pathology (e.g., NEC) that would normally cause pain.

SCORING CRITERIA

CRYING/IRRITABILITY

−2 → No response to painful stimuli:
- No cry with needle sticks
- No reaction to ETT or nares suctioning
- No response to caregiving

−1 → Moans, sighs, or cries (audible or silent) minimally to painful stimuli (e.g., needle sticks, ETT, or nares suctioning, caregiving)

0 → No sedation signs or No pain/agitation signs

+1 → Infant is irritable/crying at intervals but can be consoled
- If intubated, intermittent silent cry

+2 → Any of the following:
- Cry is high pitched
- Infant cries inconsolably
- If intubated, silent continuous cry

BEHAVIOR/STATE

−2 → Does not arouse or react to any stimuli:
- Eyes continually shut or open
- No spontaneous movement

−1 → Little spontaneous movement; arouses briefly and/or minimally to any stimuli:
- Opens eyes briefly
- Reacts to suctioning
- Withdraws to pain

0 → No sedation signs or No pain/agitation signs

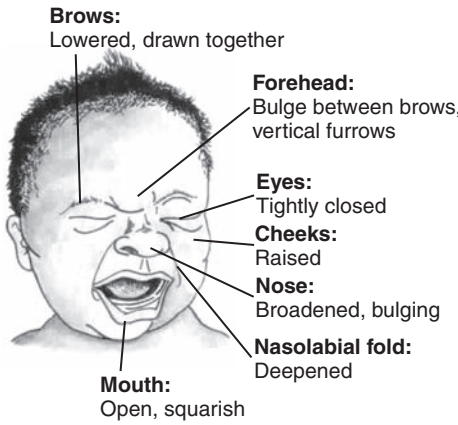
+1 → Any of the following:
- Restless, squirming
- Awakens frequently/easily with minimal or no stimuli

+2 → Any of the following:
- Kicking
- Arching
- Constantly awake
- No movement or minimal arousal with stimulation (not sedated, inappropriate for gestational age or clinical situation)

Continued

TABLE 12.4 NEONATAL PAIN, AGITATION, AND SEDATION SCALE (N-PASS)—CONT'D

FACIAL EXPRESSION



Facial expression of physical distress and pain in the infant

−2 → Any of the following:
- Mouth is lax
- Drooling
- No facial expression at rest or with stimuli

−1 → Minimal facial expression with stimuli
0 → No sedation signs or No pain/agitation signs
+1 → Any pain face expression observed intermittently
+2 → Any pain face expression is continual

EXTREMITIES/TONE

−2 → Any of the following:
- No palmar or plantar grasp can be elicited
- Flaccid tone

−1 → Any of the following:
- Weak palmar or planter grasp can be elicited
- Decreased tone

0 → No sedation signs or No pain/agitation signs
+1 → Intermittent (<30 seconds' duration) observation of toes and/or hands as clenched or fingers splayed
- Body is *not* tense

+2 → Any of the following:
- Frequent (≥30 seconds' duration) observation of toes and/or hands as clenched or fingers splayed
- Body is tense and stiff

TABLE 12.4 NEONATAL PAIN, AGITATION, AND SEDATION SCALE (N-PASS)—CONT'D

VITAL SIGNS: HR, BP, RR, AND O_2 SATURATIONS

−2 → Any of the following:
- No variability in vital signs with stimuli
- Hypoventilation
- Apnea
- Ventilated infant—no spontaneous respiratory effort

−1 → Vital signs show little variability with stimuli—less than 10% from baseline

0 → No sedation signs or No pain/agitation signs

+1 → Any of the following:
- HR, RR, and/or BP are 10%–20% above baseline
- With care/stimuli, infant desaturates minimally to moderately (Sao_2 76%–85%) and recovers quickly (within 2 minutes)

+2 → Any of the following:
- HR, RR, and/or BP are >20% above baseline
- With care/stimuli, infant desaturates severely (Sao_2 <75%) and recovers slowly (>2 minutes)
- Out of sync/fighting ventilator

BP, Blood pressure, *ETT,* endotracheal tube; *HR,* heart rate; *NEC,* necrotizing enterocolitis; *RR,* respiratory rate; *Sao*2, oxygen saturation.

TABLE 12.5 NEONATAL FACIAL CODING SYSTEM

ACTION	DESCRIPTION
Brow bulge	Bulging, creasing, and vertical furrows above and between brows occurring as a result of the lowering and drawing together of the eyebrows
Eye squeeze	Identified by the squeezing or bulging of the eyelids; bulging of the fatty pads about the infant's eyes is pronounced
Nasolabial furrow	Primarily manifested by the pulling upward and deepening of the nasolabial furrow (a line or wrinkle that begins adjacent to the nostril wings and runs downward and outward beyond the lip corners)
Open lips	Any separation of the lips
Stretch mouth (vertical)	Characterized by a tautness of the lip corners coupled with a pronounced downward pull on the jaw; seen when an already wide-open mouth is opened a fraction further by an extra pull at the jaw
Stretch mouth (horizontal)	Appears as a distinct horizontal pull at the corners of the mouth
Lip purse	Lips appear as if an "oo" sound is being pronounced
Taut tongue	Characterized by a raised, cupped tongue with sharp tense edges; the first occurrence of taut tongue usually is easy to see, often occurring with a wide-open mouth; after this first occurrence, the mouth may close slightly; taut tongue is still scorable on the basis of the still visible tongue edges
Chin quiver	An obvious high-frequency up-down motion of the lower jaw

Data from Grunau RVE, Craig KD. Pain expression in neonates: facial action and cry. *Pain.* 1987;28:399; Grunau R, Craig K. Facial activity as a measure of neonatal pain expression. In Tyler DC, Krane EJ, eds. *Advances in Pain, Research and Therapy.* Vol 15. New York, NY: Raven; 1990.

least.[176,180] **Facial activity also increases with GA, so both infant state and GA must be considered when using this scale.** Despite the fact that the Behavioral Infant Pain Profile (discussed next) is a one-dimensional pain assessment tool, both tools have been found to be more sensitive in detecting behavioral pain cues in term newborns than the PIPP tool.[37] This tool is sensitive to changes in pain intensity and useful for evaluating the effectiveness of interventions. There is evidence of reliable clinical use of this tool in term and preterm infants for acute and prolonged pain as well as postoperative pain.[177]

The Behavioral Infant Pain Profile (BIIP)[196] (Table 12.6) is a behavioral assessment tool that combines sleep/wake states, facial responses, and two-hand movements by term and preterm infants responding to procedural (any skin-breaking procedure) pain. Through psychometric testing, the BIIP is a valid and reliable tool with high internal consistency for assessing acute procedural pain in preterm infants. Additionally, the BIIP is a practical clinical tool because it is easily scored by both experienced and inexperienced observers with very high inter-rater reliability.

The Neonatal Infant Pain Scale (NIPS) (Table 12.7) is a behavioral assessment tool for preterm and term neonates responding to a needle puncture. The NIPS provides a measurement of intensity of infant responses to a painful procedure during and after the event (Fig. 12.6).[250] NIPS scores have been correlated with GA and Apgar scores. The NIPS provides an objective measure of pain-relieving interventions and their effectiveness.[250] The NIPS is objective and nonintrusive and assesses only behavioral response to pain; compared with other pain scales, it has been found to be easy and quick to use.[250] Flow sheets have also been designed to facilitate the documentation of pain scores and behaviors.[250]

The EDIN scale consists of five items (facial activity, body movements, quality of sleep, quality of contact with nurses, and consolability) and is meant to assess prolonged, chronic pain. However, because there is no accounting for the developmental immaturity of preterm infants, a modified EDIN score (adding a sixth item, postmenstrual age) has been created and tested. **The EDIN6 scale (Table 12.8) was tested against the EDIN scale and found to be more sensitive in assessing (and thus intervening in) prolonged pain in preterm infants of various gestational ages in one NICU.[332] Cumulative scores on the EDIN6 of greater than 6 are considered pain expressions that require intervention.** This study also

TABLE 12.7 NEONATAL INFANT PAIN SCALE (NIPS) OPERATIONAL DEFINITIONS

FACIAL EXPRESSION	
0—Relaxed muscles	Restful face, neutral expression
1—Grimace	Tight facial muscles; furrowed brow, chin, jaw (negative facial expression—nose, mouth, and brow)
CRY	
0—No cry	Quiet, not crying
1—Whimper	Mild moaning, intermittent
2—Vigorous cry	Loud scream; rising, shrill, continuous (*Note:* Silent cry may be scored if baby is intubated as evidenced by obvious mouth and facial movement)
BREATHING PATTERNS	
0—Relaxed	Usual pattern for this infant
1—Change in breathing	Indrawing, irregular, faster than usual; gagging; breath holding
ARMS	
0—Relaxed/restrained	No muscular rigidity; occasional random movements of arms
1—Flexed/extended	Tense, straight arms; rigid and/or rapid extension, flexion
LEGS	
0—Relaxed/restrained	No muscular rigidity; occasional random leg movement
1—Flexed/extended	Tense, straight legs; rigid and/or rapid extension, flexion
STATE OF AROUSAL	
0—Sleeping/awake	Quiet, peaceful sleeping or alert and settled
1—Fussy	Alert, restless, and thrashing

From Lawrence J, Alcock D, McGrath P, et al. Children's Hospital of Eastern Ontario; 1993.

surveyed 70 NICU nurses who were educated about neonatal pain, but of varying clinical experience, about their evaluation of the EDIN6 tool. In addition to the objective evaluation, the NICU nursing staff also perceived the EDIN6 to be better suited for the assessment of pain in more immature preterm infants.[332]

The National Practice Guidelines provide a list of assessment questions to ask when assessing pain management in the neonate (Box 12.5). Lack of validated assessment tools may leave health care providers wondering if behaviors are indicators or responses to pain. The Acute Pain Management Guideline suggests that "if care providers are unsure whether a behavior indicates pain, and if there is reason to suspect pain, an analgesic trial can be diagnostic, as well as therapeutic."[2]

Assessment of pain and delivery of effective pain-relieving interventions in daily clinical practice must *not* be delayed while adequate, objective assessment tools are developed.[98,375]

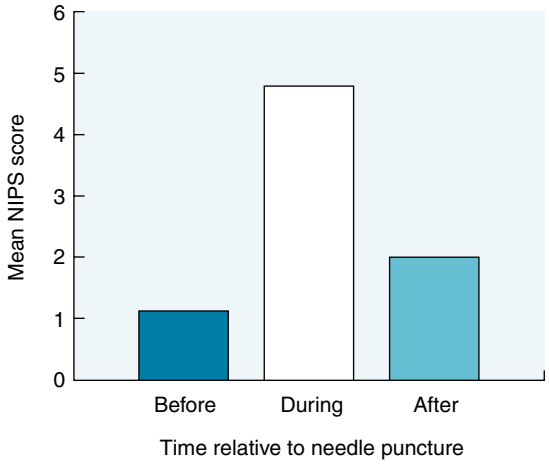

FIGURE 12.6 Mean Neonatal Infant Pain Scale (NIPS) scores over time in 22 infants. (From Lawrence J, Alcock D, McGrath P, et al. The development of a tool to assess neonatal pain. *Neonat Netw.* 1993;12:62.)

The usefulness of pain scores was recently assessed in 196 ventilated premature infant patient-days.[340] Although only 2% of pain scores suggested the presence of pain and only 0.1% of the pain scores resulted in analgesic use, these ventilated infants were obviously exposed to multiple pain-related procedures. In this study, regular reassessment and assignment of a pain score was poorly correlated with exposure to painful procedures.[340] All health care providers must use their highly developed assessment skills, along with input from the parents, to gather information about infant behavioral, physiologic, and hormonal or catabolic stress responses before, during, and after painful stimuli.[98] These same assessment skills enable care providers and parents to evaluate the effectiveness of pharmacologic and comfort interventions and institute more and/or different interventions as necessary to relieve pain and suffering.

TABLE 12.8 EDIN6 SCALE* INTEGRATED BY GESTATIONAL AGE AS A SIXTH ITEM

ITEM	DESCRIPTION	SCORE
Facial activity	Relaxed facial activity	0
	Transient grimaces with frowning, lip purse, and chin quiver	1
	Frequent grimaces, lasting grimaces	2
	Permanent grimaces resembling crying or blank face	3
Body movements	Relaxed body movements	0
	Transient agitation, often quiet	1
	Frequent agitation but can be calmed down	2
	Permanent agitation with contraction of fingers and toes and hypertonia of limbs or infrequent, slow movements and prostration	3
Quality of sleep	Falls asleep easily	0
	Falls asleep with difficulty	1
	Frequent spontaneous arousals, independent of nursing, restless sleep	2
	Sleepless	3
Quality of contact with nurses	Smiles, attentive to voice	0
	Transient apprehension during interactions with nurses	1
	Difficulty communicating with nurses. Cries in response to minor stimulation	2
	Refuses to communicate with nurses. No interpersonal rapport. Moans without stimulation	3
Consolability	Quiet, total relaxation	0
	Calms down quickly in response to stroking or voice or with sucking	1
	Calms down with difficulty	2
	Disconsolate. Sucks desperately	3
Postmenstrual age	Gestational age >37 weeks	0
	Gestational age 33–37 weeks	1
	Gestational age <33 weeks	2

BOX 12.5 CRITICAL QUESTIONS TO ASK ABOUT PAIN MANAGEMENT IN NEONATES

- Is the infant being adequately assessed at appropriate intervals?
- Are analgesics ordered for prevention and relief of pain?
- Is the analgesic strong enough for the pain expected or the pain being experienced?
- Is the timing of the drug administration appropriate for the pain expected or being experienced?
- Is the route of administration appropriate (preferably oral or intravenous) for the infant?
- Is the infant adequately monitored for side effects?
- Are side effects appropriately managed?
- Has the analgesic regimen provided adequate comfort and satisfaction from the family's perspective?

Questions to Consider About Nonpharmacologic Strategies

- Is the strategy appropriate for the infant's developmental level, condition, and type of pain?
- Is the timing of the strategy sufficient to optimize its effects?
- Is the strategy adequately effective in preventing or alleviating the infant's pain?
- Is the family satisfied with the strategy for prevention or relief of pain?

From Agency for Health Care Policy and Research, Public Health Service. Acute Pain Management Guideline Panel. *Acute Pain Management: Operative or Medical Procedures and Trauma—Clinical Practice Guideline.* AHCPR Pub No 92-0032. Rockville, MD: U.S. Department of Health and Human Services; 1992.

Laboratory Data

Hormonal and metabolic changes are listed in Box 12.1. Serum glucose levels and reagent test strips monitor for hyperglycemia, which may result in increased serum osmolality and increase the risk for IVH. Glucosuria, ketonuria, and proteinuria result in elevated specific gravity. Metabolic acidosis may result from increased serum levels of lactate, pyruvate, ketones, and nonesterified fatty acids. These data also may be indicative of other serious neonatal problems (e.g., sepsis, acute tubular necrosis).

In the search of more objective measures of pain assessment, use of heart rate variability (HRV), skin conductance (SC) measurements, and brain-oriented techniques such as NIRS, EEG, and magnetic resonance imaging (MRI) are being investigated. Although HRV is a reliable measure of the neonate's response to acute and prolonged pain,[135,155] lack of availability of monitoring devices may preclude its use clinically.[98] SC, which measures stress-induced sweating in the palms and soles of the feet, has shown conflicting results in research, especially in preterm infants.[206,292,381,402] This requires further investigation in the preterm infant before it will be ready for clinical use.[403]

After heel lance, there is an increase of skin blood flow as measured by laser Doppler imaging that correlates to NIPS scores. In a randomized placebo-controlled trial, **use of sucrose before heel lance resulted in decreased NIPS scores that correlated with lower skin blood flow.** The researchers concluded that laser Doppler imaging is potentially a useful method for assessing neonatal procedural pain.[398]

Current and future research is focused on brain-oriented approaches (e.g., NIRS, EEG, and MRI) instead of pain-assessment tools. Painful stimuli cause hemodynamic changes in the brains of preterm and term infants.[45,366,367] As early as 25 weeks of gestation, preterm infants have increased oxygenated hemoglobin in response to a heel stick.[367] Cerebral changes are dependent on GA and sleep-wake state; less robust changes are seen in the younger GA infant and while asleep compared with the awake infant.[367] The first study to assess the correlation between cortical hemodynamic activity (by NIRS) during a heel stick in 25- to 43-week PMA neonates and the PIPP score found significant correlation between the NIRS and the pain score.[366] Use of the NIRS remains clinically challenging because multiple factors (i.e., movement, external stimuli, birth weight, medications, ventilator settings, infection, PDA) alter results.[199]

EEG changes in the frontal lobes of the brain during noxious and painful stimuli have been researched in preterm and full-term infants. Developmental maturation in response to touch and pain has been found in the neonate: (1) before 35 weeks of gestation, nonspecific neuronal bursts to both touch and pain were the dominant response, and (2) after 35 to 37 weeks of gestation, specific responses to touch versus pain were present.[133] Using EEG, a template of neonatal brain activity during a nociceptive procedure (heel stick) has been developed, provides an objective assessment of neonatal pain, and is sensitive to the administration of analgesia for pain relief.[192] Another study of EEG changes in infants greater than 37 weeks and less than 42 weeks of gestation who were presented

with light touch, cold, and a heel stick found significant differences in the cortical peak responses to each stimuli.[267] The researchers also found that only 65% of these newborns cried with heel stick, but all of them had EEG changes with the painful stimuli.[267] **MRI has documented procedural, pain-related stress to alterations in brain maturation in preterm infants in an NICU.**[61] Research into the use of EEG and MRI for pain assessment, especially technical challenges such as movement artifact, is in its infancy.[96,199]

Future assessment of neonatal pain may combine validated and reliable tools as well as laboratory data collected at the point-of-care. One such study used a multimodal approach to measure pain: (1) electromyography (EMG), EEG, and NIRS; (2) video-recording of behavioral responses; and (3) EEG to monitor autonomic responses (i.e., heart and respiratory rates, oxygen saturation with pulse oximetry, and cardiovascular activity).[421] In more than 100 test occasions, this multimodal system is precise, accurate, and 100% sensitive and specific in detecting touch versus a heel stick.[421] Simultaneous use of NIRS and EEG on 30 newborn infants who were exposed to innocuous tactile stimuli and noxious (heel lance) stimuli showed that both technologies recorded quantifiable and distinct activity to each of the stimuli in group analysis, with individual variation among newborns within the group.[407] The heel lance resulted in a peak hemodynamic change on the NIRS that was 10-fold larger than the cortical response to touch. However, this study also found that hemodynamic and electrophysiologic responses do not always occur together in an individual newborn, but when they do occur together (in 64% of heel lances), the responses are significantly correlated in their magnitude.[407]

TREATMENT

The neonate relies on the skilled observations, assessment, and interventions of care providers for prompt, safe, and effective relief of pain. Pain management is an interactive, relationship-based process that comprises (1) the environment of pain management, (2) preparation of the newborn for a procedure, (3) pain relief during a procedure, and (4) restoring safety and security to the infant after a procedure.[47] Barriers in providing adequate analgesia in these patients include an unfamiliarity with medication doses and with regional techniques and concern over increased drug sensitivity in neonates. Because routine care can be irritating to newborns, differentiating between agitation, which may respond well to comfort measures, and pain, which will not, is mandatory. **Opioids are the mainstay of pharmacologic treatment; however, other useful medications and techniques may be used for pain relief.**[13] **Guidelines for managing pain in the neonate are listed in** Box 12.6. **Tables** 12.9 **and** 12.10 **present evidence-based pain management strategies for commonly performed painful procedures and surgical interventions.**

Pharmacologic Measures

Absorption, metabolism, distribution, and clearance of drugs in the neonate differ from those in the older child and adult (see Chapter 10). These differences are summarized in Table 12.11.

OPIOIDS AND BENZODIAZEPINES

Opioids have their primary effect on the μ-receptor in the brain and spinal cord. High-affinity μ-receptors are associated with analgesia, and low-affinity μ-receptors are associated with respiratory depression. **There may be fewer high-affinity μ-receptors in the newborn that are less sensitive to the analgesic effects of opioids. Higher initial doses of opioids may therefore be necessary for effect, which may in turn increase the risk for respiratory depression.** A randomized, double-blind study of postoperative (e.g., thoracic or abdominal surgery) pain relief in full-term newborns receiving either continuous or intermittent morphine found an age-related difference in morphine requirements and metabolism.[57,58] Younger infants (e.g., 7 days or younger) needed less morphine postoperatively (e.g., loading dose [50 mcg/kg], continuous dose [5 to 10 mcg/kg/hr], and need for additional "breakthrough" doses) than neonates older than 7 days (e.g., loading dose [100 mcg/kg] and continuous dose [10 mcg/kg/hr]). This study also found that neonates being mechanically ventilated had slower morphine metabolism and clearance.[57] A retrospective analysis of the postoperative use of morphine in 82

BOX 12.6 GUIDELINES FOR PAIN MANAGEMENT IN THE NEONATE

- Use strategies to prevent pain (e.g., avoid recurrent painful stimuli).
- Use developmental care and environmental interventions to reduce noxious stimuli and stress in the NICU[287] (see Chapter 13).
- Use comfort measures (e.g., breast milk/sucrose/glucose, nonnutritive sucking, containment with swaddling or facilitated tucking).
- Sucrose administration recommendations:
  - Preterm infants: 0.1–0.4 mL; dipping a pacifier into sucrose results in 0.1-mL intake
  - Term infants: 2 mL
  - Administer 2 minutes before a painful procedure*
  - Analgesic effect lasts about 5 minutes
- Use pharmacologic therapy for preemptive analgesia (see Table 12.13).
- Use pharmacologic therapy for ongoing pain.
- Use of a combination of pain interventions (e.g., sucking, containment, medication) may have an additive or synergistic clinical effect.[255]

*Recent research found that waiting 2 minutes before starting a procedure after sucrose administration is not necessary.[279]

Modified from Anand KJ and the International Evidence-Based Group for Neonatal Pain: Consensus statement for the prevention and management of pain in the newborn. *Arch Pediatr Adolesc Med.* 2001;155:173; Prince W, Horns K, Latta T, et al. Treatment of neonatal pain without a gold standard: the case for caregiving interventions and sucrose administration. *Neonatal Netw.* 2004;23:33.

full-term neonates after thoracic and/or abdominal surgery[129] found that both dosage and duration of infusion prolonged mechanical ventilation. After extubation, no apnea or hypotension was associated with morphine use.

Decreased protein binding, drug metabolism, and drug clearance may contribute to higher plasma and CNS concentrations and prolonged drug effect. Effective drug doses and metabolism by the individual neonate depend on weight, GA, postnatal age, genetic variation, and the corresponding pharmacokinetics and pharmacodynamics, which may change in the first days of life.[384,397] All doses must be titrated to the individual neonate's needs and current clinical circumstances.[397]

All of the opioids have similar mechanisms of action; however, there are a few important differences in side effects (see Table 12.13). Morphine is the most commonly used opioid and may cause hypotension in dehydrated patients or when used in high doses; it provides more sedation than fentanyl. Recent research on the blood pressure effects of morphine administration showed (1) no hypotensive effects on ventilated newborns[344] or on preterm infants[405] given analgesic doses[20] and (2) occurrence of hypotensive effects with loading and higher dosages.[28,405] **However, morphine should be used with caution in preterm infants of 23 to 26 weeks of gestation and those with preexisting hypotension.**[185] For acute procedural pain (e.g., heel stick), a loading dose of morphine followed by continuous IV infusion does not provide adequate analgesia for invasive procedures in ventilated preterm infants.[73]

Fentanyl is the preferred drug in many NICUs because of its cardiovascular stability and its ability to decrease pulmonary vascular resistance. It can, however, cause chest wall rigidity and decreased lung compliance if administered too quickly. Neuromuscular blocking agents or slow administration of the drug will prevent this problem. Fentanyl is also commonly used in patients on extracorporeal membrane oxygenation (ECMO) to provide sedation and analgesia and to prevent increases in pulmonary vascular resistance and pressure.[254] Fentanyl is also used for artificial ventilation, persistent pulmonary hypertension of the newborn (PPHN), diaphragmatic hernia, and postoperative pain.[397] Because of its rapid onset and short duration, fentanyl relieves procedural pain.[397] **Sufentanil is 10 times more potent than fentanyl** and significantly more expensive. It is shorter acting and can have even greater effects on lung and chest wall compliance. Hydromorphone and methadone have also been used, particularly in the postoperative period and for infants on long term-opioids.

Administering drugs on a PRN schedule results in peaks and valleys of pain relief and increases in side effects. Because an analgesic is most effective if given before the peak of pain (wind-up), continuous infusions or regular administration can help prevent undue neonatal suffering.[13,384]

Benzodiazepines are commonly used in the NICU for sedation. Midazolam (Versed) has been increasingly used to provide sedation in mechanically ventilated neonates. **A meta-analysis of the research on midazolam concluded that there are significant adverse effects and no clinical benefit to the use of midazolam; there is insufficient evidence to justify the use of midazolam for ventilated neonates in the**

TABLE 12.11 PHARMACOLOGIC DIFFERENCES BETWEEN NEWBORNS AND ADULTS

DIFFERENCES	CAUSE	EFFECTS
Altered gastric activity	Presence of alkaline amniotic fluids at birth Immature gastric mucosa Consumption of alkaline milk	Variable drug absorption
Decreased gastric emptying time		Increased absorption of some drugs
Decreased protein binding	Lower levels of albumin, α-acid glycoprotein Increased competition for binding sites by endogenous substances (bilirubin)	Increased levels of free drug (opioids, local anesthetics)
Increased volume of distribution	Larger volume of body water in the newborn	Larger initial dose may be needed for effect (e.g., neuromuscular blocking agents, local anesthetics)
Decreased drug metabolism	Immature liver enzyme systems	Prolonged effect of some medications (e.g., morphine, fentanyl, neuromuscular blockers)
Decreased drug clearance	Immature renal system and decreased glomerular filtration rate	Prolonged effect of some medications (morphine)

From Rovee-Collier C, Hayne H. Reactivation of infant memory: implications for cognitive development. *Adv Child Dev.* 1987;10:185.

NICU (see Table 12.13).[295] Benzodiazepines potentiate the effects of opiates.[373] Therefore, when they are used in combination (e.g., fentanyl and midazolam), lower doses of each medication may be used to gain the same effect as would be attained if either one was used separately. There is increasing concern regarding the neurotoxicity of midazolam[258] (see Table 12.13). It is important to note that although benzodiazepines provide sedation, they have no analgesic effect.[373]

The long-term effects of analgesic use on the developing brain are poorly understood because of a paucity of data on neurodevelopmental outcomes. Several researchers have found a protective effect of analgesic use on neurodevelopmental outcomes, perhaps because of decreased fluctuation in blood pressure, cerebral blood flow, oxygenation, respiratory synchrony with ventilation, and stress hormones.[19,27,32,240,266]

More recent studies on the long-term neurologic effects of morphine analgesia in ventilated preterm infants caution against the lack of protective effects and have documented (1) an increase in severe IVH,[28] (2) a decrease in the incidence of IVH that did not influence poor neurologic outcomes,[364] and (3) subtle neurobehavioral differences in preterm infants exposed to morphine analgesia.[335]

LOCAL ANESTHETICS

Local anesthetics have a variety of uses and provide analgesia by preventing the transmission of noxious stimuli at either the peripheral receptor site or the spinal cord. Bupivacaine, ropivacaine, and lidocaine are the most commonly used local anesthetics (see Table 12.12). A recent study showed that bupivacaine confers better analgesia for neonatal circumcision than that achieved with lidocaine.[380]

Bupivacaine is longer acting but more cardiotoxic than lidocaine. Both are more toxic in neonates than in adults because of increased organ sensitivity and free fraction of drug. The cardiovascular toxicity may be enhanced if epinephrine-containing local anesthetics are used. The long-acting local anesthetics *levobupivacaine* (available in Europe) and *ropivacaine* are as effective as bupivacaine but less cardiotoxic.[419] Procainamide is used as a continuous infusion in many centers because of its rapid ester metabolism and decreased toxicity.

Regional Technique. Regional techniques provide adequate analgesia, thus reducing the need for higher doses of opioids (Table 12.13). Advantages include the following[120]:

- Stress responses are significantly decreased.

TABLE 12.12 TYPES OF REGIONAL BLOCKADE
Potential Uses

BLOCK	POTENTIAL USES	COMPLICATIONS
Spinal	In place of general anesthesia for surgery below the umbilicus; decreased incidence of postoperative apnea	Inability to access space; incomplete block or inadequate duration of anesthesia
Caudal/ epidural	Intraoperative and postoperative analgesia for thoracic, abdominal, perineal, and lower extremity surgery	Inadequate block; local or opioid-related toxicity; nerve damage, paralysis
Dorsal penile nerve/ring block	Circumcision, analgesia for any penile surgery	Hematoma formation; end-organ damage if epinephrine-containing solutions are used
Intercostal nerve block	Rib fracture, thoracic surgery	Pneumothorax; local anesthetic toxicity (highest rate of absorption)

- Normal respiratory patterns return more quickly.
- The need for postoperative ventilation may be avoided or shortened.
- Intestinal motility recovers more quickly.
- Morbidity decreases, particularly with the use of epidural blocks.

Dorsal Penile Nerve/Ring Block.[231] **The dorsal penile nerve block is extremely easy to perform with a high degree of success that can provide surgical anesthesia for circumcision.**[231] The block is performed by injecting 1% lidocaine 3 to 5 mm below the skin at the 2 o'clock and 10 o'clock positions on the dorsum of the penis (Fig. 12.7). In a full-term neonate, 0.5 mL/side is used, and 0.2 mL/kg/side is used in premature infants. An alternative technique less likely to cause hematoma is to inject a subcutaneous ring of 0.5% or 1% lidocaine around the base of the penis. **All solutions should be without epinephrine, and a "wait time" of 5 to 8 minutes is necessary to achieve adequate anesthesia.**[252]

Several studies of pain responses to circumcision with a combination of pharmacologic and nonpharmacologic interventions for neonatal pain have been published. Use of a dorsal penile nerve block/ring block and oral sucrose solution found that infants receiving the combination of a block and oral sucrose had lower pain scores than those who received a ring block or sucrose alone.[341] A more recent study of **ring block, oral sucrose, and eutectic mixture of lidocaine and prilocaine (EMLA) cream found better pain relief with use of all of these methods together.**[358] Dorsal penile block, sucrose, and EMLA cream were not as effective as the ring block, oral sucrose, and EMLA. When only EMLA and sucrose were used, there was a significant increase in heart rate and duration of crying time.[358]

Liposomal lidocaine was compared with EMLA and dorsal penile block in a study of 54 full-term infants being circumcised; liposomal lidocaine was found to be a safe and effective topical anesthetic.[252] A video study found that the dorsal penile nerve block was significantly more effective for pain relief during circumcision than use of topical EMLA cream.[152] A recent meta-analysis of 14 studies of infant circumcision found that pain was dramatically decreased with the combined use of dorsal penile block, acetaminophen, oral sucrose, and topical analgesic cream.[48] However, the addition of liposomal lidocaine to sucrose did not further decrease the pain of venipuncture in healthy term newborns.[394]

Epidural Block. The epidural space is an area surrounding the dura of the spinal cord. This space can be accessed from the caudal, lumbar, or thoracic region. An epidural block is performed by a skilled pediatric anesthesiologist, often with the patient under general anesthesia.[275] A small catheter can be left in the space, or a one-time dose of medication can be given. Local anesthetics act by anesthetizing either the local nerve roots or the spinal tracts at the level of the spinal cord where they are placed. The most commonly used medications in neonates are the local anesthetics *procainamide, ropivacaine,* or *bupivacaine.* They are often used in combination with low doses of opioids and/or clonidine, which have both local and systemic action. **The major advantages of these techniques include their ability to provide continuous pain relief and the potential to minimize respiratory depression, facilitate extubation, and hasten recovery.**

TABLE 12.13 ANALGESICS, SEDATIVES, AND REVERSAL AGENTS FOR THE NEONATE

DRUG	DOSAGE	COMMENTS
	OPIOIDS	
Morphine	0.05–0.1 mg/kg/dose q 4–6 hr PRN IV, IM, or sub-Q Continuous IV infusion: 10–15 mcg/kg/hr (up to 30–40 mcg/kg for ventilator therapy and major surgery) Mean onset of action: 5 min Peak effect: 15 min Duration: 4–5 hr	CNS and respiratory depressant; bronchospasms; peripheral vasodilation with hypovolemic infants; hypotension, decreased gastric/intestinal motility; intestinal obstruction; risk for NEC; increased intracranial pressure; seizures; urinary retention. Easily reversed with naloxone; slower onset but longer duration than for fentanyl; withdrawal symptoms may occur. Ceiling effect (after reaching a therapeutic level, higher doses result in more adverse rather than analgesic effects) reached by using doses up to 0.5 mg/kg.[24] Sleep-wake cycling, measured by EEG, resumed soon after surgery in neonates ≥32 weeks of gestation who received high doses of morphine and midazolam.[306] Does not alter the physiologic response to ETT suctioning.[26] As premedication for ETT intubation: use only if other opioids not available; must wait at least 5 minutes for onset of action.[237]
Fentanyl (Sublimaze)	0.3–2 mcg/kg/dose q 1–2 hr PRN IV or sub-Q Continuous IV infusion: 0.3–5 mcg/kg/hr Onset of action: 2–3 min Peak effect: 3–4 min Duration: 30–60 min	Same as for morphine. Eighty to 100 times more potent than morphine. Rapid onset of action; decreases motor activity; does not increase intracranial pressure in the absence of respiratory depression. Easily reversed with naloxone; short duration of action; may cause bradycardia, hypotension, apnea, seizures, or rigidity if given too rapidly; hypothermia. Less hypotension, urinary retention, GI motility effects than with morphine.[345] Withdrawal symptoms occur with prolonged use (>5 days). Drug of choice for premedication for ETT intubation[237]; safe for PICC line insertion in nonintubated infants.[227]
Sufentanil citrate (Sufenta)	0.5–1 mcg/kg/dose q 30 min to 1 hr Peak effect: 5–6 min Duration: 30 min	Ten times more potent than fentanyl; has a quicker onset and shorter duration of action than fentanyl. Use with caution in neonates with intraventricular hemorrhage, hepatic or renal impairment, or pulmonary disease. Same side effects as for fentanyl. Bolus and continuous infusion affects EEG results in VLBW/ELBW infants; use of sufentanil must be considered in EEG interpretation.[297]
Remifentanil	1–3 mcg/kg/dose IV Repeat in 2–3 min PRN Onset of action: within 1 min of administration[8] Duration: 3–10 min	Same as for fentanyl. Easily reversed with naloxone. Short duration of action. Limited experience in neonates.[237] Premedication for ETT intubation, PICC line insertion, and laser surgery for ROP: acceptable analgesic.[8,39]
Meperidine (Demerol)		*Not recommended* in preterm or term infants. The active metabolite normeperidine accumulates in tissues and causes CNS stimulation (e.g., tremors, muscle twitching, hyperactive reflexes, dilated pupils) and also lowers the seizure threshold level.[13]

TABLE 12.13 ANALGESICS, SEDATIVES, AND REVERSAL AGENTS FOR THE NEONATE—CONT'D

NONOPIOIDS		
Acetaminophen/ paracetamol (Tylenol)	Oral loading dose[310]: 20 mg/kg PO; then 10 mg/kg PO q 6 hr in term infants and q 8 hr in preterm infants <32 weeks of gestation IV loading dose[310]: 20 mg/kg; then 10 mg/kg IV q 6 hr for term infants and q 8 hr for preterm infants <32 weeks of gestation Rectal loading dose[310]: 30–40 mg/kg; then 1–18 mg/kg q 6 hr for term infants and q 8 hr for preterm infants <32 weeks of gestation	Used for mild to moderately severe pain[8]: given alone does *not* relieve surgical pain, heel lance pain, or pain of eye examination[305] Potentiates the effects and significantly reduces the need for opioids after major surgery.[189,305] *Do not use* in patients with G6PD deficiency. May cause hepatotoxicity in overdose .
Ibuprofen (Advil, Motrin)	4–10 mg/kg/dose q 6–8 hr PO	Gastric irritant—administer with or after feeding; use with caution in neonates with necrotizing enterocolitis, impaired renal function, hypertension, compromised cardiac function, or pulmonary hypertension.
LOCAL ANESTHETICS		
Lidocaine	0.5%–1% solution (to avoid systemic toxicity, volume should be less than 0.5 mL/kg of 1% lidocaine solution—5 mg/kg)	Local infiltration anesthesia for invasive procedures; use solution *without epinephrine* to avoid vasoconstriction. Use topical creams (EMLA/amethocaine) before needle insertion; warm solution to body temperature; inject slowly to reduce the pain of injection.[253] One case report of a term newborn developing methemoglobinemia after circumcision with lidocaine and topical EMLA cream.[235]
Bupivacaine Levobupivacaine Ropivacaine	2.5 mg/kg one-time epidural dose Continuous IV infusion: 0.2 mg/kg/hr (maximum dose)	Monitor for CNS (e.g., seizures, irritability) and cardiotoxic (e.g., ventricular dysrhythmias) side effects. Monitor catheter integrity. Epidural infusion is titrated to effect but *must not* exceed maximum dose. Levobupivacaine and ropivacaine are less cardiotoxic than bupivacaine.
EMLA (lidocaine and prilocaine)	2.5–5 g to site for at least 60 min Peak effect: 2–3 hr Duration: 1–2 hr after removal	Vasoconstriction at the site. Site must be covered with water-impermeable dressing (e.g., Tegaderm). Single doses have not been shown to cause methemoglobinemia in preterm or term neonates.[389] Does not relieve pain of heel lance.[13] The possibility of toxicity is increased when EMLA is applied to (1) open skin and (2) a larger area than recommended by the manufacturer.[312] Cannot be used on abraded skin or mucous membranes.
Amethocaine gel* (4%) liposome-encapsulated tetracaine (Ametrope)	1.5 g to site for 30 min to 1 hr	Site must be covered with water-impermeable dressing (e.g., Tegaderm). Vasodilation at the site—mild transient (~20 min) erythema or blanching.[213,253,301,388] Case report of ELBW preterm infant developing a clinically significant cardiac arrhythmia after topical use for PICC insertion.[271]
Liposomal lidocaine (4%) cream	Onset of action: 20–30 min	Available in the United States without a prescription. Does not cause methemoglobinemia; can be applied without an occlusive dressing and has fewer vasoactive effects. Effective in relieving immunization pain in infants.[391]
SEDATIVE-HYPNOTICS		
Barbiturates		*Do not* provide pain relief; help reduce agitation precipitated by painful events. Frequently produce hyperalgesia and increased reaction to painful stimuli; contraindicated for neonates who have pain and also require sedation.

Continued

TABLE 12.13 ANALGESICS, SEDATIVES, AND REVERSAL AGENTS FOR THE NEONATE—CONT'D

SEDATIVE-HYPNOTICS		
Phenobarbital	Loading: 10–20 mg/kg IV to maximum 40 mg/kg Maintenance: 5–7 mg/kg in two divided doses beginning 12 hr after last loading dose	Prolonged sedation possible once therapeutic levels achieved (20–25 mg/mL); depresses CNS—motor and respiratory; slow onset of action; little or no pain relief; not easily reversed; withdrawal symptoms may occur; incompatible with other drugs in solution.
NONBARBITURATES		
Dexmedetomidine HCl (Precedex)	Bolus for procedural sedation: 1–3 mcg/kg Slow IV infusion: Loading dose: 0.5 mcg/kg over 10 minutes Continuous IV infusion: Maintenance dose: 0.25–0.6 mcg/kg/hr Distribution half-life: 6 min Elimination half-life: 2 hr	Sedative, analgesic, and all anesthetic properties for mechanically ventilated preterm infants and invasive procedures in ventilated and nonventilated neonates. Minimal effect on blood pressure, heart and respiratory rates, oxygen saturation, and gastric motility.[277,302] Wean slowly to avoid withdrawal symptoms. Adverse reactions: hypo/hypertension, tachycardia, hypoxia, acidosis, elevation in temperature and blood sugar, anemia, and oliguria.
Chloral hydrate	25–75 mg/kg/dose q 6 hr PRN, PO, or PR Onset: 10–15 min Duration: 2–4 hr	Gastric irritant—administer with or after feeding; paradoxical excitement; prolonged use associated with direct hyperbilirubinemia;[245] *do not* use for analgesia; respiratory depressant; adverse effects in repeated doses to premature infants: CNS depression, dysrhythmias, and renal failure.[159] For occasional procedural sedation, although *not recommended.* Recovery from chloral hydrate accompanied by a "hangover."
Benzodiazepines		*Do not* provide pain relief. Produce sedation, muscle relaxation, amnesia, anxiolysis, and anticonvulsant effects.
Diazepam (Valium)	0.02–0.3 mg/kg IV, IM, or PO q 6–8 hr	*Do not* dilute injection; venous sclerosing; may displace bilirubin and result in kernicterus; respiratory depression; hypotension; may cause agitation; induces sleep; relaxes muscles; withdrawal symptoms may occur; no analgesic effect. This drug should be used with caution in the neonate because of its long half-life, long-acting metabolites, and preservative (benzyl alcohol).[13]
Lorazepam (Ativan)	0.05–0.1 mg/kg/dose (give over ≥3 min) q 4–8 hr	Respiratory depressant, partial airway obstruction, drowsiness; respiratory depression potentiated when opioids or barbiturates also being given; infuse slowly to avoid apnea, bradycardia, and hypotension. Rhythmic myoclonic jerking in preterm infants.

TABLE 12.13 ANALGESICS, SEDATIVES, AND REVERSAL AGENTS FOR THE NEONATE—CONT'D

NONBARBITURATES		
Midazolam (Versed)	0.05–0.15 mg/kg/dose IV (give over ≥5 min) q 2–4 hr PRN Continuous IV infusion: <32 wk: 0.03 mg/kg/hr or 0.5 mcg/kg/min >32 wk: 0.06 mg/kg/hr or 1 mcg/kg/min PO: 0.25 mg/kg/dose of oral syrup Onset: IV—1–2 min; PO—15–30 min Duration: 1 hr after single IV dose For procedural sedation: Give 0.05 mg/kg IV and repeat ×1 PRN for procedure	Same as for lorazepam; continuous IV infusion enables precise titration until sedative effect is obtained; calms agitated infant on ventilator. Rapid bolus delivery and/or use with fentanyl is associated with (1) myoclonus—rhythmic twitching of all extremities that ceases with discontinuation of drug and does not return, and (2) respiratory depression and hypotension—caution use in hypotensive and hypovolemic neonates.[212,265] A systematic review shows (1) increased incidence of adverse neurologic outcomes (e.g., grade 3–4 IVH; PVL), altered CBF; (2) longer duration of NICU stay with midazolam use; and (3) conclusion that there is insufficient evidence to support IV midazolam use as a sedative for neonates in the NICU.[295] Recent study of very preterm infants who received midazolam in the NICU found decreased hippocampal volume (and associated lower cognitive scores) and increased mean diffusivity.[127]
REVERSAL AGENTS		
Naloxone (Narcan)	0.1 mg/kg	Reverses effects of opioids (both side effects and analgesia).
Flumazenil (Mazicon) 10 mcg/kg	10 mcg/kg	Reverses effects of benzodiazepines (e.g., midazolam, diazepam, lorazepam).

*Not yet approved by the Food and Drug Administration for use in the United States.

CBF, Cerebral blood flow; *CNS,* central nervous system; *EEG,* electroencephalography; *ELBW,* extremely low-birth-weight; *EMLA,* eutectic mixture of lidocaine and prilocaine; *ETT,* endotracheal tube; *G6PD,* glucose-6-phosphate dehydrogenase; *GI,* gastrointestinal; *IM,* intramuscular; *IV,* intravenous; *IVH,* intraventricular hemorrhage; *NEC,* necrotizing enterocolitis; *NICU,* neonatal intensive care unit; *PICC,* percutaneous insertion of central catheter; *PO,* per os; *PR,* per rectum; *PRN,* as needed; *PVL,* periventricular leukomalacia; *ROP,* retinopathy of prematurity; *sub-Q,* subcutaneous; *VLBW,* very-low-birth-weight.

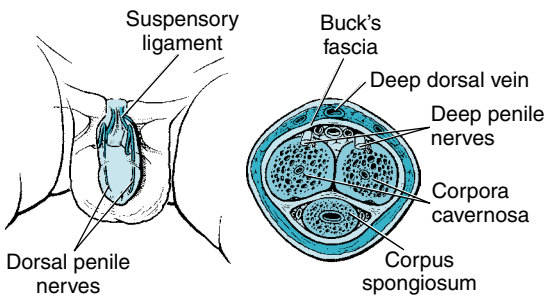

FIGURE 12.7 Anatomic landmarks for placement of a dorsal penile nerve block. (From McClain B, Anand KS. Neonatal pain management. In: Deshpande J, Tobias J, eds. *The Pediatric Pain Handbook.* St Louis, MO: Mosby; 1996.)

Eutectic Mixture of Local Anesthetic and Infiltration. EMLA is a local anesthetic cream that anesthetizes the skin and has been used for a variety of procedures (e.g., lumbar puncture, venipuncture, immunizations).[205,234,416] A study of EMLA, applied 60 to 90 minutes before lumbar puncture, showed a significant decrease in pain response during needle insertion and withdrawal but not during positioning/handling of the newborn.[228] **EMLA has been used for analgesia with circumcisions in newborns and has been shown to be efficacious.[416] However, its analgesic properties are not as effective as those of dorsal penile blocks in relieving postoperative circumcision pain.★**

A meta-analysis of the efficacy of EMLA for a variety of procedures in neonates found that EMLA diminishes pain during circumcision, venipuncture, arterial puncture, and placement of a peripheral/central IV line.[389,416] **For maximum effectiveness, EMLA should be applied and left on for at least 1 to 2 hours before starting an invasive procedure.** Unfortunately, EMLA does not appear to alleviate pain resulting from heel sticks.[142,389,416] **Infiltration of local anesthetic can help decrease pain** for procedures such as placement of percutaneous central lines, removal of Broviac catheters, and circumcision. Methemoglobinemia does not appear to be a problem when single daily doses of 0.5 g EMLA are left in place for 60 minutes,[389] but studies are ongoing to address this issue.

Amethocaine gel (lysosome-encapsulated tetracaine) is a topical local anesthetic preparation that provides more effective superficial analgesia than EMLA in adults. Amethocaine has demonstrated similar efficacy to EMLA when appropriate application times are used and has a more rapid onset and longer duration of action than EMLA.[301] Studies have documented its effectiveness in neonates as follows:

- It relieves pain during venipuncture,[213,260] IV insertion, and injections of vitamin K.[357]
- It does not relieve pain from heel sticks[315] or peripherally inserted central catheter (PICC) insertion, unless combined with morphine use.[388]
- It relieves circumcision pain.[416]
- It does not cause methemoglobinemia.
- It is effective within 30 to 40 minutes of application.

A recent Cochrane review recommends more research into the safety and efficacy of topical anesthetics, especially in the very preterm neonate and for multiple applications.[140]

OTHER MEDICATIONS

Acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs) can be helpful in providing analgesia for mild to moderate pain (see Table 12.13). These medications are more effective when administered on a regular schedule, augment the effects of opioids, and may be delayed in effect because of the rate of gastric emptying.[36,405] **Acetaminophen given 2 hours before circumcision does not reduce pain during the procedure but is effective in postoperative pain relief; repeated doses every 4 to 6 hours for the first 24 hours after circumcision are recommended.** The analgesic effects of IV NSAIDs have not been studied in preterm infants, and the adverse effects of prolonged NSAID use may lead to renal, circulatory, hepatic, gastrointestinal, and hematologic complications.[25,31] Ketorolac in a single dose has been studied in infants as young as 2 months of age and found to be safe and effective at relieving pain.[90,264] Although **use of acetaminophen as a prophylactic for febrile response to immunizations is effective, there is a significantly lower antibody response to vaccine antigen when acetaminophen is used.**[329]

Sedatives can help decrease agitation and improve comfort but do *not* **by themselves provide analgesia. Use of developmental care significantly reduces the need of VLBW infants for sedative drugs.**[411] Sedatives are appropriate to induce sleep for diagnostic procedures (e.g., MRI, computed tomography [CT]), to calm chronically irritable infants whose physiologic stability or ventilatory status is compromised by agitation, and for pain-related agitation.[27,411] Sedatives have potential toxicities, effect behavioral changes, and affect consciousness, which deprive neonates of their ability to communicate and interact with their parents, caregivers, and the environment.[412] Furthermore, the short-term and long-term effects of frequent or continuous use of sedatives on the developing brain are unknown.

Comfort/Nonpharmacologic Measures

Comfort measures alone do not relieve pain; however, their use reduces agitation, which indirectly reduces pain by promoting behavioral organization, relaxation, general comfort, and sleep.[13] Although comfort measures may prevent the intensification of pain (e.g., guarding an abdominal incision by positioning is less painful than four-point restraint), they may not relieve moderate to severe pain. Comfort measures are helpful but inadequate by themselves, considering the intensity of the noxious stimuli causing moderate to severe pain.[13,102]

Provision of nonpharmacologic interventions for neonatal pain is an evidence-based nursing practice that should be initiated by neonatal nurses and parents.[151] A recent survey of NICU nurses found that when rationing of nursing interventions (limiting or omitting interventions to particular patients) occurs, provision of comfort care is "often" and "very often" rationed.[339] Another survey

found that 64% of NICU caregivers used nonpharmacologic interventions for heel sticks or venipunctures.[50] **As partners in care, parents should be encouraged, facilitated, and educated to engage in providing comfort measures for their infants having painful procedures.[68] Nonpharmacologic interventions that have been found to offer the most comfort during a painful intervention include nonnutritive sucking, breastfeeding, skin-to-skin contact (kangaroo care) with the mother or another immediate postpartum mother,[285,293] facilitated tucking, rocking, and holding.* Who better than parents can provide these interventions? Research shows the efficacy of parental involvement.**

Initiation of skin-to-skin contact,[168] taste, and suckling was described in full-term infants receiving heel sticks for genetic screens, who experienced less crying (91%) and grimacing (84%) when being held and breastfed by their mothers.[75,167] **Numerous studies show that very preterm, healthy preterm, and term newborns (between 28 and 36 weeks' PMA) who received heel sticks experienced diminished behavioral and physiologic pain response, less crying, and quicker recovery when being held skin-to-skin (e.g., kangaroo care) by their mothers for 15 to 30 minutes before and during the procedure.** If the preterm infant's mother is not available, does provision of skin-to-skin care by the father or an unrelated woman result in lower pain responses? This question has been researched in two published studies with the following results: (1) fathers were marginally less effective than mothers in decreasing their preterm infant's pain response,[219] (2) unrelated females had a small, although not negligible, decrease in their ability to relieve infant pain, and fathers are more acceptable to the baby's mother than an unrelated female to provide this intimate care.[216] **Animal studies show that the short-term and long-term effects of repeated pain are ameliorated by the presence and ministrations of the mother;[413] perhaps the presence of the human mother or parent provides the same protection for the human neonate.*** One study found concordance between mother and infant cortisol levels during heel lance, which supports the stress regulatory role of maternal skin-to-skin care during painful procedures.[78]

Skin-to-skin care is the most effective nonpharmacologic intervention for neonatal pain,[193,321] and barriers to use need to be identified and addressed. One barrier to using skin-to-skin care and breastfeeding to relieve neonatal pain during invasive procedures such as heel stick and injections is the uncomfortable position of the professional performing the procedure. An ergonomically sound protocol using an adjustable height stool has been developed and tested in the clinical setting.[97] This protocol has resulted in a more comfortable position for the professional and more use of skin-to-skin care and breastfeeding for neonatal pain relief during the procedure.[97]

Developmental care not only prevents pain but also decreases behavioral and physiologic pain scores in preterm infants.[79,365] A recent study of a simple diaper change in VLBW preterm infants showed less physiologic response (e.g., alteration in heart rate, hypoxia, bradycardia, desaturation events) and less pain response (measured with two pain scales) when developmental care was used before and during the procedure.[365] In this study, developmental supports such as opportunities for grasping, hand swaddling, decreasing light and noise, NNS, and body support and containment were used.

NONNUTRITIVE SUCKING

NNS (e.g., the infant's own fingers or hands or a pacifier) soothes by reducing the infant's level of arousal and duration of cry while promoting the quiet alert state.[69] **NNS is effective in reducing pain in preterm infants** during heel stick, circumcision, immunizations, and ROP screening eye examinations.[59] **The effect of NNS is immediate, but the effect ceases immediately on cessation of sucking/removal of the pacifier. Combining NNS and sucrose before and during painful procedures provides a synergistic effect on pain relief for both term and preterm neonates.***

ORAL SUCROSE/GLUCOSE AND BREASTFEEDING

Distressed infants who were offered oral sucrose calmed quickly, stayed calm longer, and spent more time in a quiet alert state than did infants offered only a pacifier.[55] Sucking soothes, reduces

*References 48, 69, 79, 84, 95, 96, 99, 169, 219, 291, 300, 310, 314.

*References 56, 73, 257, 259, 298, 383, 400.

heart and metabolic rates, induces hand-to-mouth behavior, and elevates the pain threshold through opioid and nonopioid systems.[55] **Oral administration of sucrose within 2 to 3 minutes before an invasive procedure (e.g., heel stick/venipuncture, bladder catheterization, ROP examination, insertion of gavage tube, arterial stick, echocardiography, casting) has been shown to decrease crying duration, heart rate, facial activity, and EEG changes associated with pain in full-term and preterm infants.**⋆ However, in the first randomized clinical trial of 40 preterm and term infants receiving oral sucrose (24%) for peripheral intravenous catheter (PIV) placement, no efficacy in relieving the neonate's pain during the procedure was seen.[100] Replication of this study is needed before widespread application of these findings.

