During periods of fasting, tissue stores of energy provide the major source of fuel for the body. Carbohydrate is stored in the liver and muscle as glycogen. Stable blood sugar levels are maintained by hormonal regulation of glycogen production (glycogenesis) and breakdown to glucose (glycogenolysis). Newborns, particularly those who are growth restricted or preterm, have low glycogen stores and often have insufficient regulatory mechanisms.[118]

The body's greatest energy stores are in the form of fat, which provides a calorie yield of 9 kcal/g when metabolized. In addition to normal deposits of adipose tissue, newborns (and hibernating adult animals) have unique stores called brown fat. These stores, which are anatomically located between the scapulae, in the axillae and mediastinum, and around the adrenal glands, protect the body from hypothermia through nonshivering thermogenesis[91] (see Chapter 6).

Protein makes up lean body mass. Although protein generally is not used as an energy source postnatally, in fetal life, amino acids are oxidized apparently for energy.[122] This may be true for brief periods postnatally, but **extended periods of protein catabolism (breakdown of endogenous substrates), such as during times of starvation, may lead to body dysfunction**, as noted later.

The Effects of Insufficient Nutrition

The last trimester of gestation is a time of rapid fetal growth, with active transplacental transport of most nutritional substrates. **Preterm delivery interrupts the nutritional supply and abruptly results in a catabolic state, which, if prolonged, may alter growth potential.** It is unclear whether it is possible to achieve in utero growth rates for the postnatal preterm infant, but **reestablishment**

BLUE type highlights content that is particularly applicable to clinical settings.

of an anabolic state and maintenance of micronutrient sufficiency is necessary.[40,58,122] During this period of neonatal life, the rapidly growing brain is responsible for much of the nutritional requirements. Inadequate early nutrition may have irreversible effects on later neurodevelopmental outcomes.[79]

Postnatal growth restriction also is associated with neonatal medical complications, including apnea, ventilator dependence, and chronic lung disease.[36] Immune responses may be depressed with increased susceptibility to infection (see Chapter 22). Protein malnutrition is most frequently seen in extreme preterms and may contribute to poor growth potential and long-term morbidity in these infants.[36,122,123] Poor postnatal growth for most extremely low-birthweight (ELBW) infants has emphasized the need for additional strategies to improve nutrition for this population.[40,41,42]

One strategy is to initiate parenteral nutrition within the first hours after birth. Even though the exact benefits and harms are unknown, providing early, increased energy and protein support have been associated with improved short-term growth outcomes.[40] Longer-term outcomes, such as reductions in the incidence of common neonatal morbidities, increased brain growth, and improved neurodevelopmental outcomes, are more difficult to link directly to early parenteral nutrition. There is no evidence that early parenteral nutrition increases morbidity or mortality risks, but also unclear is the influence of early nutritional support on the incidence of childhood obesity and the risk for cardiovascular disease and metabolic syndrome in adults.[88]

Nutritional Requirements of the Neonate

CALORIC

Caloric requirements for preterm infants, including very-low-birth-weight (VLBW) and small-for-gestational-age (SGA) infants, are approximately 110 to 130 kcal/kg/day.[141] Caloric requirements for near-term and term infants are 90 to 120 kcal/kg/day. These estimates are based on enteral intake (see Chapter 17). Parenteral requirements are about 20% less, or approximately 80 to 100 kcal/kg/day. Factors affecting caloric requirements include the infant's gestational age, chronologic age, weight, activity level, body temperature, ambient temperature, underlying disease, and degree of stress. Infections, including nosocomial, may also contribute to additional caloric needs.[125] Resting energy expenditure is an estimate of the approximate range of basic energy needs and is approximately 45 kcal/kg/day in infants less than 900 g and 50 kcal/kg/day for infants larger than 1000 g.[141] Physical activity, which usually is infrequent in preterm infants, contributes less than 10% to the energy needs.[78]

However, in pathologic states, such as with repetitious seizures or neonatal abstinence syndrome, increased activity may increase caloric needs. An elevation of body temperature increases caloric expenditure by approximately 12% for each degree Celsius above 37.8° C (100° F). Metabolic demands of surgery and postoperative healing, or severe cardiac or pulmonary distress, may increase caloric requirements by as much as 30% and chronic failure to thrive by 50% to 100%. In addition, postnatal dexamethasone therapy may slow weight and linear growth rates and potentially may negatively affect brain growth.[31,36,90,140]

WATER

Water requirements vary with gestational and postnatal age (postconceptual age) and environmental conditions (e.g., care in an incubator versus radiant heat warmer, use of phototherapy) (see Chapter 14).

ELECTROLYTE AND MINERAL

Sodium requirements are minimal for the first days of life. After 1 week, the average requirement is 3 to 4 mEq/kg/day. Large renal losses (greater than 5 mEq/kg/day) may occur in very immature infants (less than 28 weeks of gestation) in the first weeks of life. Potassium and chloride requirements are approximately 2 mEq/kg/day and 3 to 4 mEq/kg/day, respectively. Glucosuria with resulting osmotic diuresis may increase sodium and potassium urinary losses.[49]

Calcium is an important cofactor in hemostasis, enzyme function, muscle contraction, and cell membrane stability. In the newborn, 98% of calcium is stored in the bone. The initial calcium requirement is 1 mEq/kg/day to maintain calcium homeostasis and to avoid irritability and tetany associated with low serum ionized calcium levels.

In utero, the accretion rate is 4 to 5 mEq/kg/day, which the growing preterm infant should receive in addition to adequate phosphorus and vitamin D to avoid osteopenia, rickets, and bone fractures.[134] Excess calcium intake may cause central nervous system (CNS) depression or signs of renal toxicity.

The phosphorus requirement for the growing preterm infant is 40 to 60 mg/kg/day (31 mg = 1 mmol). Bone contains 80% of the body's phosphorus. Low phosphorus intake causes increased renal calcium excretion and a depletion of bone calcium phosphate. **A calcium-to-phosphate ratio of 1.7:1 (mg:mg) or 1.3:1 (mmol:mmol) is recommended in short-term parenteral nutrition for preterm neonates.**[24] Low phosphorus intake or chronic furosemide diuretic therapy also may lead to hypercalciuria and nephrolithiasis.[29] Because phosphorus is a major constituent of cellular energy function (adenosine triphosphate, 2,3-diphosphoglycerate, creatinine phosphate), severe depletion may result in muscle paralysis, respiratory failure, and interruption of important cellular functions, such as the hemoglobin-oxygen dissociation curve and leukocyte activity.

Magnesium is essential for intracellular enzyme systems. The requirement is 0.25 to 0.5 mEq/kg/day.[7] Magnesium deficiency states mimic hypocalcemia, manifesting as irritability, tremulousness, tetany, and cardiac dysrhythmias. Magnesium excess may manifest as lethargy, hypotonia, and delayed stooling.

CARBOHYDRATE

During fetal life, glucose is the primary source of energy.[122] At birth, the preterm infant has only a small supply of glycogen, the storage form of glucose (equivalent to about 200 kcal of energy). **Glucose is particularly important for the CNS, because other substrates are not available.** Initially, a glucose infusion rate (GIR) of 6 mg/kg/min is sufficient to meet metabolic needs of the newborn infant. Requirements are greater for infants who are stressed (e.g., from sepsis or hypothermia) or hyperinsulinemic (e.g., infants of diabetic mothers or infants with Beckwith-Wiedemann syndrome).

With long-term parenteral nutrition, at least 50% of total caloric requirement should be provided as carbohydrate (GIR 8 to 10 mg/kg/min), generally as dextrose (calculated as 3.4 kcal/gm of hydrated carbohydrate). Preterm infants, especially ELBW patients, who receive early and higher amino acids in their parenteral nutrition, have been shown to have a decreased incidence of hyperglycemia requiring insulin treatment.[2] **To avoid metabolic consequences of excessive glucose loads, a GIR of more than 13 mg/kg/min (19 g/kg/day of glucose) should be avoided.**

PROTEIN

The quantity of daily nitrogen required by a term newborn infant, based on estimates from breast milk intake, is approximately 325 mg/kg/day (approximately 2 g/kg/day of protein).[8] Requirements for preterm infants are much higher, as indicated by in utero accretion rates during the latter half of pregnancy. At 28 weeks' gestation, the fetus requires 350 mg/kg/day of nitrogen. This figure declines to 150 mg/kg/day by term gestation. **When the estimated accretion rate is added to the obligatory postnatal nitrogen excretion, the requirement for a 28-week gestation preterm infant may be calculated to be approximately 495 mg/kg/day (3.1 g/kg/day of protein). If one assumes parenterally administered amino acids are converted to body proteins at 75% efficiency, the estimated parenteral amino acid requirement would be as high as 3.7 g/kg/day.**[47,125]