In these studies, the amount (0.05 to 2 mL) and concentrations (24% to 50%) of sucrose varied, but even the smallest dose administered once to preterm infants of 26 to 34 weeks of gestation reduced pain behaviors.[379] The small doses of concentrated sucrose solution used to treat neonatal pain have not been shown to cause hyperglycemia in preterm infants.[62] The AAP recommends that oral sucrose/glucose used for pain relief must be ordered and tracked as a medication.[13]

When sucrose is paired with developmental interventions such as rocking, carrying,[162] NNS,[101,422] prone positioning, facilitated tucking,[422] radiant warmth,[166] swaddling[125,128,131] or parental holding,[89,157] sucrose is more effective in decreasing behavioral pain responses. Sensorial saturation (massaging the infant's face, gently talking to the infant, and instilling a sweet solution on the tongue) is effective in newborn pain relief during minor procedures.[49] Sensorial saturation is more effective than oral glucose alone, but use of sensorial saturation without sweet solution is ineffective. A systematic review of sensorial saturation (i.e., oral sucrose, massage, and caregiver's voice) **found that it is more effective in heel stick procedures in preterm and term infants than oral sucrose/glucose alone.**[259] Combining massage and breastfeeding relieves the pain of venipuncture in term and late preterm infants.[425] In healthy full-term neonates, especially males, sensorial saturation reduces pain scores and markers of oxidative stress after heel stick.[317]

Two RCTs of the combination of NNS, oral sucrose, and facilitated tucking during heel stick in preterm infants found reduced arousal during the procedure, less crying and fussing, and better sleep than routine care alone.[422] For intrusive procedures, use of a supportive bundle (i.e., modulating the infant's state, NNS, facilitated tucking, and oral sucrose) increased premature infants' sleep time and efficiency as well as decreased bouts of awakening after the procedure.[246] **In a systematic meta-analysis of 74 studies of sucrose use for analgesia, sucrose was found to be safe, effective, and cost-effective for single painful procedures (e.g., heel stick/venipuncture/intramuscular [IM] injection) for preterm and term neonates.**[379] The addition of liposomal lidocaine to sucrose in one study did not further decrease the pain of venipuncture in healthy term newborns.[394] Despite being aware that sucrose relieves pain, only 10% of surveyed NICUs used sucrose before a heel stick, and only 11% used sucrose before venipuncture.[169] Two other surveys found that (1) only 33% of responding NICUs used sucrose before routine painful procedures, and (2) NICUs in eight European countries found poor compliance with pain management guidelines for heel stick and other invasive procedures.[262] The use of sucrose for neonatal heel lance increased by 84% after an educational intervention for NICU staff.[359]

A systematic review of eight studies for the safety and efficacy of repeated oral sucrose for repeated procedural pain found that (1) different study designs prohibited a meta-analysis; (2) repeated sucrose was effective in decreasing behavioral pain response and composite pain scores; and (3) repeated sucrose had variable efficacy in altering physiologic pain response for preterm (less efficacy in two studies) and term (less variability in one study) infants.[148] **During repeated painful procedures, combining NNS and sucrose provides better pain relief than either intervention used alone,[149] and repeated use of skin-to-skin care continues to provide pain relief for preterm infants.**[150] None of the studies reported adverse outcomes from repeated sucrose use. Neurodevelopmental outcomes were mixed and included: (1) repeated sucrose use for repeated procedural pain would not lead to poor neurologic development (two studies); (2) preterm infants less than 31 weeks' GA who received more than 10 doses of sucrose/24 hours in the first week of life had poorer neurologic outcomes than infants

⋆References 55, 212, 234, 285, 286, 329, 357, 383, 403.

receiving fewer doses; and (3) no study reported long-term neurodevelopmental outcomes. There is limited research supporting the safety and efficacy of repeated sucrose for repeated procedural pain, and multicenter, prospective, large RCTs are needed.[148]

The benefits of sucrose for pain relief have been shown to provide comfort to the infant during subsequent caregiving activities.[393] Two hundred and forty neonates were randomized to a placebo or sucrose-treated group for all needle procedures. After the painful procedure, those infants receiving sucrose reacted to a diaper change with lower pain scores than the infants receiving only a placebo. The comforting benefits of sucrose remained even after the painful procedure was complete.[393]

The Academy of Breastfeeding Medicine supports that when available, breastfeeding should be the first choice to alleviate procedural pain in neonates.[52,337] When possible, breastfeeding throughout the procedure, rather than pumped breast milk, offers more comfort because of the synergism between skin-to-skin contact with the mother, sucking, and reception of breast milk by the infant.[52] An RCT comparing breast milk with sucrose for pain relief in 71 late preterm infants (born at 32 to 37 weeks' PMA) undergoing heel lance was conducted in the Netherlands.[361] Using the PIPP assessment scale, there was no significant difference in pain scores between the preterm infants receiving breast milk (directly breastfed or bottle-fed) and those receiving sucrose. A randomized crossover study comparing expressed breast milk and oral sucrose for relief of pain associated with venipuncture found the same analgesic effect in most preterm infants; however, sucrose had better pain relief in extremely preterm infants.[92] An RCT comparing the analgesic effect of sucrose and breastfeeding during venipuncture in healthy 3-day-old newborns found equal pain relief for both methods as measured by NIRS.[338]

Salivary cortisol levels from birth to 1 year of age are 40% higher in breastfed infants compared with formula-fed infants.[79] The analgesic effect of breast milk may be a result of these higher cortisol levels.[70] **Concerns about breastfeeding as a comfort measure during painful procedures have been raised.** To explore these concerns, a study of 57 preterm infants (30 to 36 weeks' GA) were randomized to be breastfed or given a soother during a blood collection procedure.[200] **Preterm infants with mature breastfeeding skills had lower pain scores during the procedure, all breastfed infants had lower pain scores after the procedure, and use of breastfeeding as a comfort measure did not interfere with the acquisition of breastfeeding skills.**[200] A more recent study comparing breast milk and sucrose for reducing the pain of ROP examination found that preterm infants receiving 1 mL of breast milk recovered more quickly, and their vital signs returned to baseline more quickly than those preterm infants receiving sucrose.[352] Another study evaluated the use of breast milk versus swaddling versus oral sucrose to relieve the pain of ETT suctioning and found no difference between them in relieving pain.[118] Breastfeeding for immunizations lowers pain scores and heart rates, shortens the duration of crying, and prevents lower oxygen saturations.[130] When compared with skin-to-skin care and swaddling, breastfeeding was more effective than either in reducing pain of immunizations in healthy term neonates.[134]

Several studies have compared the use of glucose versus sucrose for pain relief, with conflicting results. A comparison of oral glucose versus sucrose showed that glucose solution (33% to 50%) was more effective in reducing pain response in term newborns having heel sticks.[181] Another study found that 30% sucrose solution was more effective in reducing crying time than 10% to 30% glucose solutions.[211] When (30%) oral glucose solution was given to full-term newborns undergoing venipuncture compared with (1) EMLA cream[165] and (2) subcutaneous injections,[72] the infants treated with glucose had significantly lower pain scores. **Oral glucose and facilitated tucking by parents was found to be more effective and preferred over the use of opioids in preterm infants receiving heel sticks and pharyngeal suction.**[43]

A meta-analysis of 38 RCTs found that use of 20% to 30% oral glucose solutions reduced preterm infants' pain scores and crying with both heel lance and venipuncture,[63] but was ineffective for longer procedures such as eye examnations.[103] Another more recent study of the efficacy of oral glucose (25%) versus oral sucrose (24%) use for pain relief during heel lance in 94 preterm neonates in the first 48 hours of life found comparable pain relief.[238] **Various strengths of oral glucose solutions are effective in relieving neonatal pain**: (1) a 25% solution is more effective

at relieving pain from an IM injection than NNS alone[256]; (2) 2 mL of a 10% solution relieves the pain of venipuncture and nasopharyngeal suctioning[270]; and (3) a 5% solution relieves pain, decreases crying time and heart rate, and increases oxygen saturation in preterm infants receiving IM injections.[399] Efficacy of sweet solutions to relieve neonatal pain has existed since the first trials and reviewers of a recent meta-analysis recommend that placebo/no-treatment trials be abandoned for more ethical control groups.[191]

TACTILE INTERVENTIONS

A reassuring human presence (of parents or caregivers) during painful procedures for all neonates in the NICU is *mandatory*.[47] Body containment of extremities in a flexed position (e.g., holding, swaddling, nesting; providing an opportunity to grasp a finger or pacifier) decreases gross motor movements that contribute to the infant's increased level of arousal, reduces physiologic and behavioral stress, facilitates energy conservation in the preterm infant, and lowers pain scores.[69,84,395] **When swaddling and skin-to-skin care were compared for the relief of pain during venipuncture in premature infants, pain was relieved equally between the groups when compared with the control group.**[122] **Premature infants nested in the prone position experienced lower pain scores and salivary cortisol levels after a heel lance procedure compared with nesting in the supine position.**[225] Improper body positioning contributes to discomfort and pain. An RCT combining five tactile interventions (i.e., swaddling, side/stomach lying, shushing, swinging, and sucking) for infant immunizations resulted in less crying time and lower pain scores; these outcomes were greater than those obtained with sucrose alone.[190]

Facilitated tucking—gentle containment of flexed extremities in the midline on the trunk while side-lying or supine—during a painful procedure (e.g., heel stick) results in lower heart rate, shorter crying time, less sleep disruption, and fewer sleep-state changes.[102,193,321] One study of facilitated tucking and usual positioning for heel stick found a "surprising" result: no difference between the two positions in pain intensity for the premature infants.[112] **Pairing facilitated tucking with breast milk and NNS effectively reduces pain in premature infants during heel lance.**[316] **Several studies of facilitated tucking during endotracheal tube suctioning have been conducted with the results of lower pain scores in the preterm infants receiving facilitated tucking,** when compared with no intervention.[7,261] Facilitated tucking (provided by parents for endotracheal tube suctioning) showed that participation by parents was a safe, effective pain management strategy that provided parents with an active role in their infant's pain care and was also preferred by parents.[42] A more recent study by the same researchers found **lower pain scores with oral glucose and facilitated tucking by parents during heel stick and pharyngeal suction in very preterm infants.**[43] Facilitated tucking was perceived positively by mothers who were either internally motivated to provide it or were externally motivated by nurses who suggested their involvement.[41] However, two other studies of facilitated tucking[157] and facilitated tucking and oral sucrose[89] found that using facilitated tucking alone was less effective in pain management.

Use of a 2-minute massage of the ipsilateral leg before heel stick in preterm infants was safe and resulted in a decreased pain response (decreased pain score and heart rate) compared with nonmassaged preterm infants.[214] Massage of the arms and hands of infants for 2 minutes before an invasive procedure such as heel stick or other needle stick, including venipuncture, has been shown to reduce pain scores.[84,85] A more recent pilot study of the use of vibration on the lateral aspect of the leg during heel lance resulted in lower N-PASS scores and more stable heart rate during and 2 minutes after the procedure when compared with the control group, without any physiologic or behavioral adverse effects.[274]

Motoric boundaries (e.g., containment of extremities) assist a preterm infant to maintain a more secure, controlled response and facilitate self-regulation. **Therapeutic interventions include the use of positions that support flexion and restraint in physiologic position, periodic release of restraint and exercise of extremities, gentle change in body position, and positioning to guard operative sites.** Along with comfort measures, minimizing stimulation in the NICU environment enables a neonate who is agitated or in pain to use internal and external resources in organizing his or her behavior and develop self-soothing strategies (see Chapter 13). Individualizing care and handling to the infant's likes and dislikes and listing

these at the bedside help maintain consistency of care and build trust in these developing neonates.

Picking up, holding, and rocking provide tactile soothing, vestibular stimulation, and the calming effect of rhythmic, repetitive movement. Use of massage, rocking, and water mattresses provides tactile, vestibular, and kinesthetic stimuli that modify and accelerate behavioral state control and decrease stress behaviors (see Chapter 13).

AUDITORY INTERVENTIONS

Four small studies of the use of music therapy to relieve the stress and pain of procedures evaluated physiologic and behavioral responses in a total of 75 infants.[9] In two studies, intubated preterm infants were exposed to music/no music during routine suctioning. **Positive results in the music-exposed preterm infants included (1) improved oxygen saturation, (2) heart rates between 120 and 160 beats/min for a longer period, (3) more time in sleep state, and (4) quicker recovery time after suctioning.**[64,87] Two other studies exposed irritable, agitated, infants in a naturally occurring inconsolable crying episode to music and measured their responses. Again positive results of music therapy included (1) improved oxygen saturation, (2) better respiratory and heart rates, (3) state change to drowsy or quiet alert, and (4) fewer crying episodes.[93,229] A more recent study of **recorded maternal voice played during heel lance resulted in significantly lower PIPP scores and less oxygen desaturations with no side effects in the group of preterm infants hearing their mothers' voice,** when compared with the control group.[86] **Playing the same music that mothers listened to while pregnant resulted in less pain response to heel lance in preterm infants.**[239] Breastfeeding full-term healthy neonates during a heel lance procedure effectively reduced their pain response, but the addition of music therapy did not enhance pain relief.[423] Additional data from well-designed studies are required before use of music therapy for preterm infants during painful, stressful conditions can be recommended.[9]

Combination of auditory therapies and other nonpharmacologic interventions is more effective than use of single therapies to relieve pain. A randomized study of 62 preterm infants using a combination of music and touch during painful procedures found similar cortisol concentrations at birth and at 2 weeks of life between the experimental and control groups. However, at the beginning of hospitalization and after 2 weeks, **beta-endorphin levels were higher and the PIPP scores lower in the group exposed to the combination of music and touch.**[330] **Stable neonates with a PMA of 35 weeks who were exposed to recorded music and sucrose for heel stick procedure were in less pain than when the interventions were administered separately.**[354] Preterm infant pain was relieved during venipuncture with the use of eye covering and playing intrauterine ambient sounds.[6]

COMPLEMENTARY HEALING MODALITIES

Complementary healing (e.g., therapeutic touch [TT], acupressure, acupuncture, Reiki) is gaining increasing interest among neonatal health care providers. Little research exists, but clinical reports have depicted the benefits of pain relief with integration of these modalities. A study conducted with registered nurses (RNs) who provided TT to preterm infants (25 to 37 weeks of gestation) revealed that the infants' responses to TT included (1) decreased heart and respiratory rates; (2) enhanced restful periods; (3) improved sucking, swallowing, and breathing; and (4) a greater ability to interact with the environment.[187] Two more recent studies of the use of TT with a painful procedure have been conducted. In the first study, 10 preterm infants (34 to 40 weeks' conceptual age) received TT during a low-intensity sensory punctuate stimuli and responded with an increase in cerebral oxygenation.[202] The researchers concluded that **TT may have a protective effect on the autoregulation of cerebral blood flow in the preterm infant during painful stimuli.**[202] Another randomized study of the effects of TT before and after procedural pain (heel lance) found no comforting effect for 27 preterm infants less than 30 weeks' GA.[217] These researchers recommended use of other tactile interventions for pain relief. Reiki uses healing energy to restore balance within the body. Reiki has been used for neonates experiencing neonatal abstinence syndrome without adverse effects and resulted in a slight decrease in heart rate, which may signify relaxation.[331]

Acupuncture and acupressure may be safely used to treat pain, agitation, and drug withdrawal in the neonate.[160] A retrospective review

of 10 hospitalized infants exposed to acupuncture found a decrease in the use of sedatives and analgesics for agitation, successful weaning from ventilators, and transitioning to oral intake after oral aversion without adverse effects.[153] Use of acupuncture in neonates in one NICU decreased the amount of medication needed for agitation and withdrawal, was well tolerated, and was without complications.[161] In a small RCT, acupressure before heel lance was shown to shorten the procedure and the duration of crying in preterm infants.[1] However, in another study, use of noninvasive electrical stimulation of acupuncture needles in term infants receiving heel sticks was not shown to be effective in procedural pain relief.[284] Use of noninvasive magnetic acupuncture on the outer ears of newborns (mean gestational age 34 weeks) receiving heel stick procedures resulted in lower pain scores.[82] Acupuncture used for 2-week-old to 8-week-old infants with colic resulted in less crying and less colicky crying than standard care by the second week of treatment.[247] More research is needed to validate the use of these modalities for pain management.[153]

Activation of cutaneous sensory nerves with a transcutaneous electrical nerve stimulation (TENS) unit and application of thermal topical skin refrigerant blocks transmission of peripheral pain impulses from procedural pain. Low-frequency, monotonous sounds (e.g., heartbeat, vacuums) quiet the infant and increase behavioral organization. Use of music (see Chapter 13) and recordings of family voices soothe term and preterm infants, resulting in fewer state changes, less time in the arousal state, and increased behavioral organization. However, during circumcision, music (with or without a pacifier) is not an effective distraction or soothing strategy for relief of the pain of the procedure. Another recent study showed that **preterm infants presented with a familiar odor during venipuncture exhibited significantly less crying and grimacing,** compared with the preterm infants presented with an unfamiliar odor or no odor.[164] However, scents (such as amniotic fluid, breast milk, or maternal odors) presented to premature infants during a heel stick procedure did not reduce neonatal pain scores,[233] yet **the odor of mother's own milk did decrease pain scores during venipuncture and crying after the procedure.**[46] Another RCT of preterm infants exposed to breast milk odor, or recorded maternal voice or incubator cover during peripheral intravenous cannulation found that these interventions were simple, safe, and supportive during painful procedures.[5]

END-OF-LIFE CARE

When the decision is made to terminate or not begin aggressive medical intervention, the neonate receives end-of-life care, also known as *comfort care* or *palliative care* (see Chapter 32). Neonates who receive end-of-life care are at the threshold of viability, have multiple congenital anomalies that are incompatible with life, or are not responding to NICU interventions (e.g., deterioration in condition despite medical efforts).[320,336]

End-of-life care should combine comfort measures, pharmacologic management, developmental care (see Chapter 13),[383] and spiritual and psychosocial support for the neonate and family (see Chapters 29 and 30).[77,80,320,382,383] Parents are acutely aware of (and able to recall) their infant's suffering, including perceiving the infant's pain at the end of life.[360] The family is provided a quiet, private, homelike area in which to touch, hold, and interact with their terminally ill neonate. Use of skin-to-skin care; soft, soothing music; dimmed lighting; infant massage; holding; and rocking provide both a comforting environment for the infant and family, as well as parenting and comforting opportunities.[83,383] Parents, siblings, and extended family members remain with their infant during and after death. Clergy may be present for family support and may perform a religious service, such as a baptism or blessing.

For comfort care, all invasive procedures, including measurement of vital signs, monitors, machines, and artificial feeding, are discontinued. The infant, cleaned and wrapped in a warm blanket, is held by his or her family. Intravenous access may remain in place for administration of pain medications or sedatives. **Medication is administered in sufficient doses to provide comfort, relieve pain, and ensure that the infant does not suffer at the end of his or her life.**

In the earliest study documenting the use of analgesia for dying infants whose life support was withdrawn or withheld, 165 deaths in a university-based NICU were reviewed.[313] Opioid analgesia

was administered to 84% of infants when life support was withdrawn or withheld. Infants with major congenital anomalies (93%) and necrotizing enterocolitis (100%) were more likely to receive opioids than were ELBW infants (66% to 83%). Overall, opioid analgesia was administered to at least 65% of infants. Reasons for life support discontinuation also influenced administration of opioids: (1) futility of treatment (84% medicated), (2) severe lifelong impairment (85% medicated), and (3) suffering caused by treatment (100% medicated). The median dose of opioids was within the usual pharmacologic range in 64% of infants and greater in 36%. Of the infants receiving a higher dose, 94% had previously been receiving an analgesic and may have needed a higher dose as a result of tolerance. The median time until death from the discontinuation of life support was 18 minutes for those who received the standard dose and 20 minutes for those who received the higher dose.

A recent study of end-of-life care found that 85% of infants received analgesic and/or sedative medications before the withdrawal of treatment, 55% at withdrawal and 60% after treatment was terminated.[139] The majority of medication was given by continuous intravenous medications for sedation and pain related to diagnosis. Use of nonpharmacologic interventions for end-of-life care/pain was minimally documented in this exploratory, descriptive study. If there is no intravenous access, intranasal fentanyl has also been used in palliative care with dying newborns with no complications such as chest rigidity and drug-related apnea. Neonatal restlessness and labored respiratory efforts were calmed after the intranasal fentanyl, with the average time from last dose to death of 61 minutes.[188]

A survey of hospital staff providing pediatric palliative care found that 50% of physicians and 30% of nurses reported feeling inexperienced in pain management.[99] Providers also shared how personally distressing it is to witness a child's suffering, especially when pain relief was possible but not available or delivered. In the same study, families also described their anguish in watching their child experience and suffer any amount of pain and discomfort. **Unlike the health care providers, families thought that everything had been done to alleviate their child's pain.** Another recent study found that insufficient education in pain and palliative care of pediatric care providers was a barrier to use of palliative care in children.[113]

COMPLICATIONS

A neonate's complex behavioral response to pain has both short-term and long-term ramifications (Box 12.7).

These behavioral changes may disrupt parent-infant interaction and attachment, adaptation to the postnatal environment, feeding behaviors, and growth.[29,408] **An alteration in brain development and maldevelopment of sensory systems can occur when distorted or inappropriate sensory input occurs during a critical period in development.** Because of a **neonate's memory, painful experiences increase the infant's sensitivity to subsequent medical encounters.** These initial experiences may affect the development of attitudes, fears, anxiety, conflicts, wishes, expectations, and patterns of interactions with others.*

Younger infants are more susceptible to long-term consequences (see Box 12.7) because there is heightened sensitivity at earlier developmental stages. In the most immature preterm infants, lower pain thresholds and the lack of inhibitory controls influence hypersensitivity.[171] **When tissue injury occurs early in development, increased pain sensitivity develops both at the site of the damage (primary hyperalgesia) and in the surrounding skin (secondary hyperalgesia) because of hyperinnervation at the site.**[171,319] The lower pain threshold of the more preterm infant is also influenced by repeated exposures.[171] The consequences of this altered excitability include (1) perceiving nonnoxious tactile stimuli as noxious,[9] depending on the number of invasive procedures in the previous 24 hours[175]; (2) systemic responses of chronic pain and discomfort; (3) associating earlier pain with decreased behavioral responses to pain; (4) variable physiologic responses[171]; and (5) lower pain thresholds, pain tolerance, and higher pain intensity in adolescence.[65,404] **Ongoing studies demonstrate the importance of infant and family factors (Fig. 12.8) in ameliorating developmental alterations initiated by early and repeated pain exposures.**[171]

BOX 12.7 LONG-TERM CONSEQUENCES OF REPETITIVE PAIN*

- Less physiologic stability (e.g., alterations in heart and/or respiratory rates and blood pressure)
- Less postnatal growth (less weight gain and lower head circumference) in very preterm infants[401,408]
- Alterations in basal cortisol levels in extremely low gestational age preterm infants at 8 and 18 months that suggests a "resetting" of the endocrine stress systems with potential for negative implications for neurodevelopment and later health
- Cortisol dysregulation associated with lower IQ in 7-year-old boys born very preterm (but not girls) who have the brain-derived neurotropic factor gene variant[81]
- Alterations in cerebral blood flow,[266] increasing the risk for intraventricular hemorrhage and periventricular leukomalacia; altered white matter microstructure[370]
- Significantly thinner cerebral cortex, predominately in the frontal and parietal lobes[333,370]
- Inappropriate sensory input (pain) disrupts neural activity, and chronic activation of neuroendocrine system results in abnormal brain development.
- In extremely preterm neonates, disrupts the development of brain regions involved in somatosensory processing (i.e., thalamic volume loss; reduces thalamocortical maturation), which results in poor cognitive and motor function at 3 years corrected age.[126]
- Hyperinnervation (e.g., neural reorganization in the periphery and the spinal cord) associated with increased pain behaviors such as allodynia and hypersensitivity
- Altered pain responsiveness:
  - Heightened responsiveness to pain (hyperalgesia)/lower pain threshold
  - Decreased responsiveness to pain (associated with more exposure to painful experiences) in the NICU and later in infancy and childhood
- Reduced tolerance, and lower pain thresholds and higher pain intensity in adolescence (after being born preterm)[404]
- Altered behavioral and neurodevelopment[94,163]
- Temperamental difficulties at 3 months of age[287]
- Altered hypothalamic-pituitary-adrenal (HPA) axis function up to school age in children born very preterm, especially in males.[60]
- Shortening of telomere (region of repetitive nucleotide structure at each end of a chromosome) length in very preterm infants that is associated with repeated NICU pain and stress[327]

Alteration of parent-infant interactions and relationships; temperament and pain expression

NICUs with a higher level of infant pain management are associated with better neurobehavioral performance (i.e., better attention and arousal, less lethargy, and better reflexes as measured by the NICU Network Neurobehavioral Scale [NNNS]) in very preterm infants.[286] Studies to evaluate the long-term effects of pharmacologic and comfort interventions are also needed.[61,171,182,183,278,334,408]

As mentioned, unanesthetized surgery and/or unrelieved pain causes suffering that might itself be a risk to life.[29] Maintaining metabolic homeostasis by the appropriate use of anesthetics and analgesics improves postoperative outcome by preventing (1) protein wasting, (2) electrolyte imbalance, (3) impaired immune function, (4) sepsis, (5) metabolic acidosis, (6) pulmonary and cardiac insufficiency, (7) hypermetabolic state, and (8) death.[17,30,120,158] **Increasing evidence confirms that exposure to prolonged, severe, or untreated pain increases morbidity and alters brain development and subsequent behavioral and physiologic responses to pain.**[13,16,19,20,22,29,66,138,172,268,408]

Opioid analgesics may produce respiratory depression severe enough to require mechanical ventilation. Naloxone (0.1 mg/kg IV or IM) is the specific antidote for opioid overdose (see Table 12.13). Lower doses of naloxone (0.001 to 0.01 mg/kg IV or IM) can be used for moderate respiratory depression. Complete opioid reversal with 0.1 mg/kg naloxone increases agitation and stress response in neonates with ongoing pain. Subsequently, it is more difficult to manage the neonate's pain until the effects of the naloxone wear off. **Lower doses of naloxone should be used and the dose titrated to prevent this outcome. An ampule of neonatal naloxone should always be immediately available with the appropriate dose precalculated on the infant's emergency card. Flumazenil is a specific antagonist for the benzodiazepines and should be used to treat respiratory depression (see Table 12.13). Respiratory depression may produce hypoxemia, so a pulse oximeter should be standard equipment along with cardiorespiratory monitoring.**[13,384] **All equipment for assisted ventilation should be at the bedside.**[13]

An overdose of local anesthetics can cause seizures, ventricular tachycardia, bradycardia, and cardiovascular collapse. Toxic doses for

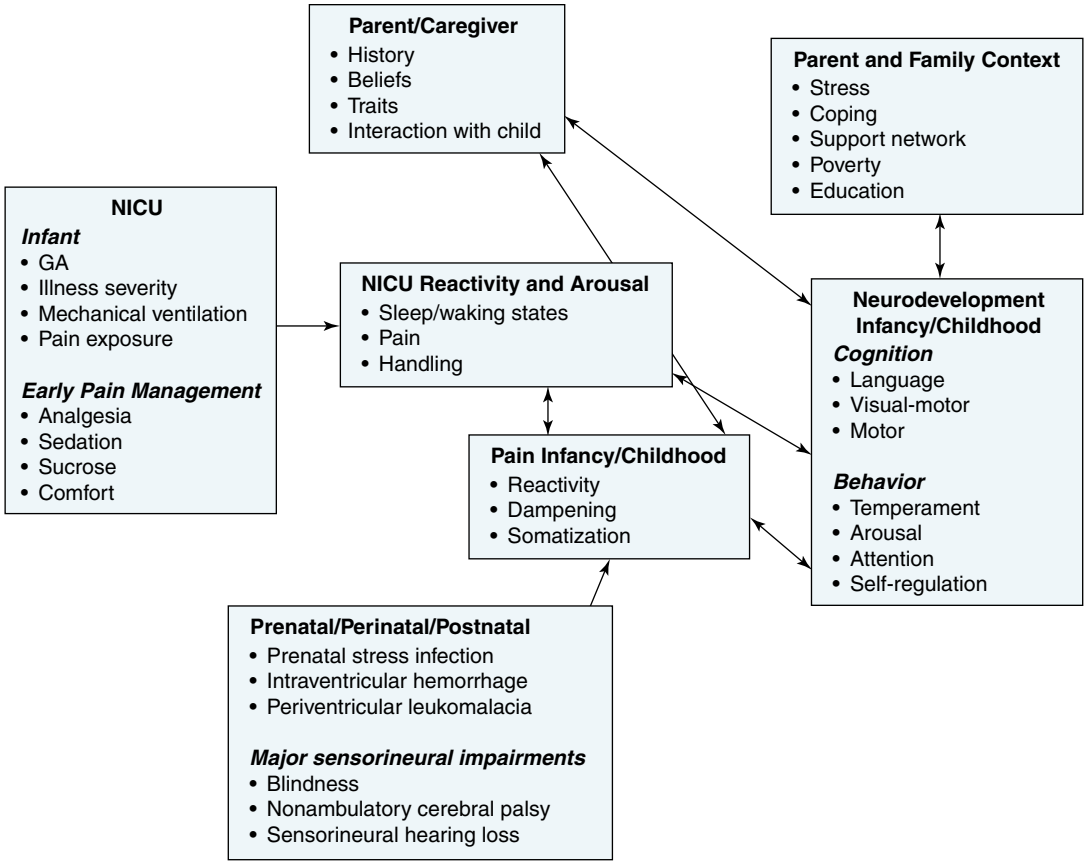

FIGURE 12.8 Model of long-term effects of pain showing complex, interactive, bidirectional relationships among multiple biologic and environmental factors. *GA,* Gestational age; *NICU,* neonatal intensive care unit. (From Grunau R. Early pain in preterm infants: a model of long-term effects. *Clin Perinatol.* 2002;29:376.)

neonates should be carefully calculated, and lower doses should be administered. Benzodiazepines or phenobarbital can be used to treat refractive seizures; cardiopulmonary resuscitation (CPR) and defibrillation may be necessary to treat cardiovascular complications. **Administration of intralipids 20% in a dose of 1 to 2 mg/kg/day is a specific antidote for cardiac toxicity from local anesthetics. Patients who are receiving epidural analgesia for postoperative pain control should be monitored for signs of potential CNS toxicity** (e.g., irritability, jitteriness, twitching, myoclonic jerking). If an opioid is being administered with the local anesthetic infusion, then respiratory depression is also a possibility, and patients should be monitored as described. Clonidine in the epidural infusion can lead to hypotension and decreased heart rate. Other extremely rare complications of epidurals are nerve injury and/or paralysis.

Hematoma formation can occur (1.2%) with the placement of a dorsal penile nerve block. Using a ring block usually avoids this problem. **Epinephrine-containing solutions must *never* be used, because this can lead to compromise of the blood supply to the penis and severe tissue damage.**

Tolerance and Withdrawal

***Tolerance* is the need for escalating doses of drug to achieve the same effect.** Tolerance (1) occurs sooner with the use of synthetic opioids (e.g., fentanyl) than with naturally occurring opioids (e.g., morphine); (2) is related to the duration

of use—the longer the use (>5 days),[25] the more likely tolerance is to develop (use for less than 72 hours usually is not associated with tolerance); (3) develops more rapidly with continuous infusions versus intermittent therapy; (4) may develop more rapidly in preterm neonates than in term neonates; and (5) occurs more often in males than in females.[24,383,384,405]

Physical dependence **is the state in which continued drug is needed to prevent the signs of withdrawal.**[405] Withdrawal arises when discontinuing the drug causes symptoms such as irritability, diarrhea, tachycardia, hypertension, insomnia, restlessness, diaphoresis, or palmar sweating and muscle twitches. **Addiction occurs when there is psychological and physical dependence** and is associated with active drug-seeking behavior and use (abuse) of the drugs for nonmedical conditions. **Infants are incapable of this level of cognition and therefore cannot become addicted to analgesics and sedatives.**[160,373] Tolerance, dependence, and withdrawal can occur with opioids and benzodiazepines. **Medications should not be restricted because of fear of addiction. Family members should be made aware of this.**

Critically ill infants sometimes need long-term infusions of opioids or benzodiazepines to provide analgesia and sedation. ECMO and prolonged mechanical ventilation are two examples of this situation. Use of fentanyl for more than 5 to 7 days can lead to tolerance and withdrawal (also known as *opioid abstinence syndrome;* see Chapter 11). **Tapering doses to wean neonates from opioids will depend on the duration of the medication's use and the infant's response to the changes.** For short-term use, decrease opioid dose by 25% to 50% of the drug dose per day, so that the drug is discontinued within 2 to 3 days. For longer opioid use, decrease doses by no more than 10% to 20% every 1 to 3 days. Infusion regimens can be changed to intermittent administration before the drug is discontinued.[384] **Oral forms of opioids should be used whenever possible.** Shorter-acting medications such as fentanyl and midazolam can be switched to methadone and lorazepam, which have the advantage of being longer acting and being available in an oral form. **Addition of oral clonidine 1.5 to 3 mcg/kg twice daily can help alleviate withdrawal symptoms. The dose of clonidine can be titrated up to 5 to 10 mcg/kg twice daily as tolerated.** The side effects of clonidine include bradycardia, hypotension, and sedation. In addition, minimal handling and a quiet, darkened environment help decrease external stimuli. A pacifier, swaddling, and holding are effective comfort measures.

PARENT TEACHING

Mothers of neonates in the NICU report dissatisfaction with pain management, worry about their infant's pain and pain management, and a desire to participate in comforting their distressed infants.[141,145,392] A multicenter international study is the first to provide a comprehensive description of parental concerns, distress, information needs, and involvement in care of their infant in pain.[141] Both mothers and fathers from 11 NICUs participated in completing questionnaires: (1) both parents reported a moderate degree of stress; (2) stress responses were slightly higher for mothers; (3) mothers' stress was related to the sights and sounds of the NICU and their inability to perform their maternal role; and (4) mothers reported higher anxiety levels. Specific parental concerns about pain included (1) effects of pain on the infant, (2) immediate medical problems caused by pain, and (3) long-term effects of pain. Parents reported few worries about the effects of pain medications. Parents rated their infant's worst pain as moderate to severe and had expected there to be less pain and that their infant would receive a high degree of pain relief.

Pain management is a priority concern for parents. Seeing their babies in pain and being unable to protect them from pain is very stressful.[223] A recent study found that when preterm infants are exposed to a greater number of invasive procedures, their mothers' memories of their infant's pain during these procedures is associated with increased PTSD symptomatology.[409] Comparing maternal and paternal responses of their knowledge, self-efficacy, and satisfaction with their infant's pain management in a single NICU resulted in findings of adequate knowledge by parents, moderate to high self-efficacy, and satisfaction with their infant's pain management.[406] **The majority of parents in this study preferred to receive written information about pain and wanted the opportunity to be present and comfort their infant during and after painful**

procedures.[406] Another study found that 97% of surveyed parents accessed the Internet daily, preferred the Internet for information rather than books or brochures, and wanted more information on how they could comfort their infant and more participation in comforting their infant during painful procedures.[308]

An RCT to increase parental involvement in pain management for their NICU infants was conducted to evaluate reduction in parental stress and postdischarge parenting ability.[144] Although NICU-related stress was not reduced, parents who received information about pain and comforting techniques were better prepared to be active participants in their infant's pain care and have more positive views about their parenting role after discharge.[144]

Parents in two studies received primarily verbal information (i.e., 81%[145] and 58%[142]) rather than any written (4%)[142] information about pain and pain relief. Nurses (41%), more commonly than physicians (28%), provided information about pain to parents.[142] Although parents were usually satisfied with the pain information they received, 30% indicated that they wished they had received more information about infant pain.[142] Fifty percent of parents reported that they were shown how to recognize if their infant was in pain and how to provide comfort.[145] In the more recent study, 18% of parents were shown how to assess pain in their infant, and 55% were shown how to comfort the infant.[142]

In the multicenter study, 57% of parents reported that they would prefer to be with their infant during procedures.[145] Yet most parents had never (52%) or not often (24%) been asked about their preference. Parents who would have preferred to be absent during procedures reported higher stress levels, anxiety, and current worry about pain for their infant than did parents who preferred to be present. **Eighty-seven percent of parents stated that they wanted greater involvement in their infant's pain care.** Generally, the parents in this survey reported a high level of satisfaction with their infant's pain care.[142]

Parental stress was related to (1) their estimation of infant pain, (2) their worries about infant pain, and (3) their degree of satisfaction about information about infant pain care.[142] The influence of these factors on the degree of parental stress were "strikingly consistent" among the diverse NICUs in the study. More research is needed to determine whether (1) more parental information, involvement, and satisfaction with pain care reduces parental stress; (2) greater parental involvement in pain care improves parent-infant attachment, interaction, competence, and confidence after discharge; (3) culturally and socially diverse families respond similarly; and (4) barriers exist to providing more parental information and facilitating more involvement.[142]

The lack of information (Box 12.8) and passive involvement of parents in pain care for their infant[12,142,323,362] should be addressed in the NICU. Parents are excellent observers of their infant and often recognize when the infant is experiencing pain, even before the care provider does.[276] The health care provider loses credibility and parental trust when he or she does not acknowledge and effectively treat the infant's pain.[276] Listening to parents' concerns about their

BOX 12.8 PARENT/CAREGIVER TEACHING
PAIN IN NEWBORNS

- The body that is in pain is "stressful" to the infant.
- The body that is in pain cannot grow, cannot heal, and may not survive.
- Newborn infants, both full-term and preterm, feel pain in the NICU. Remember that pain (and repeated pain) may have long-term consequences.
- Newborns in the NICU deserve to have their pain assessed, adequately treated with medications and comfort measures, and re-evaluated to determine whether the therapies have relieved their pain.
- Newborn infants, both full-term and preterm, ***do not*** become "addicted" to medications that are used for pain relief, although they may develop tolerance and withdrawal, which can be managed by the health care provider.
- Comforting distressed infants and children is basic to the maternal/paternal role.
- No research or reports have documented a newborn forming a negative association with the mother/parent while she or he was providing comfort during a painful event.
- Research shows that skin-to-skin contact with the mother before, during, and after a painful procedure decreases the pain response in preterm and full-term infants.[168,355]
- Breastfeeding full-term and preterm newborns before, during, and after a painful procedure markedly decreases their pain response (e.g., crying, grimacing, less tachycardia).[167,355] Other nonpharmacologic interventions that can be used by parents include NNS, oral sucrose, facilitated tucking, swaddling, and recorded music.[122,323]

infant's pain, including the parents' report of their assessment, communicating the plan of care about analgesia or sedation, and offering the rationale behind the medication decision-making help the parents become active participants in the management of their infant's pain.

Parents of medically fragile infants have identified specific sources of stress in the NICU: (1) parental role alterations, especially inability to comfort the infant, and (2) infant appearance and behavior, especially pain and difficulty breathing. **The most common fear expressed by parents is that their infant will experience undue pain while being cared for in the NICU.** Three years after their infant's NICU experience, mothers can still recall the pain and procedures that their infants endured.[417] The care provider's sensitivity to the neonate's pain and advocating for pain relief are comforting for parents.[141,276,415] Teaching parents to report their assessments and encouraging parents to comfort their infants will help them in the attachment process and foster a trusting relationship with the health care team. **Comfort measures are ideally provided by parents, who may then actively participate in their infant's pain relief.**[12,40,47,105,144,323]

13 THE NEONATE AND THE ENVIRONMENT IMPACT ON DEVELOPMENT

SANDRA L. GARDNER AND EDWARD GOLDSON

For centuries, the newborn baby has been considered a tabula rasa—a blank slate on which parents and the world "write" to create the individual. In the first half of the 20th century, research emphasized the contributions of the environment in shaping the infant and child. Only recently has the individuality of the infant been recognized as a powerful shaper of the caregiver, the care given, and thus the environment.

This chapter explores the psychosocioemotional development of term and preterm neonates. **Infant development is a reflection of the dynamic relationship between endowment and environment.** Understanding of the dynamic relationship between endowment and environment is enhanced by a review of the principles of development in Box 13.1. First, the developmental tasks of infancy are presented, along with the influences of endowment and environment on mastery. Home and family life, in which most infants are raised, is then contrasted with the experiences of babies in the neonatal intensive care unit (NICU). Intervention strategies to normalize the NICU environment also are presented, along with strategies for parent teaching. The developmental and social outcomes of infants exposed to the NICU are then presented.

DEVELOPMENTAL TASKS OF THE NEONATE AND INFANT

Neonates begin extrauterine life able to attend with their sensory capabilities, communicate with their environment through a complex repertoire of behaviors, and store remembrances. Infancy (birth to 12 months) is the time of further development and maturation of these capabilities through self-mastery and adaptation to the extrauterine environment.

Biorhythmic Balance: The Primary Developmental Task of Newborns

In utero, the fetus depends on the mother's physiologic systems to regulate its own systems. At birth, the neonate's basic physiologic needs (i.e., feeding, elimination, cleaning, heat balance, stroking, communicating) are met in new and different ways. The process of emerging from a physiologically dependent state as a fetus into a physiologically independent neonate introduces new variables for both mother and infant in the development of their extrauterine relationship.

The primary task of newborns is to establish independent biorhythmic balance by stabilizing the function of sleep-wake cycles, respiratory and heart rates, blood chemistry levels, metabolic processes, and eating patterns. Biorhythmic balance is the establishment of innate, cyclic recurrence of biologic functions. **Although biorhythmic balance is internally determined, caregiving interaction between newborn and parent or caregiver either facilitates or disturbs this transition.**[334] After birth, this balance is facilitated by contact with familiar surroundings (the mother's body) (see Chapter 5).

When immediate recontact between the neonate and the mother is not possible (e.g., when the mother refuses or is ill) or when the neonate is

BLUE type highlights content that is particularly applicable to clinical settings.

BOX 13.1 PRINCIPLES OF DEVELOPMENT

- Development is a continuous process of increasing complexity from conception to maturation (i.e., development also occurs in utero).
- Growth (i.e., number and size of cells) and development are influenced by genetic traits and environmental experiences.
- Development occurs in an orderly sequence largely determined by readiness or maturation.
- The sequence of development is the same in all children; the rate of development is individual.
- Development is cephalocaudad (head→foot), centripetal (from the outside toward the center), and from gross to specific (e.g., peripheral→central→lateralization).
- The first 5 years are marked by a rapid period of growth of all body systems. During this time, behavior patterns are developed and are greatly influenced by the environment.
- Environmental stimulation influences conceptual development and has an effect on cognitive function.
- Learning occurs when behavioral change does not result solely from maturation; learning is facilitated by reinforcement of the behavior through experience.
- Development of the infant occurs within the framework of interaction with a caregiver and the family.
- Equifinality postulates multiple paths to the same developmental outcome: complex developmental patterns rather than simple development milestones.

Modified from Barnard K, Erikson M. *Teaching Children With Developmental Problems.* 2nd ed. St Louis, MO: Mosby; 1976; Illingworth RS. *The Development of the Infant and the Young Child.* 5th ed. Edinburgh, UK: Churchill-Livingstone; 1972.

preterm or sick and requires immediate emergency medical intervention or transport, the primary "mothering" role is temporarily transferred to professional (medical and nursing) care providers. Interactional dynamics necessary for reestablishing biorhythmic balance and fostering the psychosocioemotional development of the newborn also are transferred into the NICU.

Just as in a home or family setting, the infant's personality and behavioral development are affected by the nature and dynamics of the stimuli and relationships encountered with the staff in a nursery or NICU setting. The level of function or dysfunction in the biorhythmic balance affects the neonate's long-range outcomes and is interwoven with the development of a sense of self and a basic trust.

Sense of Self

In utero, the fetus has continuous tactile-kinesthetic stimulation that contributes to the development and maturation of the central nervous system (CNS) and establishes kinesthesis as the most natural pathway for growth and development. The interaction between infants and the extrauterine environment also is kinesthetic. However, tactile contact and vestibular stimulation are also essential for (1) the development of a physical identity (body image), (2) organization and sorting of stimuli, (3) coordination of sensorimotor skills, (4) a psychological and social sense of self, (5) normal neurophysiologic development (physical and cognitive abilities), and (6) emotional stability and temperament.[52]

Daily caregiving and interactions such as feeding, diapering, holding, and playing with the parent or caregiver provide infants with reciprocal stimuli for further developing their identity. Through the manner in which the infant is handled, he or she receives messages about how the caregiver feels about him or her.

Response cues given by an infant affect the caregiver's response to and interaction with the infant.[52] As the infant quiets in response to caregiving, the parent is positively reinforced to continue nurturing and soothing behavior. Withdrawal, irritability, or continuous crying is perceived by the caregiver as rejection or inadequacy and may result in parental frustration, depression, withdrawal, and decreased interaction. Repeated exposure to the caregiver's style and nonverbal messages thus enables the infant to adapt to these patterns of caregiving. **The self of the infant is formed through interaction with people and objects within the environment.**

Because the nature (amount and type) of the kinesthetic interaction between infants and caregivers influences how infants develop and mature, a lack of appropriate stimulation can have long-term negative consequences. **Stimulus deprivation results in impairment or retardation of, or deviancy in, skill development for productive living.** The degree or extent of impairment depends on the severity of the restrictions and limitations encountered.[52,392] Institutionally reared infants who had minimal contact and no social interaction with their caregivers displayed significant developmental delays.[344] The effect of kinesthetic deprivation was seen in the minimal expression of social skills

(e.g., cooing, babbling, crying), minimal interest in objects in the environment, increased self-stimulation (rocking), touch aversion, flat or withdrawn affect, and retarded mental and motor development. **Environmental deprivation may also affect the physical growth of the infant.** Montagu[287] stated that infants can overcome mental and nutritional deprivation as long as they are not deprived of tactile stimulation.

The Psychosocial Task: Trust Versus Mistrust[122]

Trust versus mistrust in self and the environment is solidified during infancy.[52,122] The response of the environment from the moment of birth is the means through which neonates continue to develop trust in themselves and decide on the reliability of their new environment. **Two major factors influence the development of trust versus mistrust: (1) the infant's ability to communicate needs to the environment and (2) the reliability and contingency of the responding environment.**

In the course of routine caregiving, an infant associates the caregiver with either comfort and trust or lack of need satisfaction and mistrust. The infant cries to communicate a need (e.g., "I'm hungry"; "I'm wet"). The caregiver responds to the infant and meets the need—the infant is fed; the diaper is changed. Thus, the newborn learns to communicate when the need arises again, because the environment or caregiver has responded and will respond. **This *contingent response* of the caregiver to the infant's need is the necessary reinforcement for the development of trust in self, others, and ultimately humankind.** As a result, the infant develops a sense of mastery over his or her world and a sense that it is okay to experience needs and that they will be met.

Caregiving that ignores or delays needs gratification is noncontingent on the infant's cues for care. Need meeting that is externally defined by the caregiver's agenda (e.g., feeding schedule, rigid or inflexible routines, medical or nursing procedures in the NICU) discourages the infant from being aware of and experiencing needs and communicating them. Such infants eventually detach themselves (emotionally and kinesthetically) from the sensation of their needs, thus no longer experiencing or communicating them.[53]

As a result, these infants conclude that they and their needs (which they perceive as one and the same) are not important and that they have no effect on their environment. They do not cultivate their sense of self or their own existence, physically (where their boundaries end and another's begin) or psychologically (their identity, which exists independent of another).

Survival depends on the caregiver's meeting the newborn's needs. Need meeting is either contingent on the infant's cues or noncontingent on an external agenda. **The degree of the mother's emotional investment and connectedness with the newborn will determine the nature and quality of the caregiving.** Likewise, the temperament and responsiveness of the infant will affect the mother's feelings of competence, success, and emotional connectedness to her infant.[53] This relationship facilitates the ongoing development of a good sense of self (e.g., esteem, confidence, emotional security) and mastery of the world. **Caregivers who do not perceive infants as individuals do not respond to their "need cry" or interact with them during caregiving.** This style fosters the development of mistrusting, suspicious, helpless, emotionally insecure, and isolated children and adults.

ENDOWMENT

Infants possess innateness and individuality. **Primitive reflex behaviors, higher cognitive abilities, temperament, and sensorimotor competencies are the endowment of the individual infant.** Individual variation and use of these endowments are influenced by the environment of the newborn.

Even before conception, the genetic endowment of the parents and preceding generations affects the fetus or newborn. Everything that the individual will inherit from his or her parents is determined at the moment of conception. Of the vast number of possible combinations of chromosomes, chance determines which characteristics the individual receives. Thus each individual, except monozygotic twins, is genetically and biologically different from every other person. Either a faulty gene (e.g., sickle cell anemia) or an altered number of chromosomes (e.g., Down syndrome) is responsible for inherited defects (see Chapter 27).

Although after the moment of conception, hereditary endowment can never be changed, it is influenced by the intrauterine environment. Some birth defects are caused by teratogens or poisons—any environmental agent (e.g., drugs, virus, chemical, pollutant) that interferes with normal fetal development. An individual's potential for growth and development is strongly influenced by his or her genetic endowment. As Montagu[287] stated, "Genetic endowment determines what we can do—environment what we do do."

The exact influence of genetics for most psychological traits is unknown. Introverted (timid, shy, withdrawn) and extroverted (active, friendly, outgoing) personality types may be partially genetically controlled. The degree to which intelligence is inherited is currently unknown, although the intelligence of children is most often similar to parental intelligence (i.e., intelligence is more similar between child and biologic mother than between child and adoptive mother).

Freedman[145] studied newborns of many ethnic groups to determine whether there were any similarities in disposition within the group or differences from other ethnic groups. He found that Chinese American newborns were more adaptable, less irritable, and easier to console than white American newborns. Maneuvers such as the Moro and covering the face with a cloth elicited different responses, depending on the newborn's ethnic origin.

The same environmental stimuli elicit different behavioral responses, which are individual and genetically influenced. These genetically influenced behaviors are also influenced by environment—both internal and external. Thus, an individual may be more vulnerable to or more resilient in a specific environment. Therefore, we are totally endowment and totally environment (100% endowment + 100% environment = an individual).[145]

Temperament

Parents often notice behavioral differences in their children from the first day. These differences are obvious in motor activity, irritability, and passivity. Some infants are quiet and placid, others are irritable and easily upset, and others are somewhere in between (Table 13.1). These temperamental qualities enable the following three basic types of infants to be identified:

- The "easy" child, who is seen as regular, pleasant, and easy to care for and love
- The "difficult" child, who is difficult to rear and reacts with protest and withdrawal to strange events or people
- The "slow to warm" child, who reacts with withdrawal or passivity to new events

Neurologic Development

Brain growth of the fetus and newborn occurs in two stages.[109]

STAGE I

Stage I is from 10 to 18 weeks of pregnancy. **The number of nerve cells that the individual has develops during this period.** Any environmental perturbation (e.g., maternal malnutrition, medications, infections) that affects brain growth during this stage also may affect neonatal behavioral responses.

STAGE II

Stage II is from 20 weeks' gestation to 2 years of age. This period marks a brain growth spurt and is the most vulnerable period of growth of the dendrites of the human cortex.

The maturity of an infant is reflected in his or her behavior. Infants of a younger gestational age have less mature responses than infants of an older gestational age. A neurologic assessment of the newborn includes evaluation of (1) newborn reflexes, (2) neonatal states, (3) psychosocial interaction, and (4) sensory capabilities. The neonate is born with behaviors that are unlearned, instinctual, and of an adaptive and survival nature. They reflect the state of the nervous system and the level of neonatal maturation (Table 13.2). Serial testing of reflex behavior gives more reliable data than one observation. Observations indicative of major deviations include asymmetry—total absence or no response on one side or in upper versus lower extremities.

Psychological Interaction and Neonatal States

For years, newborn behavior was thought to occur only on a reflexive, instinctual level. Through the work of Brazelton[57] and

TABLE 13.1 CRITICAL FINDINGS
Behavioral Categories Descriptive of Individual Temperament

TEMPERAMENTAL QUALITY	RATING
Activity level	*Low*—Decreased movement when dressed or during sleep *High*—Increased movement when asleep; increased wiggling and activity when diaper changed
Rhythmicity	*Regular*—Establishes own feeding; sleep and bowel movement patterns are fairly predictable *Irregular*—Amounts of sleep, feeding variable; "no 2 days are alike"; no pattern established
Approach and withdrawal	*Positive*—Eagerly tries new foods, interested in new surroundings and people *Negative*—Rejects new foods, new toys, and new environments; apprehensive, cries with new people
Adaptability	*Adaptive*—Little resistance to first bath; may enjoy bath *Nonadaptive*—Startles easily; resists diapering, bathing, and other manipulating
Quality of mood	*Positive*—Pleasant, easygoing disposition; easy to comfort; smiles *Negative*—Fussy; cries easily and is not easily comforted by external stimuli; unable to comfort self easily
Intensity of mood	*Mild*—No crying when wet; frets instead of crying when hungry *Intense*—Vigorously cries; rejects food
Sensory threshold (intensity of stimulus necessary to elicit a response)	*High*—Not startled or interested by noise or other stimuli *Low*—Noise, activity, or other stimuli enough to interrupt infant's behavior
Distractibility	*Distractible*—Rocking, pacifier, toy, voice, music decrease fussing *Nondistractible*—No stimuli decrease distress until need is met—food; stop changing diaper; bath over
Attention span and persistence	*Short*—Cries when awakened but stops immediately, mild objection if needs are not immediately met *Long*—Repeatedly rejects substitutions for perceived needs (no pacifier until diaper is changed; no water if milk is wanted)

Data from Thomas A, Chess S. *Temperament and Development.* New York: Brunner-Mazel; 1977.

TABLE 13.2 CRITICAL FINDINGS
Neonatal Reflex Behaviors

BEHAVIOR	BEGINS (IN UTERO) (WK)	INTEGRATES
Protection		
Moro reflex	28	At 6–8 mo to allow sitting and protective extension of the hands
Palmar grasp	28	At 5–6 mo to allow voluntary grasping of objects
Plantar grasp	28	At 7–8 mo with foot rubbing on objects; complete at 8–9 mo for standing and walking
Babinski reflex	28	Same as for plantar grasp
Tonic neck reflex	35	At 4 mo, so rolling over and reaching or grasping may occur
Gag[a] reflex	36	Protects against aspiration—does not disappear
Blink reflex	25	Does not disappear
Crossed extension	28	Disappears around 2 mo of age
Survival		
Rooting[a]	28	At 3 mo; decreased response if baby is sleepy or satiated
Sucking[a]	26–28	Not yet synchronized with swallowing
Swallowing[a]	12	32–34 wk, stronger synchronization with sucking; perfect by 34–37 wk

[a]Although isolated components of feeding behaviors are all present before 28 weeks' gestational age, they are not effectively coordinated for oral feedings before 32–34 weeks' gestational age.[154,278,378] Coordination of respiration with sucking and swallowing during bottle feeding is consistently achieved by infants more than 37 weeks' postconceptual age.[63]

others, newborns have been shown to have the ability to interact with and shape their environment. With the Neonatal Behavioral Assessment Scale (NBAS),[57] care providers can observe and score the interactive behavior of newborns. The NBAS enables **assessment of the infant's individual capabilities for social relationships rated on the infant's best performance.** Six categories of abilities are considered in evaluating an infant's performance: habituation, orientation to auditory and visual stimuli, motor maturity, state changes, self-quieting ability, and social behaviors.

Response decrement (i.e., *habituation*) is the protective mechanism through which a fetus or infant decreases responsivity to external stimuli. Habituation represents the cerebral behavior of memory—the fetus or infant stores the memory of the stimulus and, with repeated presentation, learns not to respond.[387] Infants who are able to habituate are not interested in nonnovel repetition in the environment and protect themselves from overstimulation.

Infants who become "bored" with their toys have habituated to them—infants like variety. *Dishabituation* **represents increasing attention to a new stimulus (e.g., new mobile, toy, face) after habituation to an old stimulus.** The fetus or infant thus "recognizes" the novelty of the new stimulus and chooses to respond.

An infant who is unable to habituate will continue to react vigorously to the same stimuli. Compared with term infants, preterm infants are more reactive (e.g., less able to control their level of excitation) and less able to self-regulate (e.g., modulate reactivity, reflected in habituation rate and self-soothing abilities).[115] **Very-low-birth-weight (VLBW) infants are less able to (1) modulate attention, (2) take brief breaks from processing information, and (3) habituate to stimuli.[115] Thus the preterm is less able to deal with multiple sources of stimuli and is easily overstimulated.[6]**

Neonates are able to imitate the facial and manual gestures of adults.[280] Infants as young as 12 days imitate gestures such as mouth opening and tongue protrusion. Because a neonate has never seen his or her own face, this innate ability to match behaviors to those of another is a remarkable use of the cerebral cortex. Imitation may operate as a positive feedback mechanism to caregivers; thus it is significant in parent-infant reciprocity and represents early learning behaviors.

Learning, a function of the cerebral cortex, occurs with habituation and imitation. Early cognitive development is important to later learning and future cognitive function. Learning occurs in the context of experience and influences structural maturation; there is marked CNS development during the first 2 years of life.[57,109]

State of consciousness influences the reactions of a newborn to internal and external stimuli. The infant's state at the time of observation must be considered in interpretation of the findings (Table 13.3).

Clinical application of the NBAS includes evaluation of infant capabilities after illness, prematurity, or maternal medications. **The most important application of the NBAS is in anticipatory guidance for parents.** Demonstration of parts of the examination for parents enables them to become familiar with their infant's individual patterns of behavior, temperament, and states.

Circadian Rhythm

Circadian rhythms are cyclic variations in function that occur daily at about the same time. **Humans cycle their bodily functions (e.g., temperature, hormonal changes, blood pressure, urine volume, salivary cortisol secretion, sleep-wake cycles) in a 24-hour period.[190,358,359]** These daily fluctuations are innately controlled by the individual's "biologic clock" in the suprachiasmatic nuclei (SCN) in the anterior hypothalamus. The SCN are located at the base of the third ventricle, above the optic chiasm. The circadian pacemaker must be reset daily by the relay of photic (light) information from the retina to the SCN, along the direct pathway from the retinohypothalamic tract (RHT) to the SCN.[358] During the 18th week of prenatal life, the SCN form and continue maturation after birth. In utero, the fetus expresses endogenous circadian rhythms (in heart/respiratory rates and steroid secretion) that are influenced by the mother.[358] The RHT has been identified in human newborns of 36 weeks' gestation; SCN are functionally innervated by the retina at stages equivalent to 25 weeks after conception in human infants.[358]

In infants, the development of circadian rhythm is influenced by genetic factors, gender, brain maturation, and the environment.[358-360,416]

TABLE 13.3 **CRITICAL FINDINGS**
Newborn States and Considerations for Caregiving

NEWBORN STATE	COMMENTS
	SLEEP STATES
Deep sleep (non–rapid-eye-movement [REM] or quiet sleep): Slow state changes Regular breathing Eyes closed; no eye movements No spontaneous activity except startles and jerky movements Startles with some delay and suppresses rapidly Lowest oxygen consumption	Infant is difficult if not impossible to arouse. Infant will not breastfeed or bottle feed in this state, even after vigorous stimulation. Infant is unable to respond to environment, which is frustrating for caregivers. Term infants may exhibit a "slow" heart rate (80–90 beats/min), which may trigger heart rate alarms and result in unnecessary stimulation by NICU staff. At birth, preterm infants have altered states of consciousness. Early dominant states are light sleep, quiet, and active alert. "Protective apathy" enables the preterm to remain inactive, unresponsive, and in a sleep state to conserve energy, grow, and maintain physiologic homeostasis.[358] As maturation occurs, there is an increase in quiet alert.
Light sleep (REM or active sleep): Low activity level Random movements and startles Respirations irregular and abdominal Intermittent sucking movements Eyes closed, REM Higher oxygen consumption	Full-term infants begin and end sleep in active sleep; preterm infants are more responsive (than term infants) to stimuli in active sleep. Infant may cry or fuss briefly in this state and be awakened to feed before truly awake and ready to eat. Lower and more variable oxygenation states
	AWAKE STATES
Drowsy or semidozing: Eyelids fluttering Eyes open or closed (dazed) Mild startles (intermittent) Delayed response to sensory stimuli Smooth state change after stimulation Fussing may or may not be present Respirations are more rapid and shallow	Infants may awaken further or return to sleep (if left alone). Quietly talking and looking at the infant or offering a pacifier or an inanimate object to see and listen to may arouse the infant to the quiet, alert state. Less mature infants (30 weeks) demonstrate a more drowsy than quiet alert state than more mature infants (36 weeks).
Quiet alert, with bright look: Focuses attention on source of stimulation Impinging stimuli may break through; may have some delay in response Minimal motor activity	Immediately after birth, term newborns exhibit a period of quiet alert, which is their first opportunity to "take in" their parents and the extrauterine environment. Dimmed lights, quiet talking, and stroking optimize this time for parents. Best state for learning to occur, because infant focuses all of attention on visual, auditory, tactile, and sucking stimuli; best state for interaction with parents—infant is maximally able to attend and reciprocally respond to parents. Best state for oral feeding efficiency in term and preterm infants.[165]
Active alert—eyes open: Considerable motor activity—thrusting movements of extremities; spontaneous startles Reacts to external stimuli with increase in movements and startles (discrete reactions difficult to differentiate because of general higher activity level) Respirations irregular May or may not be fussy	Infant has decreased threshold (increased sensitivity) to internal (hunger, fatigue) and external (wet, noise, handling) stimuli. Infant may quiet self, may escalate to crying, or with consolation by caregiver, may become quiet alert or go to sleep. Infant is unable to maximally attend to caregiver or environment because of increased motor activity and increased sensitivity to stimuli.
Crying—intense and difficult to disrupt with external stimuli Respirations rapid, shallow, and irregular	Crying is the infant's response to unpleasant internal or external stimulation—infant's tolerance limits have been reached (and exceeded). Infant may be able to quiet self with hand-to-mouth behaviors; talking may quiet a crying infant; holding, rocking, or putting infant upright on caregiver's shoulder may quiet infant.

Data from Blackburn S. Fostering behavioral development of high-risk infants. *JOGN Nurse* 1983;12(suppl 3):76S-86S; and Brazelton TB. *Neonatal Behavioral Assessment Scale*. 2nd ed. Philadelphia, PA: International Medical Publishers/Lippincott; 1984.

There are individual differences in the development of circadian rhythms, in both preterm and full-term infants.[358-360,416] These circadian rhythms in the neonate are influenced by feeding, environmental lighting, interactions with mother, and chronologic/postconceptual age.[358-360,415,416] Infant biorhythms have been studied in the areas of temperature, heart and respiratory rates, blood pressure, sleep-wake cycles, rest-activity patterns, endocrine secretion, and feeding frequency.[358-360,415]

SLEEP CYCLES AND PATTERNS

Active (or light) sleep is characterized by rapid eye movements (REM), whereas quiet (or deep) sleep has no rapid eye movements (i.e., non-REM sleep; see Table 13.3). At 29 to 30 weeks' gestation, sleep differentiates into REM and non-REM sleep.[160] At birth and for the first few weeks of life, term newborns generally distribute sleep over a 24-hour period and sleep from 16 to 19 hours a day. As sleep begins, a term infant enters active, rather than quiet, sleep and spends more time in active sleep than does an adult.[111]

Active sleep durations vary from 10 to 45 minutes, whereas quiet sleep lasts about 20 minutes.[111] An infant's sleep cycle is 50 to 60 minutes, compared with an adult's 90- to 100-minute cycle. Although day-night rhythms are difficult to detect in the neonatal period, some infants exhibit such rhythms as early as 1 week of age.[358,359] **The first study of the sleep-wake cycles of healthy term newborns in the immediate postnatal period found sleep-wake cycles as early as 6 hours of life, with a preponderance (52.1%) of active sleep for longer periods than quiet sleep.[212] Mode of delivery also influenced sleep, with a longer active sleep and shorter period of quiet sleep in infants delivered by elective C-section than for those delivered by vaginal birth or emergency C-section.** Sleep-wake cycles are altered when term infants have hyperbilirubinemia.[463]

Maturation of infant sleep is characterized by (1) increased organization of sleep states, (2) decrease in total sleep time, (3) increase in quiet sleep, (4) decrease in active sleep, and (5) increase in active and quiet waking.[111] Arousability from sleep is altered by gestational and postnatal age. In term infants, arousal thresholds are significantly elevated in quiet sleep compared with active sleep (at 2–3 weeks and at 2–3 months of age), so that spontaneous arousal is greater in active (REM) than in quiet (non-REM) sleep.

Infants have their own "clock" for sleep-wake, hunger, and feeding or fussy times. This clock often does not coincide with the family's rhythms and may cause disruption and conflict. Sleep-wake states reflect the underlying status of the neurologic system. **The infant's maturity at birth greatly affects his or her rhythms and development of normal circadian rhythm.** Early relationships with caregivers provide the organization and stabilization necessary for sleep regulation and other biologic functions.[415]

In preterm infants, active and quiet sleep cycles are less organized and of shorter duration (a sleep cycle is about 30–40 minutes) than in term infants.[110] Active sleep is "lighter" than quiet sleep—there is more response to stimuli in active sleep.[110] Quiet sleep is a more controlled state and occurs more frequently in term infants than in premature infants. Quiet sleep does not become significant in the preterm until approximately 36 weeks' gestation. Hence, a third sleep state, *transitional sleep,* has been identified for premature infants.[326] This state is characterized by quiet sleep with periods of closed eyes, regular or periodic respirations, no body movements, and no REM. **Before 36 weeks' gestation, a preterm infant's predominant sleep state is transitional sleep.** As the preterm infant matures, he or she spends progressively less time in transitional sleep, has more quiet than active sleep, and has more awake, alert time. However, a preterm of 40 weeks' postconceptual age does not have sleep patterns that are as organized as those of a term newborn.[326] **Spontaneous arousal from sleep is greater in active sleep compared with quiet sleep.** Long-term follow-up studies fail to show a difference in sleep distribution between preterm and term infants when corrected for age.[383] Both preterm and full-term infants who are exposed to an appropriate light intensity at home develop day-night rhythmicity by 44 and 48 weeks' postconceptual age, respectively.[359,360,383]

As day and night rhythms in sleep-wake cycles develop, diurnal rhythm in hormone production also develops: (1) melatonin production is detectable at 12 weeks of age; and (2) variations in cortisol levels appear between 3 and 6 months of age.[358] **Sleep disruption may interfere with growth and development by altering neuronal maturation, cortex development, and growth hormone**

secretion.[5,66] Human growth hormone has a rhythmic pattern associated with sleep-wake cycles. The highest peaks of growth hormone in infants occur during REM (active) sleep. A fetus (29–32 weeks' gestation) spends 80% of the time in utero in REM sleep; a term newborn's sleep is 50% REM sleep.[110,111] **Because growth hormone secretion depends on the regular recurrence of sleep, any disturbance of the sleep-wake cycle results in irregular spikes of growth hormone during a 24-hour period. Sleep disruption, especially of REM sleep, also interferes with healthy visual development, increases behavioral problems and sleep disturbances, and reduces the size of the cerebral cortex.**[160,283]

Although infant circadian rhythms are synchronous with those of the mother, desynchronous rhythms at birth may occur.[326,358] An infant whose cycles are discrepant from his or her family's may be perceived as "difficult." Gradually, through caregiving, parents teach the infant synchronization with family rhythms.[415] By 9 months of age, most term infants develop day-night fluctuations that are similar to adult patterns.

Sensory Capabilities

At birth, a neonate's senses are developed and functioning. Sensory development proceeds in a specific order: tactile/vestibular, olfactory/gustatory, and auditory/visual. Stimuli (e.g., type, timing) to one sense affect the development of other senses. Sensory enhancement or deprivation of a later-developing sensory system (e.g., vision) could either accelerate or decelerate the development of behavior mediated by earlier-developing sensory systems (e.g., tactile and olfactory).[397] Through the neonate's sensory perception, learning occurs by (1) habituating to some stimuli while attending to other stimuli, (2) discriminating between related and unrelated sensory events, and (3) integrating multisensory stimuli. As the neonate takes in the sensory information, he or she associates features of the environment that occur together (e.g., sound, smell, sight, touch of "mother" or "father"), demonstrating complex and intermodal abilities for handling the sensory input from the environment.

TACTILE/KINESTHETIC

Touch is the major method of communication for neonates and infants. Touch is the first sense to develop (at about 7.5 weeks' gestational age) and the last sense to fade. In utero, a fetus's existence has been primarily one of movement—floating within the amniotic fluid and experiencing rhythmic maternal movements. In response to maternal touch of her pregnant abdomen, the fetus displays an increase in arm, head, and mouth movements.[264] The senses of touch, temperature, and pressure are all well developed, and receptors lie in the newborn's skin. Pleasant touch is associated with a slowing of the heart rate, a decrease in physiologic arousal, and increased engagement.[128] Even preterms as young as 28 weeks' gestation tactilely memorize the shape of an object by manipulating it in their hands and discriminate between objects.[262] **The sensitivity to touch is especially well developed in the face, around the lips (root reflex), and in the hands (grasp reflex).** Because newborns are nonverbal, they pick up messages through the manner in which they are held and handled—by the adult's "body language." Infants are often barometers for adult feelings; if the adult is tired and irritable, the infant knows and may respond with irritability and crying.

Infants love to be held, rocked, and carried; note the soothing effects on a crying infant. Adults do not spoil infants by providing these important stimuli. Increased carrying of infants contributes to less crying at 6 weeks of age.[36] In response to being held, infants adjust their body posture to the body of the caregiver. Adults describe an infant as "cuddly" (assumes a comfortable, relaxed curl; snuggles to adult body; and attempts to root or suck) or "noncuddly" (sprawls; tenses or stiffens; and pushes away). **The most comforting position for a crying infant is upright on an adult's shoulder.**[210] Responsiveness to tactile stimulation has been found to be greater in female than in male neonates.[210]

HEARING

The fetus in utero has heard the voices of mother, father, and siblings beginning in the second trimester of pregnancy, at about 27 weeks of pregnancy.[293,397] These voices are "familiar" to newborns, so they "know" and have learned their family and are able to differentiate them from the voices of strangers.[100,101,293,298] Neonates prefer their mother's voice and the maternal language that they heard in utero.[293] Studies have suggested that fetuses and neonates

exhibit memory.[100,101,293,298] Newborns who had been read a particular story while in utero responded to the story reread to them after birth with a recognition and attentiveness that was not exhibited in response to unfamiliar stories.[100,101] A more recent study presented fetuses with music five times per week and measured their brain activity at birth and at 4 months of age. Brain activity at birth and at 4 months of age was much stronger when the neonates and infants heard the "familiar" music they had listened to in utero.[327] Antenatal and postnatal maternal singing of lullabies to the fetus resulted in improved maternal-infant bonding after birth and less maternal stress.[331] Neonatal outcomes in this study included (1) significantly less crying in the first month of life, (2) less colic in the first and second months of life, and (3) less wakening during the night. Another study shows that **preterm infants have lower pain scores and better behavioral states during heelstick when they listen to the same music that their mothers listened to during pregnancy.**[214] The ability to hear the outside world, particularly the spoken word, is a prerequisite to further verbal language development.[293]

Recent research has documented a delay in the development of the fetal primary and nonprimary auditory cortex in the brain.[286] By 26 weeks' gestation, the primary auditory complex (which receives auditory signals from the ears) is more developmentally advanced than the nonprimary auditory cortex that processes and understands auditory signals. From 26 weeks to term, the nonprimary auditory cortex in preterm infants matures quickly and partially "catches up" with the maturation that would have occurred in utero. However, by 40 weeks' corrected age (CA) both auditory regions in preterm infants were less developed than in neonates born at term gestation. This **disturbance in the maturation of the nonprimary auditory complex in premature infants was associated with poorer language performance at 2 years of age.**[286]

Fetal responses to sound include increases in breathing, body movements, fetal heart rate, cerebral blood flow, and glucose use and changes in behavior states, as well as recognizing and habituating to familiar sounds.[298] In response to hearing a maternal voice the fetus decreases arm and head movements.[264] Neonates with an intact CNS are able to orient and respond to the auditory environment. In response to a sound, the neonate will demonstrate the following:

- Change in motor activity (eye blink, decrease in activity, limb movements, head turn)
- Change in heart rate (if the infant is quiet, the heart rate increases with stimuli; if the infant is crying, the heart rate decreases with stimuli) and/or change in respiration (increase in rate, decrease in amplitude, or decrease in respiratory cycle rate)
- Smile
- Startle or grimace
- Alert or arouse
- Cry or cease to cry
- Stop sucking

The response to sound depends on the sound's quality. The intensity of intrauterine noise is approximately 85 dB. When frequency and pitch are low, the infant is soothed and distress is decreased; high frequency and pitch alert and distress the infant and disturb sleep.

Frequencies less than 4000 Hz (the range of human speech is 500–3000 Hz) produce the most response in newborns. **Infants are maximally reactive to the human voice in typical speech patterns (rather than disconnected syllables). Infants prefer the high-pitched (e.g., female) voice over the low-pitched (e.g., male) voice.**

Experience with sound improves an infant's behavioral responses to sound. Stimuli presented for 5 to 15 seconds elicit the best reaction. Stimuli lasting longer than several minutes are less effective because the term infant habituates to the sound and ceases responding. **The ability to habituate to sound is indicative of an intact CNS.**[298] **Full-term newborns habituate to sound better and faster than do preterm infants.** Infants exhibit startle behavior if the stimulus rapidly reaches maximal loudness. Infant state is important in evaluation of response to auditory stimuli; light sleep is the optimal state. Infants quiet and soothe in response to rhythmic sounds (rather than dysrhythmic ones). Neonates move their bodies in rhythmic synchrony *(entrainment)* with the spoken word.

VISION

Eye development begins 22 days after conception. **The eyelids fuse at about 10 weeks' gestation and remain fused until about 26 weeks' gestation.** Eyelid opening is a function of maturity—more mature neonates open their eyes more than younger gestation neonates. At birth, photoreceptors

are already developed, but maturation is not complete for several months. The fetus can distinguish light from dark and recoils from a bright light shone at the mother's abdomen. A recent study showed that more fetuses at 34 weeks' gestation turned toward a face-shaped light shown through their mother's abdomen than toward the inverted light shape. Researchers concluded that the **preference for the human face exhibited by newborns is developed before birth.**[352] Even at term birth, the visual system is immature; significant development occurs over the next 6 months to a year. **The ability to fix, follow, and alert is indicative of an intact CNS.**[282]

At birth, infants can see an object within 8 to 10 inches of the face (visual acuity of 20/140).[130] Within seconds after birth, the neonate can recognize his or her mother's face—the voice that they have heard for the last trimester of pregnancy comes from the face they now see! The cradled-in-the-arms position of feeding is the exact distance from the adult's face that the newborn can see. In response to an interesting visual stimulus, neonates stop sucking to look, alert, and attend to the object; horizontally scan the object; and fix and follow a moving object in a 90-degree arc.

Infants prefer the human face as a visual stimulus, prefer a patterned over a nonpatterned stimulus, and attend longer to larger patterns with more complex patterns and angles.[130] Infants prefer black and white because of the greater contrast and will focus on the outside of a figure where the contrast is the greatest[282]; color discrimination occurs around 2 to 3 months.[160] Newborns are sensitive to bright light and will tightly close their eyes in its presence. They prefer moderate, diffuse lighting. **Newborns exposed to cycled light (e.g., day-night changes) open their eyes more than those exposed to continuous bright light.** Presentation of visual stimuli enables development of the neural pattern for vision. During the infant's first year of life, visual investigation of the environment is a primary mode of learning.

SMELL AND TASTE

In utero, the fetus learns his mother's scent by exposure to amniotic fluid.[45,397] The fetus increases its amniotic fluid consumption when saccharin is added to the fluid and decreases consumption with the injection of distasteful substances. Taste may be a way the fetus monitors the intrauterine environment. **Olfaction is well developed at full term and preterm birth.**[262] **Olfactory cues guide the full-term newborn to the maternal nipple.** Flavors and smells in the mother's diet are present in amniotic fluid and in mother's breast milk so that infants show a preference for these familiar flavors and smells at birth and later in infancy.[45,397,414,427]

At 5 days of age, a neonate can differentiate his or her mother's breast pad and demonstrates a preference for the smell over that of a "stranger"; full-term newborns stop crying and increase their mouthing behaviors when exposed to their mother's odor.[398] Premature infants exposed to the odor of their own mother's milk have a persistent decrease in salivary cortisol levels that continue after the stimulus is removed.[254] The infant's response to pleasant odors is to arouse and suck. After several presentations of the stimulus, the infant will habituate to the odor. Infants withdraw from unpleasant odors such as vinegar and ammonia. They are also able to differentiate tastes, preferring sweet solutions[414,427] and refusing, by turning the head away, bitter, acid, and sour substances. Intrauterine growth restricted (IUGR) 1-day-old newborns have been shown to strongly prefer a sweet solution (24% sucrose) that is inversely related to their degree of IUGR.[22] Asphyxiated infants demonstrate a loss of olfaction that parallels the suppression of brainstem reflexes and activities.

COMMUNICATION SKILLS

A neonate's ability to communicate is a naturally endowed survival skill. **Crying is an infant's language to communicate needs.**[249] Crying also may be a response to the environment: noisy, cold, overstimulating, multiple caregiving, or lack of synchrony. Because the cry brings someone to meet the need, the infant soon learns that the caregiver gives attention and the world is a trustworthy place. **The more responsive the caregiver is to the infant's crying, and thus the infant's needs, the less crying behavior is necessary.**[36,249] **Learning occurs as the infant associates comfort with the caregiver.** The temperament of the individual infant and his or her ability to habituate to disturbing stimuli influence the amount of crying behavior. Tension in the caregiver or the environment is communicated nonverbally to the infant and may potentiate or contribute to the infant's crying.

The amount and tone of the newborn's cry are influenced by birth weight, gestational age, and the events of birth. **Types of cries include birth cry, hunger cry, pain cry, and pleasure cry.**[85,86] **Infants separated from their mothers in the first 90 minutes after birth exhibit a "separation distress call" (also seen in other mammal species) that ceases at reunion.**[85,86] The newborn's cry physiologically affects the mother: her breasts change and prepare to nurse. Neonates possess a repertoire of self-quieting behaviors when in a fussy state: (1) hand-to-mouth efforts, (2) sucking on fist or tongue, and (3) use of visual or auditory stimuli from the environment.[57]

After birth, crying develops a diurnal pattern: term infants cry more during the day than at night. Persistent crying (>3 hours a day) is more likely in breastfed babies, whereas early-evening crying is more likely by formula-fed infants. Postnatal age is a significant predictor of crying. Crying decreases with increasing chronologic age.[404] The neonatal cry may be a signal of robustness or wellness, a signal of pain, or diagnostic of existing conditions or trauma. CNS insult often results in a high-pitched, shrill cry.

A smiling infant is a joy to the caregiver. Smiling may be either spontaneous (from birth) or a response to the social human face (at 4–12 weeks of life). A smile is most easily elicited by the stimulus of a moving, smiling human face. The ability to smile begins before 40 weeks in a preterm infant, as observed during REM sleep. The social implications of the smile include positive feedback to the caregiver that the infant is happy and contented, which results in parental feelings of adequacy and competence.

ENVIRONMENT

Prenatal Environment

In utero, the fetus depends totally on the mother's emotional and physical health and well-being for his or her own. Through the mother the fetus receives nurturance, housing, and stimulation to develop the body, the sensory organs, and the rudiments of personality and temperament.

Conditions present at birth may not be congenital but, rather, the result of the effect of uterine environmental conditions on development. Maternal-fetal programming, known as the *Barker hypothesis,*[29] postulates that the maternal prenatal environment influences the developing fetal brain and also the long-term permanent effects on health and susceptibility to disease.[58]

Intrapartal Environment

Birth is a major transition from physiologic dependence to physiologic independence. At term, a neonate's physiologic systems are developed, sensory organs function, and the foundation of personality and temperament is established. Birth is disorienting and disruptive. The amount of disruption depends on the degree of trauma incurred during the labor and birth processes. Not having a social support system compounds the stress, often escalating it beyond the mother's tolerance and coping skills. Anxious and fearful women have longer labors and more delivery complications than women who are confident about themselves and their infants.[372] **The shift toward family-centered birth enables mothers to receive support from their families, be active participants in the birth process, and have immediate contact with their newborns** (see Chapter 29).

A neonate also is influenced by medications and the events of labor and birth (see Chapter 2). Maternal medications for analgesia and anesthesia affect neonatal behaviors, resulting in decreased sucking ability, lethargy, and decreased habituation. They also give less feedback to their parents than unmedicated infants do. The parents may feel rejected, tend to stimulate the infant less, and thus begin a pattern of suboptimal interaction.

Postnatal Environment

Home and family are the primary media through which newborns (1) reestablish their biorhythmic balance, (2) stabilize themselves in the extrauterine world, (3) develop a sense of self and mastery in the world, and (4) become socialized as human beings. Socialization teaches the adaptive psychosocial skills necessary for survival and functioning in society. Cultural and family values, behavioral expression, and ways of meeting social and emotional needs are learned within the family. **Thus, the home and family environment is considered to be a "socializing" environment for human development.**

CAREGIVER FACTORS

The dyadic relationship continues postpartum between the caregiver and the infant—the behavior of one reinforces the behavior of the other. The infant's physical and emotional needs are satisfied by caregivers. The infant's response to the caregiver depends on how the infant perceives and receives ministrations; this response affects the level of emotional satisfaction the caregiver receives from the interaction. Parental expectations have a major effect on their perceptions and their behavior and ultimately affect the child's development. **Parents must work out the discrepancy between the wished-for and the actual child, especially if the infant is preterm or ill or has an anomaly. How attached the parents are to the infant influences their relationship with and ability to care for their infant** (see Chapter 29). If the pregnancy has failed to produce a normal, healthy infant, the parents must grieve the loss of their expectations. Parents have problems attaching to and caring for the infant until they have completed their grief work (see Chapter 30).

A caregiver and an infant have a reciprocal interaction when their cycles and signals are synchronized with each other. The biorhythmic cycle of the newborn has been in synchrony with one person (mother) in utero, and the infant is accustomed to her cycles and rhythms for developing adaptive behavior. **Consistent, sensitive maternal caregiving enables a newborn to regulate his or her rhythms to those of the mother and begin adapting to the postnatal environment.**[380,391] Mother and fathers "filter" the environment for their baby while still enabling variability and unpredictability. From the relationship with their parents, the infant expands their adaptation to the family and the larger world of society.

Experience in relating to infants influences the caregiver's efficiency in interpretation of and sensitivity to infant cues. Multiparous women have more sensitivity to infant cues than do primiparous mothers. Mothers with little or no experience exhibit more difficulty in quieting a crying infant. **The competence of parents may be improved through acquisition of knowledge about infants so that the quality of interaction between parent and infant is enhanced.** Better informed first-time mothers may result in significant differences in sensitivity to infant cues and social and emotional growth fostering behaviors in early (first 24 hours) mother-infant interaction.[450] In addition to experience, maternal hormones, oxytocin and estrogen, enable mothers to retain and respond to their infant's vocal cues.[394]

Consistency and sensitivity in maternal responses[391] is especially important as the infant continues to learn the accepted patterns of cues from the caregiver. Cared for by one or two people, an infant is able to develop synchrony with and expectations of the parents. Single caregiving improves establishment of biorhythms for sleep-wake cycles, feeding, and visual attentiveness. Consistent cues soon elicit a consistency of response from the infant. Consistency and promptness of maternal (and other caregivers) response results in less infant crying during the first year of life. A predictable and responsive environment enables the infant to progress to varied types of communication (not just crying). Care by parents provides for mutual cueing and mastery of the environment through interaction. Inconsistent cues distress and confuse the infant. **Multiple caregivers, who may not be knowledgeable about a particular infant, may confuse the infant, increase distress with feeding, cause irritability, and upset visual attention.**

Regardless of how stable or unstable, consistent or inconsistent it is, family life has a rhythm, synchronicity, and predictability of its own. Through interaction with parents and siblings, infants further develop their ability to form relationships. From these primary relationships, the foundation and format for other relationships are established. The quality of subsequent relationships depends on the quality of the relationship experienced within the primary family from birth throughout infancy.[156]

NEONATAL FACTORS

The neonate is not a passive recipient of the environment of the family but, rather, is an active participant in shaping that environment. Infants send cues about their ability and readiness for interpersonal interactions. In their first 4 months of life, infants' interactions with persons differ from their interactions with inanimate objects. The excitement generated by interpersonal interaction is seen in an infant's arm and leg movements, bodily movement toward the other person, smiling, vocalizing, and increased visual attention. Because of the infant's immaturity, he or she is unable to maintain a continuous interaction. **Maternal or care provider sensitivity**[391] **to the attention-withdrawal cycle**

of interaction enables the adult to modulate his or her behavior in synchrony with the infant's cues. Successful interaction with an infant includes reading the infant's cues, responding appropriately, and not overwhelming the infant with too much stimulation (thus overstepping the infant's tolerance for interaction). Overwhelming the infant results in withdrawal for progressively longer periods to protect himself or herself from overstimulating and insensitive others.

Attachment of the newborn to the mother/parent functions to keep the infant in proximity for caregiving and promotes brain and emotional development.[397] Just as the parent has expectations, the infant also has physiologic and emotional needs that require care. Relief from the discomforts of hunger, cold, sleeplessness, and boredom enables the infant to respond positively to the care provider.

Care-eliciting behaviors are those neonatal cues used to signal the caregiver that attention is needed. Crying, visual following, and smiling are care-eliciting behaviors. Newborn responses to care include quieting, suckling, clinging and cuddling, looking, smiling, and vocalizing. These social interactions positively reward the care provider and encourage and promote continued care. Infant characteristics that modify maternal attitudes include (1) a healthy or sickly infant; (2) an attractive, pretty infant or an infant with obvious congenital anomaly; (3) a premature infant; (4) a calm and contented or a fussy and irritable infant; and (5) an infant responsive to or rejecting of maternal care. A mother's or care provider's ability to soothe the infant reinforces a feeling of success (or failure) in his or her feelings of competence.

The infant's gender also affects the cues and the caregiver's response. Male infants exhibit more startles, more muscle activity, and more physical strength. In response, caregivers hold them more as a means of soothing.[210] Females exhibit more tactile and oral sensitivity, more smiling, and more responsivity to sweet taste. As a result, girls are more often soothed by talking, eye-to-eye contact, and a pacifier.[210]

The infant's level of neurophysiologic development influences the appropriateness of maternal and caregiving behaviors. The neurologically mature term infant who has already mastered autonomic, motoric, and state regulation is able to actively elicit and respond to caregiving behaviors.[57]

BOX 13.2 CRITICAL FINDINGS

STAGES AND CHARACTERISTICS OF BEHAVIORAL ORGANIZATION IN PRETERM INFANTS

Als & Brazelton[a]	Gorski[b]
Physiologic homeostasis—stabilizing and integrating temperature control, cardiorespiratory function, digestion, and elimination. Characteristics: become pale, dusky, cyanotic; heart and respiratory rates change—all symptoms of disorganization of autonomic nervous system.	"In-turning"—physiologic stage of mere survival characterized by autonomic nervous system responses to stimuli (rapid color changes caused by swings in heart and respiratory rates); no or limited direct response; inability to arouse self spontaneously; jerky movements; asleep (and protecting the central nervous system from sensory overload) 97% of the time. Preterms (<32 weeks) are easily physiologically overwhelmed by stimuli.
Motor development may infringe on physiologic homeostasis resulting in defensive strategies (e.g., vomiting, color change, apnea, bradycardia). State development becomes less diffuse and encompasses full range: sleep, awake, crying. States and state changes may affect physiologic or motor stability. Alert state is well differentiated from other states; may interfere with physiologic or motor stability.	"Coming out"—first active response to environment may be seen as early as 34 to 35 weeks (provided some physiologic stability has been achieved). Characteristics: remains pink with stimuli, has directed response for short periods, arouses spontaneously and maintains arousal after stimulus ceases; if interaction begins in alert state: maintains quiet alert for 5 to 10 min, tracks animate or inanimate stimuli, spends 10% to 15% of time in alert state with predictable interaction patterns. "Reciprocity"—active interaction and reciprocity with environment at 36 to 40 weeks. Characteristics: directs response, arouses and consoles self, maintains alertness, interacts with animate/inanimate objects, copes with external stress.

[a]Data from Als H, Brazelton TB. A new model of assessing the behavioral organization in preterm and full-term infants: two case studies. *J Am Acad Child Psychiatry.* 1981;20:239.

[b]Modified from Gorski PA. Stages of behavioral organization in the high-risk neonate: theoretical and clinical considerations. *Semin Perinatol.* 1979;3:61.

Because of the immaturity of the CNS, a preterm infant lags behind a term infant in care eliciting and responsivity to the care provide[275,444] (Box 13.2). Because a young preterm infant's priority is mere survival, interaction with

the environment and care providers will occur at the expense of physiologic stability.[413] Although overwhelming the term infant results in withdrawal from interaction, overwhelming the preterm infant results first in a real threat to physiologic survival and then to withdrawal from interaction.

The ability of an infant to be a social partner and to respond in a social interaction is developmentally determined and influenced by the infant's physical condition. The response of preterm infants (weight <1500 g) to social stimulation (e.g., talking and talking combined with touching) develops over time: (1) at 29 to 32 weeks' gestation, respond with distress (e.g., eye closing) to all forms of social stimuli; (2) at approximately 33 weeks' gestation, begin to respond with increased attention to talking; they remain distressed with combined stimuli; and (3) at approximately 35 to 36 weeks' gestation, pay more attention to talking; more distress at combined stimuli is seen in high-risk infants (e.g., preterms <1500 g) and better habituation seen in healthier infants.[114] **Sicker preterm infants have a more difficult time attending to and modulating their response to social interactions than do healthier preterm infants.**[114,115,444] Although VLBW preterm infants respond to talking with increased attention and eye opening, the addition of touch results in increased eye closing and facial grimacing.[107] Sicker infants demonstrate the same pattern of response but in a more exaggerated way that reflects their increased reactivity and decreased ability for self-regulation.[115,413]

Because preterm infants are not as neurologically mature as term infants, the NBAS has little value with this population. **A behavioral assessment scale for preterm infants, the Assessment of Preterm Infant's Behavior (APIB), has been developed that evaluates the preterm infant's behavioral organization along five subsystems of functioning: autonomic, motor, state, attentional-interactive, and self-regulatory.**[12] This examination delineates the quality and duration of the preterm infant's response, the difficulty in eliciting the response, and the effort and cost to the preterm infant of achieving and maintaining a response. Because it, too, is an interactive test, the nature and amount of organization provided by the care provider is an indication of the preterm infant's lack of integrative skill. As the preterm infant matures and advances in development of organization, he or she is more able to interact with the environment (animate and inanimate). However, it must be remembered that this maturation process is "uneven"; as the preterm infant advances in one area of development, he or she may become, at least temporarily, more vulnerable in other areas.[156]

Another examination, the Neonatal Intensive Care Unit Network Neurobehavioral Scale (NNNS), assesses neurologic integrity and behavioral factors of high-risk infants (e.g., preterms, drug-exposed infants) by evaluating neurobehavioral organization, neurologic reflexes, motor development, muscle tone (active/passive), and signs of (drug) withdrawal and stress.[412] The NNNS differs from the NBAS in that the NNNS (1) was developed for at-risk populations, not for the normal newborn; (2) is more structured and standardized than the NBAS; and (3) gives results more reflective of infant capabilities rather than infant-examiner interaction.[412] The NNNS is performed on medically stable infants, between more than 30 weeks' gestation and 46 to 48 weeks' postconceptual age, for research purposes and for clinical practice.[412] Clinical applications include the following[412]:

- Evaluates the infant's personality and temperament as capacities for state regulation of arousal, response to stimuli, self-soothing, and tolerance of handling
- Documents the physiologic and behavioral manifestations of drug withdrawal or stressors in the environment
- Documents the capacity to habituate, orient to stimuli, and respond to handling, as well as muscle tone and quality of movement
- Evaluates infants withdrawing from in utero drug exposure and those being weaned from analgesia in the NICU
- Determines when the infant is ready for discharge
- Is used as a teaching and care-planning tool when the examination includes parents and other care providers
- Is a tool that bridges the assessment from early gestation/neonatal period to 2 months corrected age when other tools are unreliable

INTERVENTIONS

Life in a special care nursery is characterized by sensory deprivation of normal stimuli that the preterm infant would have experienced in the womb and that term infants would experience at

home with their families. However, **the NICU is also an environment of sensory bombardment**—constant noise, light, and tactile stimulation; intrusive, invasive procedures; upset of sleep-wake cycles; and multiple caregivers. **Rather than too much or too little stimulation, infants in the NICU receive an inappropriate pattern of stimulation (e.g., noncontingent, nonreciprocal, painful [rather than pleasant], and multiple stimuli).**[7,156,158] Because the immature CNS of the premature infant cannot tolerate these stimuli, the easily overstimulated preterm infant protects himself or herself by physiologic and interactional defensive maneuvers that are maladaptive.

Inappropriate patterns of stimuli that stress the preterm infant in the NICU environment influence brain structure and function during a critical period of brain development.[96,260,397] The first study to examine a relationship between stressors in the NICU and alterations in brain development was published in 2011. This prospective cohort study used the Neonatal Infant Stressor Scale (NISS)[304] to measure daily exposure to stressors of preterms (<30 weeks' gestation) for the first 14 and 28 days of life and from admission to the NICU until term equivalent postmenstrual age (PMA) or discharge.[386] Magnetic resonance imaging (MRI) examinations were performed at term equivalent age (about 36–44 weeks' PMA) and the association between exposure to stressors and abnormal brain development was then calculated. **The most immature, sickest preterms were exposed to the highest number of stressors and procedures, particularly in the first 14 days of life. Higher exposure to stressors was associated with decreased brain size in the frontal and parietal sections.[386] Increased stress was also associated with altered microstructure in the temporal lobes,** especially the right lobe, that resulted in less mature, poorly developed connections between the temporal lobes.[386] **A combination of destructive and developmental mechanisms contribute to the encephalopathy of prematurity.**[433] White matter injury to the developing brain is recognized as the cause of common motor, behavioral, and cognitive problems in surviving premature infants[117] (see Chapter 31).

A study by the same investigators found **altered neurobehaviors at term equivalent in a prospective study of preterm infants (<30 weeks' estimated gestational age).**[338] Using the NNNS, differences in neurobehavior were examined between preterm infants at term and full-term controls, between 34 weeks' PMA and full-term equivalent, and relationship of neurobehavior to perinatal exposures (such as days of intubation, postnatal steroids, oxygen use after 36 weeks' corrected age).[338] **At term equivalent, preterm infants exhibited a broad range of altered behaviors** (Box 13.3). Studied preterms between 34 weeks' PMA and term equivalent also exhibited behavioral and motor changes that were not influenced by any of the measured perinatal exposures. At 34 weeks' PMA, preterms with significant cerebral injury had increased excitability compared with non–brain-injured preterms.[338] The researchers concluded that the **neurobehavioral changes occurring before term may present a rich opportunity in the NICU for interventions to ameliorate developmental disadvantages evident in the studied preterms by term equivalent age.**

Altered neurodevelopmental outcomes and resulting altered neurobehavior may also affect the infant's ability to attach to parents. A study

BOX 13.3 ALTERED NEUROBEHAVIOR IN PRETERM INFANTS IN NICU

Preterms (at Term Equivalent) Compared with Full-Term Infants

- Poorer orientation
- Lower ability to tolerate handling
- Lower ability to self-regulate
- Poorer reflexes
- Increased stress
- More excitability
- Altered muscle tone—hypotonic or hypertonic

Preterm Infants From 34 Weeks' Premenstrual Age Compared to Term Equivalent

- Changes in motor function:
  - Declining quality of movement
  - Increasing hypertonia
  - Decreasing hypotonia
- Changes in behavior:
  - Increasing arousal
  - Increasing excitability
  - Decreasing lethargy

Adapted from Pineda RG, Tjoung TH, Vavasseur C, et al. Patterns of altered neurobehavior in preterm infants within the neonatal intensive care unit. *J Pediatr.* 2013;162:470.

BOX 13.4 OUTCOMES OF INDIVIDUALIZED DEVELOPMENTAL INTERVENTION IN THE NICU*

Physiologic Benefits	Developmental Benefits	Cost Savings
Decrease in:	Improvement in:	Shorter length of stay
Incidence of IVH or pneumothorax and severity of BPD, ROP, NEC	Behavioral organization of autonomic, motor, attention modulation, and self-regulatory abilities	Earlier discharge at younger age
Ventilator/CPAP use	Interactive capability of infant with staff and parents	Decrease in hospital charges
Need for supplemental oxygen	Quality of parent-infant interaction (perception of preterm as better regulated, more autonomous, and more gratifying; enhanced competence in parental role)	
Need for gavage feedings/IV nutrition	Less parental personal stress	
Number of apneic episodes	Feelings of closeness with preterm	
Need for sedation/analgesia	Cognitive function/IQ	
Increase in:	Development of feeding skills (earlier full oral feedings)	
Daily weight gain; head growth/length	Fewer behavioral problems and attentional difficulties	
Stability of cardiorespiratory function	Continuation of maternal ability to read and respond to infant behavioral cues/appreciation of the infant	
Sleep states/sleep duration	Better psychomotor outcome at 2 years of age	
Significant electrophysiologic differences in frontal, temporal, central, occipital, and parietal lobes of the brain	Increase in maternal conflict and anxiety when care is not consistent	
	Better sentence comprehension at 36 months

involving very preterm/VLBW infants, full-term infants, and their mothers examined the security of the infant's attachment to the mother at 18 months of age.[455] A majority of the full-term (72%) and the very preterm infants (61%) were securely attached. However, more very preterm infants (32%) had disorganized attachment than the full-term infants (17%). **Researchers concluded that neurodevelopmental problems in the very preterm infants altered their ability in social relationship with their mothers.**

Research has shown medical, developmental, and cost benefits to low-birth-weight (LBW) infants from individualized behavioral and environmental care in the NICU (Box 13.4). **The most effective interventions (1) follow the Newborn Individualized Developmental Care and Assessment Program (NIDCAP),*; (2) are contingent on the infant's responses, thus are interactive and individualized; (3) create an environment that balances protection from sensory overload with provision of enough stimulation to promote emerging capabilities; and (4) collaborates with the parents in planning, providing, and evaluating developmental care.[7,11,255]**

The first randomized controlled trial (RCT) of individualized developmental care (NIDCAP)[11] for VLBW (inborn and transported) infants conducted in three diverse NICUs showed improvement in medical well-being and neurobehavioral and family function.[11] Neurobehavioral benefits included better autonomic or motor system regulation and self-regulation and reduced need for facilitation.[11] Given the diversity of the NICU settings and populations, the biggest differences in beneficial outcomes were appreciated in the most challenged settings (e.g., NICUs initially using the least developmental care, families with multiple social and cultural vulnerabilities, the sickest infants).[11]

Another RCT studied the effectiveness of NIDCAP initiated within 72 hours of NICU

* References 8, 9, 11, 270, 271, 335.

admission in 30 preterms (28–33 weeks' gestational age [GA]) on brain structure and function.[7] **The group of preterms receiving NIDCAP showed significantly better neurobehavioral functioning at 2 weeks' and 9 months' corrected age on mental and psychomotor development than that of the control group.** Changes in the brain on MRI included a more mature brain fiber structure between brain regions (e.g., frontal to occipital; frontal to parietal) than is consistent with enhanced neurobehavioral functioning. **The study's conclusion is that the quality of early experiences (e.g., before term) significantly alters brain structure and function.[7] Several more recent RCTs of NIDCAP show improved health and neurodevelopmental outcomes, shorter length of stay, and less chronic lung disease (CLD) for VLBW preterms and severe intrauterine growth restricted (IUGR) preterm infants at 2 weeks' corrected age, 9 months corrected age, and at 8 years. Higher quality of developmental care in the NICU is associated with better neurobehavioral performance (i.e., better attention and self-regulation, less excitability and hypotonicity, lower stress scores, and better language skills at 36 months).**[289-291]

Preterm infants are not the only infants at risk from the stress of overstimulation in the NICU. **Acutely ill infants and chronically ill infants with prolonged hospitalization also experience stress.** A term infant with persistent pulmonary hypertension (see Chapter 23) is particularly vulnerable to repeated handling, procedures, and interventions that decrease Pao_2. Thus, these infants are managed on a minimal intervention regimen: Care is organized, coordinated, and individualized to decrease noxious stimuli and physical manipulations. The chronically ill infant with bronchopulmonary dysplasia (BPD) has been shown to improve when behavioral or environmental changes were initiated.

The ultimate goal of intervention strategies in the NICU is to facilitate and promote infant growth and development and thus task mastery.[334] During rapid stages of brain development, neuroprotection of the preterm and sick term infant's brain in the NICU by providing an environment that nurtures brain growth and minimizes brain injury is essential.[50,247] **In the NICU, these goals are achieved by the following:**

- Altering the environmental and caregiving stressors that interfere with physiologic stability
- Promoting individual neurobehavioral organization and maturation by identifying and facilitating stable behaviors and reducing stressful behaviors
- Conserving energy
- Teaching parents to interpret infant behavior
- Promoting infant-parent interaction and caregiving

Core measures for evidence-based developmental care have been identified: (1) protected sleep; (2) pain and stress assessment and management; (3) developmental activities of daily living, such as positioning, feeding, and nonnutritive sucking (NNS); (4) family-centered care; and (5) a healing environment.[93]

Establishing biorhythmic balance and physiologic homeostasis is necessary for survival and is enhanced by a sensitive, responsive NICU environment. **An unresponsive environment may so stress the preterm infant that apnea, bradycardia, and other physiologic instabilities severely compromise and prolong recovery.**[156,227,334,413] For the hospitalized infant, development of the sense of self and trust is undermined by noncontingent stimulation that prevents establishing a sense of competence and control of the environment.[158] When the ventilated infant experiences hunger or is wet, he or she cannot signal the care provider with a cry because of the tube. Thus, the infant experiences a need but cannot signal and bring care and relief. The infant soon learns that he or she is not in control of the situation. Similarly, another intubated infant may be quietly asleep and not experiencing a need, but it is "care time," so the nurse moves, wakes, changes, and generally disturbs the infant. This infant also soon learns about not being in control of the situation.

Hospitalized infants, especially those with prolonged stays, may exhibit the classic signs of institutionalized infants or infants suffering from maternal deprivation (Box 13.5).[392] It is the goal of "environmental neonatology"[158] to prevent this maladaptive behavior by altering the NICU to be more developmentally appropriate and responsive to infants. **Normalizing the environment begins with an assessment of the stimulation to which the individual infant is exposed.** The type (i.e., noxious versus pleasant;

BOX 13.5 CRITICAL FINDINGS

CLASSIC SIGNS OF "HOSPITALITIS"

Asocial Behavior

- Gaze aversion—fleeting glances at caregiver with inability to maintain eye contact
- Flat affect—social unresponsiveness (little fixing and following; little smiling) to caregiver
- Little or no quiet alert state—infant abruptly changes state and often is described as "either asleep or awake and crying" (crying is only "awake" state); out-of-control crying

*Touch Aversion**

- Becomes hypotonic or hypertonic with caregiving or attempts at socialization
- Fights, flails, and resists being cared for or held
- Aversive responses (see Table 13.4) to caregiving or holding

Feeding Difficulties

- Have multiple origins, including delayed onset of oral feedings, touch aversion around mouth secondary to invasive procedures, multiple caregivers, feeding on schedule rather than demand
- Rumination syndrome—voluntary regurgitation, a form of self-comfort and gratification when environment is not nurturing or gratifying

Failure to Thrive

- Poor or no weight gain despite adequate caloric intake
- Develops mental delays (language, motor, social, emotional)

* Infant associates human touch with pain.

contingent versus noncontingent), amount, and timing of stimulation should be noted. To decrease noxious stimuli, no infant should have "routine" care (e.g., all infants are suctioned every 2 hours; all infants have a glucose test every 4 hours).[156] **Care should be individualized by asking these questions: "Why are we doing this procedure?" and "Is this procedure necessary for this infant's care?"** Overstimulation in the NICU occurs when 81% to 94% of all contacts are medical or nursing procedures, an average of 40 to 132 of which are performed per day.[124] The frequency, pattern, and trends of caregiver encounters and disturbance have not changed over the past 20 years,[19,68,334] although caregivers grossly underestimate the amount of handling to which NICU infants are exposed. Nurses, who are best able to control overstimulation, provide the majority of handling, sleep disruption, excessive disturbance, and noncontingent interaction to these fragile infants (number of contacts ranging from 79 to 164 times, evenly distributed over a 24-hour period).[19] Painful, invasive procedures that are not vital to the individual infant are stress-producing events that should be eliminated (see Chapter 12).

Rest may be the most important environmental change.[181,334] Sleep disruption is stressful to preterm and sick term neonates in the NICU and alters weight gain, visual development, state regulation, cortical growth, and physiologic stability.[66,160] **Disturbing preterm infants for care every 3 to 4 hours during the night and exposure to light for less than 15 minutes does not prevent preterm infants from developing circadian rest-awake/active patterns or appropriate weight gain as long as they are exposed to regular light-dark cycles.**[199] In a study of ventilated extremely LBW (ELBW) infants, the relationship between hypoxemia and state revealed that sleep disruption with its accompanying motor activity was associated with hypoxemia more often than when these infants were in active/quiet sleep.[227] Recommendations of this study include (1) using strategies (e.g., clustering care, kangaroo care [KC]) to promote sleep in ventilated infants and (2) sleep cycling analogous to in utero patterns (e.g., more quiet sleep) to improve ventilatory stability, decrease hypoxemia, and improve oxygenation.[227] **Quiet sleep for preterm infants is enhanced by (1) no caregiving; (2) social interaction, especially with the parents in skin-to-skin care; (3) NNS; and (4) lateral positioning.**[236] A recent study showed that rapid sleep onset in premature infants in the NICU is facilitated by distal skin vasodilation.[28] Quiet sleep is disrupted with routine and intrusive care.[184] Individualized developmental care promotes sleep.[5]

Although rest periods are necessary for normal growth and development and optimal immune function,[361] **care continues to be evenly distributed over 24 hours without adequate periods of undisturbed rest.**[5,334] **Rest periods of less than 60 minutes are ineffective and insufficient for the preterm to complete a normal sleep cycle.**[334] The length of rest periods in most NICUs has not changed (Table 13.5), and institution of a rest period (even only 1 hour in length) does not necessarily decrease the amount of disturbance.[185] A recent study of "hands

TABLE 13.4 CRITICAL FINDINGS
Self-Regulatory Versus Stress Behaviors

ORGANIZATION	DISORGANIZATION
Physiologic	
Cardiorespiratory: stable heart and/or respiratory rate; regular, slow respirations	Cardiorespiratory: increase or decrease in respiratory rate; irregular respirations; apnea; gasping; bradycardia; blood pressure instability; sneezing, hiccoughs, coughing, sighing
Color: pink, stable	Color: mottling, duskiness; cyanosis—central or generalized; pallor or plethora
Gastrointestinal: tolerates feedings	Gastrointestinal: abdominal distention; spitting up; vomiting; gagging; stooling
Behavioral	
Body movements smooth and synchronous: consistent tone of all body parts; arms and legs flexed with smooth movements	Tremors, jittery and jerking movements; hypotonia or hypertonia (flaccid trunk, extremities; movements arching, flailing, extended extremities; finger splays, fisting)
States: well-defined sleep-wake	Unable to modulate states: sudden state changes; more active than quiet sleep; awake states with gaze aversion, frowning, grimacing, staring, irritability, wide-eyed "help me" look
Self-quieting behaviors: hand-to-mouth, hand or foot clasping, finger folding or grasping, sucking, foot or leg bracing	Limited use of self-quieting behaviors (may need assistance from caregiver)
Attentive behaviors: alert gaze; fixes and follows visual stimuli; ceases to suck or slows suck rate, turns toward auditory stimuli, smiles; imitates; opens mouth, extends tongue; vocalizes: coos, babbles, habituates to stimuli	May demonstrate any of the foregoing stress signals when attempting to interact with one or more modes of stimuli (e.g., rocking, talking) simultaneously in environment (either animate or inanimate)

TABLE 13.5 REST PERIODS FOR NICU INFANTS: RESEARCH BASIS

AUTHOR, YEAR	LENGTH OF REST PERIOD
Korones, 1976[211]	Range of mean rest periods 5.6–19.2 min
Duxbury, 1984[113]	Average time of 30.2 min
Evans, 1994[124]	Time between handling: 1–38.45 min in first nursery 1–60 min in second nursery
Appleton, 1997[19]	2–59 min
Levy, 2017[233]	50.9 min (+26.2 min); median 2.3 min

NICU, Neonatal intensive care unit.

on" care evaluated 25 term and near-term infants in the NICU and found **that the maximum duration for rest between handling sessions was 50.9 minutes (+26.2 minutes) with a median of 2.3 minutes between handling contacts.**[233] Regardless of behavioral state, the infant was disturbed: (1) 29.5% in active sleep, (2) 23.1% in quiet sleep, (3) 29.9% when awake, and (4) 17.4% in an indeterminate state. With sleeping neonates, awakenings and arousals occurred 57% of the time. With "hands on" care, shallow

breathing—primarily when the infants were in active sleep—occurred between 16% and 28% of the time, apnea occurred 8% of the time, and oxygen desaturations occurred 19.5% of the time.[233] **Nurses have a low level of knowledge about neonatal sleep and should be prime advocates for guarding sleep and knowing that adequate sleep is necessary to protect the development of the neonate's brain while in the NICU.**[257]

A fetus in utero and a term infant at home relate to a minimum of caregivers and thus need to learn one or only a few sets of cues. **Consistency of caregivers is essential for an infant's developmental agenda. Multiple caregivers in the NICU confuse the infant by providing many care-related cues for the infant to learn—many techniques of handling and many emotional, nonverbal messages to decode. *Primary nursing* minimizes the number of care providers, because the primary nurse and one or two associates always (or as much as possible) care for the infant; assess, revise, and write the care plan; and coordinate care.**[247] ***Primary nursing*** **also adds consistency and continuity for parents and satisfaction for nurses.**[247]

The infant's state or level of arousal provides an appropriate context for caregiving. Some infants exhibit a low threshold for stimuli; they are easily overwhelmed and fatigued. Others with a higher threshold are quieter, more difficult to arouse, initiate less, and thus receive less interaction.[12] **Organizing care to be reciprocal to the infant's state reinforces the infant's competence in signaling a need (sense of self) and having it met (sense of trust and mastery).** As the infant matures, feeding on demand rather than on a schedule not only teaches this valuable lesson but also increases absorption and use of caloric intake.[156,384] If the infant is asleep, ask: "Should we do this now? Would another time be better?" In some centers, physicians make an appointment with the nurse to examine the infant at a time that is optimal for the infant.

Because preterm infants exhibit short duration of state cycles until around 38 weeks, they have decreased tolerance for stimuli. **The smaller, sicker, and less mature the infant, the less he or she is able to handle stimuli.** Some preterm infants tolerate all care done at once and long periods of rest; others do not and need care spread out to decrease overstimulation and decompensation. ***Clustering of care*—performance of several procedures together in a short period—**may result in more physiologic alterations (changes in cardiorespiratory stability, changes in blood pressure, increased cortisol levels, and heightened pain responses) than a single care-taking event or the actual length of the handling episode.[183] **Studies show increased and prolonged behavioral motor responses and increased cortisol levels indicative of stress during clustered care; clustered care is especially stressful for preterms less than 28 weeks' gestational age.**[182] Clustering care may not ensure long rest periods, because 50% of all rest periods in several NICUs were shorter than 10 minutes (see Table 13.5).[124] **If the practice of clustering care—with its prolonged disturbance of the preterm infant—results in alterations of vital signs, oxygen saturation, and infant stress and fatigue, then care should be individualized and provided to minimize physiologic and behavioral disturbances.**[171,183,227,334] A study of medically stable preterms found that after nursing interventions, these infants generally sleep, either from satiety or from the significant energy expenditure associated with caregiving.[399]

Even "preterm growers" may be unable to tolerate more than one stimulus at a time. They feed best if visual, auditory, and social stimuli are not provided until after the feeding. As the infant matures and is able to tolerate integrated experience, multimodal stimuli are provided.[449] Studies of multimodal stimuli (e.g., auditory, tactile, vestibular, visual) provided to preterms demonstrate (1) increased alertness, (2) earlier discharge, (3) faster progression to full oral feedings, (4) improved organization of behavioral states, (5) stable respiratory rate and oxygen saturation, and (6) a significant decrease in resting heart rate.[449,450]

Alterations in the individual infant's daily schedule are made to accommodate a more flexible or structured schedule—whichever is better for the infant.[158] **Assessing the infant before, during, and after an interaction or intervention guides the care provider in adapting care and the environment to the individual infant** (Table 13.6).

An organized infant is able to interact with the environment without disrupting his or her physiologic and behavioral functioning.[12] **When a disorganized preterm interacts with the environment, signs of physiologic and behavioral stress may occur (see Table 13.4), in which case the interaction should cease.**[171,210] The potential effects of stress and trauma to fragile preterm infants have not only short-term but also long-term impacts on their

TABLE 13.6 PARAMETERS FOR ASSESSING INTERACTION AND INTERVENTION WITH NEONATES

TIME FRAME	ASSESSMENT
Before	
Gather baseline data **before** touching the infant	Gestational age and postconceptual age Diagnosis Level of physiologic homeostasis: Previous vital signs Oxygenation state—continuous pulse oximetry or transcutaneous monitor Neonatal state: Sleep—deep, light, drowsy Awake—quiet, active alert, crying Self-regulatory versus stress behaviors (see the Critical Findings in Table 13.4)
During	
Gently and as unobtrusively as possible assess physiologic and behavioral signs during intervention	Level of (current) physiologic homeostasis—vital signs and changes: Observation (without touching infant)—color, posture, general appearance, respiratory rate, temperature (skin, incubator), blood pressure (transducer), oxygenation (from continuous monitor) Quiet (with minimal disturbance)—auscultate heart, lungs, and abdomen; axillary temperature, blood pressure (cuff); head-to-toe assessment; oxygenation (saturation decreases with distressful, disturbing stimuli) Neonatal state change: Sleep—deep, light, drowsy Awake—quiet alert, active alert, crying Self-regulatory versus stress behaviors (see Table 13.4)
After	
Assess physiologic and behavioral signs after intervention (delayed reactions may occur minutes after care)	Level of physiologic homeostasis Vital signs—Returned to baseline values? More stable or less stable than baseline values? Neonatal state change—Return to baseline state? To a higher state? Unable to be consoled? More consolable left alone?

outcomes.[337,386] An intubated preterm infant cared for in a NICU with a strict suction "routine" every 2 hours responds with profound cyanosis, lowered $TcPo_2$ and pulse oxygenation, and bradycardia and requires bagging after every suction (with no secretions obtained), an obviously unnecessary and stressful intervention. In a less rigid, more individualized care setting, that same infant may signal the need for suction by becoming restless, by a decrease in oxygenation, or by heart rate changes (tachycardia or bradycardia). Suctioning improves the infant's condition—the infant lies quietly and has improved oxygenation, and the heart pattern stabilizes. This infant has signaled his or her need, and the care providers have read the cues and responded with a stabilizing intervention—the infant has not been stressed by an unnecessary procedure.

Knowledgeable professionals are able to role model for and teach parents how to relate to their premature infant.[208] Parents are taught to recognize and use infant states to maximize appropriate interaction.[208] The drowsy premature infant may be unable to engage in eye-to-eye contact with their parents or be able to sustain it for too short (for the parents) a period. Waiting until the infant is more awake to initiate eye contact is more rewarding for the parent and less stressful for the infant. **Role model for parents that their infant is an individual and, although premature, can signal for more or less stimulation** (see Table 13.4).

A preterm infant who is lightly touched may startle, jerk, or withdraw from parental touch. In response, the parent suddenly and sadly pulls his or her hand away and is reticent to touch the infant again. Intervention includes helping parents read cues and learn appropriate responses to their infant. Teach parents how to recognize a stressed infant and how to intervene. **At the same time, be sure to acknowledge the parents' knowledge of the infant and support them. Above all, do not patronize. Professionals have much to learn from parents, who are "professionals" in their own right. The prime rule of relating to infants is this: The infant leads; the adult follows.**

Feeding a premature infant may be difficult because the infant "goes to sleep" during feedings. The usual parental ministrations of talking to the infant, soothing with touch, or holding upright on the shoulder may not work with a fussy, irritable preterm infant.

The preterm infant's behavior may be so disorganized, unpredictable, or misunderstood by the parents that an appropriate response is not possible.[6,156] Thus, parents often become exhausted, bewildered, and frustrated in their encounters with their preterm infant's behavioral response to their care as rejecting and unloving: "My baby doesn't like me." **Teach parents that their infant's disorganization with stimuli is related to prematurity (i.e., an immature CNS) and not to parent ministrations. Reassure them that as the premature infant grows and displays maturational changes, he or she will be able to tolerate more stimulation** and will be more responsive to their care.

Just as parent-infant interaction is responsible for normal development of the term infant, parent-infant interaction is crucial in the development of at-risk infants. Many parents of premature infants have been observed making heroic efforts over long periods to interact with their less alert, active, and responsive infants.[156,275] Parenting the preterm has been described as "more work and less fun." **Setting parents up to succeed involves placing parents in situations in which they will experience positive feedback from their infants.** Suggesting and role-modeling intervention strategies show parents what and how to play and interact with their infants. Parent participation in intervention strategies is ensured by stressing how important it is to infant development, that professionals are too busy to provide all the necessary interventions, and that parents are in a unique position to provide developmental care in the hospital and at home after discharge. **Parents, with help from professionals, are the ideal planners and providers of developmentally appropriate intervention strategies[380]** (see Table 13.1).

A rooming-in setting for parents and their at-risk newborns is the best environment for cues to be learned and care given according to these cues. **Unlimited and unrestricted contact of parents and newborns should be the policy in every normal, medium-risk, and high-risk nursery** (see Box 29.2). Providing a single-room NICU, a family room, bonding room, or apartment in which parents and their soon-to-be-discharged newborn can room-in helps the transition from hospital to home care. Rooming-in before discharge gives mothers and fathers an opportunity to assume full responsibility for their infant's care, tests the reality of caregiving, helps them learn caregiving activities and their infant's behavior patterns, and confirms their readiness for independent parenting and the infant's readiness for discharge.

Intervention Strategies

Because infants experience their environment through sensory processes, intervention strategies are based on tactile/kinesthetic, auditory, visual, olfactory/gustatory, and communication skills. **Interventions must be individualized according to the infant's state, sensory threshold, physiologic homeostasis, and stability or stress cues.**[124,183,227]

CIRCADIAN RHYTHMS

In utero, the states of the fetus are regulated by the sleep-wake cycles of the mother. In the NICU, multiple intrusions disrupt regulation.[358-360] How this affects an infant is not fully known, although limited energy may be drained, the infant may be subjected to further stress,[6,158] neurodevelopment altered, and outcomes of therapeutic interventions may not be optimized. To minimize interruptions and excessive handling, infants should not be awakened when asleep; if they must be awakened for care, it should be during active sleep by talking softly and stroking gently.[5,110] Appointments for examinations should be made before feeding to decrease unnecessary disturbance of sleep but with enough rest time (if needed) before actual feeding.