In fetal life, protein is actively transported from the mother's circulation across the placenta in quantities greater than needed for accretion, with the excess being oxidized by the fetus or placenta for energy.[121] Clinicians have found that increasing protein intake postnatally at all energy intake levels above 40 kcal/kg/day results in increased protein accretion. **Current evidence indicates that protein intake up to 4 g/kg/day is safe with no clinically significant increase in azotemia, acidemia, or hyperaminoacidemia.**[95] Although more studies are looking at higher amino acid administration, further investigations are needed to determine safe upper limits for maximum protein administration beyond that level.[27]

Studies have shown that administration of amino acids shortly after birth decreases protein catabolism, which is extremely important, particularly for VLBW infants.[47,71,121] Early amino acid administration is also associated with reductions in hyperkalemia and hyperglycemia.[21,27,92] **Based on the current evidence, providing VLBW**

infants with 3 g/kg/day of protein on the first day of life is safe.[41] Many NICUs have created a "stock" or "starter TPN (protein-containing) solution" to achieve the goal of providing 2 to 3 g/kg/day of protein to promote anabolism immediately after admission. Although current studies support the early use of parenteral protein nutrition, further investigation is needed to document the effect of this supplementation on post-NICU long-term growth and development.[88]

The quality of the infused amino acid mixture is important for efficacy and safety.[1] Although there is no formulation specifically for preterm infants, **pediatric solutions provide greater quantities of essential amino acids and result in plasma amino acid levels similar to those of postprandial breastfed infants.** An essential amino acid is one that cannot be synthesized in adequate quantity to meet the requirements for normal growth and development. The differentiation between essential and nonessential amino acids is not clear in newborn infants, because the ability to synthesize some amino acids may vary with the clinical situation or stage of maturity. Lysine and threonine are essential in their entirety. There is a high requirement for branched-chain amino acids (e.g., leucine, isoleucine, valine) in the growing newborn. These are metabolized primarily in skeletal muscle.[87,123]

Methionine is an essential sulfur-containing amino acid that is metabolized to cysteine and taurine. **For preterm infants of less than 32 weeks' gestation, cystathionase activity is insufficient for cysteine synthesis. Some investigators have found that cysteine supplementation results in greater nitrogen retention, and for this reason it is recommended for short-term supplementation for high-risk preterm infants, although the effects of prolonged use have not been fully investigated.[114]** Cysteine is not stable in amino acid solutions, so cysteine hydrochloride supplements must be added separately to the parenteral nutrition. Taurine is a nonprotein amino sulfonic acid that is converted from cysteine by cysteine sulfonic acid decarboxylase. Taurine concentrations are low in infants who have received nonsupplemented TPN infusions. **Taurine deficiency may have a detrimental effect on the developing nervous system.** Taurine is present in commonly used pediatric amino acids and **may prevent cholestasis in some newborns by more effectively conjugating bile salts and creating soluble end products.[116,130]**

Tyrosine is another amino acid that appears to be essential in the newborn period. It is present in small amounts in most amino acid solutions, although one manufacturer uses a soluble form, *N*-acetyl-L-tyrosine, which infants slowly metabolize to tyrosine.[101] Tyrosine is a byproduct of phenylalanine metabolism, so supplementation has an effect on the phenylalanine requirement. Histidine is considered to be an essential amino acid for newborns, with the lowest levels evident in preterm infants. Arginine may be essential only for the newborn with reduced arginine synthetase activity. This amino acid is thought to facilitate clearance of nitrogenous waste products by "priming the urea cycle." Use of amino acid infusate with insufficient arginine has been associated with hyperammonemia.[60] Glutamine also has been considered a conditionally essential amino acid, but no benefit was shown in randomized trials for parenteral glutamine in relation to mortality, incidence of necrotizing enterocolitis (NEC), or infection rates.[86]

Nonessential amino acids make up the largest percentage of the amino acid pool in the fetal body. The desired quantities of these amino acids for parenteral solutions are not known. It is thought that they should be provided in a balanced formulation. Pediatric solutions differ from adult solutions by providing glutamic acid and aspartic acid with lower glycine concentrations.[1,9]

FAT

Long-chain fatty acids are essential in the newborn for brain development and appear to be important for gene expression and other molecular mechanisms.[73] **Essential fatty acids (EFAs) include linoleic and linolenic and, in the newborn, arachidonic acid.[7]** Biochemical evidence of EFA deficiency may be seen in less than 1 week in VLBW infants receiving a deficient diet, and the administration of parenteral glucose and amino acids may accelerate these abnormalities.[119] EFA deficiency results in an imbalance in fatty acid production with an overproduction of nonessential fatty acids. **Clinical manifestations appearing at variable times after biochemical changes of EFA deficiency include scaly dermatitis, poor hair growth, thrombocytopenia, failure to thrive, poor wound healing, and increased susceptibility to bacterial infection. Clinical manifestations of EFA deficiency can be avoided if 3% to 4% of caloric intake is supplied as linoleic acid (approximately 0.5 g/kg/day of soybean-based IV lipid).[62]**

In addition to preventing EFA deficiency, lipid emulsion is a concentrated source of nonprotein calories, which promotes nitrogen retention. Preterm infants appear to have limited capability to oxidize fatty acids. This limitation may be related to deficiency of carnitine, which, in the form of acylcarnitine, promotes transfer of fatty acids into mitochondria, where oxidative metabolism occurs. However, a systematic review of randomized studies found no benefit for carnitine supplementation on weight gain, lipid utilization, or ketogenesis, so routine supplementation is not recommended.[28]

VITAMINS

The biologic role of vitamins, signs and symptoms of deficiency states, and recommended oral requirements are available in Chapter 17. Although there is not a multivitamin formulation specifically for preterm infants, the American Society for Clinical Nutrition (ASCN) has suggested that **preterm infants receive 40% to 65% of the daily recommended vitamin doses for term infants and children.**[110] These guidelines may result in excessive intakes of some water-soluble vitamins, particularly pyridoxine and riboflavin. Although preterm infants have limited stores of lipid-soluble vitamins because of low body fat, potential toxicity from excess administration is a concern. **Vitamin A is a lipid-soluble vitamin that is important for tissue growth, protein synthesis, and epithelial differentiation.** Vitamin A may be administered more effectively in lipid emulsion rather than dextrose amino acid solutions.[7,38] However, **vitamin A supplementation has been proven to be effective in lowering chronic lung disease rates only when given by intramuscular injections three times per week.**[39,128]

Vitamin E is a lipid-soluble biologic antioxidant that is deficient in preterm infants. However, **daily parenteral intake of 2 to 3 mg/kg has been associated with serum levels generally in the recommended range of 1 to 2 mg/dL.** Pharmacologic doses have been tried unsuccessfully for prevention of bronchopulmonary dysplasia and retinopathy of prematurity, and IV high-dose vitamin E may increase risk for sepsis.[25] Therefore, aiming for tocopherol levels greater than 3.5 mg/dL is not recommended. **Vitamin K production by intestinal flora is impaired by insufficient enteral feedings and use of broad-spectrum antibiotics in infants on long-term TPN.** Vitamin K is provided at the recommended dosage through parenteral pediatric multivitamin solutions.[7]

TRACE MINERALS

Although trace minerals are relatively scarce (less than 0.01% of the weight of the human body by definition), they play an important role in normal growth and development.[50] Early supplementation of selenium has shown a reduction in sepsis events.[3] Deficiencies of both zinc and copper have been identified in infants on long-term TPN not supplemented with trace minerals. Postsurgical infants with ongoing gastrointestinal losses may have negative zinc balance even if given usual zinc replacement in TPN.[109]

Manifestations of deficiency and recommendations for intake are provided in Chapter 17. Parenteral recommendations are lower than enteral, which are based on physiologic requirements. **Preterm infants receiving breast milk and not receiving frequent blood transfusions should receive 2 mg/kg/day of enteral iron supplementation starting by 1 month of age. For term, breastfed infants not receiving frequent blood transfusions, enteral iron supplementation at 1 mg/kg/day may be necessary by 4 months of age.**[12] **Infants receiving erythropoietin therapy need additional iron supplementation, given either enterally or parenterally.**[84,98]

INDICATIONS

Parenteral nutrition, including protein supplementation and carbohydrate at basal levels, should begin on the first day of life for preterm infants not being fed, as well as for other newborns who are not likely to tolerate enteral feedings within a few days. A preterm infant has limited nutritional stores and quickly develops negative protein balance without early supplementation. TPN continues to be a critical aspect of long-term management for neonatal surgical patients.[102] **When parenteral nutrition solutions are administered through a peripheral vein, caloric intake is limited because the fluid osmolarity should not exceed 900 mOsm/L, which results in relatively limited concentrations of carbohydrate (less than 12.5% dextrose) and amino acids (less than 3%).**[24] **Some recommend even more conservative limits on osmolarity**

for peripheral lines (500 mOsm/L).[53] When used with lipid emulsions, peripheral parenteral nutrition (PPN) allows caloric intake of about 70 to 80 kcal/kg/day and protein intake of 2.5 to 3.0 g/kg/day. This level of nutritional intake prevents catabolism and, in some cases, results in moderate growth. PPN usually is adequate for term newborns with transient bowel disease (such as may be seen after the repair of a small omphalocele) or for larger preterm infants whose enteral feedings are delayed for a few days. PPN is commonly used to supplement nutrition in newborns who are receiving partial enteral feedings. When caloric needs can be met by PPN, this route is preferred to the central route, because the catheter insertion risks of central catheters are avoided and generally, the risk for infection is less.

If parenteral nutritional duration is longer than 1 week, administration of TPN solution through a central line is recommended. The placement of a central line for parenteral nutrition allows a higher carbohydrate load to be used, giving more calories with less fluid. In preterm infants at risk for a patent ductus arteriosus and pulmonary edema, diminishing fluid intake and improving nutritional status may be important aspects of management.

Specific indications for TPN by a central catheter include the following:

- ELBW infants (less than 1000 g birth weight) and others who do not tolerate a significant volume of enteral feeding within the first week of age or who cannot receive adequate caloric intake by PPN
- Infants who have had gastrointestinal surgery and will have a significant delay in enteral nutrition, such as those with a gastroschisis, bowel resection after NEC, or meconium peritonitis
- Infants with chronic gastrointestinal dysfunction, such as intractable diarrhea

DATA COLLECTION

Monitoring Growth

Weight loss or insufficient weight gain is the initial effect of inadequate caloric intake. Linear growth, although less affected, is diminished after long periods of poor nutrition. Because of "brain sparing," head circumference growth is the least affected. Measurements should be obtained in a standardized fashion and recorded weekly.

Fetal weight gain in utero at each week of gestation is currently used as the standard to assess adequacy of postnatal growth. In the midtrimester (24 to 27 weeks' gestation), expected weight gain is 1.5% of body weight.[122] Charts are available to monitor postnatal growth rates based on data from a large preterm population, although for long-term monitoring, use of growth curves from normal populations, which are available from the World Health Organization (WHO), may be more appropriate.[133]

Minimum monitoring of growth should consist of the following:

- Weigh daily, or more frequently in ELBW infants with rapidly changing extracellular fluid status. Maintenance of a thermostable environment with minimal handling of ELBW infants can be achieved through the use of in-bed scales. Strict attention to consistency of technique during the weighing process is essential to obtain accurate, reliable measurements.[127] Monitoring weight gain on a weekly basis in grams per kilogram of weight gained daily (g/kg/day) may help in reducing postnatal growth restriction and positively affect long-term neurodevelopmental outcome. An ideal rate of weight gain for ELBW infants appears to be 18 to 21 g/kg/day.[46]
- Measure length weekly.
- Measure head circumference weekly.

Biochemical Monitoring

In addition to anthropometric measurements, biochemical parameters may be monitored to assess nutritional adequacy. Periodic assessment of calcium, phosphorus, and alkaline phosphatase levels is important to detect metabolic disturbances associated with osteopenia.[134] Tests for protein malnutrition include serum total protein, albumin, transferrin, retinol-binding protein, and transthyretin (prealbumin); the latter two are suggested primarily for preterm infants.[8,51] Routine clinical use of these measurements awaits greater definition of normal variation and independent effects of systemic illness and medications.

Biochemical monitoring of the infant's physiologic status is necessary to avoid complications

TABLE 16.1 METABOLIC MONITORING FOR INFANTS RECEIVING PARENTERAL NUTRITION

	FREQUENCY	
VARIABLE	ACUTE	STABLE

BUN, Blood urea nitrogen; *PRN,* as needed.

of TPN. Usefulness of the laboratory data should be balanced with the economic costs and risks from iatrogenic blood losses for the infant (Table 16.1).

When serum electrolyte levels are abnormal, urinary electrolyte levels may be useful to clarify sodium and potassium requirements (e.g., if body sodium is depleted, low urine concentration would be expected).

TREATMENT

Vascular Access

UMBILICAL ARTERY CATHETERS AND UMBILICAL VEIN CATHETERS

Umbilical artery catheters (UACs) and umbilical vein catheters (UVCs) are commonly placed in sick newborns to provide vascular access for IV fluids, blood samplings, and blood pressure monitoring. Because of the risks for thromboembolic and infection complications, these lines generally are removed as soon as possible when no longer needed. **Optimally UACs should not be left in place longer than 5 days, although UVCs can be used up to 14 days if managed aseptically.**[15,37,51]

PERIPHERAL AND MIDLINE CATHETERS

If continued venous access is necessary after this time, a peripheral, midline, or peripherally inserted central catheter (PICC) can be placed. The type of line used is determined by the anticipated length of time needed and the osmolarity of the substances to be infused.[53]

Peripheral IV lines are indicated for short-term IV access. A midline catheter, which is threaded to the proximal portion of an extremity or neck, can provide longer IV access than a peripheral IV line when prolonged peripheral strength TPN is indicated. Midline catheters appear to be associated with lower rates of phlebitis than short peripheral catheters and with lower rates of infection and cost than central lines.[77]

PERIPHERALLY INSERTED CENTRAL CATHETERS

A PICC line can provide maximal nutritional intake when long-term parenteral access is necessary.[4] Percutaneous placement of a 1.9-Fr to 3.0-Fr Silastic (silicone) or polyurethane catheter can be performed routinely in even the smallest of neonatal patients by trained nurses and physicians.[137] The catheter usually is placed in the antecubital or axillary veins in the arms, but leg, scalp, or external jugular veins may be used to achieve central access. Veins that may be needed for percutaneous central line placement should not be sites for routine venipuncture (see Chapter 7).

Percutaneous line placement involves stabilization of the vein, maximum barrier precautions (sterile gloves, gown, large drape, masks), and antiseptic preparation of the skin with 2% chlorhexidine or povidone-iodine and alcohol product.[15,72,137] Infrared vein detectors or ultrasound may be used as adjuncts to identify appropriate veins for PICC cannulation.[26,93] Fully equipped prepackaged kits are available for this procedure from a number of manufacturers. Most kits include an insertion needle that is used to puncture and tunnel through the subcutaneous tissue before entering the vein. Once the needle is within the vein, the catheter, which has been flushed with heparinized saline solution, is passed through the needle into the vein and advanced to a premeasured distance, which is the estimated location of the superior vena cava.54 The catheter tip position should be documented radiographically. The addition of heparin to IV fluids is commonly used by practitioners to prevent occlusion of vascular catheters. However, there is no indisputable evidence for this practice.[106,107]

BROVIAC CATHETER

Large-bore Silastic catheters (Broviac) are placed surgically in infants in whom the percutaneous method is not successful and long-term access is anticipated. Generally, the catheters are placed in the internal or external jugular veins or common facial vein by cutdown and threaded to a central venous site but can also be placed via the femoral vein. The distal end is tunneled subcutaneously and exited through the anterior chest wall or thigh if placed in the leg.[89] The catheter must be secured and dressed under sterile conditions.

OTHER VASCULAR ACCESS OPTIONS

Other sites that may be used for TPN infusion on a short-term basis include subclavian, jugular, and femoral veins. Some centers use a UVC for short-term parenteral nutrition when another site is not feasible.

Composition of Infusate

CARBOHYDRATE

The prime source of calories for the neonate usually is dextrose. Peripherally, dextrose fluids up to 12.5% solution can be used. When central access is obtained, more concentrated dextrose (up to 30%) can be utilized. The glucose load is increased if either the infusion rate or glucose concentration of the infusate is increased. **Too rapid an increase in glucose load may exceed an infant's carbohydrate tolerance and result in hyperglycemia. A rapid decrease in the infusion rate or the glucose concentration of the infusate may result in hypoglycemia.**

When calculating caloric intake, use the following:

$$1\,\text{g dextrose} = 3.4\,\text{kcal}$$

or

$$100\,\text{mL/kg of } D_{10}W = 34\,\text{kcal/kg}$$

or

$$100\,\text{mL/kg of } D_{30}W = 102\,\text{kcal/kg}$$

The glucose infusion rate (GIR) can be calculated as follows:

$$\text{GIR}\ (\text{mg/kg/min}) = \frac{[\text{g glucose/day} \times 1000}{1440(\text{min/day})]} \Big/ \text{weight}(\text{kg})$$

Endogenous glucose production is approximately 4 mg/kg/min. Parenteral nutrition infusions should start with a GIR between 5 and 6 mg/kg/min for VLBW and ELBW infants.[126] Daily increases in dextrose concentration or fluid volume to increase carbohydrate administration by 2 mg/kg/min usually are tolerated. **ELBW infants may be carbohydrate intolerant, and initial GIR should be lower (4 or 5 mg/kg/min) for these infants.** An insulin infusion may be considered for ELBW infants experiencing persistent hyperglycemia with physiologic glucose infusion rates.[138] **Glucose infusion rates should not exceed 13 mg/kg/min unless severe hypoglycemia is ensuing. Blood glucose determinations and screening for glucosuria should be performed several times each day when glucose delivery is initiated or altered.**