Adequate numbers of caregiving encounters—physical assessment, vital signs, diaper or linen change, and procedures—must be balanced against constant manipulations.[123,156] **Because essentially all NICU (levels II and III) infants are continuously monitored, "laying on of hands" every 1 to 2 hours is often unnecessary. Thorough physical assessment and vital sign recording every 4 hours is easily alternated with recordings from the monitors every 4 hours. Thus, the infant is evaluated every 2 hours but not disturbed that often.** An acutely ill infant may need closer observation, but alternating "hands-on" with monitor readings accomplishes the goal without overwhelming an infant with few reserves. **One systematic review recommends regulating elective care (i.e., routine laboratory draws, x-rays, and cardiac assessments) so that it is not being done during sleep.**[422]

Sleep-wake patterns are influenced by feeding method[404] and schedule,[60,61] temperature, position, CNS maturation, birth weight, caregiving practices, and environmental effects (e.g., ambient light, noise, day/night).[221,358-360,415] **In the NICU, activity/rest patterns are evident as early as 35 weeks' post-conceptual age and cycle at 3-hour intervals, related to feeding schedules.**[60] During the first week at home, the 3-hour sleep-wake cycle established in the NICU is replaced by a circadian rhythmicity.[61] Sleep-wake patterns in breastfed and bottle-fed infants differ. During the first month of life, full-term breastfed infants awaken more and sleep less during the night.[149]

Day-night cycles are facilitated by afternoon naptime and nighttime in which the dimming of lights or covering of incubators and cribs with blankets and quieting of NICU noise enable infants to sleep. Deep, quiet sleep is facilitated by quiet and dark, soft music or nature sounds, gentle stroking of the head, and self-regulated tasks (self-sought proximity of infant to "breathing bear").[403] Maintaining daily naptime and nighttime hours helps infants reset their diurnal rhythms and become accustomed to sleeping in dim light and a quiet environment. **Percentage of sleep time and duration of sleep for preterm infants in the NICU is longer at night than during the day,** and better sleep patterns were associated with being male, younger PMA and chronological age, smaller in body weight, and less illness severity.[221] Among convalescing preterm infants (<34 weeks' gestational age), four standard rest periods per day resulted in (1) increased daily weight gain, (2) increased sleep, (3) less-active states during nap time, (4) decreased occurrences of apnea, and (5) by 3 weeks, less quiet waking time and longer uninterrupted sleep episodes.[181,411] **Uninterrupted sleep and diurnal rhythmicity also are associated with improved state organization in VLBW infants and with less fussing and crying.**[359,360]

TACTILE AND KINESTHETIC INTERVENTION

Because the sense of touch is highly developed in utero, even a very immature preterm has acute tactile sensitivity. **For newborns, human touch is the most important tactile stimulation.** Not all touch is equal, however, nor is it responded to equally by term or preterm infants who are well, critically ill, or recovering from illness. One study has shown the effect of the vulnerability of LBW infants in their response to the nurturing touch of their mothers. Nurturing maternal touch was associated with a secure attachment in robust infants; in highly vulnerable, sick LBW infants, this same nurturing touch was associated with a less secure attachment.[444] Any type of tactile stimulation is composed of six factors: duration, location, action, intensity, frequency, and sensation. **Tactile sensation both arouses and quiets. Gentle but firm handling quiets infants because they feel more secure; light, uncertain touch often results in agitation and withdrawal. Handling for routine care (e.g., vital signs, changing the diaper or position, venipuncture for blood draws or placement of IV lines, feeding, heelsticks, suction, and physical or neurologic examinations) can result in hypoxia, increased intracranial pressure, episodes of apnea/bradycardia, agitation, elevated pain and stress scores for VLBW preterms, and increased or decreased heart rate and blood pressure.**★ Applying developmentally supportive care to "routine" procedures such as diapering decreases the physiologic stress response in fragile preterm infants and offers them repeated opportunities to enhance their neurodevelopment.[123]

Handling. How a neonate is handled during care affects his or her physiologic and behavioral response. Use of body containment during

★References 68, 98, 99, 123, 125, 241, 332, 399, 462.

suction decreases the physiologic and behavioral responses to this stressful procedure.[402] Comparing preterm responses to swaddled and unswaddled weighing, unswaddled infants exhibit more physiologic distress, more motor disorganization, poorer self-regulation, and more need for caregiver facilitation than when they were swaddled for weighing.[302] **Transferring preterm infants from the incubator to the parent for holding or KC is stressful.** One study evaluated physiologic disorganization in preterms according to the method of transfer from the incubator for KC (nurse picking up the baby and transferring to the parent versus the parent picking the baby up directly from the incubator).[307] Both transfer methods resulted in increased physiologic and motor disorganization (i.e., oxygen desaturation, tachycardia, cyanosis/pallor, hypotonia, decreased self-regulation, and increased need for caregiver facilitation to maintain physiologic stability during transfer). In both methods of transfer (which lasted 6–9 minutes), the ventilator was disconnected (for 5 seconds). **Both the infant's desaturation readings and tachycardia recovered to baseline levels faster with the parent transfer.**[307]

Excessive handling of preterm, VLBW, or sick neonates results in significant physiologic consequences, such as blood pressure changes, alterations in cerebral blood flow, hypoxia, and other stress behaviors.[241] One study of ventilated VLBW infants found an average of 53 handling episodes, for an average length of 3 minutes over a 24-hour period.[68] These infants had pain scores significantly higher after than before handling regardless of the reason for the handling (i.e., invasive/noninvasive or social/nonsocial).[68] A recent study compared the frequency and severity of hypoxemia episodes (SpO_2 <75%; SpO_2 <85%) in 24 mechanically ventilated premature infants during daytime (0900-1700) and nighttime (2100-0500) hours.[193] **Nighttime hours had fewer and less severe hypoxemia episodes when compared to daytime hours. The researchers concluded that the babies were handled less frequently and had less sensory stimulation during the nighttime hours.** A particularly vulnerable group of preterm infants, those with periventricular leukomalacia (PVL), react to handling and multisensory stimulation (e.g., auditory, tactile, visual, vestibular) with an increase in heart rate above their already higher resting heart rate.[377] These CNS-injured preterms require close observation and monitoring during handling, stressful procedures, and interventions.[450]

A total body position change is not considered a painful procedure, but in LBW preterm infants with endotracheal tubes and umbilical artery catheters, the handling necessary to change the infant's position elicits pain behaviors.[126] **Nonpainful tactile stimulation (e.g., routine nursery handling) of preterm infants has been shown to produce equal or higher levels of physiologic stress activation than does a painful stimulus (e.g., heelstick).**[68] In the same study, the relatively low behavioral activation during "routine handling" led the researchers to conclude that this tactile stimulus was not unpleasant to the infants, even though it produced a high level of physiologic stress response.

In the NICU, infants who are repeatedly subjected to painful, intrusive procedures develop touch aversion—the association of human touch with pain. Tactile vulnerability has also been found in infants who require multiple postnatal medical interventions, who are exposed to illicit drugs in utero, and whose mothers had their own predisposition regarding being touched (a genetic component?).[443] These infants cry uncontrollably, squirm away, flail arms and legs, and recoil when touched, knowing that pain will soon follow. An infant who has received ventilatory therapy may have touch aversion around the mouth: The infant is averse to facial stroking and rooting, has a hypersensitive gag reflex, and refuses to nipple feed. Painful procedures should be minimized to those absolutely (medically) indicated—no infant should be subjected to "routine" painful procedures. During those necessary procedures, it is essential to provide body containment, comfort measures (e.g., a pacifier), and adequate pain relief (see Chapter 12).

Touch. Touch that is not related to caregiving (i.e., social contact) should be provided by parents and professionals when the preterm infant is aware, alert, and receptive. When parents touch their babies, the amount and types of touch vary widely—most frequently, holding, stroking, rubbing, or placing a finger in the infant's hand. Preterm infants respond individually and physiologically to their parents' touch; there is more variation in heart rate and oxygen saturation levels compared with baseline values. These variations depend on gestational age, infant state, and the amount of handling before parent

handling.[170] **Less touching by the nurse within the 2 hours before parental holding results in less mean decrease in heart rate during parental holding.[170] Parents provide more positive touch (kissing and stroking); preterm infants are more likely to smile and sleep for their parents** compared with responses after a nurse's touch. In animal studies, increased parental touching in infancy results in changes in brain structure, decreased levels of stress hormones, and better ability to survive a stressful environment.[437] **Parental touch of preterm humans enables them to withstand the stress of illness and the NICU environment.** Recent research on somatosensory processing found that the degree of prematurity at birth determines the extent to which the immature brain responds to light touch, so that **supportive experiences (such as breastfeeding and skin-to-skin contact) are associated with stronger brain responses,** and **painful stimuli are associated with a reduced brain response to the same touch stimuli.**[259]

Nonpainful touch such as stroking (of the head, trunk, or hands) during care may calm, soothe, and prevent touch aversion. **Stroking of physiologically stable preterm infants has been associated with increased activity and alertness, a faster regaining of birth weight, more rapid weight gain, less crying and apnea, enhanced developmental status, and better social scores.[169,171] In another study, systematic stroking of ventilated preterms resulted in no adverse effects on oxygenation and respiratory or heart rates.[104] However, in preterm infants (26–30 weeks' gestation) who are not physiologically stable, stroking results in decreased oxygen saturation, signs of behavioral stress (e.g., grasping, grunting, gaze aversion), and more avoidance cues (e.g., grimacing, yawning, fussing or crying, tongue protrusion).** Other behavioral and physiologic effects include heart rate and blood pressure changes, changes in respiratory rate and rhythm, increase in avoidance signals (e.g., increased startle reflex, agitation, crying), increase in activity and movement, and decreased visual responsivity.[99,170,241,307]

If the preterm infant becomes agitated with stroking, a hand firmly placed on the head and lower back, buttocks, or abdomen often quiets.[91,169] **Hand placement without stroking does not decrease oxygen saturation or alter heart rate and has a soothing effect (i.e., decreases active sleep, increases quiet sleep, decreases respiratory and heart rates, decreases motor activity and behavioral distress) on small preterm infants.[171,172,188,285] Handle gently to avoid stressful reactions (e.g., flailing, arching, oxygen desaturation) and enable the infant to become calm and rest between caregiving.** Parents should be taught and encouraged to provide their preterm with "gentle human touch"[169,285] in the form of supportive containment with their hands, use of gradual and rhythmic action, observation of infant responses (see Table 13.4), and modification, alteration, or cessation of touch when necessary.[169,171]

Therapeutic touch (TT), a complementary therapy of balancing and increasing energy to promote healing, does not require physical contact, as hands are suspended over the body. A randomized double blind study of the use of TT on 10 physiologically fragile, very preterm infants showed no adverse effects (i.e., oxygen desaturations or apnea).[451] Clearly more research is indicated.[388]

Massage. The touching and stroking of massage stimulate nerve pathways and aid myelinization by increasing hypothalamic activity and production of the growth hormone *somatotropin*. In animal studies, touch deprivation decreases growth hormone secretion, which results in undergrowth of all organ systems; a return to normal secretion occurs with tactile stimulation.[374] Massage affects the maturation of the brain's electrical activity and simulates intrauterine development as observed in term infants.[166] A growth gene that responds to tactile stimulation has been discovered; this suggests a genetic origin for the touch-growth relationship.[134] Because touch stimulation of the inside of a neonate's mouth increases the release of gastrointestinal food absorption hormones (i.e., gastrin, insulin), it is postulated that the tactile stimulation of massage leads to a similar hormone release. Assays of glucose and insulin levels in heelstick samples of preterm infants suggest that massaged infants show increased levels of insulin.[134]

Research on massage therapy with preterm infants has been conducted on medically stable, growing infants (i.e., preterm growers). A recent systematic review found clear benefits of massage in hospitalized preterm infants.[14] Despite positive outcomes of massage research in Table 13.7 and its cost effectiveness in decreasing length of stay, only

TABLE 13.7 BENEFITS OF MASSAGE WITH PRETERM INFANTS: RESEARCH BASIS

STUDY	RESULTS
Three times/day massage of preterms with physiologic and biochemical measurements[373]	21% increase in daily weight gain Discharged 5 days earlier Superior performance on habituation Fewer stress behaviors (mouthing, grimacing, clenched fists) Increase in catecholamine secretion in neonatal period (analogous to the normal developmental increase after birth) Increase in vagal activity
10 healthy preterm "growers": three times/day massage for 15 min in a randomized sequence of 5 days of massage and 5 days without massage[217]	Energy expenditure significantly lower after 5 days of massage than after 5 days without massage in metabolically and thermally stable preterms Decreased energy expenditure may contribute to enhanced growth caused by massage
Massaged for 15 min three times/day for 5 days: 68 preterms (mean GA = 30 wk) with either light- or moderate-pressure massage[135]	Fewer stress behaviors and less activity from first to last day of the study Moderate-pressure group: significantly more daily weight gain; more relaxed, less aroused than light-pressure group
80 preterms randomized to moderate-pressure massage or standard care[106]	Increase in vagal activity and gastric motility, which may contribute to greater weight gain in massaged preterms
72 preterms randomized to massage or control therapy[107]	Greater increase in body temperature in massage versus control preterms (even though incubator portholes were open for the massage but not for the control group)
Massaged or exercise for 10 min three times/day for 5 days[108]: 30 preterms randomized to moderate-pressure massage *or* passive flexion and extension of limbs 21 preterm infants (8 males and 13 females)[389]	Greater weight gain in both massage and exercise groups due to different mechanisms: • Massage increased vagal tone • Exercise increased calorie consumption Massaged male infants had improved autonomic nervous system function during caregiving and sleep compared with nonmassaged male preterms. There was no difference in heart rate variability between massaged and nonmassaged female preterm infants.[389]
40 stable preterm infants randomized to 20 minutes of massage twice daily for 4 days or no massage [33]	Lower level of transcutaneous bilirubin and more defecation in massaged versus non-massage group.[33]
Mother Massage	
104 VLBW infants (≥750 to ≤1500 g; ≤32 wk GA) randomized to control or standard care with maternal massage four times/day of face and limbs with passive limb exercises[281]	Significantly lower incidence of late-onset sepsis Discharged from the hospital 7 days earlier Improved neurodevelopmental outcomes at 2 years CA with massage[343]
66 stable preterm infants (32 massaged by their mother; 34 control group)[1]	Lower pain scores after massage with heelstick and at discharge; higher cognitive scores at 12 months' CA compared with control group. No difference in weight gain, LOS, breastfeeding duration, and motor skills between two groups.
Medically stable preterms (33–37 wk GA; BW 1500–1999g) randomly assigned to massage group or massage with sunflower oil by their mothers three times/day for 14 consecutive days[129]	Oil massage group: mean weight at 1 month and 2 months of age significantly greater than body massage alone group
Eight minutes of mother massage of preterms within 24 hours of discharge and repeated on day of discharge[3]	Less maternal anxiety on the day of discharge when mothers massaged their preterm infants[3]
Olive oil massage for 10 days, three times/day for 15 minutes versus massage without olive oil[191]	Daily average weight gain with olive oil massage (21 g) compared to weight gain of 7 g without olive oil[191]

BW, Birth weight; *CA,* corrected age; *GA,* gestational age; *LOS,* length of stay; *NICU,* neonatal intensive care unit; *VLBW,* very low birth weight.

38% of NICUs practice massage on their stable preterm infants.[136,439] Massage therapy provides social touch rather than painful touch, prevents or treats touch aversion, and should be taught to and provided by parents in the hospital and at home.[276] Confidence in parenting skills and tactile communication between parents and infant is encouraged when parents massage their infant. **Because massage has not been studied in acutely ill preterm infants, its use should be confined to preterm growers.**[134,429] Chronically ill infants (e.g., babies with BPD or congenital heart disease) may exhibit physiologic and behavioral disorganization with massage, so the risk-benefit ratio must be assessed carefully. The M technique, used for fragile infants who do not tolerate conventional massage, is a gentle, structured stroking technique that reduces stress and anxiety. Outcomes of those exposed to the M technique included (1) lower heart rate, (2) increased oxygen saturations, (3) increase in quiet sleep, and (4) fewer behavioral distress cues.[388]

Varying sensations and touch patterns keep infants interested in stroking and massaging. As a preterm infant matures and is able to tolerate variety, he or she should be introduced to different textures (e.g., lambskins, stuffed toys, cotton, satin). Baby clothes provide various textures, decrease heat loss (especially hats), and make the infant more attractive. ("He looks like a real baby!"; "She looks like a girl because her shaved head is covered!")

Holding. When the infant is preterm or a sick term baby, holding him or her—an essential step of parent attachment—is disrupted. Some NICUs promote parental holding as soon as possible, whereas others have specific protocols about weight criteria and extubation before parents are able to hold their infant.[143] A national survey on holding policies found (1) written protocols for conventional holding (26%) and for KC (40%), (2) for extubated infants: 73% offered KC, 99% conventional holding, and (3) for holders of extubated babies: mothers 73% KC, fathers 68% KC, and 99% conventional holding for both parents.[143] Potential benefits of enhanced parent-infant interaction and attachment, closeness of parents to their infant, increased lactation, and improved parental self-esteem are factors that influence staff to facilitate holding.[143]

A prospective cohort study of parental presence and holding in the NICU found significant neurobehavioral benefits for preterm infants less than or equal to 30 weeks' gestation.[354] **Early parenting (i.e., holding) in the NICU resulted in lower arousal and excitability, better quality of movement, less stress, and less hypertonic muscle tone, thus a developmental advantage.**[354] Another study conducted in an urban NICU with low levels of parental presence and holding compared the neurodevelopmental outcomes of preterm infants (<30 weeks' gestation) cared for in single-family rooms versus open ward NICU rooms.[337] The study outcome showed that at age 2 years, children cared for in the private rooms had lower language acquisition, more externalizing behaviors, and a trend toward lower motor scores than those in open wards. The researchers were surprised by their findings and remarked on the relative **sensory deprivation of the preterms in private rooms whose parents were not often present and handling their infants. Long periods of sensory deprivation—lack of parental presence, holding, and auditory stimuli—may be as detrimental as the sensory overload of a noisy, open NICU.**[337] A qualitative study of factors affecting parental presence found that active involvement in the care of their extremely preterm infants, including skin-to-skin holding, increased their motivation to be present and their feelings of control.[176] Factors discouraging parental presence included excessive noise[38] and light levels in the NICU and dismissive staff attitudes.[176] A more recent study of predictors of parental involvement in the care of their premature infants (n=81; <32 weeks' gestational age) found that being Caucasian, older, married, employed, having fewer children, having familial support, and providing breastmilk were all associated with more parental presence.[339] More holding of the infant was associated with fewer medical interventions, an employed father, being Caucasian, fewer children, and having family support. **Outcomes of parental holding resulted in better reflex development at term age, and skin-to-skin holding resulted in better reflexes and less asymmetry at term and better gross motor development at 4 to 5 years of age.** [339] **Communicating to parents the importance of their presence and their care for their baby, as well as providing a welcoming, nurturing, and comfortable place for parents is the responsibility of all the NICU staff, especially nurses.**

KC (Fig. 13.1), skin-to-skin contact between parents and infant by placing the infant in a

vertical position between the maternal or paternal breasts, benefits both parents and neonates (Box 13.6). Another position, "supported diagonal flexion," for skin-to-skin care has been studied to facilitate more face-to-face exchanges between mother and infant in the NICU.[62] **Supported diagonal flexion resulted in more eye contact between mothers and their infants, more maternal vocalizations, caressing, and decreased postpartum depression scores without altering physiologic stability in the premature infants.** KC for the healthy preterm has been used in the delivery room, in the transitional period (see Chapter 5), for adoptive parents, and for transport. National surveys of holding/KC have been conducted and have found that KC is practiced more commonly in subspecialty (level III) than in specialty (level II) care NICUs.[120,143]

KC is well tolerated in the first week of life by preterm infants with current or resolving neonatal illness. KC of preterm infants for even 1 hour has been shown to provide benefits: significant decrease in heart and respiratory rates and increased temperature and oxygen saturations, especially in SGA and female preterms.[47] An RCT of healthy preterms (33–35 weeks' GA) found that KC for 3 hours improved breathing patterns and resulted in no apnea or bradycardia or periodic breathing or temperature instability.[248] KC improves gas exchange in preterm infants of less than 1800 g. The smallest infants (<1000 g) remained more clinically stable (i.e., smallest increase in heart rate, highest decrease in respiratory rate and increase in oxygen saturation, no hypothermia) compared with infants larger than 1000 g.[141]

A randomized study of three holding methods (i.e., KC, cuddled, and a no restrictions method) in preterms between 32 to 35 weeks' gestation **concluded that both KC and cuddled holding by parents may provide equal developmental**

FIGURE 13.1 Kangaroo care.

BOX 13.6 BENEFITS OF SKIN-TO-SKIN CONTACT/KANGAROO CARE

Parental

- Activates maternal/paternal processes of search for meaning and mastery of the experience of premature birth
- Increases maternal/paternal self-confidence, competence, and self-esteem; lower levels of stress related to "incompetence"[139]
- Enhances parent-infant attachment[83]
- Increases parental oxytocin levels[432] and decreased cortisol levels resulting in decreased anxiety levels[83,90]
- More stress in mothers of late-preterm infants related to more facilitated progression of the mother-infant relationship[369]
- Initiates and maintains maternal/paternal behavior
- Positively affects mother's mood/behavior; less maternal depression; calming (decrease in salivary cortisol levels)[41,83,303]
- Favorable impact on maternal parasympathetic nervous system as measured by heart rate variability[64]
- Lowers parental heart rate and blood pressure[197]
- Positive and personally beneficial experience
- Positively affects parental identity and knowledge of infant[363]; positively affects the process of becoming a parent[18]
- Increases confidence in meeting infant's needs
- More frequent visiting
- Parental eagerness for infant's discharge
- A restoring experience and an energy-draining experience[18]
- Long term:
  - More consistent/contingent maternal/paternal responses at 15 months of age
  - More sensitive, less intrusive, more reciprocal interactions from 6 months to 2 years from both mothers and fathers
  - More affectionate touch, more adaptive to infant signals, and infants more alert during interactions at 3 to 6 months
  - Less maternal/paternal separation anxiety at 6 months
  - Improved family cohesiveness
  - Fewer reports of difficulties with breastfeeding
  - 20-year follow-up of original cohort: parents more protective and nurturing[79]

Continued

BOX 13.6 BENEFITS OF SKIN-TO-SKIN CONTACT/KANGAROO CARE—CONT'D

Neonatal

- Thermal synchrony: mother's body temperature rises and falls to maintain infant in neutral state (see Chapter 6)
  - Higher body temperature resulting from advanced maturation of thermoregulation
  - Distal skin vasodilation promoting rapid sleep onset[28]
- Cardiopulmonary:
  - Adequate or improved oxygenation; reduction in oxygen requirement[197]; minimal decrease in cerebral oxygenation while gavage feeding[263]
  - Fewer/no episodes of periodic breathing, apnea, and bradycardia
  - Lower diaphragm electrical activity while being ventilated by NARS[390]
  - Lower heart rate/stable respiratory rate[83]
  - Higher vagal tone: indicative of quicker maturation of the autonomic nervous system (even in infants with complex congenital heart disease)[173]; favorable impact on premature infant parasympathetic nervous system as measured by heart rate variability[64]
  - Stable vital signs, oxygen saturation, and temperature before, during, and after cardiac surgery[174]
- Breastfeeding:
  - Increased milk supply
  - Increased incidence and length (even in very-low-birth-weight preterms)[138,381]
  - Increased exclusive breastfeeding[51]
  - Positive effect on growth in VLBW infants[381]
  - Distinct oral microbiologic pattern and an accelerated pace of microbial repertoire maturity[178]
  - Attainment of full breastfeeding in the NICU at a median age of 35 weeks' PMA[313]
- Behavioral:
  - Increased alert activity
  - The longer the period of KC the more the preterm neonate made physical contact attempts with mother during breastfeeding[308]
  - Increased deep, quiet sleep[34]
  - Improved self-regulation: sleep-wake cycles, arousal, sustained exploration
  - Better emotional regulation and arousal modulation for interaction and rest
  - Decreased stress response: decrease in beta-endorphin and cortisol levels[432]; less stress response to diaper change[253]
  - Decreased or no crying[125,126]
  - Increased en face positioning
  - Better orientation and habituation
  - Less pain response to painful procedure in both preterm and term infants (see Chapter 12)
  - Accelerated brain maturation
- Earlier discharge/ lower cost:
  - Increased weight gain[127,381]
  - No increased infection/fewer infections[51]; decreased severity of infection and mortality; decolonization from resistant bacteria on the infant's skin[220]
  - Out of incubator earlier
- Decrease in mortality of infants with birth weight <2000 g[51]
- Regulatory interaction:
  - Behavioral
  - Sucking
  - Neurochemical (decline in plasma oxytocin levels)[209,442]
  - Metabolic
  - Sleep-wake cycles/improved sleep organization
  - Cardiovascular
  - Endocrine
  - Immune
  - Circadian
- Long-term:
  - Increased length and head circumference at 9 months and 1 year of age
  - Less crying at 6 months of age
  - Higher psychomotor scales at 6 months and higher mental scales at 6 months to 2 years
  - Enhanced mental and psychomotor development at 1 year
  - Better self-regulation, less frustration, and better able to calm themselves at 1 year of age
  - Improved cerebral motor pathways and synaptic efficacy at adolescence
  - Enhanced cognitive development and executive functioning from 6 months to 10 years; by 10 years of age: attenuated stress response, improved autonomic functioning, organized sleep, and better cognitive and behavioral control
  - 20-year follow-up of original cohort: fewer school absences, less hyperactivity, aggressiveness, externalization, and socio-deviant behavior in young adults. Larger volume of left caudate nucleus on brain MRI[79]

MRI, Magnetic resonance imaging; *NARS,* noninvasive neutrally adjusted respiratory system; *NICU,* neonatal intensive care unit; *PMA,* post menstrual age.
Data compiled from references 51, 65, 89, 131, 141, 155, 242, 243, 245, 248, 250, 306, 309, 310, 362, 363, 376, 377.

benefits in the form of early behavioral organization to preterm infants.[303] All infants being held either conventionally or by KC should be monitored continuously for vital signs and oxygen saturation.[248]

Parental holding is often (17%–33%) limited or not supported by nurses and physicians.[43,143] Parents identify both the hospital staff and the environment of the NICU as barriers and supportive of KC.[43,228] A recent phenomenologic study found that NICU nurses attempt to balance the developmental needs of infants with parental readiness to participate in skin-to-skin care.[215] A second phenomenologic study found that information, communication, consistency, and support from staff to parents along with knowledgeable staff assisted in parents performing and having positive experiences with KC.[228] Barriers to holding infants include (1) infant safety concerns (e.g., accidental extubation, loss of arterial/venous lines, vital sign or oxygenation instability) and (2) reluctance of professionals and families to initiate or participate in KC (e.g., adding to RN workload and belief of losing control because of limited access to the infant, difficulty providing care, lack of experience, used for babies who are not developmentally ready, belief that technology is better than KC, belief by professionals that mother would feel trapped and stressed).[120,143,296] From the caregiver's perspective there are four themes in the process of facilitating skin-to-skin care: (1) varying thresholds of getting started, (2) defining adequate resources, (3) dealing with the demands and complexities of the neonate, and (4) balancing parental readiness for skin-to-skin care with the neonate's needs.[431] More than 60% of NICUs responding to one survey stated that low birth weight and gestational age were not contraindications for KC; many NICUs did not permit KC for babies on high-frequency oscillator ventilation (HFOV) or vasopressors.[120]

"Risky populations" for KC include infants who are intubated (Fig. 13.2), have arterial/venous lines and chest tubes, are on pressors to maintain blood pressure, and are on HFOV. A prospective, nonrandomized study in a level III NICU found **a low risk of mechanical complications and no increased risk of infectious complications with skin-to-skin contact in neonates with an indwelling umbilical venous catheter.[75]** One of the national surveys found that 64% of NICUs offered conventional holding to parents of intubated infants and 45% offered KC of intubated infants. The second survey found that 60% of NICU nurse managers thought that intubated infants should not receive KC.[120,143] In one study, 43 intubated, hemodynamically stable preterms less than 1500 g were assessed for 90 minutes (15 minutes of transfer; 60 minutes of KC; 15 minutes of transfer) and found to have stable heart rates, oxygen saturations, axillary temperatures, and mean arterial blood pressures.[23] The researchers concluded that KC was safe for these ventilated preterms under their study conditions. A more recent study of 40 preterm infants (27.6 to 28.9 weeks' gestation) receiving invasive (endotracheal tube ventilation) and noninvasive (continuous positive airway pressure [CPAP] and high-flow nasal cannulae) respiratory support found no difference in physiologic parameters (i.e., regional cerebral oxygenation, heart rate, pulse oximetry values, temperature, or FiO_2) while being held skin to skin for 90 minutes when compared to incubator care.[242]

FIGURE 13.2 Kangaroo care of awake, alert, intubated, and ventilated premature infant.

On the basis of a 3-year study in five NICUs of mechanically ventilated infants receiving KC, selection criteria (Box 13.7) and a safe protocol (Box 13.8) for KC in this population have been developed.[250,251] During this study, no adverse physiologic or behavioral events or accidental extubations occurred. None of these babies was agitated, and all slept and tolerated KC well. Previously

BOX 13.7 SELECTION CRITERIA FOR KANGAROO CARE WITH VENTILATED INFANTS

- Birth weight >600 g; ≥30 weeks' GA
- Ventilator for at least 24 hr before first kangaroo care
- SIMV: <35 breaths/min; F_{IO_2} <0.50 (50%)
- Stable vital signs (TPR, B/P) and oxygen saturation
- Stable blood gases, bilirubin level
- No signs/symptoms of sepsis
- Not receiving vasopressors; no chest tube
- Lines (Broviac, umbilical, arterial, IVs) well secured

B/P, Blood pressure; F_{IO_2}, fraction of inspired oxygen; *GA,* gestational age; *IV,* intravenous; *SIMV,* synchronous intermittent mandatory ventilation; *TPR,* temperature, pulse, respiration.

Modified from Ludington-Hoe S, Morgan K, Abouelfrettoh A. A clinical guideline for implementation of kangaroo care with premature infants of 30 or more weeks' postmenstrual age. *Adv Neonatal Care.* 2008;8:S3.

reported parental perceptions of KC with ventilated babies include the following:

- Ambivalence toward KC: yearning to hold the infant yet being apprehensive about it
- The necessity of a supportive environment
- The special quality of parent-infant interaction: intense connectedness and active parenting

Perhaps these parental and staff concerns may be overcome with careful selection of infants, education about KC, a consistent procedure for transfer, increase in confidence of the staff assisting parents in KC, and a clinical guideline for implementing KC.[177,250,251,309,310] Parents and staff need education about KC, and staff can offer KC to parents instead of waiting for parents to request this intervention.* Recommendations about KC include the following:

BOX 13.8 PROTOCOL FOR KANGAROO CARE WITH VENTILATED INFANTS

In Preparation for Transfer

1. Record baseline vital signs, oxygen saturation, and ventilator settings. Secure and maintain continuous monitoring of these parameters during kangaroo care (KC) to determine infant's tolerance of KC.
2. Place infant supine on a clean blanket (folded in fourths) with assistance of second person, and note changes in vital signs, saturations, or ventilator settings.
3. Auscultate chest and evaluate breath sounds, suction endotracheal tube, and change diaper.
4. Drain water from ventilator tubings to decrease resistance, maintain airflow, and prevent retrograde water flow toward infant when moved or positioned lower than or at the level of the ventilator.
5. Assess infant's responses: Wait 15 minutes to enable physiologic adaptation (e.g., return of baseline vital signs/oxygenation for 3 minutes). If still unstable at 15 minutes, the infant is probably not stable enough for KC at this time.
6. Position the reclining chair near the ventilator, making sure there is ample tubing length.
7. Two or three staff members will assist the parent in transfer of the infant:
   - One person gathers lines to one side of the infant.
   - One person transfers and secures the ventilator tubing.
   - One person assists the parent.

Transfer Procedure

1. After a staff member disconnects the endotracheal tube (ETT) from the ventilator, the parent slides his or her hands under the blanket and infant, lifts both, and places the infant prone against his or her chest in one movement. Reconnect the ventilator tubing and let the infant stabilize. (If the infant was not placed on a clean blanket or it was soiled before transfer, the parent can lift the baby and a clean blanket is placed over the infant when he or she is prone on the parent's chest.)
2. Disconnect ventilator tubing from ETT and move parent backward toward recliner, having him or her sit down when he or she feels the edge of the chair against the calves of the legs. Reconnect the ETT to the ventilator tubing.
3. Assist the parent in being comfortable by raising the footrest, position the infant in a flexed position with head and neck in a neutral position to avoid ETT movement (e.g., downward into the bronchi with head flexion or possible extubation with head extension) and/or obstructive apnea with head flexion or extension if the infant is on nasal continuous positive airway pressure.
4. Secure the ventilator tubing by draping it over the parent's shoulder. *Do not tape the tubing to the blanket, parent clothing, etc.*
5. If using ISC temperature control (on the radiant warmer/incubator), turn to air control, set temperature at 33°C while the baby is receiving KC, and monitor the infant's skin temperature from the temperature gauge on the radiant warmer/incubator. (There is then no need to uncover or cold stress the infant to take a temperature.)
6. Maintain continuous electronic monitoring throughout KC; check both the infant's and/or parent's condition every 10 minutes during KC.
7. If the infant's condition remains stable, facilitate KC for a minimum of 1 hour.

BOX 13.8 PROTOCOL FOR KANGAROO CARE WITH VENTILATED INFANTS—CONT'D

Transfer after Kangaroo Care

1. Slowly place the recliner in an upright position and assist parent to move forward to the front edge of the chair.
2. One staff member handles the lines and another disconnects the ETT from the ventilator lines.
3. Assist the parent to stand, reconnect the ETT to the ventilator tubing, and let the infant stabilize.
4. In one movement, disconnect the ventilator tubing and place the infant in the radiant warmer/incubator.
5. Reconnect the ventilator tubing to the ETT, stabilize, and secure all lines inside the radiant warmer/incubator.
6. Document KC, length of session, and how the infant and parent tolerated KC.

ISC, Infant servocontrol.

Modified from Ludington-Hoe S, Ferreira C, Swinth J. Safe criteria and procedure for kangaroo care with intubated preterm infants. *J Obstet Gynecol Neonat Nurs.* 2003;32:586; and Ludington-Hoe S, Morgan K, Abouelfrettoh A. A clinical guideline for implementation of kangaroo care with premature infants of 30 or more weeks' postmenstrual age. *Adv Neonatal Care.* 2008;8:S3.

- It is an important therapeutic intervention for healthy preterms (gestational age ≥34 weeks) and their mothers in a modern, well-equipped NICU[248,447] as recommended by the World Health Organization.[457]
- It is a simple, safe, cost-effective intervention that reduces severe infant morbidity without serious side effects, and more well-designed randomized controlled trials are needed.[89]
- Parents need education, a trusting relationship, individualized support, and consistent information and communication from health care providers to be comfortable with KC.[228]
- Nursing staff members need education about the benefits of KC and confidence and competence in skills to transfer and evaluate families and infants during KC.[177]
- Well-written NICU protocols for KC should contain criteria for initiation, positioning, transfer to/from KC, care practices while in KC (including use of continuous cardiorespiratory monitoring, proper positioning of head, endotracheal tube, stability of arterial and venous devices, and all life support equipment), provision of privacy, parental role, and interventions for neonatal instability.[27,228,309,310]
- Written information for parents about the benefits of KC, expectations of parents during KC, and preparing for KC (e.g., eat, go to the bathroom, bring a drink) assist parents and provide consistent, complete information to all families.[228]

One should note that fathers can also participate in KC without endangering the infant. Aside from the positive effects on the baby, paternal KC enhances the engagement and attachment of the father, helps fathers attain their paternal role, adapt to the crisis of preterm birth, includes the father in the infant's care, and facilitates more equal parenthood.[43,228,312] A recent study of the effects of the first skin-to-skin contact of fathers in the NICU with their preterm infants found a decrease in paternal physiologic stress responses (i.e., lowered blood pressure and cortisol levels).[425] The HUG Your Baby program improves fathers' understanding of their preterm infant behaviors, lowers paternal stress, and improves paternal confidence.[198]

Bathing. **There is a lack of evidence of the safety and efficacy of sponge bathing preterm babies in the NICU on a daily or every-other-day schedule.[144] Sponge bathing critically ill infants (28–34 weeks' gestational age) results in significant increases in behavior state and activity levels (i.e., motor stress behavior, stability, reorganization), increase in stress cue frequency, increase or decrease in heart rate, decrease in oxygen saturation preterm, and need for enhanced temperature support.**[234,332,401] These detrimental effects caused by handling were exhibited most frequently by neonates of younger gestational ages. Because sponge bathing of critically ill preterm infants clearly increases physiologic risk and provides no clear benefits, the procedure of routine bathing of these infants is unnecessary and not recommended.[21,252,333] **Frequency of sponge bathing can be reduced to from every other day to 3 or 4 times weekly** without increasing skin flora colony counts or colonization with pathogens.[144,225,252,348] (See Chapter 19.)

Waiting to bathe these infants until they are physiologically stable with introduction of the bath as a "recovery milestone" for parents to complete is a more developmentally and physiologically appropriate practice.[333] In one study, late preterm infants (LPI) who were tub bathed experienced less hypothermia and were significantly warmer at 10 minutes and 30 minutes after bathing compared with LPIs who were sponge bathed.[244] Parents may tub bathe the premature grower, and this may provide a soothing, relaxing, tension-relieving experience of multiple textures (i.e., water, water temperature, soap, washcloth).

A study of the effects of tub bathing on preterm infants (done by nurses) found disruption of sleep and an increase in stress behaviors. The study recommended considering the effects of "routine" nursing procedures and modifying handling of the preterm to promote recovery, growth, and development and to decrease stress.[234] It is evident that **more supportive behaviors by the nurse (i.e., position support and containment) enhanced the preterm infant's self-regulation during bathing.[235]**

Swaddled bathing (i.e., swaddled in a flexed, midline position in a blanket while bathing) provides containment and helps the infant self-regulate. Benefits of swaddled bathing are listed in Box 13.9. A protocol for swaddled bathing is available with best results occurring with an initial water temperature of 100° to 101° F and a bath length of 8 minutes.[349]

Self-Consoling. Consoling hand-to-mouth behaviors are observed more frequently during caregiving (by nurses, rather than parents) and before and after feeding (especially in gavage-fed infants). **Hand-to-midline behaviors are encouraged by cradling the infant for feedings (for both bottle and gavage feedings if the infant tolerates it) with both arms in the midline.** If a premature infant needs an oxygen hood, using one large enough so that the infant's whole upper body will fit inside encourages hand-to-mouth quieting (Fig. 13.3). VLBW preterm infants whose whole body was not inside the oxygen hood have been videotaped expending energy in persistent attempts (30–40 minutes) to self-console and reduce stress by trying to get their hands to their mouths. In a recent study, **preterm infants who displayed more stress behaviors also displayed more self-consoling behaviors.[146]**

Use arm restraints only when necessary, and immobilize the extremity in a physiologic position. Release and exercise the restrained

BOX 13.9 BENEFITS OF SWADDLED BATHING[76,116,132,349]

- Decrease in physiologic and motor stress
- Better energy conservation
- Improvement in state control
- Less crying and agitation
- Fewer stress cues
- Less temperature instability

FIGURE 13.3 Preterm infant in oxygen hood that is large enough to accommodate upper body to facilitate hand-to-mouth behavior. Note sling that helps maintain flexion without frog-leg position.

extremity with each caregiving encounter. Avoid restraining both arms so that one is free for hand-to-mouth behaviors. If both must be restrained (e.g., the infant pulls out the orogastric tube), give the infant a pacifier.

Positioning. Preterm infants display motor development that is different from that of term infants.[288,370] A continuous assessment of muscle tone, response to positioning and handling, oral-motor function, and response to sensory stimuli provide data for individualizing intervention. The goal of intervention is to provide opportunities for normal development and organization of the sensory systems, detect early developmental problems, and educate parents about stimulation, handling, and positioning. Although some studies have shown that specific positioning for premature infants does not significantly affect development, others have shown that a developmental approach to care of VLBW infants greatly reduces the long-term negative effects of prematurity.[297]

Preterm infants usually have less developed physiologic flexion in the limbs, trunk, and pelvis compared with term newborns (Table 13.8). Even at 40 weeks' postconceptual age, preterm infants have less flexion than their full-term counterparts have. For preterm infants, long periods of immobilization without a positioning device on a firm mattress with the influences of gravity result in a number of abnormal characteristics: (1) increased neck extension with a right-sided head preference, (2) shoulder retraction and abduction (reduces forward rotation and ability to reach midline), (3) increased trunk extension with "arching" of the neck and back, (4) frog-leg position: hips abducted and externally rotated, and (5) ankle and feet eversion (Fig. 13.4).[288,413] These characteristics interfere with development of eye-hand coordination, head control in prone/sitting, crawling/walking, cognitive development, and equilibrium.[370] Box 13.10 **lists the reasons for proper positioning in the NICU.**

The infant should be provided with a variety of positions to avoid overstretching of the joints, facilitate development of flexor tone, and prevent deformities. Goals of proper positioning include (1) optimizing alignment (e.g., neutral neck/trunk and foot positions), semiflexed, midline extremity posture; (2) supporting posture and movement within containment boundaries (avoiding producing a barrier of immobilization), (3) modifying positioning and handling to support behavioral state regulation of sleep-wake states; and (4) providing positions that encourage controlled, individual exposure to stimuli while monitoring for signs of behavioral stress from overstimulation and adjust stimuli accordingly. A physical therapist can be helpful in facilitating these positions. Systematic, targeted education for nurses and residents as well as "position champions" significantly improved positioning of infants in the NICU after 18 months.[78,265]

A change in body position influences ventilation by alteration of lung function, but how often should repositioning occur? Sixty preterm infants receiving respiratory support (mechanical

TABLE 13.8 DEVELOPMENT OF TONE*

GESTATIONAL AGE (WK)	DEVELOPMENT
28	Completely hypotonic and lacks all physiologic flexion
32	Hips and knees begin to show some flexion while arms remain extended
34	Flexor tone apparent in legs
36	Loose flexion of arms and legs evident and grasp reflex present
40	Develops tone in utero and develops flexed position in intrauterine space; after birth, reflex activity and central nervous system maturity help term infant unfold and extend; term infant holds all four limbs in flexed position

*Muscle tone develops in caudocephalic and centripetal (distal to proximal) directions and interacts with simultaneous cephalocaudal development of movement to help affect posture. Although knowledge of normal development before term helps detect signs of abnormality, variability of ±2 weeks' gestational age must be considered.[112]

This position promotes positional deformities and developmental gaps and delays. (From Hunter J. The neonatal intensive care unit. In: Case-Smith J, ed. *Occupational Therapy for Children.* 4th ed. St Louis, MO: Mosby, 2001.)

BOX 13.10 REASONS FOR PROPER POSITIONING

1. Inhibits or shortens dystonic phase while infant remains in fetal position during postnatal period
2. Facilitates hand-to-midline and midline orientation[112]
3. Stimulates visual exploration of environment (through head to midline)
4. Facilitates development of head control (making feeding easier and helping respiratory problems)[112]
5. Helps balance flexors and extensors to facilitate symmetric posture[288,297,370]
6. Helps develop antigravity movement
7. Enhances comfort and decreases stress
8. Has an organizing effect that facilitates development of flexor tone[112]
9. Promotes normal and prevents abnormal development[112,370]
10. Helps enhance development of motor skills, reflexes, and postural tone[297,370]

From Pelletier-Sehnar JM, Palmeri A. High-risk infants. In: Pratt PN, Allen AS, eds. *Occupational Therapy for Children.* 2nd ed. St Louis, MO: Mosby; 1989.

ventilation or CPAP) had their end-expiratory levels and ventilation distribution measured at 30 minutes, 2 hours, and 4 hours after repositioning.[186] The three body positions used during the study were prone, quarter turn from prone, and supine. **Spontaneously breathing infants had better ventilation homogeneity 2 hours after repositioning and global end-expiratory levels at 4 hours. Infants receiving both CPAP and mechanical ventilation had improved ventilation homogeneity at 2 hours after repositioning that continued to be maintained at 4 hours. Those infants on CPAP had an improved global end-expiratory level at 2 hours after repositioning.**

Side-lying is used to improve visual awareness of hands, encourage hands-to-midline movement, and discourage the frog-leg position. In this position, the infant can bring the hands to the mouth for sucking and self-comforting. Side-lying is best maintained with swaddling or commercial positioning devices rather than single blanket rolls (Fig. 13.5). Position extremities so that the bottom arm is in a comfortable position and the upper shoulder and hip are slightly forward of the weight-bearing lower hip or shoulder, provide a small roll (e.g., folded cloth diaper or washcloth or small bean-stuffed toy), and bundle for security but not so that the upper extremity compromises chest expansion. Alternating sides reduces head molding and may prevent atelectasis of the dependent lung. The head and trunk should be maintained in neutral alignment (e.g., the head and trunk are in

FIGURE 13.5 Small preterm infant in side-lying position supported in flexion and with a midline orientation of the extremities. (From Hunter J. The neonatal intensive care unit. In: Case-Smith J, ed. *Occupational Therapy for Children.* 4th ed. St Louis, MO: Mosby, 2001.)

the same vertical plane). **The left lateral position has been shown to improve oxygenation, lung mechanics, and breathing patterns in preterm infants, similar to the benefits of prone positioning.**[159] However a recent study showed that **lateral positioning of preterm infants** (median gestational age of 28.6 weeks) **receiving nasal CPAP resulted in increased respiratory rates.**[460] Left lateral position reduces gastroesophageal reflux, whereas right lateral position reduces gastric residuals.[118] **Longer sleep duration and less wakefulness in preterm infants occur when they are positioned flexed in the lateral position** compared to lateral positioning without flexion.[421]

To accommodate their ventilators, umbilical catheters, and other devices, acutely ill preterm infants may be positioned supine; the preterm neonate's head should be in the midline. Positioning VLBW infants supine with their heads turned to either side causes mechanical obstruction of cerebral venous return and alters cerebral blood flow, which may contribute to the development of intraventricular hemorrhage (IVH).[330] Cerebral (and mesenteric) tissue oxygenation was recently measured in clinically stable VLBW infants in two supine positions (i.e., with head tilted up 30 degrees and lying flat) and prone (lying flat).[103] Regardless of position these stable VLBW infants were able to maintain stable cerebral and mesenteric tissue oxygenation, both before and after feeding.[103]

Supine positioning does not promote flexion and may be stressful to acutely ill infants. Earlier studies found an increase in apnea, bradycardia, and periodic breathing in supine positioning, although a more recent study of 22 preterm infants with apnea and bradycardia found no significant difference in the incidence of clinically significant events between supine and prone positioning.[202] Placed supine, infants exhibit more startle behaviors, agitation, motor disorganization, calorie expenditure, and sleep disturbance (higher number of arousals/hour)[284] from environmental stimuli.

Prolonged supine positioning is associated with the hypertonic "arched" position (hyperextension of head, neck, and shoulder girdle) of many chronically ventilated infants (Fig. 13.6). Use of a gel or water pillow under the infant's head and neck (e.g., to the nipple level to prevent neck flexion or used as a mattress under the head or body of a VLBW infant) provides comfort and maintains neutral alignment.

Supine positioning should promote as much flexion as possible. Use of a positioning device of foam with the middle cut out and sloping under the scapulae is another method of obtaining supine flexion. Use of hip support results in less lower extremity abduction and external rotation than in infants without such hip support. Pillows filled with polystyrene beads (i.e., preterm beanbags) require skill for optimal positioning and

FIGURE 13.6 Supine positioning without positioning supports results in motor disorganization, agitation, arching posture, and burning of significant calories. (From Hunter J. The neonatal intensive care unit. In: Case-Smith J, ed. *Occupational Therapy for Children.* 4th ed. St Louis, MO: Mosby, 2001.)

close infant monitoring but are useful in providing positioning for very small premature infants (1000–1500 g).

Body containment increases the infant's feeling of security, promotes quieting and self-control, enhances physiologic stability, promotes energy conservation, reduces physiologic and behavioral stress, and enables stress to be better endured.[402] Without positional supports, many premature infants "travel" (no matter how many times they are returned) to the sides or bottom of their incubator. Parents and professionals are inclined to move the uncomfortable-looking infant back to the middle of a "boundary-less" world. Infants should be left where they feel safe and comfortable; if they become uncomfortable, they will let you know. **Providing boundaries (e.g., blanket rolls, positioning devices) stops this migration and the expenditure of precious calories that could go to growth.** Use of a **conformational positioning device that provides containment, boundaries, and security facilitates better sleep in preterm infants with less active awake time and crying** when compared to a standard mattress.[216]

Small, acutely ill premature infants who are positioned supine are often extremely agitated, thrashing arms and legs, tachycardic, and expending precious energy and calories. Instead of needing medications, these infants often are calmed by providing a nest of blankets or a commercial nesting device (which simulates the boundaries and security of the uterus). This artificial womb must be closely surrounding the infant to promote flexion, security, and quiet rest (Fig. 13.7). If agitation recurs, a limb (usually a leg) has extended outside the infant's secure boundary; flexing and returning it to the "womb" quiets the infant.[12] **Nesting and swaddling premature infants increases both total sleep and quiet sleep time.**[2]

Body containment maneuvers such as swaddling, holding on to a finger or hand, and crossing the infant's arms in the midline and holding them securely help with self-regulation during feeding, procedures, or other stressful manipulations.[91] A recent study of swaddling found wide variation in the positioning of the neonate's arms and legs.[140] **Safe swaddling includes positioning the baby's extremities in slight flexion and abduction.** Placing an infant's hips and knees in an extended position with swaddling increases the risk of hip dysplasia and dislocation.[189] Because being wrapped in a blanket with extremities flexed simulates in utero position, swaddling (1) improves flexed posture and flexor muscle tone, (2) facilitates behavioral responses, and (3) improves the development of primitive reflexes. **Swaddling is associated with a small but significant risk of sudden infant death syndrome (SIDS) when infants are placed on their backs for sleep, and swaddled infants placed prone have the highest risk of SIDS.** Swaddling is used most often in young infants to reduce crying and should not be initiated in infants older than 4 months of age; it should cease when an infant attempts to turn over and be completely stopped by 6 months of age.[329]

FIGURE 13.7 Very small premature infant resting quietly in a "nest" of pads and blankets.

Picking up the preterm infant from a supine position often produces startles, apnea, or head hyperextension. A better technique is to roll the infant prone, which flexes the head, and then flex the limbs onto the trunk and pick up the infant. If the infant has difficulty breathing in prone position, swaddle or contain the extremities before picking up the infant.

Prone positioning encourages the infant to work on using neck extension and promotes flexion of the extremities. Devices for prone positioning include a small hip roll or sling to assist in maintaining flexion, use of gel/water pillows for head support, and secure lower boundary for foot bracing. Use of a rolled cloth or gel pillow placed under the infant (from top of the head to the umbilicus) (1) provides elevation of the body to promote extremity flexion without placing excessive pressure on the knees and elbows, (2) enables the shoulders to round forward over the top of the roll, and (3) enables the legs to flex over the bottom edge of the roll. **Prone (versus supine) positioning has numerous benefits and is the position of choice for many NICU infants** (Box 13.11). The semi-prone position (¾ turn) decreases the variability of respiratory rate in preterm infants (median gestational age of 28.6 weeks) receiving nasal CPAP.[463] The quarter-prone position also has been shown to improve oxygenation of premature infants on CPAP.[420] **To improve sleep duration and quality, nurses are encouraged to assess each**

BOX 13.11 EFFECTS OF PRONE POSITIONING

1. Decreases heart rate variability
2. Improves oxygenation by 15% to 25%[39,159,357]
   a. Increased $TcPo_2$ values
   b. Increased Pao_2 values
   c. Decreased apnea, bradycardia, and periodic breathing
   d. Increased peripheral oxygenation and decreases cerebral blood flow[37]
   e. Decreases respiratory rate[69]
3. Improves lung mechanics and lung volumes[159,423]
   a. Increased lung compliance
   b. Increased tidal volume
4. Decreases energy expenditure[157]
   a. Increased quiet sleep; higher arousal threshold[194]
   b. Decreased awake time; more sleep time[69,77,194,284]
   c. Decreased caloric expenditure (median difference supine vs. prone: + 3.1 kcal/kg/day)
   d. Decreased heat loss[77]
   e. Less crying[77]
   f. Lower levels of activity[77]
   g. Lowers stress levels as measured by a reduction in salivary cortisol levels[69]
5. Decreases (by 50%) gastric residuals in the first 30 minutes after feeding[81]
6. Decreases gastroesophageal reflux[118]

individual preterm and more often use the position (prone vs. supine) that results in the least arousals.[284] Sleeping in the prone position does not improve oxygenation in preterms 32 weeks' PMA or older for infants without respiratory problems. The study concluded that **preterms older than 32 weeks' PMA and without respiratory difficulties should be placed supine and monitoring continued to ensure adequate oxygen saturation.** Use of a sheepskin or lambskin helps to further facilitate flexion and prevents skin abrasion, especially on the knees.

Sleep Position. The most recent American Academy of Pediatrics (AAP) position statement on infant sleep states that healthy infants should be placed *only* in the supine position for sleep beginning immediately after birth.[294] Infants should sleep in their own beds and in the same room with their parents for at least 6 months and preferably for the first year of life. Overheating sleeping infants; use of soft sleeping surfaces, stuffed toys, and positioning devices[418]; and inappropriate sleep environments (e.g., waterbeds, pillows, blankets, bumper pads, bed railings, bed sharing, and sitting/carrying devices)[88,148,355,375] should all be avoided in healthy infants.[294] Use of a pacifier for sleep and sleeping in proximity (same room) as parents is also recommended.[294] The Study of Attitudes and Factors Effecting Infant Care (SAFE) collected prospective data from a nationally representative sample of postpartum mothers about the intended sleep position and the actual positions infants were placed in for sleep.[88] Although approximately 70% of the mothers queried usually placed their infants to sleep supine, less than 44% who intended to use supine position actually placed their infants supine in actual practice. **African American mothers and mothers with less than a high school education were more likely to intend to use prone or side-lying position.** When advised by a doctor to use only supine positioning, mothers were less likely to use prone and side-lying for infant sleep.[88]

Use of side-lying and prone positioning, as well as containment with soft bedding for physiologically compromised term and preterm infants, is safe and appropriate in a NICU setting. Parents may question these practices; therefore, their physiologic base and rationale should be explained. **Parents should be taught that when their baby is medically stable, by 32 weeks' PMA,[294] he or she will be physiologically and developmentally mature enough to tolerate supine sleep position in preparation for discharge.[232] Many of the beneficial effects of prone positioning listed in Box 13.11 are no longer necessary[232] and become detrimental in increasing the risk for SIDS in the stable, mature preterm infant.**

Since the "Back to Sleep" campaign, the rate of SIDS has decreased by 53%,[294] but the SIDS rate in the United States (US) has minimally declined since 1999, and approximately 3500 sleep-related deaths occur in the US each year.[49,121] **SIDS rates are inversely associated with gestational age, and the risk of SIDS is three times higher in preterm infants.[168,315] VLBW infants (<1500 g), the group at highest risk for SIDS, have been found in one study to be more likely to sleep prone after discharge than larger LBW infants.[428]** Reasons cited by mothers included infant's preference and advice from professionals (NICU doctors, nurses) who may remain uncomfortable recommending supine sleep in this population[232,428] despite the AAP recommendations and the research that supports them[294] (Table 13.9). Among families with triplets and quadruplets, less than 80% of mothers used supine for sleep immediately after hospital discharge; use of supine positioning decreased over time, especially during daytime napping; 30% shared a bed with siblings; less than 50% slept in the parents' room; and use of a pacifier was low.[167]

Implementing "Safe Sleep" ("Back to Sleep") principles in the NICU remains a problem and influences parental behavior.[32,300,328] One study found that NICU nurses only followed safe sleeping practices 20% of the time before an evidence-based program promoting safe sleep began; after the implementation of the program safe sleep practices were used 90% of the time.[461] Nursing education with web-based learning and in-person teaching sessions improved compliance in safe sleep practices in two level III NICUs from 25.0% to 79.7%.[187] Another project to develop a safe sleep educational program and increase the percentage of eligible infants in a safe sleep environment in the NICU was conducted.[435] The process included a revised policy, educational updates for NICU staff, an educational packet and video for families, a wearable blanket, and an observation checklist. From a baseline of 21% of eligible NICU infants experiencing a safe sleep environment, safe sleep compliance increased to 88%.[435] Quality-improvement initiatives that

TABLE 13.9 SLEEP POSITION AS A RISK FACTOR FOR SUDDEN INFANT DEATH SYNDROME (SIDS): RESEARCH BASIS

SUPINE	PRONE
Preterm infants at 36–38 wk PCA[157] No significant difference in sleep organization based on body position More awakenings in supine vs. prone position Standard deviations of heart rate increase during quiet sleep in supine position; low frequency and high frequency of heart rate higher in supine vs. prone position in both active and quiet sleep states More sleep transitions, a lower arousal threshold, and higher heart rate variability while sleeping supine contribute to decreased vulnerability to SIDS	Prone position reduces spontaneous arousals from sleep in term infants,[322,356] which may be related to a decrease in cerebral oxygenation in prone sleeping[456] First quiet sleep after feedings significantly longer, fewer awakenings, and decrease in overall heart rate variability in prone vs. supine[157,356] Preceding characteristics of prone sleep constitute a higher arousal threshold, and thus increased vulnerability to SIDS in prone position[322,356,456] Decreased baroreflex sensitivity, which increases vulnerability to hypotensive events[459]
Full-term (n = 10) infants in prone/supine sleep positions given 0.4 mL water; instillation into the mouth resulted in airway protective responses of swallowing (95%) and arousal (54%)[195]	62 healthy, growing low BW infants (26–37 wk GA; 750–1600 g BW); sleeping position — a shift of EEG activity toward slower frequency, which may be related to mechanisms associated with a decrease in behavioral arousal in prone position[356,366]
Swallow rate rapid in supine position in response to small infusions of fluid, whereas respiratory rate remains largely unaffected When supine, term infants can coordinate rapid swallowing while maintaining breathing	A significant decrease in swallowing and breathing in active sleep in prone vs. supine position; airway protection is compromised in prone sleeping position during active sleep in healthy term infants exposed to minute pharyngeal fluid
Full-term (n = 3240) ≥37 wk GA evaluated in the first 24 hr of life for frequency/severity of spitting up incidents while asleep[400]: • 96.6% did not spit up during sleep. • 130 episodes of spitting up while sleeping supine (55% required no intervention; 37% brief bulb suction; 6% gentle stimulation; 2% wall suction). • <4% spit up while sleeping supine, and none required significant intervention or experienced serious sequelae.	Six episodes of spitting up while infants side-lying (66.7% no intervention; 33.3% bulb suction)

identify barriers, change hospital policies, and provide safe sleep education for nurses and parents are needed to improve compliance with safe sleep recommendations for preterm infants.[300]

In term infants, supine sleep position may delay some motor milestones by 1 month but does not delay walking. Increased amounts of time in supervised prone play ("tummy time") encourage earlier motor milestone attainment in supine sleepers and helps prevent head molding. Head molding (i.e., bilateral flattening of the head and elongation of the face) is a significant problem in preterm infants; it results from flattening of the skull as the baby lies against the firm incubator mattress. To parents, this head flattening is concerning, and they may find the infant less cute and desirable than a term infant with a rounded head. **To prevent head molding, preterm infants are often placed on waterbeds, water pillows, air mattresses, or eggcrate-type mattresses, with varying results.** Preterm infants (<32 weeks' gestation with birth weight <1500 g) who are turned every 3 hours, repositioned in one of six positions, and never placed in the same position twice in 8 hours had significantly rounder head shapes from 9 to 13 weeks of life compared with infants repositioned according to a standard NICU procedure.[179]

Kinesthetic. A combination of vestibular and tactile stimulation increases quieting behaviors, decreases apneic and bradycardic episodes, entrains respirations, increases visual and auditory fixation, and increases brain growth.[210] Waterbeds provide contingent stimuli because

they move in response to the infant's movement; oscillating waterbeds provide rhythmic motion. Kinesthetic stimulation is provided by rocking chairs, hammocks, baby swings, and baby carriers, the effects of which have not been investigated. In Brazil, a combination tactile/kinesthetic stimulation program enrolling 16 clinically stable preterm infants under 2500 g was conducted and compared with a control group of 16 preterms.[133] Outcomes of the preterms receiving the tactile/kinesthetic program included (1) higher daily weight gain, (2) predominance of self-regulated behaviors (i.e., regular respirations, balanced tone, state of alertness, range of postures, coordinated movements, hand-to-mouth movement control, suction, grip, and support), and (3) a trend toward shorter length of stay.[133] An RCT of parent-administered physical therapy (promotion of head and postural control and midline orientation) to preterm infants from 34 to 36 weeks PMA resulted in improved motor performance at 37 weeks PMA when compared to usual care.[419]

Upright positioning in a car seat or infant seat encourages symmetry and spatial orientation. Soft rolls or foam padding maintains flexion; a rolled blanket in a horseshoe configuration around the infant's head and shoulders prevents lateral slouching. Carrying quiets the infant, provides sensory communication with the caregiver, changes the infant's environment, and provides visual, auditory, and tactile stimuli. A nasal cannula (see Chapter 23) and portable tank enable mobility for an infant receiving oxygen.