LIPIDS

Traditionally lipid emulsion products have been derived from soybean oil. Newer lipid emulsion products contain a mix of soybean oil, fish oil, medium chain triglycerides, and olive oil. Soybean oil lipid emulsion at a rate of 0.5 to 1 g/kg/day is sufficient to prevent EFA deficiency, but additional lipids should be provided to supplement nonprotein caloric intake and support growth.[122] **When mixed oil lipid emulsions are used, a minimum of 2 gm/kg/day may be necessary to prevent EFA deficiency. Lipids should never make up more than 50% of total caloric intake. Fat emulsions should be given cautiously, beginning with 0.5 to 1 g/kg/day and advanced 0.5 g/kg every 1 to 2 days as tolerated to 3 g/kg/day maximum.** Fat emulsions are available as either 10% or 20%, but the 20% concentration is universally used for VLBW infants, because its lower phospholipid concentration results in lower plasma levels of triglyceride and cholesterol and less fluid administration (Table 16.2).[96]

Emulsified fat particles are similar in size and metabolic rate to naturally occurring chylomicrons. Most are cleared through passage in the adipose and muscle tissue. The capillary endothelial lipoprotein lipase hydrolyzes triglycerides and phospholipids, generating free fatty acids (FFAs), glycerol, and other glycerides. Most of the FFAs diffuse into the adipose tissue for reesterification and storage. A small portion circulates to be used by other tissues for fuel or for conversion by the liver into

TABLE 16.2 COMPOSITION OF FAT EMULSIONS

COMPOSITION	INTRALIPID (BAXTER) 20%	LIPOSYN II (HOSPIRA) 20%	SMOF (FRESENIUS KABI) 20%

Osmolarity (mOsm/L)	260	292	270

very-low-density lipoprotein. **Extremely preterm and SGA infants with decreased adipose tissue have prolonged clearance of fat emulsions. In general, because complications of lipids are related to delay in clearance, lipids should be infused over a 24-hour period to provide the lowest hourly rate.**[94] Infusion rates faster than 0.2 g/kg/hr for lipid infusions have been associated with hyperlipidemia.[126] The rate-limiting step for lipid clearance is the metabolism by lipoprotein lipase. The use of heparin stimulates the release of this enzyme and may enhance clearance of IV lipids. Carbohydrate also must be administered with fat to facilitate fatty acid oxidation and to promote FFA clearance.

AMINO ACID SOLUTION

Multiple amino acid solutions are available for neonatal and infant parenteral use. Each solution is sterile, is hypertonic, and contains crystalline amino acids. Each solution provides a mixture of essential and nonessential amino acids and may or may not contain taurine and a soluble form of tyrosine. The amino acid formulation provides a well-tolerated nitrogen source for nutritional support. The essential amino acids typically found in formulations are leucine, isoleucine, lysine, valine, histidine, phenylalanine, threonine, methionine, tryptophan, and cystine. The nonessential amino acids that are typically included are alanine, arginine, proline, glutamic acid, serine, glycine, and aspartic acid. The composition of amino acid varies by manufacturer.

A minimum quantity of energy substrates must be provided for effective utilization of parenteral protein. For ELBW infants, approximately 40 kcal/kg/day of carbohydrates or fat and 1.5 g/kg/day of protein are necessary for resting metabolic needs to prevent catabolism. However, urinary protein losses are greatest for preterm infants, so additional supplementation is needed to prevent protein deficits. **For each gram of protein provided above the basal amount, approximately 10 kcal of nonprotein energy is needed.**[41,47,122]

Contraindications to amino acid administration include untreated anuria, hypersensitivity to the solution, or inborn errors of metabolism, including those involving branched-chain amino acid metabolism, such as maple syrup urine disease and isovaleric acidemia.

ELECTROLYTES

Sodium and potassium may be supplied with chloride, acetate, or phosphate anions. The daily chloride requirement is approximately 3 mEq/kg/day and should be balanced with

acetate to avoid alkalosis or acidosis (acetate is converted to bicarbonate). Amino acid preparations also supply anions that must be recognized to calculate a balanced anion solution. For example, TrophAmine and Premasol supplies approximately 1 mEq of acetate per gram of protein. On the other hand, cysteine addition to the TPN solution reduces the pH, necessitating buffering with acetate.

MINERALS

Phosphorus may be provided as sodium or potassium phosphate. Calcium may be provided as 10% calcium gluconate (9.7 mg of elemental calcium/100 mg of salt). Both calcium gluconate and potassium phosphate have relatively high levels of aluminum and should be used judiciously for chronic TPN in infants with renal dysfunction (see discussion of aluminum toxicity under Trace Elements later in this chapter). When preparing a solution with both calcium and phosphate, care must be taken to avoid calcium phosphate precipitation, which may limit the intake of these important minerals. Magnesium is supplied as magnesium sulfate.

If one is using a potassium phosphate solution at pH 7.4, 4.4 mEq of potassium supplies 93 mg of elemental phosphorus (3 mM). When a solution of sodium phosphate is used at pH 7.4, 4.0 mEq of sodium is given with each 93 mg of elemental phosphorus.

CALCIUM

- **Because of increased risk for precipitation, calcium chloride generally should not be used (but may be considered for an infant at risk for aluminum toxicity).**
- **An elevation in ambient temperature, increased storage time, rise in pH, and decrease in protein or glucose concentration may increase the likelihood of precipitation. The addition of cysteine, which lowers solution pH, may enhance calcium and phosphate solubility.**[9]
- **When one is preparing the solution, calcium and phosphate salts should be added separately, but not in sequence, during the last stages of solution mixing. The solubility of the added calcium should be calculated from the volume at the time the calcium is added, not the final volume.**
- **The use of a physiologic ratio of calcium to phosphorus (1.8:1) in the TPN solution allows increased concentration of these minerals.**[97,114]

VITAMINS

A preparation approximating the American Medical Association's recommended formulation of IV vitamins is available (MVI-Ped). **The daily recommended dose is 1.5 mL/day for infants weighing less than 1 kg, 3.25 mL/day for those infants who weigh 1 to 3 kg, and 5 mL/day for infants weighing greater than 3 kg.**[85]

TRACE ELEMENTS

Zinc is supplied as zinc sulfate. Serum zinc levels usually approximate the maternal levels at birth and decline over the first week of life. **Zinc supplementation should be considered from the time parenteral nutrition is initiated.**[139] It may be important to initiate zinc intake earlier in neonates with intestinal loss, such as after gastrointestinal surgery.

Copper is supplied as cupric sulfate. Approximately two thirds of stored copper is accumulated during the last trimester. Therefore, a preterm infant may need early supplementation, but a term infant has adequate hepatic stores for at least several weeks. Because copper is excreted through the biliary system, this mineral should be decreased by 50% or removed from parenteral fluids for infants with cholestasis.[85]

Selenium, manganese, and *chromium* salts are commonly provided in long-term parenteral nutrition. **Supplementing very preterm infants with selenium is associated with reduction in sepsis.**[3] Manganese supplementation should not be provided to infants with cholestasis. The chromium dose may be reduced or discontinued in an infant with impaired renal function. Some studies have suggested that manganese and chromium should not be provided in parenteral nutrition due to the degree of cross contamination of these two trace elements in other parenteral nutrition products.[57,139]

Traces of aluminum are incorporated into parenteral solutions during processing.[70] Although aluminum is not known to have a physiologic role in the body, high aluminum levels have been associated with bone disease, encephalopathy, anemia, and hepatic cholestasis and may contribute to neurodevelopmental damage in preterm infants on chronic parenteral nutrition.[18] **Infants with disturbance of renal clearance are at greatest risk for aluminum loading.** Although the U.S. Food and Drug Administration (FDA) requires manufacturers to report the aluminum content of parenteral products, a recent Canadian study found that TPN remains

a significant source of aluminum toxicity.[56] Thirty samples of TPN in the same hospital showed that although the FDA advises the maximum exposure to aluminum be under 5 mcg/kg/day, aluminum contamination in TPN for infants younger than 30 days of age was three times higher than the FDA advisory.[56] **Clinicians should attempt to reduce aluminum intake and should monitor levels for infants at highest risk.**[6]

Table 16.3 outlines a suggested composition for a TPN solution (guideline only). Even in the most knowledgeable hands, accurate calculation and ordering of parenteral nutrition for preterm or ill infants is a complex task. **Online TPN ordering programs are available in many units to assist the clinician with this task. Use of such programs has been shown to decrease order entry errors** and are cost effective.[76,80] The Case Study illustrates considerations in writing orders for TPN solutions.

Preparing the Solution

Solutions should be prepared in the hospital pharmacy under a laminar flow hood in a work area isolated from traffic and contaminated supplies. There should be quality control checks to monitor for sterility breaks in equipment, personnel, environment, and solutions.

Because many additives potentially can be insoluble in combination, a mixing sequence should be established that separates the most incompatible ingredients. Storage increases the risk for microbial contamination; therefore **TPN solutions should be prepared on the day they are needed.**[82] **However, to be able to provide an amino acid infusion to preterm infants immediately after admission, some units maintain a "stock" amino acid solution (10% dextrose with 2 to 3 g of amino acids per 100 mL).**[119]

Administering the Total Parenteral Nutrition Solution

Proper administration of the TPN solution is as important as its preparation in preventing complications. The label on the solution always should be checked to correctly identify the patient, using at least two identifiers, and to verify current formulation order.

TABLE 16.3 SUGGESTED COMPOSITION FOR DAILY INTRAVENOUS NUTRITION REGIMEN

COMPONENT	DAILY AMOUNT
Calories	
Dextrose 3.4 kcal/g	10–15 g/kg
Lipids 2.0 kcal/mL (20%) solution	1–3 g/kg
Protein (6.25 g protein = 1 g N_2)	3.5–4 g/kg
Electrolytes	
Sodium	3 mEq/kg
Potassium	2–3 mEq/kg
Chloride	3–4 mEq/kg
Acetate	3 mEq/kg
Phosphate	2 mM/kg
Calcium	3 mEq/kg
Magnesium	0.3 mEq (range 0.25–0.5 mEq/kg) or 20 mg/kg (range 10–40 mg/kg) of elemental magnesium
Vitamins	
MVI-Ped	
<1 kg	1.5 mL/day
1–3 kg	3.25 mL/day
>3 kg	5 mL/day
Trace Elements	
Zinc (zinc sulfate)	
<3 kg	400 mcg/kg/day
≥3 kg	250 mcg/kg/day (Max of 4 mg/day)
Copper (cupric sulfate)	20 mcg/kg
Manganese sulfate	5 mcg/kg
Chromium chloride	0.2 mcg/kg
Selenium	2 mcg/kg

Standardized procedures must be established to avoid infectious complications from solution contamination. **Solutions on the nursing units may be returned to the pharmacy for additives before hanging, but no additives should be placed in the solution once it is hanging. The bag or bottle**

CASE STUDY

The following case example illustrates considerations in writing orders for total parenteral nutrition (TPN).

History

A male infant born at 26 weeks of gestation at 900 g is now 10 days old and unable to be fed because he has developed necrotizing enterocolitis (NEC). Because there will be a prolonged delay in enteral alimentation, a central vein catheter is placed for TPN. He is currently receiving $D_{10}W$ at 140 mL/kg with maintenance electrolytes. His current weight is 850 g. Serum electrolytes and blood glucose are normal. He is receiving continuous infusion pain medications and vasopressors that are equal to 21 mL/kg/day of fluid. The approach to calculating TPN requirements is as follows.

Caloric Requirement

Because the patient has already had a significant postpartum period without adequate nutrition, achieving caloric intake necessary for growth is a very important part of his care. The infant will probably require 100 kcal/kg or more for tissue repair and growth. We will begin with approximately 60 to 70 kcal/kg **(the birth weight is used until weight gain is established)** and advance the intake daily to reach this level.

Carbohydrate

Initially, a dextrose load just above what has been previously tolerated should be used. Thus the patient may receive $D_{12.5}W$ at approximately 140 mL/kg/day; the volume could vary depending on the infant's fluid requirements. When TPN is ordered, carbohydrate amount should be ordered as glucose infusion rate (GIR) rather than percent dextrose to minimize errors.[85] This represents:

$$12.5\text{g/dl} \times 140\text{ml/kg} = 17.5\text{g glucose/kg}$$

$$17.5\text{g glucose/kg} \times 3.4\text{kcal/g glucose} = 60\text{kcal/kg}$$

Fat

Lipid emulsion should be added to increase the caloric intake, starting with 1 g/kg/day.

$$5\text{mL/kg 20\% lipid emulsion (1.0g)} \times 2\text{kcal/mL} = 10\text{kcal/kg/day}$$

Thus the total nonnitrogen calories on the first day of TPN is 70 (60 + 10).

Protein

Provision of protein nutrition is critical to this preterm infant for growth and to repair damaged tissues. The initial amino acid replacement is 2.5 to 3 g/kg/day.

Electrolytes

The patient should receive maintenance sodium ion (approximately 3 mEq/kg) and potassium ion (2 to 3 mEq/kg) unless there are excessive renal or gastrointestinal losses.

Anions

Balancing anions is the next consideration. The 3 g/kg of amino acids, if given as TrophAmine, adds approximately 3 mEq/kg of acetate to the solution (1 mEq acetate/1 g amino acids). If 3 mEq/kg of potassium is provided as potassium chloride, the solution has balanced anions. Giving 3 mEq/kg of sodium as sodium phosphate provides approximately 2.2 mM/kg of elemental phosphorus:

$$(3\text{ mM } PO_4/4\text{mEq}Na^+) = (3\text{ mEq } Na^+/\text{kg}) = 2.25\text{ mM } PO_4$$

Minerals, Vitamins, and Trace Elements

Calcium, magnesium, phosphorus, vitamins, and trace elements should be ordered at this point. Calcium initially should be started at 2 to 3 mEq/kg/day but may be increased as tolerated with growth to 4 to 5 mEq/kg/day.

Use of an online TPN ordering program may assist the clinician by automating many of these calculations.[76]

TPN Orders

Thus the TPN orders would be written for this patient as follows:

Total Fluids = 140 mL/kg/day
Nutritional Volume = 140 mL/kg/day
Fat Emulsion Order: 1 g/kg/day to run at 0.19 mL/hr for 24 hours
TPN Order: 135 mL/kg/day = 5.1 mL/hr

TPN Order	Ordered Components
Glucose infusion rate (GIR)	4 mg/kg/min
Amino acids	3 gm/kg/day
Cysteine	40 mg/gram of amino acids
Potassium chloride	2.8 mEq/kg/day (2.8 mEq/kg/day K^+; 2.8 mEq/kg/day Cl^-)
Sodium phosphate	2.8 mmol/kg/day (3.7 mEq/kg/day Na^+; 2.8 mmol/kg/day phosphate)
Calcium gluconate	2.8 mEq/kg/day
Magnesium sulfate	0.3 mEq/kg/day
Multivitamin	1.5 mL/day
Zinc	400 mcg/kg/day
Copper	20 mcg/kg/day
Manganese	5 mcg/kg/day (some would not add manganese due to cross contamination of other TPN products)

CASE STUDY

TPN Order	Ordered Components
Chromium	0.2 mcg/kg/day (some would not add manganese due to cross contamination of other TPN products)
Selenium	2 mcg/kg/day

Progression

On subsequent days, the dextrose concentration and lipids would be advanced slowly to increase the caloric intake to requirement as tolerated. The quantity of protein would also be increased to about 4 g/kg/day.

of TPN solution should be changed every 24 hours, and the tubing administration sets should be changed no more frequently than every 72 to 96 hours. Lipid emulsions and tubing should be changed every 12 to 24 hours.[13,15,53,72,81,85] **Tubing for lipid administration should include a 1.2 micron filter. Polyvinyl chloride tubing and IV bags containing phthalates should be avoided to reduce potential toxicity from plasticizers.**[48,120]

Exposure of TPN to light generates peroxides, which induce vasoconstriction and oxidant stress associated with bronchopulmonary dysplasia. Photoprotection of bags, syringes, and tubing used to deliver TPN and lipids may reduce the oxidant effect on the lungs and mesenteric blood flow. Light shielding also appears to diminish oxidative stress and alterations of lipid metabolism, resulting in lower levels of triglyceride and better substrate delivery. Amber-colored tubing may be used for this purpose.[32,52,66,67]

Changes in TPN infusion rates result in changes in glucose delivery to the newborn and may lead to hypoglycemia or hyperglycemia if the glucose homeostatic mechanisms do not adjust fast enough. **Reactive hypoglycemia may occur if the glucose load is abruptly reduced or discontinued,** such as from loss of vascular access or rapid decrease in dextrose concentration or infusion rate.[10] **Parenteral nutrition solutions must infuse at a constant rate via an infusion pump. Infusion rates should not be rapidly increased or decreased. If the parenteral nutrition infusion is suddenly discontinued because of a clotted catheter or accidental removal, an appropriate solution with dextrose should be infused via a peripheral vein and blood glucose should be monitored closely.**

Use of parenteral nutrition may increase an infant's risk for hyperglycemia during surgery. Because rapid fluid infusions may be necessary during operative procedures, the TPN solution should be discontinued and replaced with a physiologic infusate during the perioperative period. After surgery, TPN should be as when the patient is euglycemic, with recent evidence of early postoperative protein tolerance and improved protein balance.[100]

Tapering of the TPN solution occurs as the infant begins to tolerate enteral feedings. When the patient is taking approximately two thirds of the necessary calories enterally, the central line may be removed.