Rather than standardized protocols, tactile interventions must be individualized by assessing each infant's physiologic and behavioral responses before, during, and after touch (see Table 13.6). **While an infant is acutely ill, tactile intervention should include minimal handling, containment, and gentle touch (without stroking).** As the infant matures and becomes physiologically stable, stroking, rocking, and holding are integrated based on the individual infant's tolerance and preferences. In healthy preterm infants, a program of range-of-motion exercises with passive resistance is associated with an increase in weight gain and growth, bone mineral content and density, and muscle mass and a decreased risk for osteopenia.[239,430]

Cobedding. Cobedding, the practice of placing medically stable twins and higher-order multiples together in the same open warmer, incubator, or crib, was initiated after the observed stress response in separated siblings. **The practice of cobedding spread based on anecdotal information, because there is limited research to support or refute its use.**[219] Few differences between cobedded and noncobedded infants have been demonstrated. A study of 117 sets of twins randomized to cobedding or sleeping alone found that cobedding promoted self-regulation (i.e., more time in the same state, less time in opposite states, and less crying) and more quiet sleep without apparent increased risk.[175] Limitations of the research on cobedding include small sample size, short follow-up periods, lack of randomization, and blinding of evaluators.

Infection, safety, and parents continuing the practice after discharge are major concerns of cobedding. To date, increased infection rates in cobedded infants have not been reported. Infection concerns are addressed by good hand washing and color-coding of equipment. Other safety concerns include proper identification for medication administration and medical emergencies and maintenance of temperature stability for all cobedded infants.[13] Because parents continue care practices at home that they have witnessed and become accustomed to in the hospital, the possibility of continuing cobedding at home (and the lack of evidence as to its safety) must be considered.

The National Association of Neonatal Nurses (NANN) recommends that a decision to cobed be made with input from parents and should involve education of staff and parents about potential benefits/risks, the experimental nature of the practice, and the development of a clinical evaluation protocol to collect data on risks and benefits.[299] The AAP recommends separate sleep areas in the hospital and at home.[294] **Both NANN[299] and the AAP[294] have concluded that neither the safety or benefit of cobedding has been established by current research and that parents should be instructed to follow established safe sleeping practices at home.[294]**

AUDITORY INTERVENTION

The NICU is a noisy environment that has no diurnal rhythm or predictability; it is as noisy at night as in the daytime (Table 13.10).[102,158,269] An infant in the NICU is exposed to an onslaught of noise 24 hours a day for days, weeks, or months. At follow-up, preterm infants exhibit a lower threshold

for sound and a reduced responsiveness to auditory stimulation.[31] Assisted ventilation, severe asphyxia, drug therapies, and possibly acoustic insult account for the increased risk for sensorineural hearing loss in NICU infants. **The incidence of hearing loss decreases with an increase in gestational age. An increased risk of hearing loss is associated with being born very preterm and late preterm.**[180] Moderate to severe conductive hearing loss also occurs in 42% of VLBW infants. Conductive hearing loss is attributed to endotracheal intubation, poor eustachian tube function, increased otitis media, and CLD in preterm infants.

The first goal in auditory intervention is to assess the current level of noise in the NICU and decrease the noise decibel level wherever possible.[269,340] The noise environment of an individual infant depends on the type of NICU (single-family rooms or open-bay), ambient sounds in the nursery, the type of incubator and support equipment, and the baby's own behavior (e.g., quiet or crying). Noise measurement protocols must sample multiple noise sources and sites.[102,269] Some NICUs have installed decimeters that present a flashing or blinking light when the noise level exceeds a preset level (about 50–65 dB). Sources of noise include heating, ventilation, and air conditioner flow units (noise levels may decrease by 2.5–10.5 dB when these units are turned off). **The greatest contributor to loud noise in the NICU is talking and conversation by the staff.** Noise levels vary with type of room, location, time of day, and day of week within the NICU; therefore various locations or various times and days should be measured.[102,269,340]

Increased environmental noise levels are a stressor to all infants in the NICU—preterm infants and ill term infants (e.g., infants with persistent pulmonary hypertension of the newborn or drug withdrawal) (Box 13.12). The sudden, high-pitched, shrill, dysrhythmic noise of equipment alarms alerts the care provider, but it also results in infants manifesting an extreme hypersensitivity to sound (as a learned conditioned response). CNS-injured preterms are particularly vulnerable to sound stress in the NICU, are less able to habituate to NICU noise, and respond with exaggerated and prolonged physiologic responses (e.g., alterations in respiratory rate, bradycardia, desaturations). **Noise is stressful not only to the infants but also to parents and care providers in the NICU.**[38,176] Three years after their NICU experience, mothers recall the noise level in the NICU as a stressor. NICU noise is stressful to care providers and has the potential to damage hearing; cause physiologic responses (e.g., increased blood pressure, altered immune response, increased stress hormone secretion, disturbed sleep); cause fatigue, irritability, and "burnout"; interfere with communication with coworkers and parents; alter concentration; and increase errors.[405]

Although the AAP recommends that noise levels be less than 45 dB,[448] most NICUs' noise levels range between 38 and 90 dB, with higher noise bursts (see Table 13.10).* Recommended standards for noise criteria have been established to protect sleep, support stable vital signs, and improve speech

BOX 13.12 EFFECTS OF LOUD NOISE[368,436,452]

- Increase in stress behaviors:
  - State lability
  - Arousal state
  - Avoidance behaviors—more fussy, more startles, etc. (see Table 13.4)
  - Sympathetic nervous system arousal measured by noninvasive skin conductance, which was higher in male preterms
- Decrease in approach behaviors (see Table 13.4)
- Cardiorespiratory changes:
  - Increased heart rate
  - Increased respiratory rate
  - Increased apnea or bradycardia
  - Increased hypoxemia (decreased pulse oximeter)
  - Increased peripheral and arterial vasoconstriction:
    - Increased systemic blood pressure
    - Increased intracranial pressure
  - Increased sensory neural hearing loss
  - Abnormal auditory development and processing
  - Prevents habituation
- Alters development of sleep-wake cycles:
  - Disturbs sleep; interrupts light sleep
  - Even moderate noise disturbs sleep
  - Increases wakefulness and agitation
- Increased risk for intraventricular hemorrhage:
  - Increase in cerebral blood flow
  - No change in cerebral oxygenation when peak sound levels increased by 5 dB for short duration; cerebral oxygenation at higher sound levels for longer durations unknown[119]

TABLE 13.10 NOISE LEVELS IN THE NICU

LEVEL (DB)	COMMENTS
48–69	Humidifiers and nebulizers
50–60	Normal speaking voice
50–73.5[a,b]	Incubator (motor noise)
53	Median noise level on conventional ventilator
55–88	Bradycardia alarm
58–85[c]	Noise in NICU (talking, equipment alarms, telephones, radio)
59	Median noise level on high-frequency oscillator
65–80[b]	Life support equipment (ventilator; intravenous pumps)
66–76	Sink on/off
67	Incubator alarm
70	Background noise mean level should not exceed
72.8–71.7	Air conduction noise levels of jet ventilator, CPAP [201]
74–89.2	Bone conduction noise levels of jet ventilator, CPAP[201]
85[d]	Noise level at which hearing damage is possible for adult; (?) neonatal effects
90	Peak sound intensity in the NICU not to exceed
90[d]	Adult exposure for 8 hours requires protective device and hearing conservation program
92.8[b]	Opening incubator porthole
84–108	Placing a plastic bottle of formula on top of incubator
96–117[b]	Placing a glass bottle of formula on top of incubator
70–116[b]	Closing one or both cabinet doors
80–124[b]	Closing one or both portholes
120	Threshold for pain
130–140[b]	Banging incubator to stimulate apneic premature infant
160–165[d]	Recommendations for peak, single noise level not to exceed to prevent (adult) hearing loss; (?) neonatal effects

[a]Modern incubators generate less than 60 dB; exceeds hourly recommendation of 50 dBA (see Table 13.11).
[b]Measures from inside the incubator.
[c]Noise levels do not vary from morning to night.
[d]Occupational Safety and Health Administration (OSHA) standard. (No safety standards for neonates have been established.)
NICU, Neonatal intensive care unit.

intelligibility. Recent noise studies in NICUs have found the following★:

- Noise levels are still louder than recommended.
- Environmental changes to reduce noise must be monitored because they may increase rather than decrease noise.
- Nurses perceived their own NICU as "pretty quiet" when, in fact, noise levels were above recommendations.
- Noise levels have not significantly decreased in the NICU.
- Single-room NICUs attenuate noise; there is more silence. However, equipment noise and noise from medical interventions is not decreased in single-room units. Parent engagement and presence is related to more language exposure.

TABLE 13.11 RATIONALE FOR SPECIFIC NOISE CRITERIA[448]

NOISE CRITERION	RATIONALE
Hourly Leq (equivalent sound level) of 45 dB in infant room; 50 dB in staff work areas	Preserves sleep for healthy term infants most of the time
Hourly L_{10} of 50 dB in infant room; 55 dB in staff work areas (sound levels may exceed 55 dB only 10% of the time or a total of 6 min/h)	Preserves sleep for infants; enables caregivers to speak at normal conversational levels and be clearly understood 12 feet away, approximately 90% of the time
L_{max} of 65 dB in infant room; not to exceed 70 dB in staff work areas (maximum decibel sound level ≤1 sec in duration—transient bursts of noise)	Minimizes rousing babies and causing startle responses

- Initial and continued staff education is necessary; monitoring and feedback every 2 to 3 months is necessary
- Quality-improvement initiatives including education and behavioral and environmental modifications decrease noise in the NICU; constant dialogue between champions and staff is required.

Table 13.11 **presents specific noise criteria and their rationale.** Parents and care providers must be involved in planning, developing, and being educated about quieter NICUs.[38,395]

Strategies to minimize external auditory stimuli include quieting alarms with suction (and remembering to reset them), not taking a shift report over or allowing medical rounds near the infant's incubator, having noisy equipment repaired immediately, emptying sloshing water in ventilator or nebulizer tubing, maintaining cardiac monitors in a quiet state with alarms on (decreasing the sound of alarms by 50%), and purchasing quieter equipment (e.g., plastic instead of metal trash containers; quieter incubators). Choosing heated humidifiers (48 dB) rather than nebulizers (69 dB) and keeping the containers full of water, rather than low, decrease noise from respiratory equipment. Nursery design changes[448] include smaller cubicles rather than one large room, soundproofing materials, lights for phones and alarm systems, and minimizing equipment noise. Placing a blanket on top of the incubator or using an incubator cover muffles the noise of equipment placement; gentle, considerate (to the infant) placement of equipment on or in the incubator muffles sound; and closing portholes and drawers gently decrease the structural noises of caregiving. Prohibiting placement of equipment (e.g., clipboards, stethoscopes, formula bottles) on top of the incubator prevents such noises.

Tapping (by parents or siblings) or banging (by medical, nursing, or ancillary personnel) on the incubator Plexiglas should *never* be permitted. This (along with a brisk startle reflex from the infant) is an opportunity to teach about the noise levels generated by such activity. Infants should be kept in incubators as long as necessary to maintain heat balance. **Older incubators do *not* protect the infant from noise. A well-managed NICU environment may be much quieter than the continuous noise of an incubator. Noise in modern incubators varies according to the model.** Sound sources within an incubator include its motor, infant sounds, equipment sounds inside the incubator, equipment sounds transmitted from outside the incubator, and ambient nursing noise (e.g., personnel, phones). **Modern incubator walls attenuate impulse noises from the NICU and may decrease the infant's noise exposure.** Inside modern incubators, motor noise does not exceed 60 dB, but this level exceeds the more recent recommendation of 50 dB. However, impulse noises from the incubator (i.e., doors, latches) are louder on the inside of the incubator (see Table 13.10). **Prolonged stays in an incubator not only expose the infant to repeated caregiving noises but also mean there will be a dearth of kinesthetic stimulation (e.g., carrying, holding, rocking, swinging, sitting upright in an infant seat) and socially relevant speech patterns.** Both the internal noise generated by the incubator and how well the incubator attenuates external noise should be considered in incubator purchases.

Noise levels in the NICU may interfere with development of other sensory systems and delay the development of hearing and language. Radios have been banned in most NICUs. **Day-night cycles (naptime, nighttime) when auditory stimulation**

is decreased should be established in the NICU. Institution of a quiet time or rest period—through reduction of (1) noise from talking, equipment, telephones, and so on; (2) light by dimming overhead light; and (3) procedures to only emergency treatment—has resulted in enhanced infant sleep (34%–85%), less crying (14%–2.4%), and less parental and caregiver stress.[395] A more recent study found **low noise levels during quiet time, with total sleep time highest during quiet time with longer awake periods after quiet time, prompting the researchers to recommend quiet time as a nursing intervention in all NICUs.**[347] At discharge, NICU infants often will not sleep in a quiet room. Softly playing a radio facilitates sleep, and the infant gradually is weaned from it. Signs such as "Quiet . . . baby sleeping" or "Do not disturb, I'm asleep (talk to my nurse)" ensure undisturbed sleep *if* they are heeded.

The "in-turning" premature infant (see Box 13.2) of less than 34 weeks' gestation probably receives enough auditory input from the NICU. Auditory enhancement at this stage is probably overstimulation. Just as high-frequency sounds arouse, low-frequency ones, such as the heartbeat, respiratory sounds, and vacuum cleaners, quiet and facilitate sleep.[110] One study showed less behavioral response and less salivary cortisol release by infants who were presented with a heartbeat sound or white noise (both at 85 dB) during and after heelstick.

Although music has been shown to soothe full-term babies, the use of music with preterm infants has been studied with inconsistent results. Two meta-analyses of music therapy show benefits to preterm infants in: (1) physiologic parameters (heart and respiratory rates, oxygen saturations, quiet sleep, and behavioral state), (2) feeding behaviors and length of stay, (3) pain management, and (4) reduction of maternal anxiety and parental stress.[40,316] The most recent analysis also found studies showing no significant differences between preterm infants exposed to various types of music therapy and no harmful effects, possibly due to the lack of measurement of the ambient noise in the NICU during music therapy.[316] A literature review of music therapy (more live music) and musical stimulation (more recorded music) found more individualized care with music therapists that resulted in more effects on premature infants' physiologic and behavioral responses.[321]

Presentation of in utero sounds and a female voice to agitated, intubated preterm infants has resulted in improved oxygen saturation and behavioral states. An RCT of the effects of live music replicating womb sounds was conducted at multiple sites with preterm infants (≥32 weeks' gestation).[240] Music therapists chose lullabies identified by parents as important to their cultural heritage and that were within the parents' vocal range, and parents were taught to entrain their singing to their infant's respiratory rate and activity. **Outcomes included (1) lower heart rates during lullabies and music with a rhythm, (2) increased caloric intake and sucking behavior with parent-selected lullabies, and (3) decreased parental stress.**[240] Using music by Mozart has been shown to lower resting energy expenditure by 7.7% in preterm infants.[203] Preterm infants have lower pain scores and better behavioral states during heelstick when they listen to the same music that their mothers listened to during pregnancy.[214] However another recent article by board-certified musical therapists who specialize in music in the NICU states that classical music, pop/rock music, and instrumental or nature sounds (preferred by nurses and parents) are all contraindicated for premature infants in the NICU (especially if music is meant for calming) because of musical complexity.[105]

Music therapists in the NICU concentrate on neurologic enhancement for sensory integration, pacifier-activated sound to enhance NNS and feeding readiness, live music to enhance physiologic stability and calming, and education and emotional support for parents in the NICU.[105,393] **Careful decision-making and consultation with music therapists is recommended prior to use of recorded music for premature infants in the NICU.[105] Evidence-based guidelines for the use of recorded music for premature infants are listed in** Box 13.13.[105] Music therapy should be individualized according to infant tolerance and cues, decibel levels monitored and maintained in appropriate ranges, and staff and parents educated about benefits.[316] Exposure of 20 healthy preterm infants to low-intensity recorded maternal voice over a 3-day period resulted in an increase in oxygen saturations and a decrease in heart and respiratory rates during the voice period that persisted into the after-voice period.[367] Recorded maternal voice enables premature infants 35 weeks' and later gestation to be awakened less frequently by noises in the NICU and to exhibit a sleep-wake pattern that responds increasingly with age to their mother's recorded voice.[382] However, premature infants less than 35 weeks' gestation did not have better sleep and less wakening in response to their mother's recorded voice.

BOX 13.13 EVIDENCE-BASED RECORDED MUSIC GUIDELINES FOR PREMATURE INFANTS IN THE NICU[105]

Eligibility Criteria
- At least 28 postmenstrual weeks[15,162,341]
- Daily nursing approval

Music Characteristics
- Initial use for very premature infants: music should be as simple and nonalerting as possible[393]
- Soothing, constant, stable and relatively unchanging[393]
  - Voice alone or voice with only one instrument
  - Light rhythmic emphasis and slow tempo
  - Constant rhythm and volume
  - Melodies in a high vocal range, which infants hear best
  - Female (mother preferred) or child vocalists
  - In the native language of the family
- Least alerting music for premature infants include:[305]
  - Three chords or less
  - Major chords
  - Lullaby style (repetitious: no separate melody for chorus/bridge)
  - Music played slowly and softly

When to Play
- State—awake or at beginning of sleep[162]
- During skin-to-skin care[218]
- Immediately after painful/stressful procedure
- Audio recordings should not be left unattended with the high-risk infant[161]

When to Stop
- If infant exhibits frequent/continuous signs of overstimulation (e.g., squirming, arched back, grimacing, increased heart/respiratory rates, irregular breathing pattern, changes in skin color, crying, splayed fingers, hiccoughing)
- During painful/ stressful procedures[393]

Duration and Frequency
- Maximum of 4 hours/day, alternating between 30 minutes of music and 30 minutes of no music[25,424]

Volume
- 65–75 dB, scale C[15] (measured at ear, not source)
- Music should be played with background noise not exceeding 50 dB[162]

Presentation
- Place speakers on each side of the infant's head or feet so sound stimuli are received binaurally[393]
- Music equipment must be tested to ensure it does not create electrical interference with medical equipment such as cardiac monitors and ventilators and is resistant (if used in the incubator) against high temperatures (~36°C) and humidity (~75%) levels[277,323]

Contraindications
- Musical toys and mobiles because of the highly repetitive nature of the sole music selection usually available with these toys, the inability to adjust sound levels, and the lack of research on their use[393]
- Radio, white noise, or nature sounds[393]
- Earmuffs[277]
- Headphones on the infant[161] or directly on the mother's abdomen while pregnant[162]
- Music played free field in an open bay because the volume is difficult to manage for each infant and it may not be appropriate because of the gestational age for those subjected[393]

Adapted from Detmer MR, Whelan ML. Music in the NICU: the role of nurses in neuroprotection. *Neonatal Network.* 2017;36(4):213–216.

The human voice is the most preferred sound. The preterm in an incubator may be isolated from important exposure to his or her mother's voice that would have occurred over months in utero. A systematic review of the effects of **maternal voice on preterm infant's development found that an infant's mother's voice is a non-noxious intervention that is consistent with developmental care and should be embedded in developmental care strategies.**[345] Parental talking to their preterm infant in the NICU has been shown to be a strong predictor of infant vocalizations at 32 weeks and conversational turns (i.e., infant coos and parent gives a vocal response) at 32 and 36 weeks.[72] This study found that **preterms begin vocalizing at 32 weeks and that the rate increases over time. When parents are present in the NICU, preterm vocalizations increased by as much as 129%, particularly at 32 weeks.**[72] Another study of **maternal talking and singing found greater oxygen saturation levels, fewer negative critical events, and a prevalence of calm alert state in the preterms who were reconnected to their mother's voice while in the NICU.**[137] An exploratory study of VLBW preterms (16 exposed to biologic maternal sounds [BMS] matched with 16 exposed to usual NICU

sounds) was conducted to measure weight gain.[464] **VLBW infants exposed to BMS (maternal voice and heartbeat) gained more weight and had a higher growth velocity compared with the control group.**[464] While in the NICU, parents reading to their newborns resulted in parental feelings of closeness to their infants, developing a sense of control, intimacy, and normalcy.[222,438] Follow up of **preterm infants who were read to by their parents shows better cognitive development at 2 years of age.**[54]

Increasing **preterm infant's language exposure (by parents talking to their infant) improves the infant's language development, enhances parent-infant attachment, and decreases parental stress.**[258] In the NICU, verbalizations to their preterm infant and positive affective involvement during feeding by mothers is associated with the same parental behaviors at 24 months.[150] **Teach parents the neonate's preference for high-pitched voices speaking in typical speech patterns (not baby talk). While in the NICU parents, can talk to the baby about their day, essentially conversing with the baby, and listening for responses. Parental talking to the baby in the NICU is associated with higher scores on language and cognition at 7 and 18 months corrected age.**[73] The degree of attenuation of the higher frequency of mother's voice by the lower frequency of incubator noise, the incubator walls, and the ambient noise of the NICU has not been measured. Role model and teach parents to gently talk to the infant while touching and giving care. Teach parents to talk to their infant while presenting their faces in the infant's range of vision. Watch for infant tolerance, and increase or decrease talk time to avoid overload. For older infants, imitate the infant's coos and babbles; this reinforces and encourages vocalizations.

For a neonate, hearing is more important than vision for attachment and bonding to the parents. Within seconds after birth, newborns are able to discriminate and prefer their mother's face. They have connected her familiar voice with her unfamiliar face. A high index of suspicion about hearing loss is warranted if caregivers do not observe normal responses to sound stimulation. **Hearing screening by high-risk factors alone identifies only about 50% of newborns with significant hearing loss; therefore, universal newborn hearing screening is the standard of care.**[17]

VISUAL INTERVENTION

The NICU is lit with bright, cool-white fluorescent lights 24 hours a day. Light levels vary between and within various NICUs. Early studies showed light levels in the low range, from 34 to 100 lux at night and 184 to 1000 lux during the day; more recent studies report light levels ranging from low levels of 1 to 25 foot-candles (ftc) to high levels of 235 ftc.[385] **The amount of light to which the preterm infant is exposed is influenced by (1) location in the NICU, (2) seasonal or climactic variations, (3) use of phototherapy, (4) ophthalmoscopic examinations (e.g., at birth and for retinopathy of prematurity [ROP] follow-up), (5) use of procedure lights,[317] and (6) infant-related factors (e.g., maturity and amount of eye opening, head position, or eye shielding).** Ambient light levels in the NICU should be adjustable through a range of 10 to 600 lux (approximately 1–60 ftc) at every bedside.[448] Other light recommendations for newly built NICUs are outlined in Table 13.12.

Although decreased light levels and response to bright light have not been shown to reduce the incidence of ROP, ophthalmic sequelae of preterm birth are common.[160] (See Chapter 31 for a discussion of ROP.) There are three broad categories of ophthalmic sequelae: (1) decreased visual function, (2) strabismus, and (3) decreased eye size (arrested growth) and abnormal refractive state (increased myopia). In addition, there is abundant animal, child, and adult research documenting negative biochemical and physical effects (e.g., change in endocrine function, increased hypocalcemia, cell transformations, immature gonadal development, chromosome breakage).[158] **Very preterm infants are able to detect and react to small variations in light levels.**[465] Exposure to bright lights in the NICU is associated with the following[158,317,465]:

- Decreased oxygenation (on pulse oximetry); decreased regional cerebral saturation
- Increased incidence of retinopathy
- Altered vital signs (increased heart and respiratory rates)
- Alteration in state organization (i.e., altered sleep patterns, poorer circadian rhythms; more wakefulness/less sleep[314])
- Skin changes (e.g., tanning, rashes)
- Alteration of nutrients in total parenteral nutrition (TPN) solution, formula, and breast milk

TABLE 13.12 LIGHT RECOMMENDATIONS IN THE NICU[448]

ILLUMINATION LEVEL	PURPOSE
High levels: 60 foot-candles (ftc)	Evaluate and assess skin color and perfusion
Lower levels: 10–20 ftc	Safe and adequate because of concerns over retinal/ocular damage from continuous exposure to high levels (60 ftc)
Nighttime levels: 0–5 ftc	Diurnal variation in light levels
Procedure light: 185 ftc	Available at every bedside to temporarily increase lighting for infant assessment/procedure without increasing light exposure to all other babies Prevent light from reaching infant's eyes
Support areas	For charting, medication preparation, etc., should provide adequate and separate light to accommodate sleeping babies and working health care providers Lighting should be located to avoid any infant's direct line of sight to the fixture
Daylight	One source visible from care areas for its psychological benefit for staff and families

NICU, Neonatal intensive care unit.

Rapid increase in the intensity of ambient light causes a decrease in oxygen saturation in younger, immature preterm infants; slower increasing of light levels enables easier adaptation.[317]

The first goal in visual intervention is to assess the current level of light and decrease it wherever possible. A very immature preterm infant is accustomed to the muted light of the uterus (light filtered through the abdominal and uterine walls) and has fused eyelids (if the infant is less than 26 weeks' gestational age). Draping blankets on top of the incubator or using a handmade or commercial incubator cover decreases the light at the infant's level during rest but allows immediate maximal illumination when the cover is pulled back. Using adjustable lighting at each infant's bedside enables every infant to have more or less light depending on the care and rest circumstances of the individual infant. Because infants are continuously monitored, not all infants need to be subjected to maximal illumination at all times.[158]

Cycled light—dimming the lights in day-night cycles—is associated with positive effects (Box 13.14). Randomized controlled studies show that the circadian clock of the preterm infant is entrained by cycled light.[160] Preterm infants exposed to low-level cycled light for 2 weeks before discharge showed night/day rest-activity patterns within the first week after discharge. Preterms

BOX 13.14 EFFECTS OF CYCLED LIGHT[a]

- Behavior:
  - Decreases/no change in movement or motor activity
  - Increases motor coordination
  - Increases sleep time
  - Decreases fussing and crying
  - More eye opening
- Cardiorespiratory changes:
  - Decreases heart rate
  - Decreases respiratory rate
- Feeding behavior:
  - Quicker progression to oral feedings
  - Feeds more efficiently and in less time
  - Increased weight gain and better growth
- Circadian rhythm development:
  - Melatonin level
  - Temperature
  - Heart rate
  - Rest and activity patterns
- Decreased cortisol levels
- Decreased incidence and severity of retinopathy of prematurity
- Decreased parental and/or care provider stress
- Decreased infant handling and noise levels
- Shortens length of stay

[a] References 55, 56, 224, 295, 359, 360, 426.

exposed to low-level uncycled light were delayed in their development of day-night differences in activity and rest till 3 weeks after discharge.[358-360] A recent randomized controlled **trial of early (28 weeks' PMA) versus late (36 weeks' PMA) introduction of cycled light to extremely preterm infants (<28 weeks' gestation) found improved weight gain and shortened hospital stay with early introduction of cycled light.**[56]

Visual attentiveness is correlated with birth weight and gestational age; the more mature the infant, the more the infant is able to fix and follow. An infant at 28 weeks' gestation fixes and follows but may become apneic, behaviorally disorganized, and stressed as a result. Visual stimulation is very tiring and taxing (increases the heart rate) for the immature infant. Those of less than 34 weeks' gestation probably receive enough stimulation from the NICU environment. Premature visual stimulation also may interfere with auditory neurosensory development. When these infants reach the "coming-out stage" (see Box 13.2), they may signal their readiness for visually enhancing activities.

Infants receiving phototherapy are deprived of visual sensory stimuli because of their protective eye pads. These should be removed during care and feeding and interaction with parents and professionals. Interesting visual stimuli include inanimate objects (e.g., toys, black-and-white faces and patterns, pictures of family members, artwork from siblings, mobiles) and animate objects (e.g., faces of parents, siblings, professionals) (Fig. 13.8). **Infants prefer the human face as a visual stimulus, especially the talking face, which stimulates both visual and auditory pathways.** Parents often need to be encouraged that their infant prefers to watch and listen to their faces and voices rather than toys.

Teach parents the abilities of the infant and appropriate methods of visual stimulation:

- Place mobiles, pictures, and faces of high contrast (i.e., black and white) within the visual range of the newborn: 8 to 12 inches for term infants, a little closer for preterm infants.
- Quiet alert is the best state for visual encounters after feedings, if awake; swaddle the infant to quiet or unwrap the infant to arouse; hold infant upright.
- Place the infant on the abdomen (called "tummy time") with objects of various sizes and shapes within visual range.

FIGURE 13.8 Premature infant fixing the gaze on a black-and-white face.

- Change toys and visual stimuli. Infants become bored with the same thing.
- When the preterm infant tolerates multiple stimuli, hold him or her in en face position (see Chapter 29) to feed, talk to, and rock. Whether the infant is nipple or gavage fed, alternate sides so the infant sees both sides of the care provider's face (especially important if the preterm infant exhibits the common preference for right-sided head turning).
- Place the infant at varied heights (in a baby carrier, crib, swing, infant seat, on the floor) so the infant sees the world from various angles.
- Place the infant so that he or she can bring the hands to midline and see his or her hands and fingers and eventually reach for toys.

Infants who exhibit gaze aversion should not be "pursued" by the face of the parent or professional, because this only potentiates the time "spent away" with their gaze to protect themselves from overload. Gaze aversion, flat facial affect, and absence of a smile may cast doubt on the ability of these infants to see because there is no eye "language" or caregiver feedback of preference, recognition, and delight. These infants do see, but they fix only fleetingly. **Minimizing the number of care providers is crucial for these babies so that they deal with as few caregiver cues, styles, and ways of being handled as possible. Most important, the caregiver must be sensitive and responsive to the infant's negative and positive cues.**

BOX 13.15 BENEFITS OF NONNUTRITIVE SUCKING (NNS) FOR PRETERM NEONATES

Physiologic

- Promotes physiologic stability[142]:
  - Better oxygenation
  - Decreased heart rate
  - Pain relief (see Chapter 12)
- Alters cardiac control during supine sleep (increased blood pressure during sleep from 2–3 months after term corrected age, which is peak occurrence of SIDS)[184]
- Increased insulin and gastrin secretion that may stimulate digestion and storage of nutrients[246]
- Better milk absorption and improved digestion related to better glucose utilization[142,246]
- Fewer gavage feedings, faster transition from gavage to oral feedings[42,142]
- Accelerated transition to full oral feedings (both breastfeeding and bottle feeding)[154]
- Shorter time to full transition to breastfeeding and to discharge; lower weight at full breastfeeding and at discharge; better sucking skills.[200]
- No effect on acid/nonacid GER—safe to use in premature infants with symptoms of GER[92]
- Better weight gain[20,42,142]
- Earlier discharge[142,154,200]

Behavioral

- Comfort, soothing, and self-consoling behavior[196]
- Improved behavioral organization that decreases energy consumption[246]:
  - Quieter, more restful behavior; more sleep
  - Less stress and tension
  - Improved self-consolation and soothing
  - Improved state modulation
  - Improved neurobehavioral organization and maturation
- Increased readiness for nipple feedings because of a more alert state (see Chapter 18)
- No negative effect on breastfeeding[87]

Neuromotor Development

- Acceleration of the sucking reflex[142,154,200]
- Improved muscle tone and coordination
- Accelerated neurologic maturation

SMELL AND TASTE INTERVENTION

Newborns, including preterms, can detect, discriminate, respond (e.g., facial expression, change in respirations, apnea), learn, and remember olfactory stimuli.[262,427] The neonate's well-developed sense of smell is not stimulated in the NICU with pleasant odors. A high-risk infant is stimulated by the smell of forgotten alcohol, skin prep, or povidone-iodine (Betadine) pads inside the incubator and the unpleasant taste or smell of oral medications.[262] Because a premature infant cannot respond by crying or moving away, **the infant responds to noxious smells by a decrease in respiratory rate, transient apnea, or an increase in heart rate.**[262] Removal of noxious odors from the incubator is as critical as removal of sharp instruments after a procedure. **Alcohol vapors from alcohol-based hand rubs that had not completely dried before touching the preterm was cited as the most common unpleasant smell to which the infants were exposed.**[213] Other unpleasant odors included cleaning solutions, detergents, soaps and skin care products, and wipes such as alcohol or adhesive removers.

Enhancing the olfactory environment includes having parents hold the infant or sit close if the infant cannot yet be held. **The smell of the mother's breast milk is especially pleasant and elicits more suckling than the smell of formula.**[45,427] Olfactory stimulation of sucking in preterm infants increases with increasing postnatal age. **Placing a drop of human milk on the infant's lips with a cotton ball or gauze sponge helps the infant recognize the mother's smell and associate that smell with food and feeding when the infant is able to nipple feed.**[45] An RCT of preterm infants **under 28 weeks' PMA exposed to the smell and taste of their own mother's milk prior to feeding found that those very preterm infants attained full oral feeding 2 days earlier and had better weight gain than very preterm infants who did not smell or taste their mother's milk.**[35]

The benefits of nonnutritive sucking (NNS) during gavage and between feedings are listed in Box 13.15. **Meta-analyses of NNS studies have found a significant effect on the transition to**

full oral feedings (from gavage feedings), transition from beginning to full oral feedings, and length of hospital stay.[142] Sucking on a pacifier satisfies the infant's sucking needs and may facilitate early learning that satiety and sucking are associated. However, nutritive and nonnutritive suckling are not alike (see Chapter 18). The fact that an infant vigorously sucks on a pacifier does not mean the infant will be able to suckle nutritively, because the expressive and swallow phases have not been present in nonnutritive suckling and coordination of suck, swallow, and breathing has not been necessary. This is confusing to most parents and many professionals and should be clarified for them.

High-risk infants often undergo prolonged periods during which a nil per os (NPO) status has been ordered, and during these times, their sensation of hunger is not relieved. Although pacifiers are soothing, these infants may learn that sucking and satiety are not related. **NICU infants also experience many aversive stimuli around and within the mouth** (e.g., oral intubation, oral and endotracheal tube suction, intermittent gavage) **that result in touch aversion of the mouth and a hypersensitive gag reflex.** Feeding difficulties may result from the following:

- Severity of illness[272,364]
- Neurologic damage (e.g., IVH)
- Structural abnormalities (e.g., cleft palate or submucous cleft, recessed chin)
- Prematurity: The infant is too neurologically immature and tires easily with "work" of feeding
- Aversive feeder (acquired or developmental: sucking defect; psychological: "hospitalitis," rumination) and aversive feeding experiences[380] that alter brain structure[386,389]
- A combination of these types

Neural maturation (34–35 weeks' gestation) is the developmental guideline for initiation of oral feedings (see Table 13.2),[154,384] although some infants are ready at an earlier age (30–34 weeks' gestation) (see Box 13.2). Maturation of feeding skills occurs because of developmental changes in the CNS, coupled with experiential learning.* So intimately interrelated are these indicators **that maturity depends on experience and experience depends on maturity; therefore, the more opportunities to nipple feed, the more improved the preterm neonate's feeding performance.** However, preterm infants may exhibit periods of apnea and tachypnea with bottle feeding, because consistent coordination of breathing with sucking and swallowing does not occur until 37 weeks' gestation (see Table 13.2). **In preterm infants with a PMA greater than 32 weeks who are ready to initiate oral feeding, delaying their start by 1 week has been shown to reduce physiologic distress (i.e., oxygen desaturations) with feedings.**[440]

The research basis for determining readiness for initiation of oral feedings is discussed in Chapter 18 **and in Box 13.2. *Cue-based or infant-driven feedings* are individualized feedings initiated and discontinued based on the infant's cues of readiness to feed and satiety, rather than on time or volume of feeding.**[206,207,380] Benefits of cue-based or infant-driven feedings are listed in Box 13.16. However, the most recent *Cochrane* review of **responsive (i.e., related to infant's cues) versus scheduled feedings found weak evidence to support benefits and overall no strong or consistent evidence that responsive feedings affect important outcomes for preterm infants or their families.**[441]

Coregulated feeds—the ability of parents to know their infant's cues and read and respond dynamically to changing needs of the infant—focuses on the feeding relationship rather than

BOX 13.16 BENEFITS OF CUE-BASED/INFANT-DRIVEN FEEDING

Physiologic
- Improved physiologic outcomes[223,409]
- Increased intake of nutrients[206,223,274]
- Increased weight gain[346]
- Fewer adverse events[206,346]
- Earlier discharge home[274,346,445,446]

Behavioral
- Enhanced behavioral maturity[206,223,409]
- Enhances the development of self regulation and reinforces sleep-wake cycles[343]
- Earlier achievement of full oral feedings[206,380,445,446]
- Safe, pleasurable experience for the infant and parents[408]

No additional workload[206,274,346]

Adapted from Lubbe W. Clinicians guide for cue-based transition to oral feeding in preterm infants: an easy-to-use clinical guide. *J Eval Clin Pract.* 2018;24(1):80.

*References 59, 278, 380, 384, 410.

the volume consumed.[408] Parents learn from professional care providers how to individualize every feeding encounter by (1) respecting infant cues, (2) seeing their infant as an active partner, (3) evaluating readiness to feed, (4) adjusting feeding to be contingent with the infant's breathing rhythm and other physiologic cues, (5) using proper positioning, and (6) decreasing physical and environmental stimuli that interfere with feeding.[365,380,408] A coregulated feeding intervention in which mothers of premature infants received five nursing intervention sessions during their **infant's transition to oral feeding identified the top five issues of concern for both mothers and nurses: (1) reading cues, (2) coregulating breathing, (3) providing motoric stability, (4) regulating milk flow and (5) providing rest periods.**[409] Both mother and nurse worked together on joint attention to infant's feeding challenges, auditory assessment of breathing and swallowing, review of feeding session by videotape, and planning for the next feeding session. Another study of preterm infants using a **coregulated approach to oral feeding found fewer apneic episodes and higher respiratory rate when compared to infants being fed by the standard feeding method.**[324] Although there were no differences in oxygen saturation, heart rate, or bradycardia between the groups, the infants fed by the standard method showed significantly higher SD12, a measure of heart rate variability indicative of randomness of the heart rate, a potential marker of increased stress.[320] These strategies enable a safe learning experience for both parents and their infant, provide a pleasant feeding experience, and lay the foundation for positive feeding outcomes and improved neurodevelopment.[380,408] **There is no one approach for feeding preterms; strategies in** Box 13.17 **are individualized to each infant and parent.**

BOX 13.17 STRATEGIES TO FACILITATE ORAL FEEDING

1. Minimize noxious stimuli to the mouth.
   a. Suction only as needed (not routinely).
   b. Consider indwelling gastric tube rather than intermittent gavage (e.g., an infant fed every 2 hours would have a gavage tube passed 12 times a day).
   c. Pass intermittent gavage tube down mouth through hole in pacifier nipple; if infant has hypersensitive gag, passing smaller tube down nose stimulates gag reflex less than passing tube down mouth.
   d. Perioral and intraoral techniques*
      i. These techniques are only more aversive, rather than therapeutic, on babies with touch aversion at mouth area; individualizing therapy is important.
      ii. When performing oral exercises, do so with care—do not stimulate aversion reflexes (e.g., gag reflex).
      iii. Use of a new motorized pulsating pacifier results in faster emergence of NNS and increase in proportion of oral nutrition.[30]
2. Enhance pleasant stimuli to mouth (first experiences with suckling have lasting neurobehavioral effects).[365]
   a. Have infant smell or taste breast milk; use colostrum/human milk for oral care.[35,45]
   b. Provide nonnutritive suckling[20,165] and NNS with mother's voice[84] while tube feeding[365] (see Box 13.15).
   c. Facilitate hand-to-mouth behaviors.
   d. Use nipple with proper flow rate.[153,267,379] If flow rate is too fast, increased flow stimulates anxiety and/or gag reflex and causes bradycardia—promotes incoordination. If flow rate is too slow, fatigue and frustration are increased and may result in inadequate consumption/growth failure.
   e. Perioral and intraoral stimulation—facilitates development of normal sucking behaviors.[26,165,229,237]
   f. Use Lact-Aid nursing supplementer (see Chapter 18):
      i. Never frustrate infant with dry breast.
      ii. Positive reinforcement for infant to nurse.
      iii. Calorically and energy efficient method.
      iv. Oral therapy—teaches infant proper nutritive suckle.
   g. For infants with difficulty in coordination of respiration with suck or swallow (prevents stress of apnea and hypoxia and enhances pleasure of feeding experience) (see Chapter 18)[97,406,407]:
      i. Assess feeding pattern (e.g., continuous or intermittent suck), pulse oximeter, muscle tone, breathing pattern, heart rate.[410]
      ii. Remove nipple from mouth to enable infant to breathe (pace feeding).[223]
      iii. Begin breastfeeding before bottle feeding.[396] (See Chapter 18 Critical Findings: Readiness for Initiation of Oral Feedings: Research Basis in Table 18.5.)
      iv. Use of orthodontic nipple results in physiologic stability and more effective feeding behavior in some infants.
      v. Use of soft-walled bottle system improves oxygenation and coordination and is more like breastfeeding than rigid-walled bottle[153]

Continued

BOX 13.17 STRATEGIES TO FACILITATE ORAL FEEDING—CONT'D

3. Positioning: Use proper position to facilitate swallow and improve suction—symmetric positioning with predominance of flexion.[410]
   a. Hold with feedings (even gavage) as much as possible.
   b. Consistent caregivers—parents, primary nurses, foster grandparents.
   c. Kangaroo care before feeding improves alertness; does not tire infant and should not be avoided before feeding; promotes breastfeeding.[89,152,365]
   d. Swaddle[380,410,454]:
      i. Decreases startles
      ii. Optimizes postural stability and control
      iii. Infant may become too warm and sleepy.[28]
   e. Facilitate swallowing:
      i. Position with chin tucked.
      ii. If breastfeeding, turn infant's whole body toward mother so head and trunk are in alignment (infant is not trying to swallow with head turned to one side).
      iii. Upright position with neck, shoulders, and back supported—slows gravitational flow of formula from nipple (as when infant is in semireclined position); restricted milk flow (e.g., milk flows only with active sucking, not with gravity) beneficial (e.g., more efficient; more volume obtained).
      iv. Head-elevated, side-lying position results in more physiologic stability (fewer and less severe bradycardia; slower, more relaxed breathing) for bottle feeding;[380] systematic review of side-lying position found conflicting results in studies and a large RCT with a diverse group of premature infants is recommended.[324]
      v. Cuddling, semireclined position increases flow of formula by gravity—may be too fast, regardless of nipple chosen; results in increased gags, choking, and bradycardia.
      vi. Prone with neck extended (slightly): Keeps tongue forward and airway unobstructed.
      vii. Good for aversive feeder who chokes.
      viii. Gentle, upward pressure under chin (chin support) or at base of tongue facilitates swallowing, because it mimics upward thrust of tongue with swallowing.
   f. Improve formation of suction:
      i. Semireclining (>45-degree angle) on lap of caregiver—frees both hands to work with infant on oral control.
      ii. Cupping both cheeks (check support) with fingers of free hand (i.e., hand not holding bottle) improves lip closure, suction formation, minimizes fluid loss, stabilizes the jaw, and organizes deglutition.[46,454]
      iii. Gentle tugging at nipple (as if to take it out of mouth) may smooth and strengthen suck; avoid prodding infant to suck.[380]
   g. Improve sucking organization[279]
      Multimodal intervention:
      Auditory (10 minutes of mother/female voice)
      Tactile (moderate touch stroking or massage)
      Visual (eye to eye) stimulation
      Vestibular (5 minutes of horizontal rocking)
4. Timing
   a. Do not allow infant to cry to exhaustion before feeding—infant will be too tired to eat.
   b. Keep external stimuli to a minimum in immature preterm infants (<34 weeks) for optimal intake and weight gain.[379,408]
   c. If or when satiated, infant will not suck:
      i. Feed by cue-based/infant-driven/coregulated feedings (see Box 13.16)
      ii. If feeding on schedule, note whether infant gives cue of hunger: fussiness and crying, hand-to-mouth behaviors or rooting, hiccups. Infants as young as 32 to 33 weeks can provide cues so that feeding can be individualized.[364,365,380]
      iii. If feeding on schedule, space time and see whether infant exhibits cues of hunger (as described earlier).
      iv. First, nipple what infant is able to feed; then tube feed (presence of an indwelling nasogastric tube may result in compromised respirations, oxygen desaturation, and bradycardia in the VLBW infant).[384]
   d. Try to nipple feed for no longer than 20 to 30 minutes (infant becomes too tired and uses up energy and calories to feed instead of to grow).[364]
   e. Infants of advanced age (around 6 months) may be unable to nipple if they have never had the opportunity. It may be more developmentally appropriate to cup feed or spoon feed infant, because normal infants begin cup drinking between 6 and 8 months of age.

* References 20, 24, 26, 46, 164, 165, 229.
NNS, Nonnutritive sucking; *VLBW,* very low birth weight.

Feeding difficulties at the beginning of life often lead to eating problems in infancy and later in life.[365,380] Severe behavioral eating difficulties are associated with prematurity, low birth weight, CNS injury, distress during feeding in the first 6 months of life, neurodevelopmental problems (cognitive, language, motor, socioemotional delays), and regular or frequent vomiting. Feeding difficulties are stressful to all family members, complicate parenting, and strain the parent-infant bond.[94,365,380]

Because criteria for discharge include full oral feedings with adequate weight gain, transition to full oral

feedings is a topic of ongoing research. A recent multicenter retrospective analysis of the **feeding behaviors of 6146 preterm infants born at 29 weeks' to 33 weeks' gestation found that the median PMA at first oral feeding was 33.9 weeks.**[59] This study also found that **for every week earlier that oral feeding was begun, full oral feedings occurred 4.5 days earlier and discharge occurred 3.4 days earlier.** Factors influencing earlier full oral feedings and earlier discharge included higher birth weight and black maternal race.[59] **Longer transition time to full oral feedings is significantly influenced by (1) apnea, (2) birth weight or gestational age, (3) younger age at first oral feeding, (4) BPD/CLD, (5) number of days being tube fed/receiving ventilatory therapy, (6) desaturations of oxygen with feeding and (7) location of the NICU.* Shorter transition time to complete oral feeding is associated with (1) earlier skin-to-skin care and oral feeding by parents[152]—first feeding at the breast before bottle feeding,[396] (2) greater weight, (3) older postconceptual age at initiation of nipple feeding,[63,278,336](4) use of oral stimulation (e.g., stroking, NNS, NNS with lullabies, NNS with mother's voice),† (5) use of oral colostrum,[35,45] and (6) a cue-based/infant-driven/coregulated feeding protocol (see Box 13.16).**

A randomized study of early introduction of oral (bottle) feeding (e.g., within 48 hours of full tube feeding) found the following[384]:

- Transition time to all oral feedings was significantly shorter.
- Oral feeding was introduced 2.6 weeks earlier.
- Total oral feeding was achieved at earlier postmenstrual age (e.g., 54% of 33 weeks' PMA infants versus 12.5% of control group).
- Weight gain and discharge weights were similar for both groups.
- Episodes of feeding-related bradycardia and desaturations were similar for both groups.
- Discharge was 10 days earlier for the earlier fed infants.

These researchers postulate that feeding opportunities in young infants provide them with practice and experiential opportunities to develop their oral motor skills and coordination of suck-swallow-breathe.[384] **A more recent study found that every 1% increase in the proportion of missed oral feeding opportunities extended the time to full oral feedings by 1.45 days and the time to discharge by 1.36 days.**[417]

For infants with BPD/CLD, the more days receiving positive-pressure ventilation and supplemental oxygen, the older (in postconceptual age) the infant when he or she is first fully nipple fed. For these infants, transition time to full nipple feeding may be lengthened because of the increased work of breathing, the precedence of breathing (at an increased rate) over feeding, and changes in heart rate variability.[97,273] However, a randomized study found that infants with BPD/CLD fed by an individualized, semi-demand method (using the infant's behavioral cues and cardiorespiratory state to determine frequency, length, and method) achieved nipple feeding earlier (5.9 days) compared with control infants (12.3 days).[272]

The goals of intervention include (1) a safe feeding (i.e., diminished risk for aspiration), (2) a functional feeding (i.e., adequate caloric intake for optimal growth and with minimal energy expenditure), and (3) a pleasant, social interactive experience for the infant and parents or caregivers.[165,342,380,410]

The use of individualized developmental care may assist VLBW and preterm infants with BPD/CLD in obtaining and maintaining an optimal condition for progression to oral feedings. **Use of skin-to-skin KC improves weight gain, supports and promotes breastfeeding, and shortens length of stay** (see Box 13.6). **Because KC improves alertness and does not tire the infant, it can be used as a strategy to facilitate oral feeding** (see Boxes 13.6 and 13.14). The use of developmental care enables VLBW preterm infants to initiate the first oral feeding and have the last gavage feeding at an earlier age compared with VLBW infants not receiving developmental care. Preterm infants successfully completing oral feeding spent significantly more time in awake states than did preterm infants who were unsuccessful in their feeding.

Using developmental principles, health care providers are able to facilitate both the preterm infant and parents in effective feeding experiences.[364,380] **A self-regulating preterm infant shows these signs of stability during feeding: (1) smooth, regular respirations (no or minimal increase in respiratory rate or effort); (2) consistent postural control—flexed, hands near face, maintains muscle tone, calm/organized behavior; (3) maintains optimal**

*References 192, 278, 384, 458.

†References 84, 164, 237.

color; (4) quiet, alert state, focuses on feeding; and (5) coordinates suck-swallow-breathe.[379,410] Coordination of feeding is facilitated by (1) imposing breaks/pacing (e.g., removing the nipple from the mouth; tipping the bottle so that the nipple is empty but remains in the infant's mouth), (2) limiting bolus size (limiting the number of sucks before a swallow results in smaller bolus size) by limiting the number of successive sucks before the infant becomes stressed, and (3) slowing the flow rate (e.g., using low-flow-rate nipples,[267] upright positioning to decrease hydrostatic pressure and gravitational flow).[379]

Signs of stress during nipple feeding, their significance, and appropriate interventions are listed in the Critical Findings in Table 13.13. **Stress can be avoided and oral feeding efficiency enhanced by ensuring that the preterm infant is awake and alert for feeding.**[165] **Even preterm infants who are near discharge still have oxygen desaturations when fed by their mothers; the incidence is decreased in infants receiving supplemental oxygen, beginning a feeding with a higher baseline oxygen saturation, and in those of an older postconceptual age.**[406,410] **Parents must be taught how to interpret their infant's cues of stability and stress so that they can modify their behavior and learn to intervene to help their infant safely and successfully feed.**[380,408] Skills parents need for effective feeding include (1) following the infant's lead about readiness to feed—preterms are able to root and open their mouths to the stimulus of a nipple; (2) assessing breathing cues, providing adequate rest (see Table 13.13), and not interrupting by "jiggling" or moving the nipple to stimulate sucking; and (3) recognizing that noisy swallowing and drooling indicate dysfunction[380,408] (see Table 13.13). Strategies that parents consider helpful in mastery of these skills are (1) being included in decision making about feeding and its success, (2) observing a nurse feed their baby, and (3) having a nurse spend time with them while they are feeding their baby to give them feedback, ideas, and tips about feeding.[380,408] For parents, learning to feed their infant is viewed as a significant symbol of parenting, as an opportunity to read and react to infant cues, and as a coregulator of feeding.[380,408]

Recent research shows that **maternal psychological well-being influences feeding of their premature infant.** Maternal depression, worry, and role stress were highest one week prior to the onset of the first oral feeding. **Maternal depression and role stress were associated with less use of developmentally supportive feeding behaviors such as minimizing tactile stimulation, providing steady tactile containment and stabilization, and regulating milk flow in response to neonatal cues.**[325] Additionally, maternal psychological functioning influences maternal presence in the NICU (distress associated with decreased maternal presence) and the length of stay.[82,163]

A feeding plan, developed with parents,[365,380,408] must be individualized for each infant and posted at the bedside (see Box 13.15 and the Case Study). All care providers must adhere to the plan for consistency and continuity of stimuli and to promote infant learning.[380] Evidence-based approaches to nipple feeding (for NICU preterms and sick term infants) have been developed that integrate contingent, developmental principles with more nurse autonomy and multidisciplinary collaboration and support. The Early Feeding Skills (EFS) Assessment checklist has been developed to assess a preterm infant's readiness for oral feeding, oral feeding skill, and ability to maintain physiologic stability and tolerance of oral feeding.[410] The Premature Infant Oral Motor Intervention (PIOMI) is an evidence-based, validated intervention that facilitates the development of oral feeding skills, improves oral feeding, shortens length of stay, and lowers costs.[229] The Preterm Oral Feeding Readiness Scale (POFRAS) evaluates aspects of physiology, behavior, and nonnutritive sucking and is moderately accurate in determining oral feeding readiness.[48] The Supporting Oral Feeding in Fragile Infants (SOFFI) method contains an algorithm to assist nurses in decision making, using specific evidence-based strategies and interpreting behavioral cues for bottle feeding preterm, sick, and fragile infants.[364] SOFFI is recommended to be used in conjunction with the National Association of Neonatal Nurses Guideline for Practice: *Infant directed oral feeding for premature and critically ill hospitalized infants.*[365] The Infant Driven Scale assesses feeding readiness in preterm infants and identifies infants at risk for delayed full oral feedings.[151] The Neonatal Eating Assessment Tool (NeoEAT) Bottle Feeding is a valid and reliable parent-report assessment of bottle feeding in infants younger than 7 months of age.[319] NeoEAT Bottle Feeding can be used in clinical practice to identify infants who need assessment and/or intervention and to measure their response to intervention. Three versions of the NeoEAT tool (NeoEAT Breastfeeding, NeoEAT Bottle Feeding, and NeoEAT Breastfeeding and Bottle Feeding) have been developed and tested for validity.[318]

TABLE 13.13 CRITICAL FINDINGS
STRESS* DURING NIPPLE FEEDINGS

SIGN	SIGNIFICANCE	INTERVENTION
Color change Pallor, dusky, gray, central cyanosis—perioral/periorbital	Oxygen desaturation[406,407] Feeding too rapidly with brief, shallow breaths Low hematocrit level Breath-holding	Assess baseline color before feeding Assess bottle-feeding delivery system: soft-walled system significantly improves oxygen saturation, coordination of suck/swallow/breathe, and more like breast feeding compared with rigid-walled feeding bottle[153,267,364,365] Periodic removal of nipple to facilitate deep breathing Monitor changes in color during feeding Use pulse oximeter during feeding to maintain saturation ≥92%[406,407]
Changes in state of alertness	Quiet alert state optimal for successful feeding Increased infant focus on feeding Increased organization of oropharyngeal muscle movements	Offer preterm opportunity to suck on pacifier before feeding—encourages awake/alert behavior[407]
	Increasing drowsiness, falls asleep: Respiratory fatigue resulting from rapid feeding, desaturation, increased respiratory rate, and/or work of breathing Fatigue resulting from behavior/energy expenditure (e.g., crying; bathing) before feeding	Pulse oximeter monitoring during feeding—give and/or adjust oxygen to maintain saturations ≥92% during nippling efforts Unwrap if sleepy
	Fussiness/restlessness—resulting from oxygen desaturation (e.g., hypoxia) because of the work of breathing (WOB) and nippling; disorganized behavioral state	Periodic rest periods and pace energy expenditure with nipple feeding Swaddle/rock if fussy
Breathing	Increased respiratory effort resulting from work/exercise of feeding,[266,406] especially in the infant with CLD/BPD[97,272]	PMA >32 weeks who are ready to initiate oral feedings: delay of start by 1 week reduces physiologic distress (oxygen desaturations) with feeding[440]
1. Respiratory fatigue: Falls asleep, ceases feeding before adequate volume obtained	WOB before feeding is increased further with effort of feeding Infants with poor endurance may be unable to feed or may demonstrate poor weight gain despite acceptable intake	Pulse oximeter monitoring with feeding to ensure adequate oxygenation; give oxygen PRN to keep saturation ≥92% Provide chin/cheek support (see Box 13.7) that decreases energy expenditure, enhances state organization and sucking activity
2. Tachypnea Respiratory rate >60/min	WOB increases with feeding; respiratory rate increased with work of feeding Increased incoordination of suck-swallow-breathe with feeding; predisposes to aspiration Increased risk for aspiration if gasping for breath	Brief and/or frequent breaks in feeding to enable deep breaths and reorganize breathing patterns[407]
3. Nasal flaring	Attempts to increase oxygen intake because of hypoxia or increased WOB	Pulse oximeter; supply adequate oxygenBrief breaks to reorganize breathing
4. Nasal blanching	Distress of breathing/hypoxia Incoordination of suck-swallow-breathe with possible aspiration if flaring/blanching occur	
5. Chin tugging/head bobbing/"catch-up" breathing/grunting	Attempting to increase air entry because of "air hunger"/hypoxia/WOB/decreased tidal volume Incoordination of suck-swallow-breathe; increased risk for aspiration	As for signs 1 through 3

Continued

TABLE 13.13 CRITICAL FINDINGS—CONT'D
STRESS* DURING NIPPLE FEEDINGS

SIGN	SIGNIFICANCE	INTERVENTION
6. Crowing sounds—high-pitched stridorous noise on inspiration	Incoordination of opening/closing of vocal cords that increases the risk for aspiration into the trachea[454]	As for signs 1 through 3
7. Swallowing	Primary swallow dysfunction predisposes to aspiration,[380] swallowing may be evaluated by videofluoroscopy	
A. Drooling	Loss of bolus control because of: Inability of tongue to collect and hold fluid that is flowing too fast Rapid respiratory rate, excessive WOB that shortens time for swallowing to occur, so that only part of bolus is swallowed	Give fewer sucks in a row, followed by brief break (pacing) so that bolus is smaller and easier to completely swallow[223]
B. Gulping	Use of prolonged sucking pattern or long sucking bursts (especially at the beginning of feeding) without deep breathing at the appropriate intervals Results in oxygen desaturation, bradycardia, apnea resulting from suppression of respiration Increases incoordination of suck-swallow-breathe and stimulates pharyngeal stretch receptors, resulting in vagally stimulated apnea	Give brief breaks (pacing) to assist the infant in slowing down the feeding[223]
C. Gurgling sounds in the pharynx (breathing sounds are wet/noisy)[380]	Fluid collecting in the throat, pharynx, or supraglottic space above vocal cords Noisy respirations caused by breathing through fluid in hypopharynx because bolus is too large or flow is too fast	Brief break from feeding to enable extra swallow/dry swallow to clear fluid from throat
D. Swallowing (several times) in succession	Deliberate swallows in succession to clear bolus (that is too large/flow is too fast) from pharynx Breathing is delayed with successive swallowing and may result in apnea/ bradycardia[268]	Break from feeding to clear throat and regain control of respiration
E. Coughing, choking, gagging, spitting up	Fluid has entered (or nearly entered) the airway[266] Changes in color, heart rate, respiratory rate suggest swallowing problems Occurrence toward end of feeding suggests gastroesophageal reflux; frequent or intense spitting up also may indicate reflux	Usually can be prevented by close attention and intervention to previous signs of feeding difficulty Breaks from feeding to clear airway, regain control of respiration and state organization Ability to cough enables infant to clear airway Inability to cough, color change, hypotonia, bradycardia, and apnea are symptoms of airway obstruction that may require suction and cardiopulmonary resuscitation Change nipple and/or bottle system

*Stress signals delay the transition to full oral feedings.[458]

BPD, Bronchopulmonary dysplasia; *CLD,* chronic lung disease; *PMA,* post menstrual age; *PRN,* as needed; *WOB,* work of breathing.