Administering Fat Solution

Rapid infusion of the fat emulsion may exceed its clearance rate from the body and accentuate complications; therefore fat emulsions should not be infused faster than 0.2 g/kg/hr.[7,96] Lipids generally are given through a Y-site connection to bypass the filter in the TPN line or may be given through a separate venous site. However, some hospitals use a combined dextrose, amino acid, and lipid solution known as three-in-one or total nutrient admixture (TNA).[19,110] **A 1.2 micron filter is used with this solution to remove certain drug precipitates (Ca/PO_4), air, and Candida species but is not effective in removing bacteria.** The decision to use TNA should be approached with caution in infants. Lipid emulsions increase the pH of the TPN solution, limiting the amount of calcium and phosphorus that can be delivered because of the risk for precipitation. Precipitates are particularly difficult to detect in TNA, which is a milky solution. High concentration of calcium and low pH of the solution also can disrupt TNA, causing it to "crack" and leading to

separation of oil from the rest of the solution. One must store the admixture emulsion at an ambient temperature below 28° C to prevent coalescence.[74] **When administering lipids to ill infants receiving other infusions, care must be taken to ensure that medications are compatible with lipids or medications must be provided by a separate IV route to prevent precipitation. It should also be noted that IV compatibility is different between lipid products, with mixed oil based lipid emulsions having limited data regarding compatibility with other medications or fluids.**

COMPLICATIONS

Metabolic Complications

GLUCOSE METABOLISM

Hyperglycemia may occur with increased carbohydrate load, especially in ELBW[138] infants who may have inadequate endogenous insulin production or decreased sensitivity to insulin. ***Hyperglycemia*** **is arbitrarily defined as a blood glucose concentration greater than 125 mg/dL (6.9 mmol/L) or a plasma or serum blood glucose concentration greater than 150 mg/dL (8.3 mmol/L).**[59,103] Elevated blood sugar may lead to hyperosmolality and osmotic diuresis, resulting in dehydration. Manifestations include polyuria, glucosuria, and excessive weight loss. Serum sodium is not a reliable measure of serum osmolality if there is hyperglycemia. Direct measurement or estimate by use of the following formula is necessary:

$$\text{Serum osmolality} = (1.86)\ Na^{+} + (\text{BUN}/2.8) + (\text{Glucose}/18)$$

Transient glucose intolerance may be seen with stress. If hyperglycemia occurs without apparent change in glucose infusion, the possibility of sepsis, pain, hypoxemia, intraventricular hemorrhage (especially if the infant is less than 34 weeks' gestation), glucocorticoid administration, or inadvertent increase in carbohydrate administration (mistake in preparation or rate of infusion) should be considered. **Glucose intolerance also may be accentuated during infusions of lipid emulsion, especially in an ELBW infant.** Discontinuation of the lipid infusion without alteration of the carbohydrate load will often eliminate hyperglycemia in this situation. Some ELBW infants remain hyperglycemic even on reduced carbohydrate intakes. Controversy still remains over the use of a continuous insulin infusion to attain adequate caloric intake. A recent *Cochrane* review of neonatal hyperglycemia and insulin treatment showed no improvement in outcomes with continuous insulin infusion compared with reduced glucose infusion rates.[23] **Treatment with insulin varies, but the usual infant dose is 0.05 to 0.1 unit/kg/hour and should be reserved for severe hyperglycemia,** with clinical symptoms and resistance to other medical management changes.[6] **Routine use of insulin to promote growth in the preterm infant is not advised because of side effects.**[14]

Hypoglycemia may result from an abrupt interruption of glucose infusion or excessive exogenous insulin administration. Manifestations of hypoglycemia include apnea, lethargy, jitteriness, and seizures. If these signs occur immediately after an interruption of the TPN infusion, an IV glucose infusion must be initiated at once, followed by close monitoring of the blood glucose to allow appropriate glucose administration. The glucose concentration of the infusate may usually be safely decreased by a glucose infusion rate (GIR) of 2 mg/kg/min every 12 hours. Blood glucose values should be monitored hourly until stable after each change.

AMINO ACID METABOLISM

Hyperammonemia may be seen in preterm infants given excessive protein loads. Hyperammonemia will occur also in an infant with a congenital metabolic disturbance, such as a urea cycle defect, when challenged with an amino acid load. **Hyperammonemia may manifest as somnolence, lethargy, seizures, and coma.** Biochemical screening is necessary to identify this complication before symptoms appear.

Azotemia may occur before hyperammonemia, but blood urea nitrogen (BUN) elevation in the first week of life of a preterm infant is usually associated with dehydration and has not been a reliable marker of protein excess.[41] Therefore, **although daily monitoring is common in the first week, rising BUN is not an indication by itself to decrease the protein load.**

CHOLESTASIS

Infants receiving TPN for more than 2 weeks frequently develop cholestatic jaundice (direct

bilirubin greater than 2 mg/dL).[34,99,117] The risk appears to be greatest for the least mature infants and those receiving the longest period of TPN without enteral feeding. The cause appears to be multifactorial, including lack of bile flow stimulation, delayed enteral feedings, malnutrition, or inflammation after localized or generalized infection.[135] More recently, IV fat emulsions, particularly polyunsaturated fatty acid, are thought to contribute to cholestasis.[124] Serum amino transferases often are normal early in the clinical course. Serum albumin and prealbumin levels usually remain normal. An abnormality in hepatic synthetic function or early rise in isoenzyme levels should lead the clinician to investigate other forms of liver disease.

The differential diagnosis of cholestatic jaundice includes the following:

- **Bacterial sepsis**
- **Congenital viral infection**
- **Postpartum acquisition of cytomegalovirus**
- **Neonatal hepatitis**
- **Bile duct obstruction, such as biliary atresia or choledochal cyst**
- **Galactosemia**
- **Cystic fibrosis**
- Alpha$_1$-antitrypsin deficiency

Management of cholestatic jaundice should include the following (when possible):

- **Increase enteral feedings** as tolerated and decrease proportionately the parenteral nutrition
- **Dose reduction** of soybean-based IV fat emulsion[129,132]
- **Reducing copper** by 50% or eliminating copper
- **Eliminating manganese** from trace minerals in TPN
- **Protecting solutions from light** by covering the bag and IV tubing to reduce levels of light-induced toxic peroxides[33,66]
- **Trial of an agent that induces bile flow**[30,111]
- For infants with short bowel syndrome, controlling intestinal bacterial overgrowth[64]
- Considering an alternative type of fat emulsion[55,75]

LIPID METABOLISM

High-risk infants, including preterm and SGA low-birth-weight infants, may demonstrate intolerance to fat emulsion infusions. Hyperlipidemia may result, causing elevation of triglyceride, FFA, and lipoprotein levels. In extreme cases, lactescence may be visible in serum on a spun blood specimen (increased plasma turbidity). **For screening, a triglyceride level should be checked after initiation of therapy and then weekly and doses adjusted based on results.** Steroid therapy may elevate the triglyceride level.[104] Transient hyperglycemia may result from lipid infusion. This complication is usually dose related and rarely requires treatment.[43]

Competitive displacement of bilirubin by FFA theoretically may increase the risk for kernicterus in preterm infants with hyperbilirubinemia. However, studies of preterm infants have indicated that lipid infusions may be used in jaundiced infants, but attention to the infusion rate and monitoring of FFAs are necessary.[96]

Mechanical Complications

Pneumothorax, hemothorax, hydrothorax, air embolism, thromboembolism, catheter misplacement, cardiac perforation, and tamponade are all recognized complications of Broviac, subclavian, or jugular catheter insertions. Potential mechanical complications of percutaneous central lines include catheter occlusion, accidental dislodgement, erythematous tracking, phlebitis, thrombosis, superior vena cava syndrome, catheter migration, perforation, and catheter entrapment or breakage.[5,20,105,136] (See Box 7.1.) A pleural or pericardial effusion may be blood or chyle or may be a signal that the catheter has eroded into the pleural or pericardial space. The effusion may be the infusate. **Therefore chest x-ray examination is necessary to document correct catheter placement before a hypertonic solution is instilled,** with the superior vena cava the preferred catheter tip location.

The preceding complications may occur at any time while the catheter is present. Documentation of catheter position should be repeated if there is any history of pulling or tension on the catheter or any apparent change in its external position or change in the clinical condition associated with the preceding complications.

Any signs of catheter malfunction require troubleshooting and assessment for potential interventions to salvage the line. Some clinicians will flush a partially occluded line with a thrombolytic agent, such as recombinant tissue plasminogen activator (rt-PA).[65,115] The risk of this practice must be weighed against the benefits of maintaining the central line.

In most cases, if the catheter is a temporary line, it may be better to remove it and place a new line in another site.

Infectious Complications

Infections associated with the central line may occur from contamination of the solution, tubing connections, or hubs. Although organisms may contaminate the solution during preparation, usually **colonization occurs with entry into the line or bag. Intermittent administration of medications, removal of blood samples through the line, or multiple tubing changes provide opportunity for organisms to contaminate the solution.**

Rigid criteria for sterile preparation of the solutions are mandatory (see Preparing the Solution earlier in this chapter).

An in-line 0.22 mcm membrane filter, which is incorporated into the IV tubing for TPN administration, is capable of trapping bacteria and fungi (although not endotoxin) and should help minimize the risk for septicemia from a contaminated IV bag. In addition, filters lessen the risk for an air embolism. An in-line filter setup is available that decreases the number of connections.