Modified from Shaker C. Nipple feeding preterm infants: an individualized, developmentally supportive approach. *Neonatal Netw.* 1999;18:15.

The latest *Cochrane* review found no RCT or quasi-RCT of instruments for assessing readiness to commence oral feedings in preterm infants.[95]

A case report has been published of the progress of one preterm infant's nutritive sucking and development of effective feeding skills using the nfant® Feeding Solution system.[70] The noninvasive assessment system measures tongue movements against a bottle nipple and streams the data to a tablet as the infant sucks. The real-time data is then used to evaluate not only sucking ability and progression but also the efficacy of interventions with a goal of providing safe, cue-based feedings that progress to full oral feedings quickly, resulting in earlier discharge and cost savings.

CASE STUDY

Tommy was a 28-week preterm infant with severe RDS, prolonged ventilation, and now BPD. He is now 38 weeks' postconceptual age, receiving hood and nasal cannula oxygen and trying to learn to nipple feed. In the morning report, the night nurse says that Tommy "has bradycardia with tube passage so that 24 hours ago he had a cardiorespiratory arrest that required resuscitation. He also has bradycardia and tachypnea with bottle feeding."

Tommy's nurse evaluated his initial attempts to bottle feed (after waiting for him to demand) and wrote the care plan (see Box 13.18) after feeding him 45 mL in 20 minutes without tachypnea, cyanosis, or bradycardia.

BPD, Bronchopulmonary dysplasia; *RDS,* respiratory distress syndrome.

BOX 13.18 TOMMY'S FEEDING PLAN

1. *Sit upright.* This decreases the flow of formula from the bottle and thus decreases:
   a. His gag reflex, which causes the bradycardia
   b. His anxiety, which is caused by a bolus of formula in his mouth
2. *Use a blue nipple.* This is the shortest nipple and decreases stimulation of his hypersensitive gag reflex, which causes his bradycardia. (All other nipples stimulated him to gag.)
3. *Gently push up under his chin when he gets a mouthful of formula.* This pushes his tongue upward against his palate, the same way the tongue moves during swallowing. (READER: Swallow and note your tongue motion.) He becomes frightened (i.e., eyes wide open and fearful; increased respiratory rate; arching and struggling) when he has a mouthful of formula, because he is used to sucking only on a dry pacifier and having nothing to swallow. His fear raises his heart rate, respiratory rate, and gag reflex, which causes bradycardia.
4. *Talk to him.* Softly and gently, tell him he can swallow, and praise him when he does.
5. *Nipple.* Have him do this as much as possible (he will only get better with practice) and supplement feeding with the indwelling nasogastric tube (no more intermittent tube passage).

CRYING OR SMILING INTERVENTION

Crying is the infant's innate care-eliciting behavior, a signal that he or she needs attention. The energy expenditure of a crying infant is increased by 7.5% compared with the resting state.[351] Immediate response decreases the infant's physiologic stress, increases the infant's trust in the environment, and enhances the sense of self and of control over the world.[249] The infant's need to escalate to "out-of-control" crying is decreased with immediate response so that infants are easier to soothe. Consoling the crying infant also helps the infant change states so he or she is able to attend to and interact with the environment.

Term infants vocalize, cry, and look at their caregiver more than do preterm and ill infants.[158] Although preterm infants are more irritable than full-term infants, preterm infants cry less throughout the day than do full-term infants. **NICU infants exhibit fewer care-eliciting behaviors (some preterm infants in one study never cried, vocalized, or looked at their caregiver).[158]** Preterm infants thus are less responsive to the caregivers (both parents and professionals), who receive less positive feedback from the infant and hence are less rewarded. In one study, those NICU infants who were able to cue the care provider (cry, look, vocalize) were consistently responded to 80% to 100% of the time.[158]

Intubated infants who cannot produce an audible cry signal their needs by agitation, heart rate changes, and changes in oxygenation. Preterm infants (<32 weeks' gestation) may recover better from agitation when left alone, because active consolation is overstimulating. How caregivers attempt to soothe a crying infant while giving NICU care includes (1) no response to cries (58.1% of the time), (2) response by talking (29.2% of the time), (3) response by social touching (5.5% of the time), and (4) response by talk and social touching (7.2% of the time).[158]

Parents and staff should use graduated interventions in quieting a crying infant by the following:

- Soothing with gentle, high-pitched talking (loud enough that the infant can hear it above his or her crying)
- Placing the palm of the hand across the infant's chest or holding arms on chest with the palm of the care provider's hand
- Swaddling with blankets to decrease self-upsetting startles
- Picking up infant, holding (upright is the most soothing position), and rocking
- Placing the infant skin-to-skin on the parent's chest
- Offering a pacifier

Most stimulation in the NICU is procedural. The lack of social stimulation in the NICU not only affects the infant but also teaches parents that their infant is too weak for, too fragile for, uninterested in, or incapable of social interaction. Again, social stimulation must be paced according to the stage of development and stability of the infant[115] (see the Critical Findings in Box 13.2). Enhancing the infant's social environment includes presenting the smiling, moving, talking care provider's face to the alert infant; touching and stroking; and soothing and consoling the distressed infant.

In many busy NICUs, parents and a foster grandparent program provide this sensory integrated social experience. If the infant has been transported to a referral center, parents may live some distance away and be unable to visit daily. A chronically ill 4- to 5-month-old infant who begins to recognize the foster grandmother may smile, relax, and feed better for her and is often fussier and more irritable on her day off. A foster grandparent program benefits both infants and seniors—the infant receives love and socialization, and the senior "has a reason to get up in the morning."

If possible, parents should be encouraged to perform the "firsts" with their infant (e.g., first nipple feeding, first bath, first time out of the incubator). Because parents are not always present, they will miss some important milestones for their infant (e.g., extubation). Many NICUs have developed baby diaries (or calendars) and/or use videotaping in which the nurses, physicians, and foster grandparents write or record important information about the infant's day (as if the infant were the author). The text is accompanied by self-developing pictures with humorous captions (e.g., "Look at me. I've got my tube out!"). Staff members are very creative in relating what's been happening so that the parents have not only a verbal report (that may be forgotten over time) but also a keepsake of NICU progress.

BOX 13.19 ADVANTAGES OF SINGLE-FAMILY ROOM NICU CARE[230,231,350,434,453]

Increased developmental and family-centered care
Increased parental participation in their infant's care:

- More skin-to-skin care
- More visits; more time in NICU
- Ability to stay overnight in the NICU
- Received more breastmilk
- Lower gestational age at full oral feedings
- Growth: faster weight gain; higher weight at discharge mediated by increased developmental support
- Increased parental satisfaction, reduced stress, more privacy, and fewer interruptions

Cost-effective:

- Shorter length of stay
- Less sepsis
- Fewer medical procedures due to enhanced maternal involvement

Improved neonatal outcomes:

- Better attention due to increased developmental support
- Less stress, hypertonicity, and lethargy due to developmental care
- Less pain and physiologic stress due to enhanced maternal/parental involvement
- Higher language and cognitive scores at 18 to 24 months of age

The pursuit of "humane,"[204] **relationship-based**[10,11] **developmental care continues** with redesign of NICU environments,[448] including single-room care and changing the attitudes and care practices among health care providers. Advantages of single-family room care are listed in Box 13.19.

A comparison study of single-family NICU rooms versus open-ward NICU was conducted in an urban NICU with low levels of parental visiting and holding and found poorer outcomes at 2 years—**rather than the room configuration, the presence and care-by-parents influences improved outcomes.**[337] More recent follow-up studies comparing the outcomes of preterm infants cared for in single-family rooms to open-bay NICUs also found **improved outcomes in those infants cared for in single-family rooms because of enhanced maternal involvement and better developmental support.**[230,231]

Creating an integrated, relationship-based, family-centered, developmental care philosophy requires the following:

- A commitment by individual care providers to alter practice for the benefit of neonates and families and to integrate family-centered developmental care into their individual practice
- Relationship building with neonates, families, and colleagues
- The use of effective change strategies within the institution's organizational climate
- Implementing the guidelines of national professional organizations[16,448] to satisfy ethical, legal, and professional standards of care
- Changing health care providers' knowledge base, which requires multidisciplinary educational opportunities (e.g., orientation, in-service, continuing education, consultation) and written resource materials[6]

Developmental care can no longer be considered "nice, but optional," especially with the evidence that not only brain function but also actual brain structure are positively affected by the early experiences of family-centered developmental care in the NICU.* A study **evaluating the effect of developmental care on the neurodevelopmental outcomes of preterm infants found less psychomotor delay (16.1%) at 2 years of age in those toddlers who received developmental care in the NICU than those toddlers cared for without developmental care (27.4%).**[205] Another recent study of toddlers who were born prematurely (75% very preterm; 25% moderate/late preterm) found those with a **longer stay in the NICU had the highest risk for behavioral problems.**[74] The level of prematurity or the presence of BPD/CLD and ROP did not affect temperament, whereas a longer stay in the NICU was associated with more pervasive developmental and emotionally reactive problems. Based on these findings, these researchers **emphasize the need for developmental care in NICUs to reduce stressful and painful experiences for premature babies and to provide protection from overwhelming stimuli in the NICU during the premature infant's initial development.** Developmentally appropriate care in the NICU must also be accompanied by "proactive developmental monitoring and implementation of timely therapeutic and educational early intervention services … to continue to support optimal outcomes for preterm infants."[238]

14 FLUID AND ELECTROLYTE MANAGEMENT

MICHAEL NYP, JESSICA L. BRUNKHORST, DAPHNE REAVEY, AND EUGENIA K. PALLOTTO

Advances in the management of specific neonatal disorders have contributed to a remarkable decline in morbidity and mortality rates in newborns. Fluid and electrolyte therapy, nutritional support, thermal regulation, and maintenance of oxygenation remain central features of modern, supportive neonatal intensive care. Fluid and nutrition data have accumulated over time, but opportunities remain for increasing knowledge in order to optimize clinical management and long-term outcomes. For example, the restrictive fluid policies of the 1950s were misguided efforts that caused hyperosmolarity, hyperbilirubinemia, and hypoglycemia. On the other hand, the degree to which initial fluid, electrolyte, and glucose administration should be "liberalized" remains uncertain—particularly in very-low-birth-weight (VLBW) infants (infants with birth weights less than 1500 g).[1,15,21] **Many high-morbidity outcomes, such as patent ductus arteriosus (PDA), necrotizing enterocolitis (NEC), bronchopulmonary dysplasia (BPD), intraventricular hemorrhage, and hyperglycemia, in VLBW infants are associated with larger volumes of fluid, electrolyte, and glucose administration.[1,25,52]** At best, clinicians make approximations for therapy in many clinical situations, which is why good measures of fluid and electrolyte requirements are needed. Infants requiring neonatal intensive care commonly receive parenteral fluids, often for prolonged periods of time. The fluid requirements of both premature and term infants vary based on the underlying diagnosis and therapies used to treat these disease processes.

This chapter discusses the implementation of the following fundamental principles: (1) rapidly assessing the infant's initial condition; (2) developing a short-term, time-oriented management plan; (3) initiating therapy; (4) monitoring the infant; and (5) modifying the plan based on clinical and biochemical data.

PHYSIOLOGY

Neonates show physiologic differences when compared (on a per-kilogram basis) with older children and adults: (1) their basic metabolic rate is greater, even double; (2) their fluid requirements are four to five times higher; (3) their sodium excretion is only 10% that of older children and adults; and (4) their glomerular filtration rate is 5 to 10 times less than that of adults.[15] The subdivisions of total body mass (TBM) are illustrated in Fig. 14.1. Total body water (TBW) as a percentage of TBM demonstrates a curvilinear decline with increasing gestational age (Fig. 14.2). **During the early fetal period, the fetus's TBW is 95% of total weight and decreases to 80% at 8 months' gestation and then to 75% at term.**[15] Intracellular fluid (ICF) and extracellular fluid (ECF) as percentages of TBM change in opposite directions as gestational age advances, ECF decreases, and ICF increases with growth.

BLUE type highlights content that is particularly applicable to clinical settings.

An understanding of the physiologic and body composition phenomena is important to accurately calculate fluids and electrolytes for the neonatal patient. Caregivers should independently calculate all requirements and compare calculations with standard guidelines. **Intravenous (IV) fluid should be administered by a special infusion pump that can regulate fluid with a precision of at least 0.01 mL/hr. Intake should be measured hourly and all output measured. The balance of intake versus output should be assessed at least every 8 to 12 hours using a standard format** (Fig. 14.3).

FIGURE 14.3, cont'd

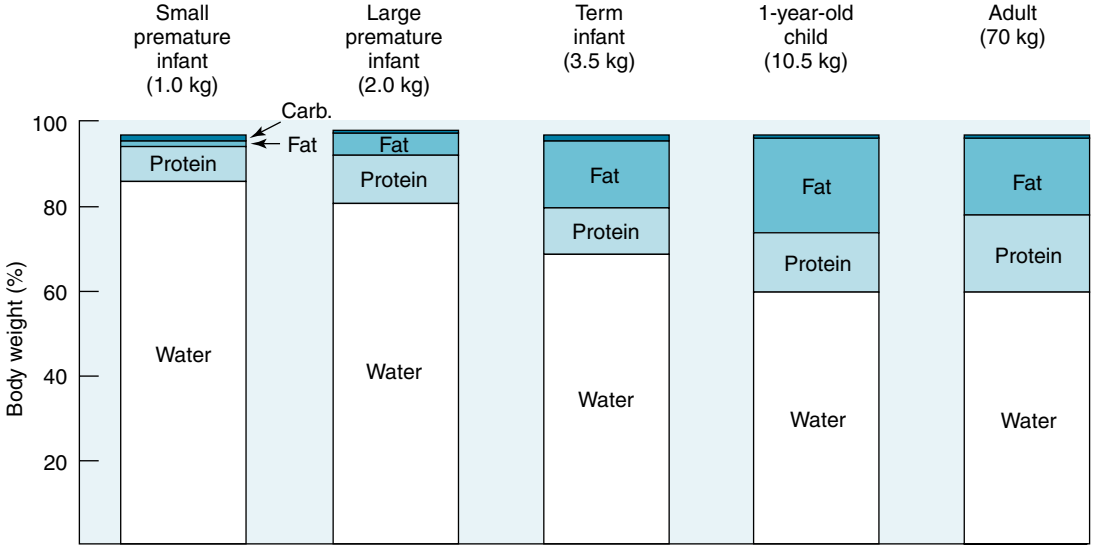

FIGURE 14.4 Effects of gestational age on body composition compared with older children and adults. (From Heird WC, Driscoll JM Jr, Schullinger JN, et al. Intravenous alimentation in pediatric patients. *J Pediatr.* 1972;80:351.)

The ability of infants, especially those who are **premature, to remove free water and/or remove a solute load is impaired. Once clinical signs of fluid overload or deficit occur, it may be difficult to regain balance**. Fluid balance should be managed prospectively; consistent assessments and laboratory evaluations should be a part of every initial care plan.

The effect of gestational age on body composition is striking (Fig. 14.4). Because gestational age is a determinant of the percentage and distribution of TBW, accurate assessment is important. In utero, fetal fluid and electrolyte balance occurs through feto-placental exchange. Changes in the distribution and percentage of body water will be influenced by intrauterine growth, maternal fluid balance, maternal medications, maternal health conditions, and placental blood flow. For example, a preterm infant born to a mother receiving magnesium sulfate may have elevated serum magnesium levels at birth, which may remain elevated for up to 3 to 5 days following birth. Small-for-gestational-age (SGA) infants have reduced amounts of fat, and their TBW (as a percentage of TBM) increases. Conversely, large-for-gestational-age (LGA) infants with an increased amount of body fat have a lower percentage of TBW.

The initial (first 3 to 5 days of life) weight loss of healthy term (up to 5% to 10% of TBM) and preterm (up to 10% to 15% of TBM) infants should be considered a normal physiologic loss of fluid. This loss is from the interstitial fluid (ISF). It is not a pathologic catabolism of body tissues but a result of the maturation of specific regulators of fluid and electrolytes. One such example, vasopressin (antidiuretic hormone), is secreted during the early stages of labor. This hormonal secretion contributes to renal maturation and has an antidiuresis effect at birth.[26]

After birth, contraction of the ECF compartment occurs, followed by natriuresis, diuresis, and weight loss.[15] **This weight loss is then regained over 7 to 10 days as muscle and fat, provided there is good nutrition. Neonates often demonstrate relative oliguria during the first 24 to 48 hours.** Disease processes, such as asphyxia, pneumonia, and respiratory distress syndrome (RDS), increase vasopressin release; thus, the fluid and electrolyte transition during the first few days of birth may be altered in these conditions.[22,42,59] Neonates with RDS will also have delayed postnatal contraction of the ECF compartment, further delaying diuresis. The onset of the diuresis, during the first few days of life, usually coincides with the initial stages of recovery from RDS.[27]

Despite the period of natriuresis after birth, infants usually do not require additional sodium during the first 24 to 48 hours of life. It is normal to have an initial negative sodium balance, but later it is necessary to retain sodium for appropriate growth; additional sodium supplementation may be required.[27] A review of maternal history and the intrapartum course may be helpful in calculating the infant's fluid

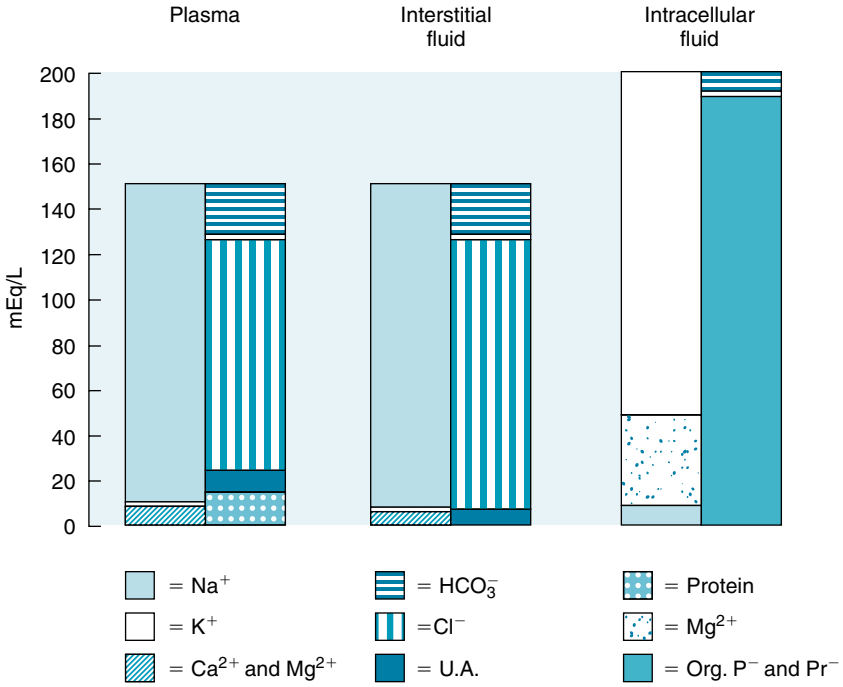

FIGURE 14.5 "Gamblegram" of plasma interstitial fluid and intracellular fluid. (From Winters RW, ed. *The Body Fluids in Pediatrics.* Boston: Little, Brown; 1973.)

and electrolyte requirements. For example, if the mother received large amounts of electrolyte-free fluids in the intrapartum period, the neonate may be hyponatremic and have an expanded ECF space at birth.[34,66]

Extracellular fluid comprises both intravascular fluid (plasma) and ISF. The electrolyte composition of ISF and plasma is similar, but it is strikingly different from ICF (Fig. 14.5). Sodium is the major cation in ECF (both ISF and plasma) and is easily measured. Potassium, the major cation in ICF, on the other hand, cannot be measured readily because ICF is not easily accessible. Because 90% of the total body potassium is intracellular, low levels of plasma potassium are assumed to reflect low total body potassium.

Maintaining appropriate fluid and electrolyte balance may be difficult due to the immaturity of the neonatal renal system: (1) inability to dilute urine secondary to lower glomerular filtration rate (GFR) and (2) inability to concentrate urine secondary to renal tubular immaturity. The neonatal GFR, a measure of renal function, is low in utero but increases rapidly within a few hours after delivery and throughout the first postnatal week as renal blood flow increases. This increased GFR is a result of increasing cardiac output and increasing glomerular permeability.[27]

GFR is independent of gestational age. It rises rapidly during the first 6 weeks of life, increases more slowly during infancy, and reaches adult values by 12 months of age. A VLBW infant in satisfactory condition at 6 weeks should have a similar GFR to that of term infants. The formation of nephrons is complete at 34 to 35 weeks' gestation, whereas maturation of the nephrons continues beyond 40 weeks' gestation.[15,21] **The GFR can be compromised in critically ill neonates.**

In addition to fluid balance, the renal tubules are responsible for mineral and electrolyte excretion and reabsorption. **Renal tubular function is influenced by gestational age.[27] At birth, immature tubular function is associated with sodium wasting and an impaired ability to reabsorb water.[28] These characteristics are exacerbated in premature infants.[62] Preterm infants with immature tubular function are more likely to experience electrolyte imbalance.**

The use of the urinary fractional excretion of sodium (FENa) [FENa = (Urine sodium × Plasma Cr)/(Urine Cr × Plasma sodium)] is an important

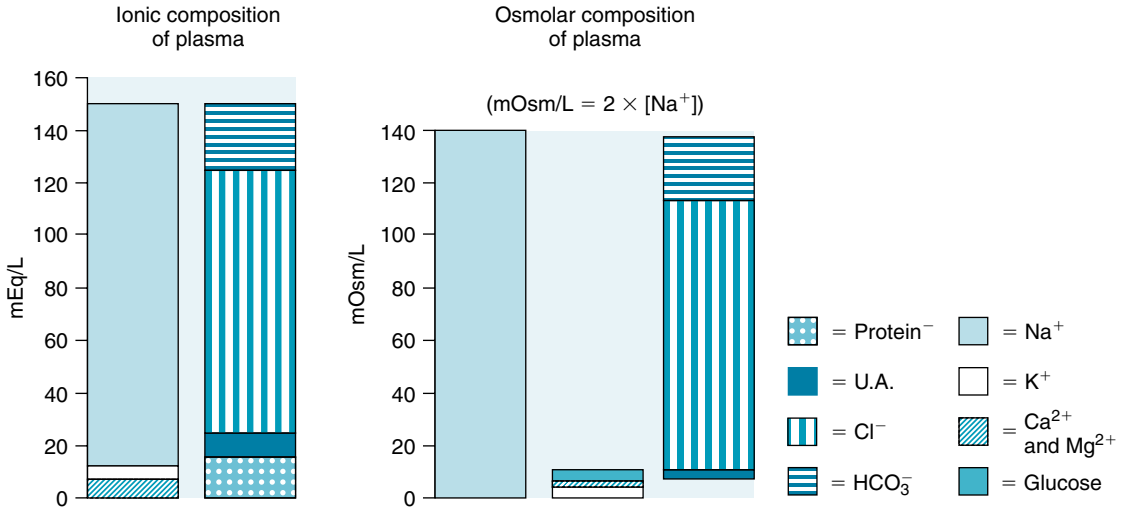

FIGURE 14.6 Ionic and osmolar composition of plasma. (From Winters RW, ed. *The Body Fluids in Pediatrics.* Boston: Little, Brown; 1973.)

tool in assessing sodium balance but must be interpreted cautiously, especially shortly after birth, due to the immaturity of renal tubular function. When using **FENa to diagnose the etiology of hyponatremia, a value greater than 3% reflects an intrinsic renal problem, whereas a value less than 2.5% reflects a prerenal problem** (e.g., volume depletion); both values are higher than that expected for an adult.[18] A falsely elevated FENa may be present when excessive sodium is lost in the urine due to prematurity or with diuretic use.[30,69]

The ability to excrete potassium is impaired at birth, especially in low-birth-weight infants, thus increasing their risk of hyperkalemia, particularly when given a potassium load before establishing stable renal function. **Calcium reabsorption is also reduced with immaturity and results in higher urinary levels of calcium; thus, early use of loop diuretics may lead to an increased risk of renal stones.**[31]

The capacity to concentrate urine in VLBW infants appears limited but can be influenced by gestational age and nutrient intake. The immature concentrating ability (maximum of approximately 600 mOsm/L) (Fig. 14.6) coupled with an inability to rapidly excrete an acute water or sodium load results in a narrow margin of safety when prescribing fluid and electrolytes, especially in the VLBW infant.[1,15,21]

In general, urea is the major component of urine osmolality (and hence specific gravity). When total parenteral nutrition is provided, urine specific gravity may rise because of a low renal threshold for glucose and amino acids. **Very preterm infants will have glucosuria despite serum glucose levels in the normal range. The renal protein and glucose threshold increase with advancing gestation.**

Neonatal urinary acidification is also limited, and the threshold for bicarbonate excretion is reduced, leading to both decreased bicarbonate retention and acid excretion. Both physiologic and pathologic factors can contribute to this urinary alkalinization. Acidemia develops in premature infants due to this limited capacity for hydrogen ion excretion. **Alkaline urine pH will precede the development of acidemia. Closely monitoring and replacing losses can prevent the development of severe acidemia.** In more mature infants, urinary alkalinization will occur in the setting of more acute illnesses, such as a urinary tract infection or bicarbonate-losing tubular necrosis that may occur in neonatal diagnoses associated with acute kidney injury or with nephrotoxic medications.[53] The ability to distinguish acidemia occurring from an acute illness versus a developmentally impaired urinary acidification system is important for proper treatment. The **anion gap (serum Na^+/[serum Cl^- + serum bicarbonate]) is a useful tool in this assessment. The normal anion gap typically is less than 8. A widened anion gap is suggestive of increased production of organic acid, in particular lactic acid (a pathologic condition),**

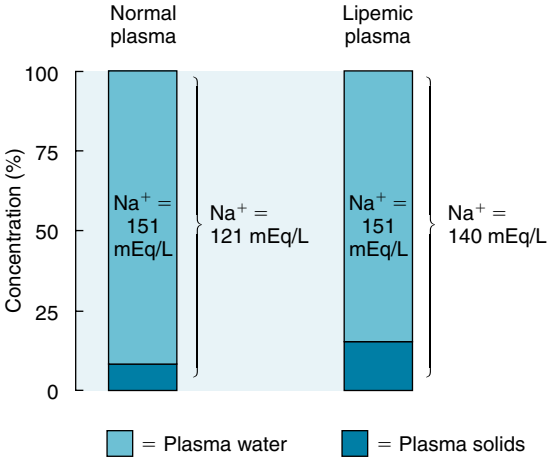

FIGURE 14.7 Effects of hyperlipidemia on plasma water and plasma sodium concentration. (From Winters RW, ed. *The Body Fluids in Pediatrics.* Boston: Little, Brown; 1973.)

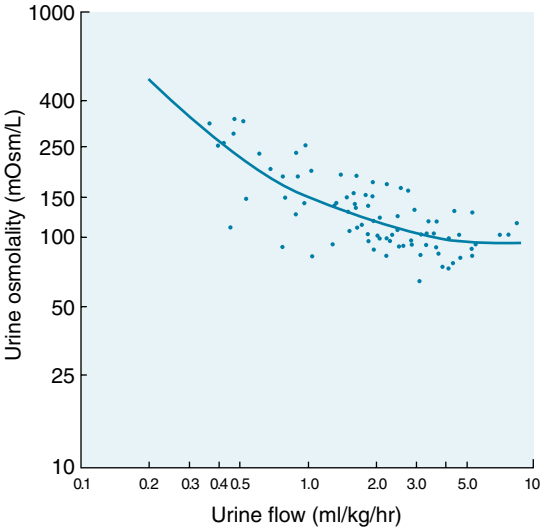

FIGURE 14.8 Normal urine flow rates. (From Jones MD, Gresham EL, Battaglia FC. Urinary flow rate and urea excretion rates in newborn infants. *Biol Neonate.* 1972;21:322.)

whereas a normal or narrow gap suggests bicarbonate loss due to the lowered threshold for bicarbonate excretion in the neonate. Further details are available in Chapter 8.

Hormones, including antidiuretic hormone, aldosterone, atrial natriuretic factor, and parathyroid hormone, are involved in regulating the neonatal fluid and electrolyte balance, yet the specific roles are not well defined. **Most hormonal effects occur by modifying renal function through a change in either GFR or renal tubular permeability. For example, the increased osmolality that occurs in dehydration is a trigger for antidiuretic hormone release, leading to changes in the permeability of the distal tubule and collecting duct. This change results in more water reabsorption and thus more concentrated urine.**

Osmolality can be satisfactorily estimated in many clinical settings by the following formula (Fig. 14.7):

$$\text{Osmolality} = \left[2\left(\text{Na}^{+}\right) + \text{Glucose (mg / dL)} \div 18\right] + \left[\text{BUN (mg / dL)} \div 2.8\right]$$

Osmotic forces are responsible for apparently low plasma electrolyte concentrations in some common clinical settings. For example, in hyperglycemia, the plasma sodium concentration reported by the laboratory is usually low, but the total effective osmolality may be normal. An analogous situation exists for the less frequent condition of hyperlipidemia, in which low laboratory plasma sodium values are reported with a normal osmolality (Fig. 14.8). **Low laboratory values for plasma sodium (pseudohyponatremia) can be present in the setting of hyperlipidemia or hyperglycemia.** This occurs because the increase in plasma solids (lipids) causes a lower plasma water content, resulting in water displacement and hence a lower sodium concentration per liter of whole plasma.

Osmotic forces largely determine shifts in the internal redistribution of water in hydration disturbances. An example of changes in osmolality occurs in preterm infants who undergo insensible water loss because of skin immaturity, decreased body fat, and a large surface-to-volume ratio leading to increased evaporation. This water loss from the interstitial space results in a hyperosmolar extracellular compartment exhibited by hypernatremia and occasionally hyperkalemia and hyperglycemia.[15]

Another key concept in fluid and electrolyte balance involves insensible water losses (IWLs) that occur via pulmonary and cutaneous routes and are influenced by the factors listed in Table 14.1. **However, IWL varies greatly depending on gestational age and birth weight** (Table 14.2). The neonate's environment also can affect the fluid balance. **Radiant warmer usage decreases the**

neonate's radiant heat loss but can increase IWL by 50% to 200%, resulting in hypernatremic dehydration.[40] Incubators reduce radiant heat loss via their double-walled Plexiglas design.

Modern incubators provide sterile humidity (80% or greater) and are very effective in decreasing IWL by reducing evaporative heat loss. Internal incubator humidification was discontinued in the 1970s when it was associated with *Pseudomonas* infections.[41] Presumably, the nature of *Pseudomonas* promoted its stability and growth in the water humidification reservoirs. However, present humidification designs provide for direct heating of water in an external reservoir to a temperature that kills most organisms. The water is transformed into vapor, rather than mist, and carried in a gaseous state by the incubator's convective air flow, thus reducing the possibility of airborne bacterial transfer.[41]

Because added environmental humidity reduces transcutaneous evaporative water loss, an extremely preterm infant managed in humidity needs less fluid than those managed without humidity to achieve the same water balance. A relative humidity of 80% can reduce water loss to one tenth of the water loss of a preterm infant receiving care in 50% humidity.[40] This reduction in evaporative water loss affects the management of fluid requirements and the electrolyte balance in premature infants. **For infants with a birth weight of less than 1000 g, the use of humidity at 70% to 80% in the first week of life results in lower fluid intake and improved electrolyte balance and growth velocity.** A decreased risk of severe BPD has also been reported in extremely low-birth-weight (ELBW) infants cared for in humidified incubators.[36] Despite these improvements, the optimal level and duration of humidification have yet to be determined.

The ability to provide the proper fluid and electrolyte balance is determined by assessing initial fluid status, renal function, and estimated insensible fluid losses. Frequent assessment of fluid balance remains essential in preventing fluid deficit or overload, which can be difficult to correct once it has occurred.

ETIOLOGY

The causes of common electrolyte problems and common clinical syndromes are discussed under Treatment later in this chapter.

PREVENTION

Prevention of fluid and electrolyte imbalance in neonates begins with knowing how to calculate fluid and electrolyte requirements correctly. **The estimated metabolic rate forms the reference base for all calculations. The metabolic rate (and hence oxygen consumption) normally increases steadily over the first weeks of life, so changes in water and electrolyte requirements should be anticipated.**

If the daily caloric requirement is approximately 100 *kcal/kg/day,* the physiologic basis of metabolic rate may be used to calculate needs; however, most institutions determine an infant's daily fluid need on a *milliliters per kilogram (mL/kg)* basis, which is modified by factors that influence IWL and is usually adjusted depending on body weight, clinical composition, serum chemistry results, and urine volume and composition (Fig. 14.9; see also Table 14.2).

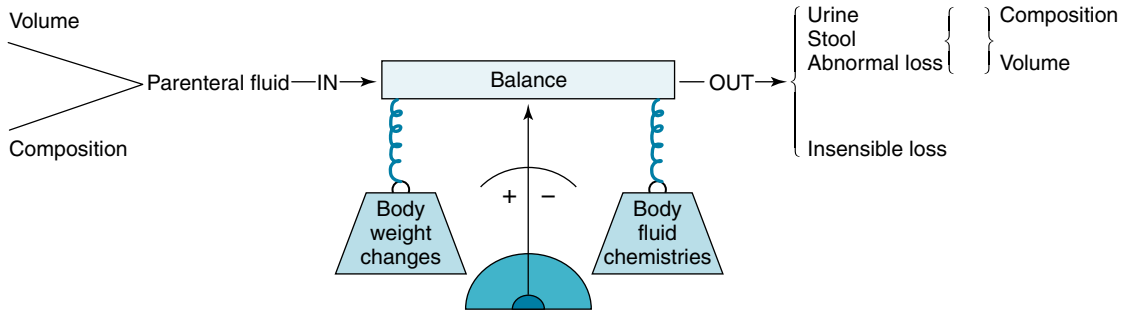

FIGURE 14.9 Basic scheme for monitoring and modifying fluid therapy.

Preterm infants have lower metabolic rates than those of term infants.[8] SGA infants may have higher metabolic rates than those of preterm infants of similar weight,[7] which may be because of their relatively large ratio of brain to body mass. Infants with congenital heart disease,[44] as well as infants in the immediate postoperative period,[48] also have higher metabolic rates compared with appropriate-for-gestational-age (AGA) infants. Both SGA and preterm infants, especially VLBW infants, should be expected to require more frequent assessment and modification of requirements.

Preterm infants, however, are subject to other problems that may diminish the influence of this metabolic rate when calculating fluid needs. SGA infants may require less water per kilogram than either preterm or term AGA infants due to their increased extracellular volume.[45] **Input should be recorded every hour. Output should be recorded hourly in critically ill infants but may be recorded every 4 to 6 hours in infants who require minimal stimulation.** The smallest infants require frequent fluid balance monitoring, so if output is unusually large, intake can be adjusted immediately. If fluid intake lags behind losses, critically ill infants may develop hypernatremia and may not tolerate "catching up." Continuous monitoring is necessary to ensure that fluid is administered in appropriate amounts. **Current infusion pumps can accurately infuse volumes of 0.01 mL/hr and must be used for the smallest, sickest infants.**

Requirements for fluid and electrolytes are divided into maintenance and deficit needs. ***Maintenance* indicates the infant remains in a zero-balance state** and can be subdivided into (1) normal loss, which consists of water and electrolyte loss through stool, urine, and insensible (lung and skin) routes; and (2) abnormal or increased losses, such as gastrointestinal/diarrhea, ostomy, and chest tube drainage.

All diapers should be preweighed using a gram scale and marked with dry/tare weight. After each stool or void, the diaper is reweighed; the difference equals the amount of loss. For example, if the dry weight is 20 g and the wet weight is 26 g, the difference is 6 g, or 6 mL of stool or urine. All losses should be calculated to the nearest milliliter.

The term *deficit* refers to previously incurred losses. These should be uncommon in the newborn but can occur when there are unrecognized losses, such as "third space" or interstitial losses with NEC (see later discussion). In older neonates, deficits may occur with disorders that have an insidious or delayed onset, such as renal tubular dysfunction or nonvirilizing congenital adrenal hyperplasia.

Deficits are best estimated by body weight comparisons. **Weight loss greater than 10% to 15% in 1 week should be considered excessive, although in VLBW infants it can be difficult to maintain within 10% to 15% of birth weight during the first week of life.[71] Infants who are SGA have less weight loss compared with AGA infants[72]** in the first 10 days after birth. Growth charts assist with calculations of weight loss and/or gain and help consider the normal physiologic weight loss that occurs during the first several days after birth when calculating an infant's fluid needs.

The initial choice of parenteral solution depends on the weight and postnatal age of the infant (Table 14.3). Also important is whether the infant is in an incubator with a heated humidified environment or under a radiant warmer without a plastic blanket or heat shield. **Uncovered VLBW infants under radiant warmers demonstrate IWLs of up to 170 mL/kg/day,[27] and the use**

TABLE 14.3 GUIDELINES FOR FLUID (mL/kg/day) AND SOLUTE PROVISION BY PATIENT WEIGHT AND DAYS OF AGE

Increment for phototherapy: 20–30 mL/kg/day if patient is in open warmer and has radiant phototherapy. No adjustment if baby is in humidified environment and/or has fiberoptic phototherapy source.
Increment for radiant warmer: 20–30 mL/kg/day.
Maintenance solutes: glucose: 7–12 g/kg/day (4–8 g/kg in VLBW infants)
Na: 1–4 mEq/kg/day (2–8 mEq/kg/day in VLBW infants)
K: 1–4 mEq/kg/day
Cl: 1–4 mEq/kg/day
Ca: 1 mEq/kg/day

*Adjustment based on a urine flow rate of 2–5 mL/kg/hr and a stable weight.
†May be reduced by 30% if the infant is on a ventilator.
IWL, Insensible water loss; *VLBW,* very-low-birth-weight.

of radiant warmers should thus be avoided if possible. Maintenance of water and glucose needs in larger infants on the first day of life can usually be met by a 10% glucose solution infused at 60 to 80 mL/kg/day, which provides an acceptable glucose infusion of about 4.2 to 5.5 mg/kg/min. The infusion rate can be gradually increased over 4 to 5 days to 120 to 140 mL/kg/day using principles of monitoring discussed later in this chapter.[5]

All sick infants require IV access for fluid administration. Placement of an IV line is the most common procedure in the neonatal intensive care unit (NICU).[50] The IV equipment should include (1) a needle or catheter, (2) connecting tubing, and (3) an infusion pump.

Electrolytes such as sodium and potassium are usually omitted for the first 1 to 2 days of life and then added as the salt of acetate, chloride, or phosphate in amounts of 1 to 4 mEq/kg/day. Mildly acidotic and VLBW infants may be given their sodium requirements as sodium acetate.[5] **Potassium should never be added to IV fluid until urine flow and renal function have been assessed. The initial requirement for calcium is 1 mEq/kg/day (20 mg/kg/day), but this rises to a maintenance requirement of 3 to 4 mEq/kg/day (about 60 to 80 mg/kg/day) of elemental calcium, preferably given as calcium gluconate (about 600 to 800 mg/kg/day).**[65] This maintenance is most important in VLBW infants and those who are severely ill. **Careful observation of peripheral IV sites with the infusion of IV fluids containing calcium is critical due to the risk of tissue necrosis associated with infiltration.**[35]

Factors that influence IWL must be identified early and maintenance needs adjusted appropriately to prevent problems with water and electrolyte balance. Humidified incubators significantly decrease the IWL of ELBW infants. They require less fluid intake, have lower percentage of weight loss, and have fewer episodes of hypernatremia than infants cared for in a nonhumidified incubator.[36] **Management of VLBW infants presents special, complex problems, and continued research is needed.** The following observations may be helpful:

- **Total fluid requirements should typically start at 100 to 120 mL/kg/day at birth, although some authors suggest as low as 80 mL/kg/day,**[12,46,67] and often need to be increased by 20 to 40 mL/kg/day over days 2 to 6 of life, typically plateauing at 150 to 160 mL/kg/day. Higher fluid requirements may be necessary for VLBW infants managed on a radiant warmer or in nonhumidified incubation. **Careful restriction of fluids, without allowing dehydration, has been shown to decrease the risk of PDA and NEC.**[10] **A lower risk of BPD has also been associated with early appropriate weight loss in ELBW infants.**[36,72] Careful restriction of fluids allows for the normal contraction of extracellular fluid and appropriate weight loss while maintaining physiologic needs.[10,25,46]
- **Cumulative weight loss plateaus at 10% to 15% of birth weight by postnatal day 3 to 5.**
- **Sodium requirements (including medications) are 2 to 3 mEq/kg/day after 24 to 48 hours of age** and may reach a maximum of 4 to 5 mEq/kg/day during the first few weeks of life.[18]
- **Maintaining serum glucose concentrations (60 to 150 mg/dL) in VLBW infants may initially require relatively less glucose** than that of term or near-term infants because their own endogenous glucose production may not be effectively suppressed. **However, in order to preserve endogenous stores of glucose (e.g., glycogen) in clinical practice, the preterm infant may need up to 8 to 9 mg/kg/min of glucose, whereas the term infant requires about 6 mg/kg/min.**[19] **In VLBW infants, a gradual increase in the glucose infusion rate to 11 to 12 mg/kg/min by the end of the first week of life is usually well tolerated.**[5] The glucose concentration of the fluids administered may need to be changed, sometimes frequently, to maintain an appropriate serum glucose concentration. **With the larger initial fluid requirements of very tiny babies, lower glucose concentrations, sometimes down to D_5W (5 mg% or 5 mg/dL) in IV fluids, are often prescribed for ELBW infants as the initial fluid.** As anticipated, infants weighing less than 1000 g are the most difficult to manage without inducing excessive weight loss, hypernatremia, or hyperglycemia, especially those stabilized under radiant warmers. They may have greatly increased IWL with fluid requirements in the range of 175 to 200 mL/kg/day or greater. By the end of the first week of life, as the epithelium cornifies, their daily requirements decrease to 120 to 150 mL/kg/day. **When enteral caloric intake is low (fewer than 50 kcal/kg/day), neonates will require administration of IV fluids, which should be provided as parenteral nutrition**[43] containing glucose, amino acids, lipids, vitamins, and micronutrients in order to support growth (see Chapter 17).

DATA COLLECTION

Parenteral therapy should be based on the following principles: (1) assess the patient's clinical status for maintenance needs, factors that modify IWL, and confounding medical or surgical disorders; (2) calculate short-term (12 to 24 hours) fluid and electrolyte needs; (3) initiate therapy at the proper site and infusion rate; and (4) monitor and adjust the fluid infusion rate and content based on clinical and biochemical data.

History

Factors influencing IWL (see Table 14.2) include gestational age, birth weight, and postnatal age. When the patient's condition changes, it is important to detail the change to evaluate the potential effect of the new condition on fluid and electrolyte balance and requirements. Thus, NEC may be associated with an acute need for additional volume expansion–type fluids because of "third space losses," whereas with acute renal failure, anuria should prompt clinical reassessment and usually indicates the need for reducing daily fluid administration.

Signs and Symptoms

Weight, urine output (Box 14.1), and **serum sodium concentration** (Box 14.2) are the best overall clinical guides to assess whether therapy is

BOX 14.1 DATA COLLECTION

Clinical Evaluation of Fluid and Electrolyte Status

- Serial weight (sometimes two to three times per day)
- Heart rate
- Blood pressure
- Skin perfusion
- Urine output
- Other drainage (ostomies, gastric, chest tubes)

BOX 14.2 DATA COLLECTION

Laboratory Evaluation of Fluid and Electrolyte Status

Essential values are included in this box. Other measurements are routinely made but are less valuable in the rapid determination of fluid status and complications of imbalances.

- *Sodium* (most sensitive indicator of water loss in excess of electrolytes, as is insensible water loss)
- *Potassium* (may rise with decreased kidney perfusion and acidosis)
- *Hematocrit* (will rise with extracellular fluid contraction)
- *Blood urea nitrogen* (relatively insensitive indicator of dehydration in neonate)
- *Creatinine* (will rise slowly with renal failure)
- *Total CO_2* (low level indicates acidosis, either because of bicarbonate loss or metabolic acidosis from poor tissue perfusion and anaerobic metabolism)

adequate. **Weight is the most sensitive index of IWL and must be accurately determined at least every 24 hours.** Accurate daily weights in VLBW infants require special nursing efforts and may be facilitated with electronic bed scales.

Urine output should be 2 to 5 mL/kg/hr with a specific gravity of 1.005 to 1.012.[24] Blood pressure and peripheral perfusion may be used to reflect changes in vascular volume and cardiac output. **Normal capillary refill is typically less than 3 seconds and is more reliable when tested on the forehead or sternum.** However, its sensitivity and specificity have been questioned in infants and should be interpreted with caution as a sign of adequate hydration. **Blood pressure and heart rate should be evaluated in conjunction with capillary refill time.**

Loss of skin turgor is a late and variable sign and usually is not helpful in assessing therapy, but vital signs (heart rate, respiratory rate, and temperature) provide useful signs about metabolic rate and stress. However, temperature may be affected by many external factors. Drainage volume and content from ostomies, chest tubes, nasogastric tubes, and other sites should be quantitated accurately. Fluid samples can be submitted for laboratory analysis to improve the accuracy of the replacement fluids. The amounts of drainage represent maintenance requirements that must be added to the calculation of baseline daily maintenance needs (abnormal + normal = total maintenance).

Laboratory Data

Tests for concentrations of electrolytes (Na^+, K^+, Cl^-, Ca^{2+}), red blood cells (hematocrit), glucose, blood urea nitrogen (BUN) or creatinine, and acid-base status should be performed serially (see Box 14.2). Occasionally, serum osmolality and protein concentrations are helpful in assessing the neonate's condition. The anion gap may be calculated from the difference of the positive and negative ions, sodium, chloride, and bicarbonate: $[Na]^+ - ([Cl^-] + [HCO_3^-])$.

Urine volume must be recorded with every void. Measuring urine osmolality and glucose and electrolyte concentrations helps clarify fluid and electrolyte balance when amounts of glucose, protein, or other solutes appear in the urine. In a preterm infant, especially a VLBW infant, an elevated urine pH may signal bicarbonate loss due to renal function immaturity.[56]

All drainage must be collected and measured, with the concentration of solutes determined (see Box 14.2). Accumulations over 4 to 6 hours are preferable to a single "spot" collection, which may be misleading. Occasionally, determining the trace electrolyte elements, hematocrit, and protein content of urine or drainage can be crucial to management. However, there are no "normal" values for urine electrolyte concentrations because they must be interpreted with respect to the infant's clinical diagnosis, medications, and serum electrolyte concentrations.

Electronic health records allow for real-time evaluation of fluid balance. Data can be downloaded directly from IV pumps or entered manually on an hourly basis. The practitioner can review

actual intake and output (see Fig. 14.3), evaluate total fluid balance, and quickly make adjustments, if needed, to ensure optimal fluid balance in the neonate. Graphs are also available to provide further detail and trend changes over time.

TREATMENT

Techniques of IV Therapy

In modern neonatal intensive care, peripherally inserted central venous catheters (PICCs) have become an invaluable tool. Placement permits long-term administration of IV fluids, avoiding multiple painful procedures for peripheral IV placement and the need for surgical placement of a long-term central catheter. **This is particularly valuable for ELBW infants for whom the time to establish full enteral feedings may be prolonged.** This technique is also helpful for long-term parenteral nutrition. **Complications of long-term indwelling central catheters include infection, thrombosis, phlebitis, infiltration, effusion, occlusion, and catheter breakage.**[73] Some reports suggest that the risk for infection significantly increases after the PICC has been in place for longer than 2 weeks;[39] therefore, these catheters should be discontinued as soon as enteral nutrition is adequately established. **Thrombosis is more likely to occur when the flow rate of IV fluids is extremely low** (less than 1 mL/hr). Although the use of heparin in PICC-line fluids has been shown to prolong patency of the line, it does not decrease the incidence of thrombosis.[54] **Infiltration usually occurs at the site of the catheter tip.** This includes infiltration into the mediastinum, pleural space, or pericardium, depending on the location of the tip of the catheter (see Chapter 7).

Peripheral insertion of central venous catheters can be accomplished readily but requires clinical training and experience. Insertion sites include the saphenous, antecubital, axillary, basilic, cephalic, popliteal, posterior auricular, and external jugular veins.[55] Avoidance of upper extremity PICCs in infants with single-ventricle cardiac anatomy is recommended to prevent thrombosis or occlusion of upper extremity veins required in the eventual Fontan procedure.[2] The **catheter is advanced so that the tip is in the superior or inferior vena cava; suboptimal positioning is associated with increased risk of complications.**[14,33] **The position of the catheter tip must be confirmed radiographically.** Confirmation by lateral radiograph is recommended with saphenous insertion due to a risk of inadvertent placement in spinal vessels.[58] Cannulation of the subclavian vein of VLBW infants requires insertion by a pediatric surgeon. Venesection or cutdown of peripheral or central vessels can be performed with appropriate training.

Midline catheters can be used for infants who will require more than a few days of IV fluid administration. Midline catheters are longer than peripheral IVs and are inserted deeper into the vein, where blood flow is greater, but remain outside of central vessels. Because of their placement, **midline catheters can only be used to provide fluids appropriate for peripheral access.** The length of duration is an advantage of midlines compared with peripheral IV lines; catheters can last 1 to 2 weeks, with some reports of midlines lasting up to 3 months.[38]

Peripheral venous access continues to be a valuable approach to IV therapy when short-term vascular access is needed. The advent of extremely small catheter and introducer sets has permitted prolonged use of a single peripheral infusion site. "Butterfly" infusion sets are rarely used for IV access.

A rubber band is an effective tourniquet for the extremity of a small infant. Attention must be paid to antiseptic technique when acquiring venous access. Before puncturing the skin, prepare materials for placement. It is **important to recognize the significant risk for infiltration and skin necrosis with a peripherally inserted IV line. Calcium-containing solutions in parenteral nutrition present an additional risk, particularly for skin damage.** Prevention of such extravasation injuries is paramount because few treatment options are available. Although the needle or catheter must be taped in place, the tape should allow for adequate visualization of the site. **The fluid administered should be recorded at least every hour, and the site should be observed for signs of infiltration.** Although traditionally, splints/padded boards have been used to decrease movement and increase catheter duration, there are no studies to support the practice in neonates.[16] If splints/padded boards are used to stabilize an IV line, it should be **taped in a manner that allows visual inspection of the insertion site.** The most common complication of

IV therapy is infiltration, with rates as high as 70%.[74] **If extravasation occurs, the infusion should be stopped immediately and the IV catheter removed. The affected extremity should then be elevated to limit swelling.**[20] Hyaluronidase is an enzyme that degrades hyaluronic acid, a constituent of the normal interstitial barrier, which increases the distribution and absorption of locally injected substances.[9] By facilitating more rapid absorption of potentially damaging fluid, tissue necrosis may be lessened. A plastic surgery consultation should be considered when tissue necrosis is anticipated.

Umbilical vessel catheterization should be limited to several days' duration until a central catheter can be placed (see Chapter 7).

It is important to provide pain relief during the placement of peripheral IVs, midlines, and/or PICC lines. Methods that have been shown to decrease pain during venipuncture in infants include oral sucrose,[61] swaddling, nonnutritive sucking, breastfeeding, kangaroo care, and topical anesthetics.[4] The use of sucrose has been found to be superior compared with topical lidocaine in infants[64] (see Chapter 12).

The combination of pharmacologic and nonpharmacologic pain management modalities is recommended, but additional research is needed. When undergoing venipuncture, the use of topical lidocaine and sucrose was found to be superior compared with sucrose alone in preterm infants[11] but not in term infants.[64] IV morphine and the combination of morphine and topical tetracaine reduces the pain associated with peripheral central line placement in ventilated neonates; however, the use of morphine also increases the need for respiratory support,[63] so it should be used with caution. **At a minimum, nonpharmacologic pain treatments should be used for all venipuncture procedures in neonates.**

Common Problems

In NICUs, virtually all patients initially receive IV fluid therapy. Therefore, conventional rules of pediatric fluid therapy that estimate losses and project deficit replacement may not be appropriate. Weight, urine output and concentration, and the concentration of various solutes in serum and other body fluids are usually known. The correct diagnosis usually rests on clinical and laboratory measurements (not estimates). Attempts should be made to identify the etiology of the deficit or excess while these conditions are being corrected.

HYPOCALCEMIA (INFANTS WITH TOTAL SERUM CALCIUM LESS THAN 7 mg/dL)

Hypocalcemia is a common finding in critically ill babies. Clinical findings may correlate poorly with biochemical data (total or ionized calcium). **Jitteriness, irritability, and twitching are common, but nonspecific, initial signs. Both serum calcium and glucose should be measured.** Hypocalcemia is often a clinical concern in infants of diabetic mothers and in infants with asphyxia, prematurity, and delayed nutrition. **The risk for "early" hypocalcemia within 72 hours of birth is minimized by supplementing IV fluids with 35 or more mg/kg/day of elemental calcium or initiating parenteral nutrition with 60 or more mg/kg/day for preterm infants.**[32] Alternatively, early neonatal hypocalcemia may be prevented with oral calcium supplementation of 80 mg/kg/day of elemental calcium gluconate[32] (100 mg of calcium gluconate = 9.3 mg of elemental calcium).