Nothing should be added to the TPN solution after it leaves the pharmacy.

AVOIDING LINE COLONIZATION

Use of a dedicated central line team for placement, monitoring, maintenance, and troubleshooting has been found to improve line outcomes and reduce the incidence of neonatal catheter-related bloodstream infections. Line insertion and maintenance bundles, which include hand hygiene, skin antisepsis, maximal barrier precautions, strict adherence to proper hub care, and daily review of line necessity, are also important for avoiding line complications.

In addition, pay attention to the following to avoid line colonization[15,53]:

- When changing IV fluids, one should **avoid bleed-back into the catheter.**
- Line setups should be designed to **minimize number of ports and connections.**[69]
- **Generally, medications should not be given into injection ports in the IV tubing but should be given into a dedicated heparin-locked Y-site entry port instead.** Stopcocks are not recommended.
- **The source of an infection is usually contamination with an organism that has colonized the hub or surrounding skin.** Scrupulous attention to hand hygiene and disinfection of catheter tubing, hubs, ports, and connections by vigorous rubbing with 70% alcohol before tubing changes or entry are critical infection-prevention strategies.[15,68,69]

Dressings are not routinely changed on PICC lines. If the dressing becomes nonocclusive or moistened, the site should be cleaned according to hospital protocol and redressed with a sterile transparent dressing.[53] This should be performed using sterile gloves. The exposed catheter should be remeasured to ensure that it was not inadvertently moved during this process. **Dressings are changed routinely on Broviac, subclavian, jugular, and femoral catheters.** Dressing changes are recommended at least weekly or more frequently if drainage is noted or the dressing is no longer occlusive.

EVALUATING INFANTS FOR INFECTIOUS DISEASE COMPLICATIONS

Central line–associated bacteremia represents an important source of nosocomial infections in the intensive care nursery. The prevalence of this complication varies by unit based on patient demographics including birth weight, gestational age, diagnoses (proportion of surgery and medicine), and care practices.

Bacteremia must be considered in a newborn with a central line in place who exhibits signs of sepsis (e.g., temperature instability, lethargy, poor skin perfusion, increased cardiopulmonary distress, apnea). Some neonatal infections may be treated successfully with the line in place. **However, if the infant remains systemically ill, even if the blood culture result is negative, the central line should be removed.**[22]

Altered immune function by lipid deposition in macrophages and the reticuloendothelial system must be considered in infants with sepsis. ***Malassezia furfur* is a lipophilic, opportunistic fungal organism that may cause sepsis in infants receiving long-term lipid infusions.**[112] Although this organism is infrequently seen, it may contaminate the line and appear as a white film. This organism often will not grow in routine blood culture media. Specific culture techniques are necessary when *Malassezia* is suspected.[35]

Guidelines for management of an infant with a central line in place with suspected sepsis are as follows:

- **The infant should be evaluated for potential sources of infection,** including a general physical examination looking for non–TPN-related sources and inspection of peripheral and central venous sites for erythema.
- **Laboratory assessment** should include (1) complete blood cell count with platelet count and (2) aerobic blood cultures. Other cultures, including urine, tracheal aspirate, and cerebrospinal fluid, may be indicated, based on clinical findings. A blood fungal culture should be considered if the infant has had preceding antibiotic treatment or signs of fungal infection.[16,17,63]
- **A chest x-ray evaluation** should be performed if the infant demonstrates signs of respiratory distress or there is a need to reassess catheter position.
- **Consider decreasing or discontinuing lipid infusion** until the infection has been treated for 24 to 48 hours.[11,108]
- **If the infant is critically ill, the central line should be removed immediately. If the infant is stable, treatment may be considered through the line.**
- **A positive blood culture generally is considered to indicate bacteremia or sepsis in a newborn with a central line in place.** However, the coagulase-negative *Staphylococcus,* an opportunistic organism that is a common cause of catheter-related sepsis, also is normal skin flora and frequently contaminates blood cultures. Use of ancillary diagnostic tools, such as the C-reactive protein levels and complete blood counts, are helpful to distinguish false-positive results from true infections. Some clinicians also recommend obtaining two cultures (two peripheral, or one peripheral and one from the line) before starting antibiotics. If both yield positive results, catheter-related sepsis is confirmed.[83]
- **If bacteremia is documented but the signs of sepsis are improved, the catheter may remain in place while being used for antibiotic treatment.** One should be sure that the antibiotics are compatible with the TPN solution (to avoid stopping the TPN during the antibiotic infusion). A follow-up blood culture and close clinical monitoring are necessary to document that the infection has been treated adequately.

If a central line is pulled because of sepsis, a new central line should not be placed for 48 to 72 hours.

PARENT TEACHING

In-Hospital Total Parenteral Nutrition

Clinicians caring for an ill newborn must be attentive to the involvement and emotional state of the parents. There remain a number of concerns for child abuse, foster placement, and relinquishment among infants who have been cared for in the NICU compared with healthy term newborns, especially when care has been prolonged and complex.

Clinical conditions or policies that promote separation of parents from their infant increase the risk for bonding problems. When a newborn infant cannot be fed orally, an important, normal part of the infant's care is no longer available for the parents. The placement of a central line may be frightening to parents and result in less handling and caregiving. **Infants requiring continuous care, including TPN, should have primary nursing (one regularly scheduled nurse), and the parents should have regular and consistent communication with a primary physician. Care providers should attempt to keep the parents involved in other parts of the infant's care because the parents are unable to feed the infant. Parents should be fully informed about the purpose and appropriate care of the infant's central line so they will feel comfortable handling their infant with the line in place.**[53]

Home Total Parenteral Nutrition

Home parenteral nutrition has been used in infants with congenital intestinal anomalies or after massive bowel resection for NEC. TPN is initiated in the hospital. If growing and otherwise well, the infant may be a candidate for TPN at home. Issues to be addressed include ability and willingness of parents to care for the infant at home, available financial support, adequate home setting, pharmacy support services, and additional skilled nursing care needed. The infant should have a more permanent central line placed as early in the discharge process as possible. Parent teaching should begin early, including verbal and written instruction and hands-on practice and return demonstrations (Box 16.1).

Administration of TPN at home is different from hospital administration of TPN and is typically

BOX 16.1 PARENT/CAREGIVER TEACHING HOME ADMINISTRATION OF PARENTERAL NUTRITION

- Strict handwashing and aseptic handling of tubing connections and hubs
- Use of infusion pump
- Monitoring of site for signs of infection, phlebitis, or leaking
- Troubleshooting for occlusion, leaking, extravasation
- Evaluation for signs of systemic infection
- Emergency response to broken or dislodged catheter, loss of electrical power
- Developmental care: oral stimulation, holding, appropriate play activities
- Dressing care and changes
- Monitoring for signs and symptoms of hypoglycemia
- Securing or taping of line to avoid dislodgement with positioning and handling

managed by a pediatric gastroenterology service in conjunction with a home infusion therapy or pharmacy service. Infants often go home on a cyclic TPN regimen (12 hours/day). An ambulatory pump improves the mobility and flexibility of the parent and infant and allows a more normal life.

Compliance and success with home TPN are greatly increased when the parents understand the need for and the appropriate way to administer TPN and how to troubleshoot and care for the catheter.[54]

17 ENTERAL NUTRITION

LAURA D. BROWN, KENDRA HENDRICKSON, RUTH EVANS, JANE DAVIS, AND WILLIAM W. HAY JR.

Providing optimal nutrition to support term and preterm infants in the neonatal intensive care unit (NICU) continues to be challenging, but it is fundamental for improving infant health. **Recent research has provided new evidence-based guidelines for clinicians that have led to adoption of human milk as the primary enteral feeding for all term and preterm infants. For very preterm infants, it is important to start enteral feeding as soon after birth as possible, advance feedings briskly, and fortify "mature" mother's milk or donor milk.** Other research has emphasized the importance of early enteral feeding for the best support of gastrointestinal (GI) development, somatic growth, metabolic homeostasis, prevention of infection, neurodevelopment, and future health. **Taken together, starting enteral feeding as soon after birth as possible complements parenteral nutrition and allows for expeditious weaning from parenteral nutrition, thereby reducing its potential complications. Early enteral feedings are now accepted as fundamental and not optional in neonatal management.**

This chapter provides an overview of the physiology of fetal and neonatal nutrition and growth, anatomic and functional development of the GI tract, and the fundamentals of neonatal enteral nutritional requirements. Specific details about the assessment and monitoring of growth, feeding strategies and techniques, and the possible complications of enteral feeding of at-risk infants are included. The ongoing nutritional needs of infants recovering from complications of preterm birth and other disorders also are presented, as well as the elements of providing for these needs after hospital discharge.