The normal physiologic neonatal calcium nadir occurs at around 48 hours of neonatal life.[29] At birth, when the infant is disconnected from the maternal calcium supply, calcium levels begin to fall, and parathyroid hormone secretion is stimulated. The parathyroid gland's response is somewhat insufficient, leading to a **calcium nadir within the first 2 days of life.** During this nadir, ionized calcium typically remains within the normal adult range but undergoes a substantial decline from fetal levels.[29] **Early administration of calcium to the neonate may interfere with the anticipated natural history of calcium homeostasis.** Treatment during this physiologic nadir, in term infants, is often not necessary unless the infant has a confirmed low level of ionized calcium. This would typically be associated with other medical concerns, such as hypoxic-ischemic encephalopathy or in infants of diabetic mothers.

Confirmation of low serum calcium values with an ionized calcium level is necessary because the albumin level, acid-base balance, and other factors could affect serum calcium levels. **Attempts to rapidly correct hypocalcemia, using bolus infusions and slow infusions over 2 to 3 minutes, are not as successful and may induce dysrhythmias, compared with more gradual attempts to correct hypocalcemia.**

Either repeated slow infusions every 6 hours or a continuous infusion is best. Additional calcium should be given intravenously as 100 to 200 mg/kg/dose of calcium gluconate over 4 to 6 hours if seizures or biochemical abnormality persists. **"Late" hypocalcemia, occurring at more than 7 days of age, usually has a specific cause,** such as malabsorption, hypomagnesemia, hypoparathyroidism, long-term diuretic therapy, or rickets, and should be evaluated in detail.[32]

Care should be taken when administering IV calcium: (1) the infant should receive cardiac monitoring to detect bradycardia; (2) calcium administration should be discontinued immediately if bradycardia occurs; and (3) the peripheral IV site should be checked for patency before and during administration because of the potential for skin necrosis, sloughing, and dystrophic calcification caused by infiltrated calcium.

HYPERCALCEMIA (INFANTS WITH SERUM CALCIUM MORE THAN 11 mg/dL)

Hypercalcemia is typically asymptomatic but may present with nonspecific symptoms in the infant. **Symptoms can include poor feeding, emesis, lethargy, irritability, polyuria, and constipation.** Both serum and ionized calcium should be measured, along with phosphate and alkaline phosphatase. The most common presentation of hypercalcemia is iatrogenic in the setting of excessive vitamin D or calcium supplementation or in response to inadequate phosphorus supplementation during the administration of parenteral nutrition. Hypercalcemia may also be seen secondary to maternal hypoparathyroidism or increased maternal vitamin D intake. Neonatal disease such as hyperparathyroidism, hyperthyroidism, Williams syndrome, and hypophosphatasia can also present with hypercalcemia. Hypercalcemia has been reported due to subcutaneous fat necrosis and as drug-induced hypercalcemia with thiazide diuretics.[13,51]

Initial management is often directed at adjusting the calcium-to-phosphorus ratio in parenteral nutrition solutions. Hypercalcemia in the setting of inadequate phosphorus supplementation results from increased bone reabsorption of calcium, and therefore treatment should be aimed at providing appropriate phosphorus supplementation as opposed to decreasing calcium. If hypercalcemia is severe, furosemide can be given to facilitate calcium excretion in the urine. Electrolytes must be monitored carefully, as well as the infant's volume status, with careful avoidance of dehydration. Normal saline can be given if there is concern for dehydration. Hydrocortisone can also be used to decrease intestinal calcium absorption. If the etiology of hypercalcemia is not apparent, further evaluation with additional laboratory studies, such as parathyroid hormone, 1,25-dihydroxy-vitamin D, 25-OH-vitamin D, urine calcium, and urine phosphate, should be considered.[13]

HYPERNATREMIA (INFANTS WITH SERUM SODIUM MORE THAN 150 mEq/L)

Clinical signs of hypernatremia are rare, except for late-occurring seizures. The most common causes of hypernatremia are (1) dehydration, usually caused by too little "free water" administration; (2) injudicious use of sodium-containing solution, such as sodium bicarbonate bolus infusion and sodium-containing medications; and (3) congenital or acquired reduction in antidiuretic hormone resulting in excess loss of "free water," diabetes insipidus. Intracranial bleeding correlates strongly with hypernatremia.[40] **Management should be directed toward prevention, and infants with hypernatremia should have serum sodium reduced slowly to prevent seizures.** Infants who experience hypernatremic dehydration often appear better hydrated than they are because hypernatremia shifts fluid into the intravascular space.

HYPONATREMIA (INFANTS WITH SERUM SODIUM LESS THAN 130 mEq/L)

Hyponatremia is usually asymptomatic because it develops chronically rather than as an acute imbalance; however, **a late clinical sign is seizure.** The most common causes include (1) excess hydration as a result of administration of electrolyte-free solutions; (2) renal loss of sodium in neonates receiving diuretic therapy, especially in VLBW infants; and (3) the **syndrome of inappropriate antidiuretic hormone secretion (SIADH) that is suspected when decreased serum sodium and decreased urine output occur.** This syndrome is associated with central nervous system and lung pathologic conditions. Clinical criteria include (1) low serum sodium, (2) continued inappropriately high urine sodium loss, (3) urine osmolality greater than plasma, and (4) normal adrenal and renal function. Management is by volume restriction until diuresis follows, and treatment is directed toward resolving the etiology.

TABLE 14.4 HYPERKALEMIA (INFANTS WITH MORE THAN 7 mEq/L SERUM POTASSIUM)

CLINICAL SIGNS	ELECTROCARDIOGRAM CHANGES
Muscular weakness	Short QT interval
Cardiac dysrhythmias	Widening QRS
Ileus	Sine wave QRS/T

In the case of sodium deficit as the primary etiology, one can compute the amount of sodium required to correct a deficit using the following formula:

$$\text{Necessary sodium} = (\text{Sodium desired} - \text{Sodium observed}) \times 0.6 \times \text{Weight (in kilograms)}$$

The target goal amount and the replacement rate given are a matter of clinical judgment based on underlying diagnosis and treatments for individual patient situations. In practice, the clinician often prescribes a percentage of the calculated deficit, repeats the serum measurement, and modifies the IV solution.

HYPERKALEMIA (INFANTS WITH SERUM POTASSIUM MORE THAN 7 mEq/L)

Causes of hyperkalemia include (1) acidosis with or without tissue destruction, (2) renal failure (water overload may limit management), (3) adrenal insufficiency (relatively uncommon), and (4) iatrogenic secondary to inappropriate potassium administration. **Nonoliguric hyperkalemia may be seen in ELBW infants; even in the absence of potassium intake, it tends to occur more frequently in infants at a younger gestational age who did not receive antenatal steroids.** Other electrolyte imbalances, such as elevated phosphate, can also predispose ELBW infants to nonoliguric hyperkalemia. If potassium levels are low at birth, the infant is less likely to develop nonoliguric hyperkalemia. Careful monitoring for electrolyte disturbances must occur in this population.[37,68]

Table 14.4 outlines clinical signs and electrocardiogram (ECG) changes that may be seen in hyperkalemia. Management is directed toward resolving the causes and nonspecific treatment, depending on the severity of the hyperkalemia and the associated clinical signs:

- **Stop all potassium administration.**
- **Evaluate total and ionized calcium.**
- **If hypocalcemia is present, infuse 100 to 200 mg/kg of calcium gluconate** to lower the cell membrane threshold. This is transient therapy but may be lifesaving.
- **Infuse sodium bicarbonate 1 to 2 mEq/kg, slowly over 30 minutes or longer.** This is also a transient therapy designed to promote intracellular sodium and hydrogen exchange for potassium. It is particularly useful when the hyperkalemia is associated with acidosis. However, if hyperkalemia is associated with acute renal failure, the relatively large volume of fluid required to deliver the sodium bicarbonate may be concerning.
- **Administer 1 g/kg cation exchange resin (sodium polystyrene sulfonate [Kayexalate]) as an oral or rectal solution.** Little experience has been reported in neonates, and technical problems of retention can be substantial. Furthermore, this may not be an option if the infant is on nothing-by-mouth status or has an injured gastrointestinal tract. When this resin is used, sodium in the resin is exchanged for serum potassium, which may result in hypernatremia. Therefore, careful attention must be paid to serum electrolyte concentrations. Necrotizing enterocolitis has also been reported with this therapy.[17]
- **An insulin infusion given simultaneously with a dextrose infusion can help shift potassium to the intracellular space.** There are several challenges to this form of therapy. First, the actual dose of insulin administered to the patient varies unpredictably because the insulin adsorbs to plastic IV tubing. Second, significant hypoglycemia and seizures may occur. The serum glucose concentration must be monitored frequently and the glucose infusion adjusted accordingly.
- **Administer albuterol.**[17,57] Albuterol inhalation may be useful in rapidly lowering serum potassium. Albuterol and other beta-adrenergic agents induce the intracellular movement of potassium.
- **Administer furosemide.** The administration of furosemide, a loop diuretic, will result in renal excretion of potassium. This may be useful in patients who are not experiencing renal failure, although the amount of potassium excretion is not predictable.[17]
- **Perform peritoneal dialysis.** With neonatal hyperkalemic peritoneal dialysis, sodium bicarbonate frequently must be added to dialysate to prevent acidosis. Peritoneal dialysis is a complicated procedure in neonates, involving catheter

placement and dialysis monitoring. It may be technically impossible in VLBW babies and difficult or impossible when there is injured bowel, as with NEC.

HYPOKALEMIA (INFANTS WITH SERUM POTASSIUM LESS THAN 3.5 mEq/L)

About 90% of the body's total potassium is intracellular. Low serum potassium always implies significant intracellular depletion; most potassium is intracellular, and total body potassium can be low even with normal serum levels. Management is directed toward the cause. The most common causes of hypokalemia are (1) increased gastrointestinal losses from an ostomy or nasogastric tube and (2) renal losses from diuretic therapy. **Diuretic-induced hypokalemia can be treated with supplemental potassium chloride.** Caution is needed, particularly if sending the patient home on this medication, because incorrect dosing can have serious consequences. Caution must also be used in providing supplementation if the patient is treated with potassium-sparing medications such as spironolactone or captopril.

Clinical signs of hypokalemia are related to muscular weakness and cardiac dysrhythmias. Ileus may also occur. Electrocardiographic changes include decreased T waves and ST depression.

Common Clinical Syndromes

RESPIRATORY DISTRESS SYNDROME

Before the widespread use of surfactant, pulmonary function in RDS tended to improve following a period of brisk diuresis on the third or fourth day of life. It was hypothesized that increased endogenous surfactant production led to improved pulmonary capillary integrity and lymphatic drainage. As a result, hypotonic interstitial lung fluid was reabsorbed back into circulation, and a delayed physiologic diuresis occurred. **Although antenatal corticosteroids and routine use of exogenous surfactant have altered the natural history of RDS, the preterm infant remains at risk for a more severe course should excessive fluid overload occur. Daily fluid intake should be monitored closely and restricted** to allow for the natural contraction of extracellular volume to occur.

Because of the observation of improved lung function associated with diuresis, furosemide and other diuretics have been suggested for the treatment of RDS. Although short-lived improvements in lung function were seen, no long-term effects on morbidity or mortality rates were shown.[23] The use of diuretics shortly after birth could also lead to hypotension and compromised peripheral perfusion, as well as electrolyte disturbances. **Aggressive use of diuretics is not indicated in the setting of RDS.**

PATENT DUCTUS ARTERIOSUS

Excessive fluid overload can increase the risk of PDA in premature infants. Treatment of a PDA with nonsteroidal antiinflammatory drugs can lead to renal vasoconstriction, with a resultant decrease in renal blood flow and the glomerular filtration rate. Therefore, it is not uncommon to see an increase in serum creatinine, oliguria, and hyponatremia during PDA treatment. Nonsteroidal antiinflammatory drugs should be given in the lowest effective dose, and concomitant administration of other nephrotoxic drugs should be minimized. Once the drug effect diminishes, accumulated free water should be excreted rapidly, especially if the ductus has closed and cardiovascular status has improved. Fluid status and electrolytes must be monitored closely before, during, and after PDA treatment.

BRONCHOPULMONARY DYSPLASIA

Infants with BPD typically have increased metabolic needs and require higher caloric intake. **However, volume overload can potentiate the worsening of pulmonary disease.[21] It becomes a delicate balance to provide adequate nutrition while avoiding excess volume.** Diuretics are often used in this population, creating an additional set of complications, as discussed previously. Electrolytes must be monitored closely, and diuretic dose and duration should be minimized.

CONGENITAL HEART DISEASE

Knowledge of the underlying physiology associated with the infant's specific heart lesion will ultimately guide the infant's fluid needs and management. **Fluid restriction is typically indicated in lesions with left-to-right shunting to manage pulmonary overcirculation.** Diuretics are also commonly used in this population. Lesions with outflow tract obstructions will typically respond well to liberal fluid volumes.

Careful attention must be paid to meeting the nutritional needs of infants with congenital heart disease. Surgical outcomes can be improved by

providing optimal nutrition, but this can be difficult to achieve in the face of increased metabolic demands, poor mesenteric perfusion, and delayed enteral feeding.[70]

PERSISTENT PULMONARY HYPERTENSION

Fluid management in the infant with persistent pulmonary hypertension is crucial because hypovolemia can exaggerate right-to-left shunting, leading to worsening disease. Once euvolemia is achieved, there is no additional benefit to repeated volume boluses. Hypoglycemia and hypocalcemia should be avoided because these states can also exacerbate pulmonary hypertension.[60]

NECROTIZING ENTEROCOLITIS

Necrotizing enterocolitis often results in a shock-like state in the infant. Capillary integrity and lymphatic drainage are often compromised, leading to fluid accumulation in the interstitium and diffuse bowel or other tissue edema (the "third space"). As effective circulating volume is diminished, antidiuretic hormone is released, and the renin-angiotensin-aldosterone system is activated, leading to sodium and free water retention. **Management is aimed at maintaining adequate intravascular volume and perfusion with the use of volume expanders, vasopressors, and/or inotropes.** Corticosteroids may also be useful to mitigate the effects of capillary leak. Discontinue all potassium-containing fluids because the combination of oliguria and bowel necrosis can quickly result in hyperkalemia.

If an oral-gastric tube is placed to facilitate intestinal decompression, monitor output closely, and consider partially replacing this volume every 8 to 12 hours. Gastric fluid is typically sodium rich, so the sodium loss should be replaced as well. Strictly monitor fluid intake and output, and attempt to maintain adequate urine output.

CONGENITAL ADRENAL HYPERPLASIA

The most common form of congenital adrenal hyperplasia is caused by the absence of 21-hydroxylase, which is required to produce aldosterone. Whereas affected females typically present at birth with ambiguous genitalia, males classically present in crisis at 1 to 3 weeks of life with profound hyponatremia, hyperkalemia, and metabolic acidosis. Treatment is initially guided at correcting electrolyte abnormalities. **Sodium bicarbonate administration at 1 to 2 mEq/kg may be most useful in correcting hyperkalemia, hyponatremia, and acidosis.** Additional treatment strategies for hyponatremia and hyperkalemia are discussed earlier in this chapter. Long-term treatment is aimed at appropriate replacement of mineralocorticoids and glucocorticoids.

RENAL DYSFUNCTION/RENAL DISEASE

Acute renal failure is most often caused by (1) extrinsic factors such as perinatal asphyxia, shock, and heart failure; (2) intrinsic factors such as congenital or acquired lesions; and (3) obstructive uropathy, including urethral obstruction or extra-genitourinary mass. Oliguria or anuria usually occurs initially.

During initial oliguria, electrolyte-free glucose infusion should be limited to IWL and urine output. Frequently, this entails providing total fluids of 50 to 80 mL/kg/day. Recovery is usually associated with natriuresis (excessive urinary sodium loss) and osmotic diuresis. This may develop rapidly with sodium losses as high as 20 mEq/kg/day. **Body weight and fluid losses must be carefully and frequently measured, at least every 12 hours.**

Nonrenal losses, such as gastrointestinal drainage, must also be measured. **Ideally, fluid and electrolyte therapy is directed toward maintaining the current weight or a weight loss of 1% per day until recovery is nearly complete.** This may be accomplished initially by ordering replacement of IWL as a basal fluid order and replacing a percentage of additional fluid losses on a per-volume basis. The choice of fluid used for replacement depends on the electrolyte content of the fluid lost. Thus, it may be helpful to measure urinary sodium and potassium loss concentrations and urine volume, recognizing that any "spot check" of these electrolytes will not fully reflect the loss over a 24-hour period.

Serial determination of serum electrolytes will help refine the fluid orders. As the patient recovers and renal function normalizes, the transition to more standard fluids and electrolytes should occur. The renal ability of the patient to concentrate urine must be evaluated serially. **If the patient remains in high-output renal failure and fluids are restricted, dehydration may occur.** Dehydration will result in weight loss, increased serum electrolyte concentration, and hypernatremia with dilute urine. **Weight change during renal failure demands a careful reevaluation of the fluid plan.**

ASPHYXIA

Perinatal depression can result in renal insult and acute tubular necrosis, leading to decreased urine output. SIADH may also occur following perinatal asphyxia, further reducing urine output. Fluids must be restricted to avoid fluid overload. The use of therapeutic hypothermia for the treatment of hypoxic-ischemic encephalopathy may further worsen fluid retention and the risk of hyponatremia.[49] **Fluid restriction to as low as 30 to 40 mL/kg/day may be required because this amount should replace only insensible losses.** Potassium supplementation should be avoided. As the kidney recovers from acute tubular necrosis, a polyuric phase may ensue, with large sodium losses. **Urine output must be monitored closely, urinary sodium quantified, and fluid replacement adjusted accordingly.**

Major Surgery

Surgical trauma is superimposed on the normal metabolic responses of the neonate. The type and extent of surgery and the gestational and postnatal age of the infant determine the clinical impact. **In healthy term infants, a negative balance of water, electrolytes, nitrogen, and calories with associated weight loss occurs during the first 3 to 5 days, followed by a transition to a positive balance and weight gain by 7 to 10 days.** Parallel transition times for preterm infants vary enormously. Deficits may exist as a result of delayed diagnosis, with external loss or internal loss. **"Third space" losses can be significant, with peritoneal losses being a notorious source of deficit underestimation.**

Predicting the metabolic response to surgery is difficult, reflecting wide variation among individual patients, even patients with similar lesions. **Uncontrollable and immeasurable variables prevent a standardized postoperative physiologic response for neonates, especially those weighing less than 2 kg.** Thermoregulation is a particular challenge for operative procedures. The patient is draped and shielded from radiant heat sources. Measuring and managing the patient's internal temperature with evaporative heat and water loss complicating the situation is difficult once the incision is made. Transport incubators, prewarmed operating rooms, radiant warmers, warming pads, and prewarmed solutions may help achieve thermoneutrality.

Intraoperative fluid balance is rarely precise despite the clinicians' best efforts. Blood loss on sponges, drapes, and other objects should be measured, but IWL from open body cavities is difficult to estimate.

The principles of postoperative management are as follows:

- **Monitor clinical and chemical variables frequently,** at least every 4 to 6 hours; evaluate fluid balance and measure drainage.
- **Recognize that insensible water losses may include "third space losses."** These include water lost into the lumen of the bowel or into the peritoneum secondary to peritonitis, resulting in the loss of both water and electrolytes from the intravascular compartment. At least a proportion of the fluids used to anticipate these losses should contain high sodium content similar to plasma. **Clinical judgment is used to estimate the third space losses because they cannot be measured. Serial evaluations of blood pressure, heart rate, urine output, and skin perfusion together may help determine if the volume prescribed is sufficient.**
- **Gastric output in patients undergoing intestinal surgery should also be closely assessed** in order to provide adequate replacement of free water and electrolytes, particularly sodium and chloride.
- **Provide parenteral nutrition early if significant enteral feedings (less than 50 kcal/kg) cannot be achieved by 3 to 5 days postoperatively.** Gastrointestinal motility returns rapidly in term infants compared with adults. Almost all VLBW infants require parenteral nutrition after surgery.

Diuretics and Electrolytes

Diuretics represent one of the most common classes of drugs administered to sick neonates and infants. **Electrolyte disturbances are the most common adverse effects of diuretic therapy and can lead to a variety of consequences. Clinical indications for the use of diuretics in neonates and infants include BPD, congenital heart disease, and renal failure.** The classes of diuretics most commonly used in this age group include loop diuretics, thiazides, and potassium-sparing diuretics. A discussion of the mechanism of action, diuretic efficacy, and common side effects follows.

LOOP DIURETICS

Loop diuretics bind to one of the chloride binding sites on the $Na^+/K^+/2Cl^-$ transporter, thus

inhibiting the reabsorption of sodium and chloride in the thick ascending limb of the loop of Henle. Water passively follows the movement of sodium and thus allows for diuresis.

Furosemide **is the most widely studied diuretic in neonates** and is consequently the prototype loop diuretic. **It produces a 3-fold to 5-fold increase in sodium excretion and a 10-fold increase in urine flow.**[47,75] Therefore, **hyponatremia, hypochloremia, and hypovolemia are common with chronic use of furosemide. Hypokalemia is also of significant concern with chronic use of furosemide.** The mechanism of potassium loss is due to blockage of tubular reabsorption of potassium and increased aldosterone production in the presence of sodium losses.[65] In addition to potassium losses, furosemide also promotes urine calcium and magnesium excretion. The reabsorption of these cations is decreased because of furosemide's ability to eliminate the transepithelial potential difference. **Chronic hypercalciuria leads to hypocalcemia and the possibility of renal calcifications and nephrocalcinosis.** Compensatory mechanisms lead to increased parathyroid hormone secretion with associated bone resorption, bone demineralization, osteopenia, and possibly rickets.

Bumetanide is another loop diuretic commonly used in neonates and infants. **It is 40 times more potent than furosemide.** The side effects are the same as those seen with furosemide.

THIAZIDES

Hydrochlorothiazide and chlorothiazide are the most widely used thiazide diuretics in neonates and infants. Thiazides exert their effect by blocking the Na^+-Cl^- transporter at the distal convoluted tubule, collecting tubule, and early collecting duct. Because only a small portion of sodium reabsorption occurs in the distal tubule, thiazide diuretic efficacy is limited.

Chronic use of thiazide diuretics leads to electrolyte disturbances, although they usually are less severe than with loop diuretics. **Hyponatremia and hypokalemia are the most common side effects.** Hypokalemia is the result of greater sodium-potassium exchange that occurs secondary to a higher concentration of sodium found in the distal tubule.

Whereas loop diuretics promote calcium loss, thiazide diuretics can increase serum calcium concentrations by increasing renal calcium reabsorption both proximally and distally.[40] This decrease in urinary calcium can be used to reverse loop diuretic–induced renal calcifications.

POTASSIUM-SPARING DIURETICS

Whereas loop and thiazide diuretics directly alter sodium reabsorption via direct inhibition of sodium transporters, **potassium-sparing diuretics such as spironolactone competitively antagonize the aldosterone receptor.** The primary binding site is the principal cell of the cortical collecting tubule. Aldosterone enhances sodium reabsorption in the collecting tubule and promotes potassium secretion. Therefore, antagonizing aldosterone results in diminished sodium reabsorption with a consequent increase in serum concentrations of potassium and hydrogen. **However, spironolactone inhibits the reabsorption of less than 2% of filtered sodium and is thus not an effective primary diuretic.** The major use is to prevent urinary potassium loss induced by other diuretics.

Hyperkalemia is the primary electrolyte disturbance to monitor with the use of spironolactone. This side effect is usually not of great concern because spironolactone is frequently used in conjunction with other potassium-wasting diuretics. Spironolactone should be avoided in renal failure.

COMPLICATIONS

Excessive fluid administration has been associated with BPD and PDA and is increasingly being shown to demonstrate a negative effect on clinical outcomes in critically ill infants.[3,6,25] **Inadequate fluid administration may also have adverse effects, having been associated with dehydration, decreased urine output, hypernatremia, poor tissue perfusion, and potentially, tissue damage.**

PARENT TEACHING

The need for and presence of an IV line in a newborn may be frightening for the parents. Clear, medically and physiologically sound explanations (in nonmedical jargon) of the need for fluid and electrolyte support for their infant help allay parents' fears (Box 14.3). **Scalp vein IV lines are of particular concern because a common misconception is that the needle is positioned**

BOX 14.3 PARENT/CAREGIVER TEACHING

Parent Teaching About Fluid and Electrolyte Management

- Most babies cannot be fed immediately and will require intravenous (IV) fluids.
- Umbilical venous and arterial catheters must be removed in a few days.
- IV fluids will be given through percutaneous central venous catheters, peripheral IV lines, or surgically placed lines.
- Scalp IV lines go only into subcutaneous veins, not into the brain.
- Placing the IV line is painful, and analgesia will be provided during the procedure, but the IV line will be painless afterward, unless infiltrated.
- Peripheral IV lines are subject to infiltration, which may be serious if the fluid is hyperalimentation fluid or contains calcium. IV lines are checked every hour.
- Central venous catheters (percutaneously or surgically placed) carry the risks of thrombosis, infection, or infiltration into body cavities such as the pleura or pericardium.
- IV fluids will be discontinued as soon as enteral nutrition is sufficiently advanced.

in the infant's brain. Explain to parents that scalp vein IV lines are in the large veins of the head and not the brain and that an IV line in the head may stay in longer, thus decreasing the need for multiple vein punctures, and allows the infant mobility of all four extremities. In answer to the question "Does it hurt?" a truthful answer is "Yes, when it is put in, but not after it is in the vein." Explaining the strategies used to decrease pain associated with IV line placement may also help allay their concerns.

The concept of the use of central venous catheters should be presented to the parents early in the hospital course if a delay in enteral nutrition is anticipated. **The advantages are fewer painful procedures, increased mobility of the patient, and decreased risk for infiltrate.** These should be clearly explained in lay language. Explaining the potential complications—such as infection; thrombosis; and the specific risk for the extravasation of fluid into body cavities, pleura, and pericardium—is also necessary. **Potential infiltration of peripheral IV sites should be addressed *prospectively* with parents. Erythema and edema are expected. Sloughing of the skin occasionally occurs in VLBW infants and is more common on the feet and hands than on the scalp.** Well-illustrated parent education materials often are very helpful when explaining these situations to parents.

Including parents in the care of their sick neonate requires an explanation about the importance of measuring intake and output. Inadvertent disposal of diapers and giving fluids that are not recorded should be prevented, emphasizing the importance of saving diapers for the infant's nurse. "A little spitting up" after feeding may be inappropriately dismissed if parents are not instructed in the importance of telling the nurse and saving it for evaluation.

15 GLUCOSE HOMEOSTASIS

PAUL J. ROZANCE, JANE E. MCGOWAN, WEBRA PRICE-DOUGLAS, AND WILLIAM W. HAY JR.

During intrauterine life, the fetus depends on the constant transfer of glucose across the placenta to meet his or her glucose requirements. After birth, neonates must maintain glucose homeostasis by producing and regulating their own glucose supply. This requires activation of a number of metabolic processes, including gluconeogenesis (synthesis of glucose from nonglucose precursor substrates) and glycogenolysis (release of glucose via breakdown of glycogen stores) and intact regulatory mechanisms for glucose metabolism and an adequate supply of metabolic substrates.

FETAL PHYSIOLOGY

Throughout gestation, maternal glucose provides the principal source of energy for the fetus via facilitated diffusion across the placenta. Fetal glucose uptake varies directly with maternal glucose concentration; **fetal glucose concentration usually is about 70% of the maternal value.** Changes in maternal metabolism, including increased carbohydrate and lipid intake and decreased sensitivity of the maternal tissues to insulin, augment maternal glucose production and provide the additional glucose necessary to meet fetal energy demands.[9] **With normal maternal glucose concentrations and rates of glucose supply to the fetus, the fetus produces little, if any, glucose,** although the enzymes for gluconeogenesis are present by the third month of gestation.[124] **If fetal demand exceeds maternal supply, however, the fetus is capable of adapting by using alternate substrates provided from the maternal circulation, such as ketone bodies, for energy production.** This may be the case when maternal fasting or even starvation is severe enough to produce maternal and fetal hypoglycemia. In addition, data from animal models suggest that there may be fetal glucose production under these conditions.[92] Even in the basal state, the fetus relies on fuels such as lactate and amino acids to meet up to 25% to 30% of his or her energy demands, whereas lipids are used primarily for fat production.

Fetal glycogen synthesis begins as early as the ninth week of gestation, but the majority of fetal glycogen is produced in the third trimester. The major sites of glycogen deposition are skeletal muscle (greater than 90% of body glycogen), liver (the only organ whose glycogen can be released for use by other organs), lung, and heart.[131] By 40 weeks of gestation, hepatic and skeletal muscle glycogen contents are several times adult levels. By contrast, lung and cardiac muscle glycogen stores decrease as the fetus approaches term, although these stores are still sufficiently large to be of physiologic significance. Survival in animals exposed to anoxia and human infants after asphyxia, for example, is directly related to cardiac glycogen content. The decrease in lung glycogen, which begins at 34 to 36 weeks' gestation, may be related to ongoing developmental processes, such as the synthesis of surfactant.

In addition to glycogen, **the human fetus also stores energy as fat in adipose tissue.**[128] Most triglyceride synthesis occurs during the third trimester. **By 40 weeks' gestation, the human fetus has a body fat content of about 16%,** making it the fattest of all terrestrial newborn mammals. The human placenta transports some free fatty acids, although the amount transported to the fetus is not sufficient to account for the amount of adipose tissue present; therefore the fetus also must synthesize triglycerides,

BLUE type highlights content that is particularly applicable to clinical settings.

using glycerol derived from glucose, as well as fatty acids transported across the placenta. **Conditions in which fetal glucose supply is reduced will result in less adipose tissue accumulation and reduced glycogen stores.**

In addition to increasing glucose utilization, insulin also stimulates cellular hypertrophy and hyperplasia and thus is an important stimulus for fetal growth.[52] Fetal pancreatic insulin content and glucose-stimulated insulin secretion increase over the second half of gestation to levels comparable to those found in neonates.[85] **Fetal insulin secretion is augmented by higher glucose concentrations;** increased concentrations of amino acids add to this effect.[53] Increased concentrations of insulin increase fetal glucose and amino acid utilization and glucose oxidation rates without increasing total fetal oxygen consumption.[45,68] This implies that other substrates, primarily amino acids, become available for nonoxidative metabolism when glucose and insulin are plentiful; such conditions promote tissue accretion and growth.

Fetuses of diabetic mothers who have very unstable plasma glucose concentrations during late gestation have an increased islet cell response to hyperglycemia compared with normal fetuses of nondiabetic mothers, releasing more insulin than normal fetuses at any given blood glucose concentration. The **higher insulin levels in turn lead to increased growth consisting primarily of adipose tissue, producing the *macrosomia* typically seen in infants of diabetic mothers (IDMs).**

In contrast, **fetuses with intrauterine growth restriction (IUGR) have reduced numbers of pancreatic islets and beta cells and produce less-than-normal amounts of insulin in response to glucose and amino acid stimulation.**[21,112,160] In IUGR fetal sheep, hepatic insulin resistance develops,[153] augmenting hepatic glucose production. Such conditions can lead to postnatal hyperglycemia. In some neonates this propensity for postnatal hyperglycemia may be counterbalanced by other factors. Recent studies in IUGR fetal sheep show increased insulin sensitivity in peripheral tissues (e.g., heart and skeletal muscle) that persists into the neonatal period.[12,25,123,153] Furthermore, islet cells obtained from IUGR fetal sheep when removed from the environment with elevated catecholamines and adrenergic signaling in response to placental insufficiency and reduced fetal oxygen supply and blood oxygen content show insulin secretion at greater than normal levels.[25,30,93,98] These observations may account for the **apparent hyperinsulinemia that occasionally occurs in such IUGR infants several days after birth when oxygenation is restored and norepinephrine concentrations diminish, contributing to their common risk of hypoglycemia.**[8,91] Not surprisingly, therefore, **glucose homeostasis in IUGR neonates is highly variable.**

It also is important to note that although correction of acute insulin deficiency promotes growth, exogenous insulin appears to have little effect on growth in human newborns or animal models with chronic insulin deficiency, suggesting that **insulin infusion to promote growth in growth-restricted infants is unlikely to be beneficial and may lead to additional complications.**

The related pancreatic hormone glucagon, **which, like insulin, does not cross the placenta, has been detected as early as 9 to 16 weeks of gestation.**[117] In postnatal life, glucagon is a potent inducer of gluconeogenic enzymes, the opposite of insulin, which suppresses gluconeogenesis.[124] In fetal life, glucagon plays a much less important role in regulating glucose metabolism than insulin, reflecting the developmental insensitivity of fetal glucagon receptors. As a result, the insulin-to-glucagon effectiveness ratio in the fetus is high, which is important in preferentially maintaining glycogen synthesis and suppressing gluconeogenesis.

NEONATAL PHYSIOLOGY

At birth, the newborn infant is removed abruptly from his or her placental glucose supply, and blood glucose concentration falls. Several hormonal and metabolic changes occur at birth that facilitate the adaptation necessary to maintain glucose homeostasis. **Catecholamine levels increase markedly right after birth,** possibly as a response to the decrease in environmental temperature and to the loss of the placenta, which is responsible for as much as 50% of the clearance of circulating fetal epinephrine.[152] **Glucagon concentrations and receptor sensitivity also increase,** reversing the relatively high insulin/glucagon effectiveness ratio characteristic of fetal life.[136] **The increased glucagon and norepinephrine concentrations activate hepatic glycogen phosphorylase, which induces glycogenolysis.** Simultaneously, the decreasing glucose concentration and perinatal surge in fetal cortisol

secretion stimulate hepatic glucose-6-phosphatase activity. **Together these changes lead to an increase in hepatic glucose release.**[40] **Increased catecholamines also stimulate lipolysis, releasing fatty acids that can be metabolized to provide precursors for gluconeogenesis** and providing energy in the form of adenosine triphosphate (ATP) and cofactors such as nicotinamide adenine dinucleotide phosphate that enhance the activity of gluconeogenic enzymes. **Catecholamine release also activates brown fat triglyceride turnover, producing heat necessary for postnatal thermoregulation.** The normal postnatal decrease in insulin, augmented by the acute postnatal increase in catecholamines, combined with the increase in glucagon, induce synthesis of phosphoenolpyruvate carboxykinase (PEPCK), which is considered the rate-limiting enzyme in hepatic gluconeogenesis. The concentrations of PEPCK and other gluconeogenic enzymes continue to increase over the first 2 weeks of life, regardless of gestational age. These changes act in concert to provide glucose produced by the neonatal liver to replace the supply previously received via the placenta.

Maintenance of glucose homeostasis in the newborn infant depends on the balance between hepatic glucose output and glucose utilization by the brain and peripheral tissues. Hepatic glucose output is a function of rates of glycogenolysis and gluconeogenesis. Peripheral glucose utilization varies with the tissue- and organ-specific metabolic demands in the neonate. Studies in normal human newborn infants using several different methods have estimated that the steady-state glucose production/utilization rate in a term neonate ranges from 3 to 5 mg/kg/min, approximately twice the weight-specific rate measured in adults.[43] As in the fetus, approximately half of this glucose is oxidized to CO_2 during normal metabolic processes, whereas the remainder is used in nonoxidative pathways, such as glycogen and fat synthesis. **Neonatal glucose utilization increases (1) during hypoxia, because of the inherent inefficiency of anaerobic glycolysis**[97]**; (2) in the presence of hyperinsulinemia, which increases glucose uptake by insulin-sensitive tissues**[82]**; (3) in newborns with respiratory distress, because of increased respiratory muscle activity**[116]**; and (4) during cold stress, which leads to increased sympathetic nervous system activity with subsequent release of norepinephrine, epinephrine, and thyroid hormone, which increase metabolic rate.**[32] If rates of glycogenolysis and gluconeogenesis do not match the rate of glucose utilization because of insufficient or excessive hormonal control mechanisms or variability of substrate supply, disturbances of glucose homeostasis occur. These disturbances are recognized clinically by the presence of hypoglycemia or hyperglycemia.

Data Collection

HISTORY

The history of any neonate must include a detailed prenatal and family history. The most important information to be obtained from the infant's history is gestational age, fetal growth, Apgar scores, and details of events in the delivery room, especially any findings that suggest the presence of significant perinatal compromise. **An infant with a history of any of the conditions listed in** Box 15.1 **or** Table 15.1 **should be considered at high risk for developing a problem with glucose homeostasis.**

BOX 15.1 INDICATIONS FOR ROUTINE MONITORING OF BLOOD GLUCOSE FOR PREVENTION OF NEONATAL HYPOGLYCEMIA

Maternal Conditions

- Presence of diabetes or abnormal result of glucose tolerance test
- Preeclampsia and pregnancy-induced or essential hypertension
- Previous macrosomic infants
- Substance abuse
- Treatment with beta-agonist tocolytics
- Treatment with oral hypoglycemic agents
- Late antepartum to intrapartum administration of intravenous glucose

Neonatal Conditions

- Prematurity
- Intrauterine growth restriction
- Perinatal hypoxia-ischemia
- Sepsis
- Hypothermia
- Polycythemia-hyperviscosity
- Erythroblastosis fetalis
- Iatrogenic administration of insulin
- Congenital cardiac malformations
- Persistent hyperinsulinemia
- Endocrine disorders
- Inborn errors of metabolism

TABLE 15.1 NEONATAL HYPOGLYCEMIA: ETIOLOGY AND TIME COURSE

MECHANISM	CLINICAL SETTING	EXPECTED DURATION
Decreased substrate availability	Intrauterine growth restriction	Transient
	Prematurity	Transient
	Reduced glycogen stores	Transient
	Reduced fat stores	Transient
	Reduced ketogenesis	Transient
	Glycogen storage disease	Prolonged
	Inborn errors	Prolonged
	Carbohydrate metabolism defects • Fructose 1,6-diphosphatase deficiency • Pyruvate carboxylase deficiency • Phosphoenolpyruvate carboxykinase (PEPCK) deficiency • Galactosemia	
	Amino acid metabolism defects • Propionic acidemia • Methylmalonic academia • Glutaric aciduria • Maple syrup urine disease (branched-chain alpha-keto acid dehydrogenase deficiency)	
	Fatty acid metabolism defects	
Endocrine disturbances		
Hyperinsulinemia	Infant of diabetic mother	Transient
	Persistent hyperinsulinism of infancy	Transient
	Congenital hyperinsulinism (HI) • Recessive K_{ATP} HI • Focal K_{ATP} (focal adenomatosis) HI • Dominant K_{ATP} HI • Dominant glucokinase (GCK) HI • Dominant glutamate dehydrogenase (GDH) HI • Short-chain 3-hyroxyacyl-CoA dehydrogenase (SCHAD) HI	Prolonged
	Beckwith-Wiedemann syndrome	Prolonged
	Erythroblastosis fetalis	Transient
	Exchange transfusion	Transient
	Islet cell dysplasias	Prolonged
	Maternal beta-agonist tocolytics	Transient
	Improperly placed umbilical artery catheter	Transient
	Inadvertent insulin administration	Transient
Other endocrine disorders	Immaturity of hepatic enzymes necessary for glucose production	Transient
	Reduced or failed counterregulation	Prolonged
	Hypopituitarism	Prolonged

TABLE 15.1 NEONATAL HYPOGLYCEMIA: ETIOLOGY AND TIME COURSE—CONT'D

MECHANISM	CLINICAL SETTING	EXPECTED DURATION
	Growth hormone deficiency	Prolonged
	Hypothyroidism	Prolonged
	Adrenal and cortisol insufficiency	Variable
Increased utilization	Increased brain weight to body weight and liver weight ratio with increased brain consumption of glucose	Prolonged
	Perinatal asphyxia	Transient
	Hypothermia	Transient
Miscellaneous/multiple mechanisms	Sepsis	Transient
	Congenital heart disease	Transient
	Central nervous system abnormalities	Prolonged

HYPOGLYCEMIA

Definition

The absolute blood or plasma glucose concentration that defines hypoglycemia as a pathologic condition remains difficult to establish and has not been determined. Furthermore, there is no absolute correlation between blood or plasma glucose concentrations, clinical signs or symptoms, and either short-term or long-term outcomes. Instead, "reference" glucose concentrations generally reflect the lower limit of the normal range in a specific population of newborn infants, determined by statistical analysis of data collected in that population. Thus there is no consensus about threshold glucose concentrations below which diagnostic evaluation or treatment is mandated or that identify those infants likely to have adverse neurodevelopmental outcome.

Published definitions of hypoglycemia range from a blood glucose concentration of less than 20 mg/dL in preterm infants and less than 30 mg/dL in term infants to **a plasma concentration of less than 45 mg/dL.**[33-35] **Some sources have even suggested raising the lower limit of normal to 50 to 70 mg/dL,** although others have emphasized that such higher concentrations should be used primarily as target values during treatment for relatively severe and symptomatic hypoglycemia rather than thresholds for instituting treatment.[33] Published reports fail to distinguish between threshold glucose concentrations below which physiologic responses may occur (and below which clinical monitoring may be indicated) and those below which pathologic consequences are likely to develop (thus requiring aggressive treatment). In 1992 the majority of pediatricians in one survey in the United Kingdom defined a safe glucose concentration to be at least 36 mg/dL in blood or 45 mg/dL in plasma.[83,84] Fig. 15.1 shows that 95% of normal term infants have a blood glucose concentration of more than 30 mg/dL in the first 24 hours after birth and more than 45 mg/dL after 24 hours of age.[137] **A number of current references use 40 to 45 mg/dL as the lower limit of "normal" plasma glucose concentrations in the first 72 hours of life. By 72 to 96 hours of age mean plasma glucose concentrations in normal infants are very similar to those seen in older children and adults.***

Using these definitions of hypoglycemia, the overall incidence has been estimated at 1.3 to 4.4 per 1000 live births. Differences in incidence figures probably reflect variable inclusion of data from symptomatic versus asymptomatic infants. **In preterm infants, the incidence of hypoglycemia is increased; estimates range from 1.5% to 5.5%** (Fig. 15.2). **The incidence of hypoglycemia in term infants with IUGR may be as**

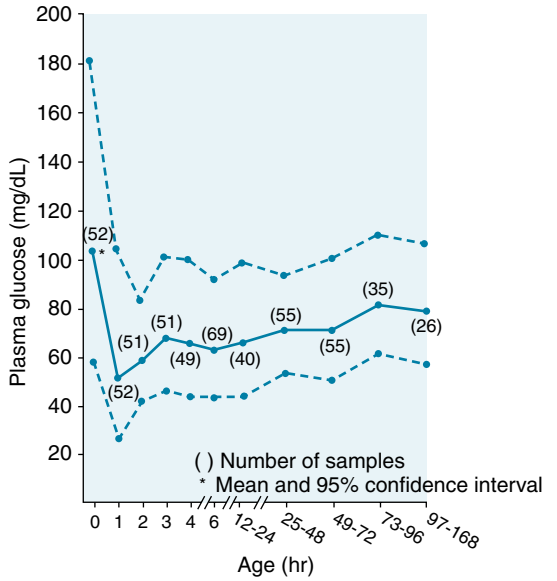

FIGURE 15.1 Plasma glucose concentrations during the first week of life in healthy appropriate-for-gestational-age term infants. (From Srinivasan G, Pildes RS, Cattamanchi G, et al. Plasma glucose values in normal neonates: a new look, *J Pediatr.* 1986;109:114.)

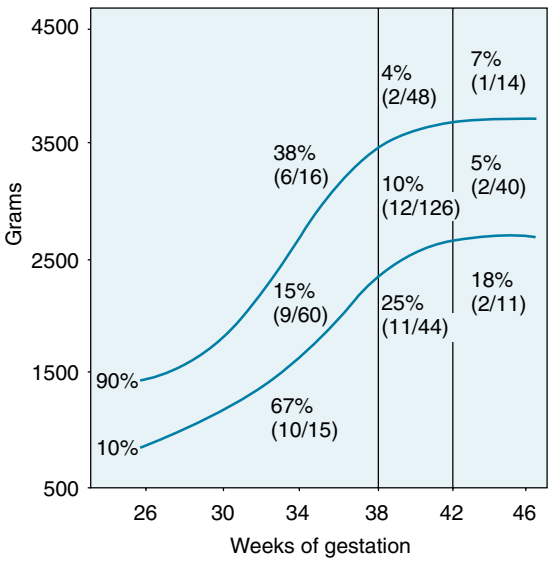

FIGURE 15.2 Incidence of neonatal hypoglycemia (blood glucose less than 30 mg/dL) by birth weight and gestational age. (From Lubchenco LO, Bard H. Incidence of hypoglycemia in newborn infants classified by birth weight and gestational age, *Pediatrics.* 1971;47:831.)

high as 25% to 50%, with an even higher rate seen in preterm small-for-gestational-age (SGA) infants.[62,95]

Hypoglycemia also may be defined clinically as the glucose concentration in a neonate that is associated with clinical signs that resolve when glucose is administered ("symptomatic" hypoglycemia), fulfilling Whipple's triad: (1) low blood glucose concentration; (2) signs consistent with neonatal hypoglycemia; and (3) resolution of signs and symptoms after restoring the blood glucose concentrations to normal values. This value is difficult to determine, however, because the clinical signs of hypoglycemia are nonspecific and may not be noticed initially. **From a physiologic point of view, an infant may be said to be hypoglycemic when glucose supply is inadequate to meet demand.** Unfortunately, no method is available to establish this value in a given infant. Infants with increased glucose utilization demand or limited capability to alter glucose delivery (which is a function of both blood supply and glucose concentration) are at increased risk for impaired organ function at low blood glucose concentrations. Specifically, animal studies have shown that insufficient glucose supply for relatively long durations (hours rather than a few minutes) may contribute to neuronal death, augment functional deficits, and increase the risk for long-term neurologic injury in the presence of cerebral hypoxia and/or ischemia. Clinical studies suggest that this may be true also in newborn infants. However, it is not clear whether the low glucose concentrations in cases of hypoxia and ischemia contributed directly to worse outcomes or were simply a marker for those infants with more severe and prolonged metabolic compromise during hypoxia-ischemia who were, therefore, more likely to have worse outcomes. Furthermore, it remains unclear whether earlier detection of hypoglycemia, such as in the delivery room, in this population could improve subsequent neurologic outcome.

Rather than defining hypoglycemia as an absolute blood glucose value, some investigators have suggested using specific glucose concentrations as an indicator that further management of low glucose concentrations is warranted. Threshold values are based on evidence available in the literature (see further discussion under Treatment later in this chapter).[33] **This approach considers the overall metabolic and physiologic**

status of the infant when determining what constitutes an acceptable blood glucose concentration. Some infants may undergo metabolic derangements at glucose concentrations above the hypoglycemic threshold, whereas others may be able to tolerate lower concentrations of blood glucose without developing metabolic stress. An infant with polycythemia, for example, may have a normal blood glucose concentration but decreased cerebral delivery of glucose because of reduced brain plasma flow. In contrast, breastfed infants have normal substrate delivery to the brain even with "hypoglycemic" blood glucose values, because they have increased plasma concentrations of ketone bodies compared with formula-fed infants, though these concentrations are still lower than what is observed in fasting children.[65,79] **Concentrations of ketones are even lower in preterm and IUGR/SGA infants than in term infants who are feeding normally, suggesting that preterm birth and IUGR are associated with less capacity to generate alternate brain energy substrates.** This decreased capacity might increase the vulnerability of such infants to cerebral energy deficits when plasma glucose concentrations are decreased.[65,66]

In summary, **the definition of the blood glucose concentration at which intervention is indicated must be tailored to the clinical situation and the particular characteristics of a given infant. Further investigation and treatment should be instituted in the symptomatic infant at blood glucose concentrations of less than 45 mg/dL, whereas asymptomatic term infants with known risk factors should be treated if their blood glucose concentration is less than 36 mg/dL.**[76,77] Several authors suggest that these thresholds for intervention should be higher in preterm infants and lower in breastfed full-term infants.[33,64] **The American Academy of Pediatrics' Committee on the Fetus and Newborn has recommended different guidelines for late preterm infants and term SGA, large-for-gestational-age (LGA), and IDM infants, emphasizing initial screening, feeding if tolerated, and prompt (within 1 hour) reassessment for clinical signs and repeat measurement of glucose concentrations.**[1] **The Pediatric Endocrine Society also has issued a set of guidelines that focus on targets for glucose concentrations once an infant has been identified as having hypoglycemia.**[155] However, it is important to recognize that there have been no systematic studies to demonstrate the risks or benefits of using any specific blood glucose concentration as a threshold for intervention in neonatal hypoglycemia. Given the apparently wide range of glucose values associated with normal neonatal outcomes and the inherent inaccuracies in measuring glucose concentrations and the absence of a specific level below which injury inevitably occurs, any individual blood glucose measurement should be considered a one-point-in-time-only representation of the balance between glucose supply and utilization rather than as an absolute indicator of glucose sufficiency or insufficiency.

Hypoglycemic Neuronal Injury and Neuropathology

A schema of how hypoglycemia can contribute to neuronal injury is presented in Fig. 15.3. **Hypoglycemic brain damage in the newborn infant occurs predominantly in gray matter structures, although severe hypoglycemia in newborn infants may also be associated with white matter injury, particularly when the hypoglycemia occurs simultaneously with hypoxic-ischemic injury.**[125,162] Pathologic studies of such severely hypoglycemic newborn infants have shown widespread neuronal injury in the cerebral cortex, hippocampus, basal ganglia, thalamus, brainstem, and spinal cord. Late neuropathologic lesions associated with severe and prolonged low glucose concentrations include microcephaly associated with cortical atrophy and diffuse neuronal loss, as well as astrogliosis. Abnormalities may also be seen in white matter, whereas the cerebellum is generally spared. Such severe outcomes are extremely uncommon and are very seldom seen in normal clinical practice.

Neuroimaging of Hypoglycemic Injury

Magnetic resonance imaging (MRI) performed 2 to 3 weeks after such severe but very infrequent hypoglycemia demonstrates abnormal signals in the cortex, often most apparent in the occipital lobes.[10] More recent neuroradiologic investigations have shown a much **wider variety in the pattern of injury involving both white matter and gray matter as a consequence of severe neonatal hypoglycemia.**[23,148] MRI-defined lesions after severe hypoglycemia in the newborn period

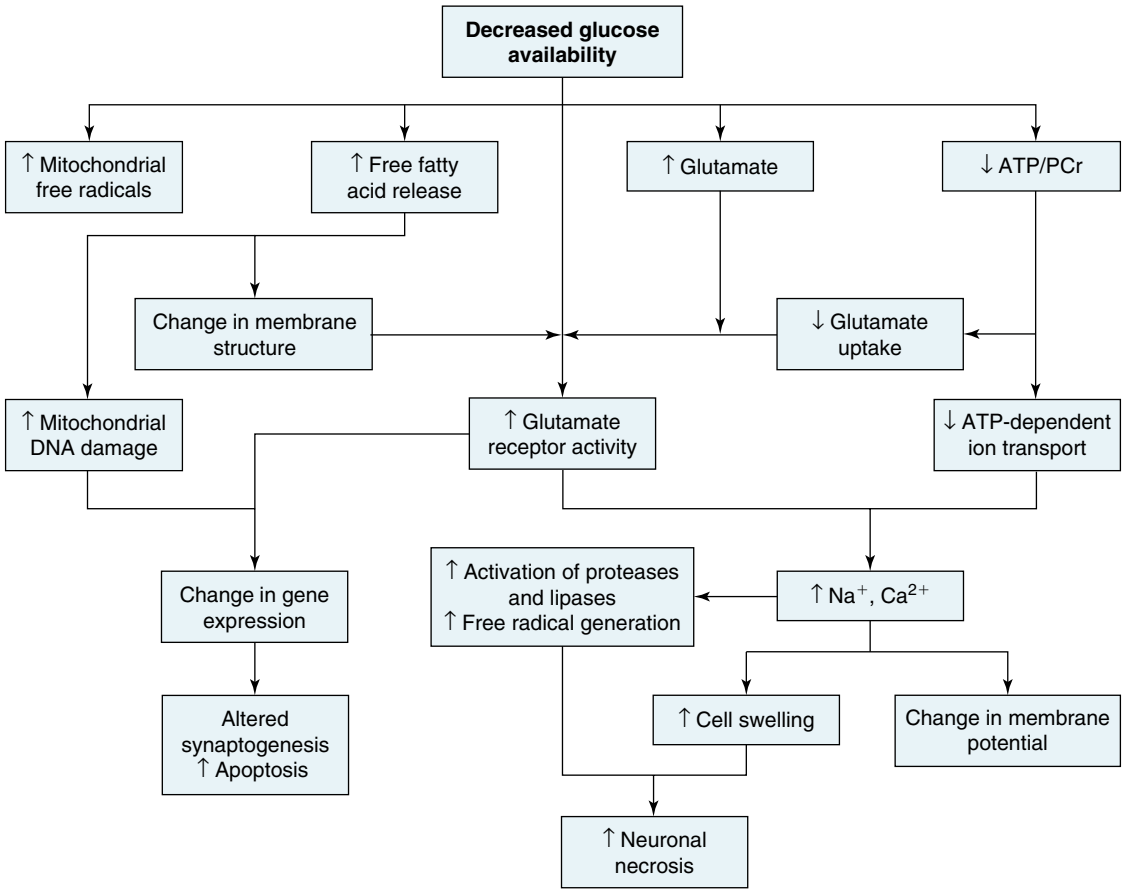

FIGURE 15.3 Proposed mechanism for the pathogenesis of hypoglycemic brain injury in the newborn. *ATP,* Adenosine 5′-triphosphate; *DNA,* deoxyribonucleic acid; *PCr,* phosphocreatine. (McGowan JE: Role of glucose in cerebral function. In Hay WW Jr, editor: Semin Neonat Nutr Metab 1997; 4:2-3. Columbus, OH: Ross Products.)

can be transient and not associated with long-term neurologic consequences, indicating that follow-up MRI scans should be considered to determine the permanency of the lesions.

Etiology of Hypoglycemia

The causes of hypoglycemia can be grouped into several broad categories based on the mechanisms producing the hypoglycemia (see Box 15.1[121];Table 15.1). These categories include inadequate substrate supply, abnormal endocrine regulation of glucose metabolism, and increased rate of glucose utilization. There also are several proposed causes for which mechanisms are not well defined.

INADEQUATE SUBSTRATE SUPPLY

If substrate availability is inadequate, hepatic glucose output will not meet metabolic demands. Most often this results from subnormal fat and glycogen stores that consequently do not provide sufficient energy to maintain glucose homeostasis until gluconeogenesis reaches adequate levels. **Because most hepatic glycogen is accumulated during the third trimester, infants born preterm have diminished glycogen stores.** In the past, infants with IUGR secondary to placental insufficiency also were considered to be at risk for decreased glycogen accumulation, presumably because of diminished transfer of glycogen precursors (e.g., glucose, lactate) across the placenta. In these infants, relative hypoxemia

caused by placental dysfunction also could stimulate increased production of adrenaline and noradrenaline, leading to increased glycogen breakdown and further compromising substrate supply. Evidence from more recent animal studies and human observations, however, suggest that **because of increased glucose uptake mechanisms in response to glucose deficiency (e.g., increased expression of cell membrane glucose transporters), muscle and hepatic glycogen stores are normal or even increased in IUGR infants.**[26,92,109,122,154]

Postnatally, catecholamine- and glucagon-stimulated glycogenolysis rapidly depletes glycogen supplies at a time when gluconeogenesis may be insufficient to provide enough endogenous glucose, resulting in hypoglycemia. **After the first few postnatal days, preterm infants may still be at risk for hypoglycemia even though glycogen stores are adequate**, because of low levels of hepatic microsomal glucose-6-phosphatase activity. Activity of this enzyme in preterm infants is low before birth and can remain low for several months after birth in some infants.[124,142,145] Because this enzyme catalyzes the dephosphorylation of glucose-6-phosphate to glucose and regulates the final step in hepatic glucose production, the decreased activity could contribute to diminished glucose production from both glycogenolysis and gluconeogenesis. Infants with low hepatic glucose-6-phosphatase activity may not be symptomatic with the initial episode of hypoglycemia but can become symptomatic if the hypoglycemia persists.

Up to 18% of preterm infants have problems maintaining normoglycemia at the time of discharge if a feeding is omitted or delayed.[59] Inadequate cortisol secretion in very preterm infants, particularly during periods of stress, also has been cited as a cause of limited activation of gluconeogenic enzymes. The underlying mechanisms for cortisol deficiency are not clear but may be related to a lack of adrenal stimulation as a result of limited hypothalamic-pituitary axis activity.

ABNORMALITIES OF ENDOCRINE REGULATION

Hyperinsulinemia is the most common endocrinologic disturbance producing neonatal hypoglycemia and may be the leading cause of the infrequent cases of persistent hypoglycemia in infants. Excessive insulin secretion in the newborn increases glucose utilization by stimulating cellular glucose uptake in insulin-dependent tissues, including muscle and liver. Brain glucose uptake, however, does not appear to be significantly altered by increased insulin levels. At the same time, the high circulating insulin concentrations promote continued glycogen synthesis and inhibit both glycogenolysis and gluconeogenesis, impairing the infant's glucogenic response to the increased glucose demand and decreasing plasma glucose concentrations. Suppression of ketone body production from free fatty acids by high levels of insulin also might limit the availability of alternative fuels for cerebral metabolism, thereby contributing to the increased risk for adverse long-term outcomes in this patient population.

The most common clinical condition in which hyperinsulinemia occurs is in the infant of a diabetic mother (IDM). In utero, the fetus becomes hyperglycemic because of increased transfer of glucose across the placenta during episodes of maternal hyperglycemia. **The fetal pancreatic beta cells are stimulated by the increased fetal glucose concentration to produce increased quantities of insulin. The pancreatic islet beta cells also appear to become abnormally sensitive to increases in glucose concentration after repeated hyperglycemic stimuli.** Before birth, the increase in cellular glucose uptake in response to the increased insulin secretion is matched by the increased availability of glucose from the mother. **After delivery, the maternal source of glucose is abruptly removed, whereas the hyperinsulinemia persists, producing hypoglycemia.** The decrease in glucose concentration after birth is a result of insulin-stimulated peripheral glucose uptake and inhibition of gluconeogenesis and glycogenolysis by the high insulin concentrations. Although some studies have reported other abnormalities in glucose metabolism in IDMs, Cowett and colleagues[37] found no difference in glucose kinetics in IDMs versus controls, perhaps because maternal diabetic control was well maintained during pregnancy in the group studied. A large review of pregnancies in diabetic mothers found no association between the incidence of neonatal hypoglycemia and the number of episodes of maternal hyperglycemia (a reflection of the degree of control) late in pregnancy.[67] **The incidence of neonatal hypoglycemia in IDMs correlates better with intrapartum, rather than antepartum, maternal glucose concentrations.** The results of these studies emphasize that it is a sudden increase

in glucose concentration that stimulates insulin secretion after a longer period in utero during which the fetal pancreatic beta cells have been sensitized to hypersecrete insulin as a result of repeated episodes of hyperglycemia.[38]

The incidence of hypoglycemia in IDMs is approximately 50%[62]; these infants usually are asymptomatic. The large and comprehensive Hyperglycemia and Adverse Pregnancy Outcome study has shown (1) that the complications typically associated with IDMs, including neonatal hypoglycemia, may be seen in women without overt gestational diabetes but with values at the upper end of the "normal" range on formal glucose tolerance testing; and (2) that the incidence correlates with the elevation in glucose values. This suggests that there is a continuum of abnormal glucose tolerance during pregnancy that is associated with increased fetal insulin secretion and that gestational diabetes represents the most severe degree of disturbed glucose homeostasis.[108]

Other causes of islet cell hyperplasia and resultant hyperinsulinemia include (1) severe erythroblastosis fetalis,[11] possibly resulting from inactivation of insulin by glutathione released from hemolyzed red blood cells; (2) exchange transfusion,[127] in which insulin release is stimulated by the high dextrose content of commonly used blood preservative agents; and (3) in utero exposure to drugs such as beta-agonist tocolytics.[115] In utero exposure to valproate and postnatal exposure to indomethacin also may result in hypoglycemia, but the mechanisms responsible are not known.

Idiopathic hyperinsulinism (i.e., increased, persistent insulin secretion without a known predisposing factor) may occur as a result of altered regulation of insulin secretion in pancreatic beta cells.[59,72] Two general forms of persistent idiopathic hyperinsulinism are recognized: prolonged neonatal hyperinsulinism and congenital (genetic) hyperinsulinism. Prolonged idiopathic neonatal hyperinsulinism appears to be common although not well recognized or understood. Affected neonates usually have some evidence of stress before or during delivery, such as low birth weight (LBW) with IUGR (this disorder may affect 10% or more of IUGR/SGA infants), birth asphyxia, or maternal preeclampsia. **Prolonged neonatal hyperinsulinism usually manifests in the first days after birth and often may be severe, requiring high dextrose infusion rates of 15 mg/kg/min of glucose or more.** Prolonged neonatal hyperinsulinism also may last several weeks to months and does not respond well to glucocorticoids but can be treated with diazoxide at doses of 5 to 10 mg/kg/day.[8,71]

Congenital (genetic) persistent hyperinsulinism is the most common form of persistent hypoglycemia in neonates and infants and is the most difficult to diagnose and treat.[77] The pancreatic abnormalities observed may be diffuse or focal, depending on the mutation present. Although the overall incidence of *persistent hyperinsulinemic hypoglycemia* (PHIHG) is low (approximately 1 in 50,000 births), the incidence of the inherited forms may be as high as 1 in 2500 infants in certain genetically homogeneous populations.[60] Depending on the degree of hyperinsulinemia in utero, these infants also may be macrosomic at birth. Most often, **infants with PHIHG present with repeated episodes of hypoglycemia in the immediate neonatal period, followed by severe, recurrent hypoglycemia after the first few days of life, often after discharge from the newborn nursery.** Recognizing such infants requires prolonged evaluation of an infant's capacity to maintain normal blood glucose concentrations between feedings after initial episodes of hypoglycemia are noted.

Several different genes have been associated with congenital hyperinsulinism.[119] Mutations in several regions on the short arm of chromosome 11 occur in many of infants with PHIHG; these mutations most often are inherited in an autosomal recessive pattern. Abnormalities of either the SUR1 or the Kir6.2 component of the K_{ATP} complex are most common. Because the K_{ATP} complex—the site of diazoxide action—is disrupted by the mutations, these infants usually do not respond to diazoxide treatment. Octreotide (long-acting somatostatin) can be more helpful in the short term, but near-total (95% to 98%) pancreatectomy usually is necessary. Pancreatectomy often requires continuous feedings and even insulin therapy[119] and replacement of pancreatic enzymes. Infants who have this form of hyperinsulinism typically are LGA, present with early neonatal hypoglycemia, and often require high rates of IV glucose infusion.

Hyperinsulinism resulting from a focal pancreatic lesion *(focal adenomatosis)* may occur in 50% of patients with congenital hyperinsulinism.[135] The adenomas are small—3 to 5 mm in diameter—and represent a localized clone of beta cells expressing a paternally derived mutation in the gene for either

SUR1 or Kir6.2 because of loss of heterozygosity for the maternal allele. The clinical course of these infants is similar to that of infants with hyperinsulinism due to widespread mutations of the pancreatic K_{ATP} channel. Localization of the focal adenomatous region of the pancreas via positron emission tomography (PET) with ^{18}F-fluoro-L-dopa may allow definition of the abnormal region of the pancreas, thereby guiding limited resection and avoiding more extensive, often near-total pancreatectomy.[20,86]

Several other mutations lead to genetic forms of PHIHG, including mutations in genes coding for glucokinase *(GCK HI),* glutamate dehydrogenase *(GDH),* hexokinase *(HK1),* hydroxyacyl-CoA dehydrogenase *(HADH),* and the nuclear transcription factors *HNF1A* and *HNF4A.*[119] These different genetic disorders are much less common and have variable presentations, usually later in the neonatal period or even in early infancy.

In addition to hyperinsulinemia, **global endocrine disturbances also can result in hypoglycemia.** These disturbances include a range of abnormalities of the hypothalamic-pituitary axis, the most severe being *panhypopituitarism.* Such infants frequently have growth hormone deficiency and hypothyroidism in addition to severe hypoglycemia. If pituitary dysfunction has resulted from a structural central nervous system (CNS) lesion, other neurologic problems may be present, including abnormal muscle tone and neonatal seizures. Adrenal failure and hypoglycemia can occur as a result of adrenal hemorrhage, often in association with neonatal sepsis. Isolated endocrine defects, including primary hypothyroidism and cortisol deficiency, also may be associated with hypoglycemia.

Infants with *Beckwith-Wiedemann syndrome* also are macrosomic and hyperinsulinemic; in addition, they have other associated anomalies, including macroglossia, which may cause airway obstruction, and omphalocele.[49] Asymptomatic hypoglycemia may occur in 30% to 50% of infants with Beckwith-Wiedemann syndrome and usually resolves in the first 3 days of life. However, up to 5% of affected infants may have persistent, frequently symptomatic hypoglycemia.[41] Infants with Beckwith-Wiedemann syndrome have abnormalities with a specific region on the short arm of chromosome 11, the same region in which mutations associated with other hyperinsulinemic syndromes have been identified.

ENZYMATIC AND GENETIC DISORDERS (TABLE 15.1)

Hypoglycemia can result from a wide variety of hormonal and enzymatic deficiencies.[75] Growth hormone and cortisol are counterregulatory hormones (i.e., they oppose the actions of insulin) and increase blood glucose concentrations by reducing glucose uptake in muscle tissue and stimulating lipolysis and gluconeogenesis during hypoglycemia. **Hypoglycemia is a common complication of growth hormone and cortisol deficiency. Thyroid hormone deficiency is another situation in which hypoglycemia can develop.** Deficiency of one or all of these hormones can be seen in cases of panhypopituitarism. Appropriate hormone replacement is the treatment of choice.

Hereditary disorders associated with deficiencies of specific enzymes that regulate substrate mobilization, interconversion, or utilization of carbohydrate, fat, or amino acids individually are rare disorders but collectively are frequently associated with hypoglycemia. These disorders are almost always inherited as autosomal recessive traits. Many infants with these disorders can be identified on routine and expanded neonatal screening, and early dietary interventions can be critical in the long-term management of their condition.

Glycogen storage disorders cause hypoglycemia from one of several enzyme deficiencies that prevent or limit glycogenolysis and release of glucose into the circulation.

INCREASED GLUCOSE UTILIZATION

Some term infants may have normal energy stores at birth and intact regulating mechanisms but may be stressed by one of several conditions so that the available supplies do not meet their energy requirements. An asphyxiated newborn is one common example. **During and after asphyxia, when tissue oxygen supply is limited, the neonate relies largely on anaerobic metabolism for energy production.** Anaerobic metabolism utilizes more glucose than aerobic metabolism to produce a given amount of energy. As a result, glucose produced by lipolysis and glycogenolysis is rapidly consumed. **Hypoxic-ischemic damage to the liver may further impair synthesis of gluconeogenic enzymes and thus delay the normal postnatal onset of gluconeogenesis. Elevated insulin concentrations also may be present, providing an additional cause for the hypoglycemia.**[39] **Other**

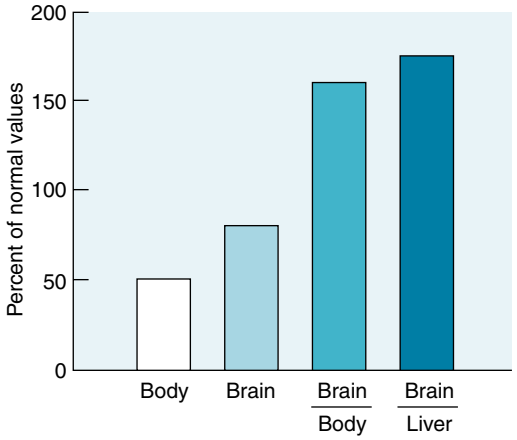

FIGURE 15.4 Differences in organ/body weight ratios in small-for-gestational-age infant compared with appropriate-for-gestational-age counterpart. (From Lafeber HN, Jones CT, Rolph TP. Some of the consequences on intrauterine growth retardation. In Visser HKA, editor: *Nutrition and Metabolism of the Fetus and Infant.* Boston: Martinus Nijhoff; 1979.)

conditions in neonates that lead to a shift from aerobic to anaerobic metabolism, thus predisposing the infant to hypoglycemia, include hypotension, severe lung disease with hypoxemia and hypoventilation, and septic shock.

Hypothermia may result in hypoglycemia through rapid depletion of brown fat stores for nonshivering thermogenesis and secondary breakdown and exhaustion of glycogen stores. Hypothermia is most often seen in infants born at home, but milder degrees may occur in the delivery room. **Hypoglycemia also has been observed in some infants with sepsis.** A study done in several such infants found that they had an increased rate of glucose disappearance in response to an IV glucose infusion, suggesting an increased rate of glucose utilization.[87] Stimulation of glucose utilization may be a result of circulating endotoxins, which increase the rate of glycolysis.

Several other factors also contribute to the risk for hypoglycemia in infants with other identified risk factors. **Preterm infants with respiratory distress syndrome (RDS), for example, have increased metabolic demands because of the increased work of breathing. Chronic hypoxia in IUGR fetuses stimulates catecholamine secretion, which can deplete glycogen stores.** Infants with IUGR and hypoglycemia may have increased rates of glucose disappearance when receiving an IV glucose infusion and reduced fat mobilization in response to hypoglycemia compared with normoglycemic SGA newborns. Because of the **increased brain weight/liver weight and brain weight/body weight ratios in all newborns (12% in term newborns for the latter comparison vs. 2% in adults), cerebral glucose requirements are markedly higher relative to the liver's capacity to respond than in the adult, even if glycogen stores are normal for size** (Fig. 15.4).[85] This is especially true in infants with asymmetric growth restriction. In addition, **increased insulin sensitivity has been reported in SGA newborns within the first 48 hours of life.**[14,130] These observations indicate that disturbances in glucose metabolism in addition to lower-than-normal energy stores may be present in some growth-restricted infants.

PREVENTION OF HYPOGLYCEMIA

Recognition of those infants at risk for disturbances in glucose homeostasis is the most important step in preventing both hypoglycemia and hyperglycemia. In infants with conditions predisposing to hypoglycemia, such as preterm infants, infants with IUGR, or IDMs, **early feeding and frequent monitoring of blood glucose concentrations may prevent a decrease in blood glucose concentration or allow early detection of decreased blood glucose levels. Maintenance of a neutral thermal environment is especially critical to minimize energy expenditure in those infants at risk for hypoglycemia.** Other conditions associated with hypoglycemia, such as asphyxia and hypothermia, may be avoided through appropriate obstetric and neonatal intervention. As many as 70% of infants requiring transport may not have had appropriate glucose evaluations documented in the referring centers.[44] A prompted intervention (STABLE Pretransport Stabilization Self-Assessment Tool [PSSAT])[44] may result in significant improvement in glucose monitoring.

DATA COLLECTION

History

The history of any neonate at risk of hypoglycemia must include a detailed prenatal and family history.

Important maternal risk factors associated with neonatal hypoglycemia are listed in Box 15.1. Other important data include a history of family members with atypical diabetes or other abnormalities of glucose homeostasis, family history of metabolic disease, and previous unexplained stillbirths.

The most important information to be obtained from the infant's history is gestational age, Apgar scores, and details of events in the delivery room, especially any findings that suggest the presence of significant perinatal compromise. **An infant with a history of any of the conditions listed in** Box 15.1 **or** Table 15.1 **should be considered at high risk for developing a problem with glucose homeostasis.**

Physical Examination

Careful measurement of birth weight and head circumference in combination with accurate gestational age assessment will establish whether the infant is preterm, LBW, SGA, or LGA and thus at increased risk for hypoglycemia. IDMs frequently have small heads relative to their general macrosomia and have been described as having "tomato facies" because of plethora and increased buccal fat. The physical findings associated with Beckwith-Wiedemann syndrome have already been described. The presence of midline facial defects, such as cleft lip or hypertelorism, may indicate the presence of a CNS malformation with associated pituitary dysfunction. Glycogen storage diseases should be considered in infants with hepatomegaly.

Clinical Signs

Signs of neonatal hypoglycemia are nonspecific and extremely variable (Box 15.2).[121] They include general findings, such as abnormal cry, poor feeding, hypothermia, and diaphoresis; neurologic signs, including tremors and jitteriness, hypotonia, irritability, lethargy, and seizures; and cardiorespiratory disturbances, including cyanosis, pallor, tachypnea, periodic breathing, apnea, and cardiac arrest. These features also occur in preterm infants and in neonates with sepsis, intraventricular hemorrhage, asphyxia, hypocalcemia, congenital heart disease, and structural CNS lesions, among other causes. **In the presence of any of the preceding signs, however, hypoglycemia always should be considered, because the diagnosis can be made relatively easily and prompt treatment is essential.**

BOX 15.2 CLINICAL SIGNS OF HYPOGLYCEMIA

- Mild to moderate changes in level of consciousness*
- Stupor or lethargy
- Tremulousness
- Irritability
- Coma
- Seizures (depend on duration, repetitive occurrence, and severity of hypoglycemia)
- Respiratory depression or apnea, leading to cyanosis
- Hypotonia, limpness, inactivity
- High-pitched cry
- Poor feeding (after previously feeding well)
- Hypothermia

* Most frequent and should be alleviated with correction of low glucose concentrations.

If a problem with glucose homeostasis is suspected, documentation of the aforementioned data, history (see Box 15.1**), physical examination, and clinical signs (see** Box 15.2**) must reflect ongoing monitoring and measures taken. The use of risk assessments, guidelines, or protocols that consider the data just mentioned helps systematize detection (**Fig. 15.5**).**

Laboratory Data

When hypoglycemia is suspected, the plasma or blood glucose concentration must be determined promptly. **Ideally, this determination should be made with one of the laboratory enzymatic methods, such as the glucose oxidase or hexokinase method, but even bedside reagent test strip glucose analyzers (i.e., glucometers) can be used if the test is performed carefully and with awareness of the more limited accuracy of these devices.** Although more expensive, some blood gas analyzers have the capability of measuring glucose concentrations as accurately as laboratory enzymatic methods. If present in the nursery or as a portable device, these instruments may offer the optimal combination of short turnaround time and accuracy.[73] In the clinical setting, early and rapid determination of glucose concentrations in the high-risk or symptomatic neonate is essential.[54] **Prompt detection of hypoglycemia permits early treatment and potentially helps prevent**

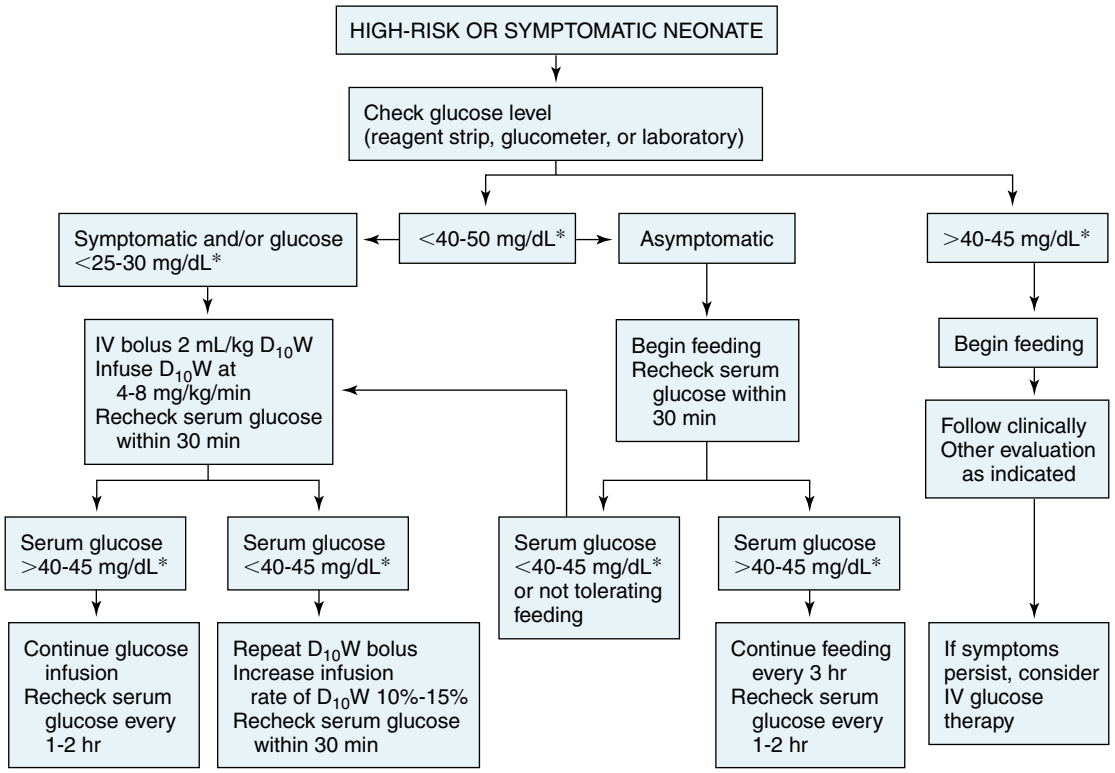

FIGURE 15.5 Decision tree for management of neonate with acute hypoglycemia. *IV,* Intravenous.

long-term neurologic sequelae.[34] Although laboratory measurements of glucose concentrations are the most effective methods for detecting hypoglycemia, requests for confirmatory glucose concentration measurements by the laboratory must be requested and accomplished STAT (15 minutes or less). Routine requests are often not available for up to 1 hour—far longer than appropriate for diagnosing hypoglycemia and thereby delaying the initiation of critically important treatment. The sample of blood can be obtained from a warmed heelstick or venipuncture specimen.

These methods can be useful in screening infants in whom abnormal glucose concentrations are suspected if the user is aware of their limitations. The accuracy of test strip results depends in part on the technique used. An adequate sample must be placed on the test strip pad, and the timing of reading the result is critical. Recently developed devices automatically read the result at the appropriate time, reducing one source of error. Hospital personnel should be trained and certified in the use of test strip methods and the bedside instruments used to quantify glucose concentration. With proper technique, test strip results demonstrate a reasonable correlation with actual blood glucose concentrations, but the variation from the actual blood glucose value may be as much as 10 to 20 mg/dL. A number of studies have compared the results obtained with specific commercial products with results obtained with laboratory methods.[6,57,99] Regardless of the test strip or instrument used, correlations with actual blood glucose concentrations are lowest at the lower glucose concentrations at which neonatal hypoglycemia must be accurately determined. Several studies have shown that use of test strips alone may fail to detect from 11% to as many as 67% of infants with statistically defined hypoglycemia.[56,57,88] There also is a significant incidence of false-positive results.

Because of the limitations of these methods, whenever a diagnosis of hypoglycemia is

suspected by test strip or glucometer results, the blood glucose concentration should be confirmed by a specimen sent to the chemistry laboratory for rapid (STAT) determination and reporting. Although laboratory results are more accurate and reliable than screening methods, a long delay in processing the specimen can result in a falsely low level as the erythrocytes in the sample metabolize the glucose in the plasma. This problem can be avoided by transporting blood in a tube containing a glycolytic inhibitor. ***Treatment of suspected hypoglycemia, however, should not be postponed until confirmation is obtained from the laboratory. Also, if hypoglycemia is suspected on the basis of clinical symptoms, initial treatment should be instituted even if the test strip result is "normal."*** If the actual value is abnormal, a delay in therapy could be harmful; if the actual value is within the normal range, therapy can be stopped without serious side effects.

Most cases of neonatal hypoglycemia have an identifiable cause (e.g., maternal diabetes or IUGR). In a term infant with no known risk factors for hypoglycemia, sepsis must be considered as the most likely cause of hypoglycemia and an appropriate evaluation should be performed. Of those infants without an identifiable cause, most have idiopathic hypoglycemia, which resolves spontaneously within 2 to 5 days, and no further evaluation is needed. However, in rare cases, hypoglycemia persists beyond the first week of life with no obvious cause, requiring a logical and rapid approach to diagnosis of the particular form of persistent hypoglycemia.[70,155] The diagnostic evaluation of these infants should include (1) simultaneous determination of glucose and insulin concentrations and alternate substrates, such as ketones and FFAs; (2) evaluation of pituitary function, including measurement of thyroid-stimulating hormone (TSH), thyroxine (T_4), adrenocorticotropic hormone (ACTH), cortisol, and growth hormone levels; and (3) appropriate studies to diagnose inborn errors of metabolism, such as lactate and pyruvate concentrations. Ideally, these studies should be obtained during an episode of hypoglycemia. Once hypoglycemia is identified in a neonate as persistent, a fasting study should be performed to measure plasma insulin concentration when plasma glucose concentration drops below 45 to 50 mg/dL. If this fasting study demonstrates hyperinsulinism, treatment should be immediately instituted.[77]

TREATMENT OF HYPOGLYCEMIA

Early identification of an infant at risk for developing hypoglycemia and institution of prophylactic measures to prevent its occurrence provide the best treatment for this disorder. The goals are to recognize at-risk infants, evaluate early and frequently for decreasing glucose concentrations, treat when indicated, and provide glucose and enteral feeding as needed to achieve and maintain glucose concentrations in the range that most normal infants achieve via their own homeostatic mechanisms within 6 to 12 hours after birth.

A decision tree suggesting guidelines for management of infants with hypoglycemia is shown in Fig. 15.5. **Most asymptomatic infants can be managed with early and frequent feedings (by breastfeeding or with expressed milk, with donor milk when appropriate as for very preterm infants, or with formulas). All symptomatic neonates should receive treatment with IV dextrose infusion to provide glucose at an initial rate of 4 to 6 mg/kg/min.** These suggested infusion rates cover the range of hepatic glucose production in normal term newborns. **In some circumstances (neonates with glucose concentrations of 20 mg/dL or less and/or with very severe clinical signs, such as seizures and/or coma), it may be useful to use a minibolus of 200 mg/kg dextrose (2 mL/kg of $D_{10}W$) plus the dextrose infusion regimen** originally described by Lilien and colleagues.[90] **Rapid normalization of blood glucose may be particularly beneficial in such severely symptomatic infants,** although no data confirm this assumption. **However, in asymptomatic newborns it may not be necessary to use the 200 mg/kg dextrose minibolus.[120] In IDMs or other infants suspected of having hyperinsulinism with asymptomatic hypoglycemia, the initial minibolus can be eliminated and the infusion rate kept at the minimum necessary to produce and maintain normal blood glucose concentrations (3 to 5 mg/kg/min).[120]** This practice helps prevent an excessive insulin response to the sudden increase in glucose concentration produced by the minibolus. When glucose infusion rates are being calculated, it is important to remember that commercially prepared glucose solutions actually contain glucose in its hydrated form (molecular

weight [MW] 198, versus MW 180 for anhydrous glucose), which lowers the actual glucose content of the solution by approximately 8%. **Thus $D_{10}W$ contains approximately 9.2 g of glucose per deciliter.**

Once the infant's glucose requirement has been determined, **the glucose infusion should be maintained at that level until blood glucose concentrations are stable and in the desired range. The target blood glucose concentration during IV therapy should be above the "hypoglycemic threshold" defined for that particular infant.** For example, if the hypoglycemia threshold is defined as 40 mg/dL, glucose concentrations should be maintained at or above 50 mg/dL.[33]

Adjusting therapy to maintain a blood glucose concentration higher than the "symptomatic" threshold allows a margin of safety in the absence of any data establishing a correlation between specific glucose concentrations in this range and long-term outcome. There is no evidence that diagnosis or treatment thresholds for preterm infants should differ from those for term infants.

If the infant was being fed before IV therapy was instituted, feedings may be continued. However, the calculated minimum glucose requirement should be provided by the IV infusion alone rather than by the combination of glucose infusion and feedings. In infants who were not previously fed, feedings can be instituted when clinically indicated. There are several advantages to feeding a hypoglycemic infant during treatment with IV glucose. In the hyperinsulinemic infant, galactose (one of the components of lactose) stimulates less insulin release than glucose and therefore helps stabilize blood glucose concentrations. **Continuation of oral feedings also aids in the process of weaning the infant off IV glucose. When feedings are well tolerated, the IV infusion generally can be slowly tapered if the glucose concentration and clinical status remain stable.** Although enteral feeding has the theoretical risk for augmenting insulin secretion and subsequent hypoglycemia as a result of the food-stimulated release of gut peptides that may potentiate insulin release from the pancreas, there is no evidence that withholding feedings actually prevents this potential problem. **It probably is better to continue breast milk or formula feedings using smaller, more frequent amounts or even continuous gastric infusion than to stop enteral feedings and try to maintain normoglycemia exclusively with IV glucose.**

Additional consideration should be given to the use of buccal dextrose gel.[120] In a large placebo-controlled, randomized trial, **40% oral dextrose gel, 200 mg/kg, placed on the buccal mucosa, restored normal glucose concentrations, reduced the recurrence rate of low glucose concentrations, and allowed enteral feeding, particularly breastfeeding, to continue or even advance. This therapy also decreased rates of NICU admissions for hypoglycemia and increased rates of continued successful breastfeeding.[63] Such therapy seems appropriate for the term or late preterm infant with transient hypoglycemia and probably for SGA, LGA, and IDM infants who are otherwise clinically stable.**[120] When buccal dextrose gel is utilized and these infants are managed outside the NICU, nursing staffing must allow for additional observation and monitoring. **Parental teaching regarding the signs of hypoglycemia and the need to avoid hypothermia must be provided and documented.**

In rare cases, such as infants with severe, refractory hyperinsulinemic hypoglycemia or infants with other morbidities such as hypoxic-ischemic encephalopathy or heart failure, enteral feedings might be contraindicated. In these infants, once glucose concentrations are stabilized and/or the other adverse clinical conditions have resolved, then enteral feedings can be used to treat hypoglycemia.

Adjunctive Therapy

Table 15.2 offers a summary of adjunct therapies for hypoglycemia.

GLUCAGON

Glucagon, 30 mcg/kg IV or intramuscular (IM), releases glycogen from hepatic stores when insulin concentrations are normal. However, IDMs and other infants with hyperinsulinemia may require much larger doses, up to 300 mcg/kg IV or IM, to produce a response. **Administration of glucagon may be useful diagnostically, because failure to respond to glucagon administration with an increase in serum glucose concentration suggests depletion of hepatic glycogen stores or a glycogen storage disorder. Glucose infusion should be maintained after injections of glucagon are administered, because**

TABLE 15.2 ADJUNCT THERAPIES FOR HYPOGLYCEMIA

THERAPY	EFFECT	DOSAGE
Corticosteroids	Decrease peripheral glucose utilization Enhance gluconeogenesis	Hydrocortisone 5–15 mg/kg/day or Prednisone 2 mg/kg/day
Glucagon	Stimulates glycogenolysis Releases glycogen from hepatic stores when insulin concentrations are normal	30 mcg/kg IV or IM 300 mcg/kg if hyperinsulinism is present
Diazoxide	Inhibits insulin secretion	15 mg/kg/day
Somatostatin (long-acting: octreotide acetate)	Inhibits insulin and growth hormone release	5–10 mcg/kg every 6–8 hr
Pancreatectomy	Decreases insulin production/secretion	

IM, Intramuscular; *IV,* intravenous.

there is a risk for rebound increased insulin secretion in response to the glucagon-produced surge in glucose production. Some have suggested using continuous IV glucagon infusions, but this practice is not universal.[109] In addition, the rapid but transient increase in glucose concentration immediately after glucagon injection may produce a false sense that the hypoglycemia has resolved, even though the underlying cause still exists. Continuous infusions of glucagon have been used to treat refractory hypoglycemia.[26]

OTHER AGENTS

Glucocorticoids (hydrocortisone), somatostatin, and diazoxide have been used to treat hypoglycemia in refractory cases. **Glucocorticoids can be used to reduce peripheral glucose utilization and increase gluconeogenesis, particularly when glucose infusion rates of 12 to 15 mg/kg/min or more are needed to maintain normal glucose concentrations.** Somatostatin and diazoxide, which suppress insulin release, are most often used in infants with islet cell dysplasias.[77]

MISCELLANEOUS THERAPIES

In infants with hypoglycemia caused by a specific medical problem, therapy should be directed toward alleviating the underlying illness. This includes administration of antibiotics to treat sepsis, partial exchange transfusion to reduce hyperviscosity, hormone replacement in cases of hypopituitarism, and dietary intervention for metabolic disorders. A trial of diazoxide should be initiated in infants who have been identified as having hyperinsulinism. If diazoxide is not effective at a maximum dose of 15 mg/kg/day divided into two doses per day for 2 to 3 days, it may be stopped and octreotide could be tried. However, medical therapy alone fails to control hypoglycemia in 40% to 90% of infants with severe PHIHG.[42] If octreotide is not successful, surgical management is generally necessary. Before surgery, imaging procedures should be performed to determine whether the pancreatic abnormalities are focal or diffuse. Focal disease generally is cured with partial pancreatectomy, whereas diffuse disease requires near-total pancreatectomy and then treatment of the exocrine and endocrine deficiencies that invariably result.[51]

COMPLICATIONS OF HYPOGLYCEMIA

The outcome for infants with neonatal hypoglycemia appears to be related to the duration, repetitive occurrence, and severity of the hypoglycemia and the underlying etiology. Those with *asymptomatic hypoglycemia* usually have clinically normal neurodevelopmental outcomes, though in research outcomes assessments **there may be an association between low glucose concentrations and impaired neurodevelopment.[103] Furthermore, there is no evidence yet that treatment prevents**

such abnormal outcomes. *Symptomatic hypoglycemic* infants (primarily those with severe, protracted, and recurrent neurologic abnormalities such as seizures and coma associated with plasma glucose concentrations below 20 to 25 mg/dL for several hours or more) have a **poorer prognosis, with abnormalities ranging from learning disabilities to cerebral palsy and persistent or recurrent seizure disorders, as well as mental retardation of varying degrees.**[50] Prompt initiation of treatment is thought to be associated with a more positive outcome, although this has not been well documented.

In preterm infants, data indicate that hypoglycemia may adversely affect long-term outcome.[47,80,96] A follow-up study of more than 600 former preterm infants found significantly lower mental and motor indices in those with five or more documented episodes of moderate hypoglycemia (defined as a blood glucose concentration less than 45 mg/dL) during the neonatal period. This difference remained significant even when confounding factors such as intraventricular hemorrhage (IVH), need for ventilator support, and asphyxia were considered. However, not all comorbidities can be controlled for in this type of study. Furthermore, differences in cognitive function were less apparent at school-age follow-up in the same cohort of patients, and **newer studies have not confirmed any adverse outcomes associated with hypoglycemia in preterm infants.**[61,157] It may be that because nearly all preterm infants receive early IV dextrose infusions separately or as part of parenteral nutrition, low glucose concentrations—particularly repeated low values—are less likely to occur.[69,166] These discrepant results indicate the need for further long-term studies in preterm infants.

The incidence of neurodevelopmental abnormalities in IDMs ranges from 0% to 35%; the lower figures are from more recent studies and may represent improvement in obstetric and neonatal care. Some studies have been able to detect causes other than hypoglycemia that may have contributed to the overall outcomes.[67,129] These causes include such factors as prematurity, presence of congenital anomalies, congenital iron deficiency, and degree of control of maternal disease. However, Stenninger and colleagues[139] found that **IDMs who were hypoglycemic as newborns (glucose less than 27 mg/dL) had an increased frequency of deficits in attention, motor control, and perception at 8 years of age compared with both IDMs without hypoglycemia and normal newborn controls.** This association was also documented in a more recent study.[103] A number of other neonatal complications are associated with maternal diabetes, including polycythemia, which may add to disturbances of glucose homeostasis; hypocalcemia secondary to maternal hypoparathyroidism; dystocia secondary to macrosomia; and congenital anomalies. Infants of mothers with severe diabetic vasculopathy, in contrast to most IDMs, may have IUGR caused in part by decreased placental blood flow, with hypoglycemia resulting from inadequate glycogen and fat stores as occurs in all cases of IUGR rather than hyperinsulinemia alone.

Adverse neurologic outcomes have been reported in as many as 40% to 50% of infants with PHIHG, possibly because these infants cannot effectively generate ketone bodies, which could serve as an alternative source of energy for cerebral metabolism during periods of hypoglycemia.[105-107] In addition, infants with PHIHG who require a greater than 95% pancreatectomy often develop glucose intolerance or even frank diabetes mellitus later in life.[94] Hypoglycemia secondary to hypopituitarism also is associated with a poor outcome; often this results from other CNS or endocrine dysfunction rather than from the hypoglycemia itself.

PARENT TEACHING

Parent teaching should begin before delivery, with emphasis placed on good nutrition and early and regular prenatal care. Teaching also should include information about those conditions that increase the risk for hypoglycemia (e.g., IUGR associated with maternal cigarette smoking and poor maternal nutrition). Regular prenatal care ensures the early detection of potentially serious problems, including preeclampsia, gestational diabetes, and abnormal fetal growth.

Prenatal teaching is especially important in the woman with known diabetes mellitus, because overall outcome (although not necessarily the incidence of hypoglycemia) is directly related to the degree of control before and during pregnancy. Breastfeeding information and encouragement to breastfeed must be included in the prenatal education. In addition, the possibility of neonatal hypoglycemia and requirement for

IV therapy can be discussed with the parents before delivery so that they will be aware that the infant may require a longer hospital stay even if delivered at term.

If IV therapy is needed to treat neonatal hypoglycemia, regardless of cause, a thorough explanation of the treatment plan must be given to the parents at the time therapy is instituted. Frequent progress reports should be provided to resolve unanswered (and often unasked) questions and relieve parental anxiety. **When buccal dextrose gel is utilized and infants are managed outside the NICU, parental teaching must include the need for additional observation and monitoring, the signs of hypoglycemia, and the need to avoid hypothermia. Parents of children with islet cell dysplasias need to be aware of the clinical signs of hypoglycemia and emergency treatment measures that can be instituted,** because recurrent hypoglycemia may occur in these cases. Parents of infants with inborn errors of metabolism also need counseling with regard to prognosis and genetic counseling about risks for recurrence in future pregnancies.

HYPERGLYCEMIA

Definition of Neonatal Hyperglycemia

Hyperglycemia in newborns is usually defined, based on population data, as a blood glucose concentration of more than 125 mg/dL (greater than 150 mg/dL plasma) in a term infant or more than 150 mg/dL in blood in a preterm infant. In fetal life, the upper limit of the normal range of glucose concentrations is 108 mg/dL.[100] Unlike neonatal hypoglycemia, however, there are no reported "clinical" definitions of hyperglycemia (i.e., the appearance of physiologic disturbances associated with a specific high blood glucose concentration). The incidence of statistically defined neonatal hyperglycemia is difficult to determine; estimates range from 5.5% of all infants receiving intravenous (IV) infusions of $D_{10}W$ to as high as 40% in infants weighing less than 1000 g who are receiving IV dextrose infusions. Dweck and Cassady[48] noted that 86% of infants with birth weights under 1100 g were hyperglycemic, and of these infants, 84% had one or more serum glucose concentrations greater than 300 mg/dL. In 2006, Blanco and colleagues[19] found that 88% of infants with birth weights less than 1000 g had at least one blood glucose concentration greater than 150 mg/dL in the first week of life. **Neonatal hyperglycemia has been increasing in recent years in preterm infants as IV nutrition has become universal**[140,159] but has been balanced more toward energy with relatively high IV infusion rates of dextrose and lipid.[163]

Etiology of Hyperglycemia

Hyperglycemia is most common during the first week after birth (Box 15.3), although more recent studies have shown that hyperglycemia in very-low-birth-weight (VLBW) infants can persist well after birth, even after weaning off TPN or IV dextrose infusion and well beyond the immediate postnatal "stress" period when hyperglycemia is most common.[140,146]

Typically, **a neonate with hyperglycemia is an LBW infant (less than 32 weeks' gestation and less than 1200 g birth weight)—often one with IUGR—who cannot tolerate an IV glucose infusion at the usual rate of 4 to 8 mg/kg/min (i.e., $D_{10}W$ at 60 to 100 mL/kg/day).** This relative glucose intolerance appears to be caused by general immaturity of the usual regulatory mechanisms. In immature infants, especially those with IUGR, these differences include fewer pancreatic islets and beta cells and decreased pancreatic insulin secretion in response to glucose, a direct result of suppression by catecholamines both before and after birth.[89] After birth, persistence of

BOX 15.3 ETIOLOGIC FACTORS IN NEONATAL HYPERGLYCEMIA

- Iatrogenic (e.g., during intravenous glucose infusion)
- Decreased insulin production (e.g., with increased catecholamine production in very-low-birth-weight or intrauterine-growth-restricted infant; catecholamine infusion side effect)
- Decreased insulin sensitivity (e.g., with increased catecholamine production in very-low-birth-weight infant or transient diabetes mellitus; catecholamine infusion side effect)
- Sepsis
- Methylxanthine side effect
- Glucocorticoid side effect

catecholamine secretion can continue to suppress insulin secretion.[31] Catecholamine excess also can lead to insulin resistance, both peripheral (leading to decreased glucose utilization) and hepatic (leading to increased glucose production), and peripheral glucose intolerance.[48] Stress-induced production of cortisol and glucagon promote hepatic glycogen breakdown and gluconeogenesis with release of glucose into the circulation. These infants also have relatively decreased insulin-sensitive tissues (e.g., skeletal muscle and heart) as a fraction of body weight. There also is some evidence of abnormal insulin processing by the pancreatic beta cells such that more immature forms of insulin (proinsulin and proinsulin split products) are released. Because these immature forms of insulin are much less active in stimulating the insulin receptor, they may contribute to a relative insulin resistance in these infants.[110] Some investigators also have reported that, unlike adults, **most preterm and term infants fail to suppress endogenous glucose production despite the administration of an adequate exogenous supply (e.g., IV infusion),[27,36,28] but other investigators did not measure any glucose production in premature infants receiving IV glucose at a rate of more than 2 mg/kg/min.[168]**

Hyperglycemia is most commonly iatrogenic in extremely low-birth-weight (ELBW) infants (less than 750 g) who require excess water to replace fluid lost through insensible water losses and who receive excess glucose along with the infused water because it is necessary to provide an isotonic IV solution. The risk for developing hyperglycemia is significantly increased with decreasing birth weight (up to 18 times greater in infants with birth weights <1000 g than among those weighing 1000–2000 g) and with an increasing rate of glucose infusion, even if the absolute infusion rate remains within the accepted range.

Delay in initiating enteral feedings may be an additional risk factor. The incidence of **hyperglycemia is higher in LBW infants receiving all of their nutrition parenterally than in those who receive at least a part of their nutrition enterally, and prolonged intravenous nutrition may contribute to insulin resistance, particularly when hyperglycemia is present.[110,141] Enteral feeding increases gut secretion of incretins (GLP-1 and GLP-2) that stimulate endogenous insulin secretion.[7]**

The rate at which the glucose concentration is increased in IV solutions, including intravenous nutrition, also may contribute. **Hyperglycemia is increasingly common at glucose infusion rates greater than 6 to 8 mg/kg/min (normal basal glucose utilization rates are 4 to 6 mg/kg/min).** The presence of illness (e.g., sepsis), treatment with corticosteroids, and RDS that requires mechanical ventilation are associated with increased risk for developing hyperglycemia, most likely because of increased circulating catecholamine and cortisol concentrations that lead to increased lipolysis and glycogenolysis and inhibit pancreatic insulin secretion and insulin action.

Several other etiologic factors must be considered in infants with hyperglycemia. **Increased blood glucose concentrations have been reported in association with sepsis.[16] Intravenous lipid infusions also contribute to hyperglycemia by simple mass action of competitive lipid carbon supply to the mitochondria[144] and by glycerol that is a component of IV lipid emulsions.[143] Such effects are worsened if given rapidly at rates of more than 0.25 g/kg/hr,** but current practice is to administer lipids at a slower rate.[164] Lipid oxidation in hepatocytes also produces cofactors (e.g., ATP, NADP, NADPH, acetyl Co-A) that activate and fuel gluconeogenesis.[58,113] **Methylxanthines are frequently used to treat apnea in preterm infants and may be a cause of hyperglycemia.** This problem has been well documented after theophylline overdose but may occur also with appropriate administration. One study, for example, found that blood glucose concentrations in infants with therapeutic theophylline levels were higher than in untreated control subjects, with glucose concentrations in the hyperglycemic range in two treated infants.[138] Neonates undergoing surgical procedures also are at increased risk for hyperglycemia, probably because of a combination of the large quantities of glucose-containing fluids and blood products that may be administered during the procedure and the effects of stress-related hormones. Infusions of catecholamines and glucocorticoids compound the effects of stress production of these hormones on inhibiting insulin secretion, promoting hepatic glucose production, and reducing peripheral insulin action and glucose intolerance.

Neonatal Diabetes

Neonatal diabetes is rare, and 40% to 50% of cases are due to *transient neonatal diabetes mellitus*

(TNDM). TNDM is associated with IUGR and may be difficult to distinguish from hyperglycemia due to increased levels of catecholamines and other stress hormones and related decreased insulin secretion and sensitivity. Genetic mutations or epigenetic anomalies in the chromosome region 6q24 have been identified in 70% of patients with TNDM.[132,151] In TNDM, unlike true diabetes mellitus, ketosis does not develop. Most cases self-resolve, but insulin therapy may be necessary. *Permanent neonatal diabetes mellitus* (PNDM) also occurs, although this is a rare disorder, with incidence estimated at 2 to 3 per 100,000 live births. Only about 25% of infants with PNDM have IUGR. Causes include mitochondrial diseases, pancreatic hypoplasia or aplasia, abnormal pancreatic glucokinase activity, and mutations of pancreatic K_{ATP} channel. Neonatal diabetes may be associated with other abnormalities including developmental delay, skeletal dysplasias, and intestinal atresia.

Prevention of Hyperglycemia

Recognition of those infants at risk for disturbances in glucose homeostasis is the most important step in preventing hyperglycemia. Hyperglycemia occurs most often in preterm infants receiving high rates of IV glucose. **In a VLBW infant, hyperglycemia may be avoided by starting IV glucose infusions at rates of 2 to 3 mg/kg/min and checking blood glucose concentrations frequently (as often as every 3 to 4 hours) while the infant continues to receive IV glucose.**[140] There is some evidence that **starting amino acid infusions shortly after birth in very preterm infants may limit the development of hyperglycemia,** perhaps by increasing insulin production and secretion and also by promoting protein turnover and its attendant glucose (energy) requirements.[17,22,156] As noted, introduction of **small-volume enteral feedings as soon as possible may also reduce the incidence or duration of hyperglycemia** in VLBW infants by stimulating incretin secretion and increasing glucose metabolism.[7,81]

Clinical Signs

Hyperglycemia usually is asymptomatic and most often is diagnosed on routine screening of the infant at risk. It should be suspected in any preterm infant, and is likely to be more exaggerated the more preterm the infant. It also should be suspected in infants who had hypoxic-ischemic conditions shortly before or during birth and in any sick or physiologically unstable infant.

If a problem with glucose homeostasis is suspected, documentation of the aforementioned data, history, physical examination, and clinical signs must reflect ongoing monitoring and measures taken.

LABORATORY DATA

Plasma (serum) glucose concentrations should be measured in any infant as soon as possible after starting IV dextrose (alone or as part of TPN). These measurements should be continued at reasonable frequencies depending on whether hyperglycemia is found and is very high or highly variable. During treatment, measurement continues until normal values are achieved and maintained for reasonable periods. Since hyperglycemia can persist in very preterm infants even after IV dextrose infusions have been discontinued, intermittent glucose concentrations should be measured for several days after stopping IV dextrose infusions or TPN. Persistent hyperglycemia has been associated with worse morbidities and even mortality and should not be allowed to continue. Enteral feeding is the best treatment, as it promotes secretion of incretins from the gut, which stimulate insulin secretion.

Treatment of Hyperglycemia

GLUCOSE

Most cases of hyperglycemia can be treated by reducing the neonate's IV glucose infusion rate. This approach, when combined with other measures such as early use of IV amino acids and early enteral feeding with reasonably rapid feeding advancement, commonly reduces glucose concentrations into more acceptable ranges within 24 hours. **Many LBW infants will tolerate glucose infusions at rates as low 4 mg/kg/min with normal glucose concentrations, although Zarif and colleagues[167] reported that more than 40% of infants weighing less than 1000 g had a blood glucose concentration higher than 125 mg/dL while receiving glucose at an average rate of 4.4 mg/kg/min.** VLBW infants with high fluid requirements resulting from large insensible

water losses through the skin may require a combination of water and glucose intake that could be administered only by using a hypotonic solution such as $D_{2.5}W$ to avoid hyperglycemia. **The use of a low glucose concentration in the IV infusate necessitates the addition of sodium** (e.g., $D_{2.5}W$ has approximately 130 mOsm/L, requiring the addition of sodium chloride to produce an isotonic solution with 280 mOsm/L), which may further complicate management of fluids and electrolytes. Another approach is to continue a lower fluid rate of IV dextrose infusion with D_5W but infuse sterile water through a gastric tube to meet fluid needs. A **VLBW infant needs adequate caloric intake (50–60 kcal/kg/day) to avoid a negative nitrogen balance and tissue catabolism. These needs often cannot be met without resultant hyperglycemia.** If the glucose is only mildly elevated (e.g., concentrations of 125–150 mg/dL) and the infant has no evidence of contributing adverse pathologic conditions, reducing the rate of IV glucose administration may not be necessary, as long as amino acid infusions and enteral feeding are increased, as they generally promote insulin secretion and incretin production and promote glucose utilization. There is little evidence, however, to determine whether this practice will lead to better or worse longer term neurodevelopmental outcomes. Regardless, such infants should have repeated glucose measurements made to ensure that the hyperglycemia resolves.

LIPID AND AMINO ACIDS

Intravenous lipid infusion rates can be decreased to help reduce hyperglycemia. This limits the contribution of FFAs produced by lipid metabolism that, on oxidation, generate energy to drive gluconeogenesis (acetyl CoA and reducing equivalents, NAD/NADH). Decreasing lipid supply also limits the competition of fatty acids with glucose for oxidation and the direct enhancement of gluconeogenic enzymes in the liver and thus the production of glucose. Limiting lipid supply also reduces the supply of glycerol, which is the primary support for gluconeogenesis in newborn infants. **As with reducing the glucose infusion rate, reducing lipid infusion rates also reduces energy supply.** The risks of reducing energy intake to lower glucose concentrations, versus those of the hyperglycemia itself, are uncertain.

Amino acid infusions should be started early to promote insulin secretion and enhance protein turnover with its obligatory energy (hence, glucose) requirements.[22,156] Amino acids do not contribute measurably to enhancing gluconeogenesis, even though they provide more substrate.[144]

INSULIN INFUSION

Because of the foregoing considerations, some authors have suggested the use of a **continuous insulin infusion in the infant who cannot tolerate infusion of glucose solutions with concentrations greater than 5 g/dL (e.g., D5W).**[18,46] **Infusion of insulin at rates of 0.2 to 0.8 mU/kg/min (0.01 to 0.05 U/kg/hr) for 12 to 24 hours may improve glucose tolerance.** However, insulin avidly binds to plastic IV tubing; thus the actual rate of insulin administration may be difficult to determine and may vary over time. Although various methods have been proposed, such as priming the tubing with insulin-containing solution or albumin, these have not been shown to be consistently effective.[149]

Hypoglycemia during administration of exogenous insulin can be avoided by starting with a low infusion rate (0.05 to 0.1 mU/kg/min) and increasing the rate by 10% to 20% every 60 to 90 minutes until the glucose concentration is less than 200 mg/dL. Blood glucose concentrations should be monitored every 15 to 20 minutes during initiation of the insulin infusion, and an IV glucose infusion should be maintained to avoid any abrupt changes in blood glucose concentration and to allow rapid correction of glucose concentration if it starts to fall below "normal" values. Use of **insulin infusion has been reported to improve tolerance to glucose infusions, resulting in increased carbohydrate intake and weight gain.**[4,15] **Most of the weight gain is fat,** however, and there is risk for fatty infiltration and secondary inflammation in the liver and heart when insulin and glucose infusions are maintained for long periods. Such insulin treatment inhibits glucose production, though not as readily as in adults.[27] The effect of insulin to promote glucose utilization is modest in very preterm infants, given the small amount of insulin-sensitive tissue (primarily skeletal muscle) per body weight. Acutely, **insulin infusion has been noted to increase lactate production, with lactate concentrations up to threefold greater than baseline, and may be associated with metabolic acidosis.** Administration of glucose and insulin at high rates also enhances CO_2 production, which might lead

to hypercarbia in infants with respiratory disease. Also, episodes of hypoglycemia can occur even with careful monitoring during insulin infusion. **The use of insulin to prevent hyperglycemia in neonates has been evaluated in a randomized prospective prophylactic study that showed no obvious benefit and considerable morbidity, particularly a significant increase in the incidence of hypoglycemic episodes.** The authors of this study and an editorial commentary concluded that **chronic insulin infusion cannot be recommended and must be used cautiously even in cases of acute hyperglycemia.**[15,78] This is especially true because there are no clinical studies that have demonstrated a cause-and-effect relationship between brief periods of neonatal hyperglycemia and adverse long-term outcomes, and long-term neurodevelopmental outcomes are not necessarily adversely affected by neonatal hyperglycemia in preterm infants.[158] **Theoretically, hyperglycemia can induce an osmotic diuresis, and close attention should be paid to fluid balance in the hyperglycemic infant.** However, this is rarely seen at blood glucose concentrations less than 400 mg/dL or when hyperglycemia occurs intermittently and for brief periods. Finally, as in hypoglycemia, efforts should be made to treat any underlying etiology, such as sepsis.

Two recent studies, one in neonatal lambs and one in **extremely preterm infants with chronic hyperglycemia, have shown reduced mortality when insulin was used to reduce plasma glucose concentrations.**[5,166] These studies did not include subjects who had their glucose concentrations lowered by other means. Thus, it remains unclear whether insulin itself has a specific beneficial effect on lowering mortality or whether it is just one approach to lowering glucose concentrations and avoiding their adverse effects. **A *Cochrane Review* of one study showed that insulin infusion versus reduced glucose infusion to treat hyperglycemia in ELBW preterm infants showed no difference between groups in all age/weight groups on death, sepsis, retinopathy of prematurity, necrotizing enterocolitis, intracranial hemorrhage, chronic lung disease, NICU days, or growth.**[104,134] **Insulin should be used with caution, therefore, and only when safer and more conventional approaches to lowering glucose concentrations have failed.**[69] Insulin actually makes the infant fatter and contributes to excess mitochondrial carbon load and production of reactive oxygen species. **Insulin does not increase glucose uptake by the brain or enhance neuronal growth or dendritic development**—in fact, it might do just the opposite (see later). **It does not increase linear growth or consistently increase lean mass growth when given in excess of normal physiologic doses;** positive effects are only found to a minimal extent when the insulin is accompanied by protein.

Complications of Hyperglycemia

Although there is no direct evidence, **hyperglycemia in the preterm infant has been postulated to increase the risk for IVH by causing rapid changes in osmolarity** with resultant rapid fluid shifts within the brain and germinal matrix. Increased mortality rate in hyperglycemic premature infants compared with their normoglycemic counterparts has been reported, although hyperglycemia may have been a marker for those infants with more severe illness rather than a direct cause of the increased mortality rate.[2] **Osmotic brain injury and death have occurred in infants accidentally infused IV with an erroneously high dextrose solutions, such as $D_{75}W$ rather than $D_{7.5}W$.** Increased morbidity may be seen in the form of greater difficulty with fluid and electrolyte management because use of dextrose-containing fluids must be limited and problems establishing adequate nutrition. Several studies also suggest **an association between hyperglycemia in ELBW infants and increased incidence of retinopathy of prematurity,**[29,55,111] perhaps due to increased production of reactive oxygen species and reduced angiogenesis and secondary neuronal necrosis, but no definitive cause-and-effect relationship has been demonstrated as of yet.

Complications of hyperglycemia are increasingly recognized in adults and children in ICUs, and many of the associated morbidities are seen in newborn infants even if not considered to be caused by hyperglycemia. Such morbidities include increased morbidity and mortality, impaired immunity and increased rates of infection, poor wound healing, suppressed autophagy, diminished cellular repair and organ recovery, and loss of skeletal and cardiac muscle. **Enteral feeding rather than continued IV feeding has been most successful in preventing or reversing these problems.** Similar evidence in

preterm infants is less clear. Other established effects of marked hyperglycemia are documented in preterm infants, including increased energy expenditure, increased O_2 consumption, increased CO_2 production with tachypnea, increased fat deposition in excess of lean mass, increased fatty infiltration with inflammation in the heart and liver, increased risk of deep venous thrombosis due to suppressed anticoagulant proteins and increased procoagulant proteins, risk of right ventricular dysfunction, interventricular septal hypertrophy, amplified sympathetic nervous and renin-angiotensin-aldosterone systems, increased health care–associated infections,[169] and accumulation of myocardial collagen and fibrosis from excessive production of free radicals.[24,114,118,147] There also is the **potential for increased bacterial sepsis with persistent hyperglycemia,** as bacteria thrive with excess glucose, leading to worse infections and death of the organism. **In the NICU, where bacterial infections are more common as causes of serious sepsis, normal to low-normal plasma glucose may be protective.**[165] **Hyperglycemia also worsens outcomes in infants with hypoxic ischemic encephalopathy, even more so than hypoglycemia.**[13] Perhaps more worrisome are animal studies that demonstrate marked adverse effects of chronic and marked **hyperglycemia in fetuses and neonates on neural development (reduced numbers of dendritic spines and synapse formation),**[74] and decreased neuronal density, increased oxidant status, and decreased antioxidant status in the brain along with increased mortality.[150] **Clinical studies in preterm infants also have shown that growth may or may not be affected (increased or decreased) with prolonged hyperglycemia in VLBW preterm infants, but linear growth is reduced,**[4] perhaps due to down regulation of the growth hormone axis, and such **poor growth is associated with reduced cognitive development.**[126] Most worrisome are continued reports of associations between severe hyperglycemia (two or more consecutive blood glucose concentrations greater than 216 mg/dL at least 3 hours apart) as part of **early enhanced TPN in ELBW preterm infants and increased mortality, as early as the first day of life and even after 7 days.**[140,161]

Infants with TNDM usually recover spontaneously within the first week; persistent insulin resistance is extremely rare. However, those infants with chromosomal mutations have an increased incidence of adult-onset diabetes later in life.[132] No neurologic sequelae have been directly attributed to the presence of transient hyperglycemia in these neonates.

16 TOTAL PARENTERAL NUTRITION

STEVEN L. OLSEN, ALEXANDRIA OSCHMAN, AND KELLY TRACY

Total parenteral nutrition (TPN) support for critically ill newborns was first reported four decades ago.[44] However, in the modern era of neonatal care, TPN continues to be a critical aspect of intensive newborn care. Availability of **TPN has been one of the developments responsible for improved outcome of neonatal surgical patients.**[94,100,102] Increased survival of extremely preterm infants has provided new challenges for neonatal parenteral nutrition.[61] **Current evidence would suggest that early nutritional support is important to prevent postnatal growth restriction, which has been commonly recognized in these infants.**[40,45,61]

A neonatal service that uses TPN has the best results if it includes an experienced "nutrition team" comprising a neonatologist, surgeon, nutrition support nurse, pharmacist, dietitian, and social worker, with each member playing a vital role to make TPN a safe and effective therapy. This chapter discusses the nutritional needs of the high-risk newborn, specific indications for TPN, and guidelines for formulation and administration of intravenous (IV) nutritional solutions. An overview of mechanical, infectious, and metabolic complications is also presented with emphasis on prevention and early identification.