PHYSIOLOGY

Fetal Growth

Fetal growth is regulated by complex genetic, nutritional, endocrine, environmental, and epigenetic factors.[49,102,271] Maternal factors such as prepregnancy weight, body composition, weight gain during pregnancy, and a diet rich in simple sugars and high in fat directly correlate with placental[274] and fetal size and fetal fat mass.[1,45,140] **Maternal nutrition and the quality of the maternal diet (protein, energy, vitamins, and minerals) are critically important in the regulation of placental-fetal development and therefore directly affect fetal growth.** For example, a growing body of evidence shows that maternal obesity, and even modestly increased maternal body mass index (BMI), increase the risk of perinatal complications, including fetal and neonatal death,[19] increased birth weight,[205,266] and lifelong risk of obesity in the offspring.[210] **Conversely, suboptimal nutrition during pregnancy can result in low birth weight and also increases the risk of metabolic complications for offspring later in life.**[29,242] The growth and function of the placenta strongly determine fetal growth by providing oxygen and essential nutrients.[62,131] Critical fetal anabolic hormones, such as the insulin-like growth factors (IGF-1 and IGF-2) and insulin, are regulated by circulating concentrations of nutrients and are themselves regulators of fetal nutrient uptake and metabolism. Infants with intrauterine growth restriction (IUGR), who have very little glucose supply from the placenta and very little circulating insulin, are among the smallest of infants; infants of gestational diabetic mothers, who respond

BLUE type highlights content that is particularly applicable to clinical settings.

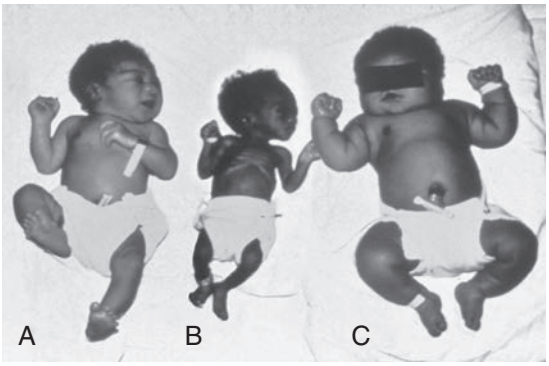

FIGURE 17.1 Fetal nutrition and patterns of fetal growth. **A**, 3200-g birth weight term appropriate-for-gestational age (AGA) infant. **B**, 1500-g term small-for-gestational age (SGA) infant who had intrauterine growth restriction (IUGR). **C**, 5200-g large-for-gestational age (LGA) macrosomic infant of a gestational diabetic mother (IDM). (Courtesy Newborn Service, University of Colorado Hospital, Denver, Colorado [WW Hay Jr].)

to increased maternal glucose concentrations and maternal-fetal glucose delivery with increased insulin secretion, are among the largest (Fig. 17.1). Thyroid hormone also contributes to fetal growth by regulation of oxidative metabolism. Infants with other endocrine deficiencies, such as those resulting from anencephaly, panhypopituitarism, or hypothyroidism, are near normal in age-specific size at birth, indicating a complex interplay between the fundamentally required supply of nutrients to the fetus and the supporting roles of the fetal endocrine milieu that regulate intrauterine growth.

Gastrointestinal Development

Enteral feeding supports GI development in the preterm infant that normally would occur during fetal life. The fetal GI tract is anatomically complete by 20 to 22 weeks after conception. Functional development of the GI tract begins in utero and continues into infancy (Table 17.1). In utero, the fetal intestine is exposed to nutrients and growth factors from the mother, placenta, amniotic fluid, and fetal tissues. The fetal GI tract elongates 1000-fold from 5 to 40 weeks, but strikingly the length doubles during the last 15 weeks of gestation, or from about 25 to 40 weeks, the period of neonatal intensive care of extremely preterm infants. The mean length of the GI tract at 40 weeks is 275 cm. **The fetal GI tract is in communication with the external amniotic fluid environment by 7 weeks postconception.** Growth factors, enzymes, immunoglobulins, and hormones present in amniotic fluid and swallowed by the fetus support early development and functional priming of the GI tract.[183] Fetal swallowing can be observed as early as 11 weeks of gestation.[83]

TABLE 17.1 DEVELOPMENT OF THE HUMAN GASTROINTESTINAL TRACT: FIRST APPEARANCE OF DEVELOPMENTAL MARKERS

DEVELOPMENTAL MARKER	WEEKS OF GESTATION
Gastrulation	3
Gut tube formed, early differentiation of foregut, midgut, and hindgut	4
Gut lumen in continuity with amniotic cavity	7
Growth of intestines into umbilical cord	7
Intestinal villus formation	9
Intestines into abdominal cavity	10

Data from Lebenthal E. The impact of development of the gut on infant nutrition. *Pediatric Ann.* 1987;16:215–216; Montgomery RK, Mulberg AE, Grand RJ. Development of the human gastrointestinal tract: twenty years of progress. *Gastroenterology.* 1999;116:702–731.

The components of the amniotic fluid, including carbohydrates and amino acids, change during development, as does the volume of amniotic fluid swallowed, varying from a few milliliters per day to more than 450 mL/day, or 20% of fetal weight, late in gestation.[104,112] Amniotic fluid contains growth factors that promote intestinal mucosal cell differentiation. Such growth factors and nutrients in the amniotic fluid stimulate production of enteric hormones that act locally to promote further gut development. The timing of the appearance of GI hormones, polypeptides, gut-stimulated neurotransmitters that link central nervous systems conditions of hunger or satiety to GI motor and secretive functions, and digestive enzymes in the fetus is variable, but most are present in the GI tract by the end of the first trimester of pregnancy. Nutrient transport systems are in place by 14 weeks for amino acids, 18 weeks for glucose, and 24 weeks for fatty acids.

After birth, the GI tract must further adapt for mucosal growth and differentiation, peristalsis, digestion of food, and absorption of nutrients. **Some GI functions are "switched on" at birth** (e.g., decrease in intestinal permeability, increase in mucosal lactase activity), regardless of the length of gestation. **Others, however, are intrinsically "programmed" to occur at a certain postconceptual age** (e.g., the onset of peristalsis at 28 to 30 weeks and the coordination of suck, swallow, and breathing at 33 to 36 weeks). Environmental influences, including colonization of the GI tract by bacteria and the introduction of nutrients into the GI tract, also affect postnatal GI and immunologic development.[10,54,167] The microbial population within the GI tract, termed the *gut microbiome,* **is acquired at birth and may even begin to develop in utero with influences from the maternal microbiome via ascending migration from the maternal genital tract.**[260] Many factors influence the development of the gut microbiome, including mode of delivery (vaginal vs. cesarean delivery), early exposure to antibiotics, maternal health conditions (e.g., diabetes or obesity), and composition of the diet (breast milk vs. formula, high- vs. low-protein formulas, cow vs. human milk supplements, degree of protein hydrolysis, and inclusion of long-chain polyunsaturated fatty acids [LC-PUFAs], particularly docosahexaenoic acid [DHA]).[52,172] **Importantly, evidence shows that establishment of the gut microbiome during infancy may influence the development of obesity later in life, among other noncommunicable diseases.**[232,253]

Infants born before term have both anatomic and functional limits to the digestion and tolerance of enteral feedings. Neurologic maturation is important not only for coordination of sucking, swallowing, and breathing during feeding but also for GI motility. **Peristalsis in the esophagus is immature and bidirectional in the preterm infant, with forward movement of food to the stomach developing only near term.**[128] **Abnormal esophageal peristalsis and transient relaxations of the lower esophageal sphincter muscle likely contribute to the common problem of *gastroesophageal reflux (GER)* seen in preterm infants. Enteral feeding, however, promotes the ongoing maturation and development of the GI tract in both term and preterm infants.**[51]

Intestinal motor activity in the preterm infant is immature and disorganized compared with term infants. Term infants have distinct fasting phases of GI quiescence and nonmigrating motor activity followed by migrating motor complexes. Very preterm infants have absence of migrating motor complexes and prominence of nonmigrating clusters rather than mature coordinated peristalsis. Additional suck-swallow incoordination necessitates tube feedings in very preterm infants. After feeding, term infants show a dramatic increase in the intensity of motor activity that is not observed in preterm infants. **A measure of GI motility is provided by the passage of stool within 24 hours of birth in more than 95% of full-term infants; however, the more preterm the infant, the greater the delay in passing the first stool. Initial gastro-anal transit time is 2 to 5 days in extremely low-birth-weight (ELBW) infants, but only 12 to 24 hours in term infants.**[38] **Passage of meconium is delayed in about 20% of infants less than 1500 g birth weight, and is delayed up to 10 days in infants less than 1250 g birth weight.**[133,177,270] **Once enteral feedings are established, however, gastric emptying rate and gastro-anal transit time are similar in term and preterm infants.**[194,265] Coordinated, mature GI motility and peristalsis with feeding develop in the preterm infant between 33 weeks and term.

Digestion occurs in the lumen of the intestine. Nutrient absorption occurs at the enterocyte interface (microvillus membrane [MVM]). **Protein digestion and absorption are remarkably efficient in the preterm infant at 26 to 30 weeks of gestation** despite the fact that *enterokinase,* a rate-limiting enzyme in the activation of pancreatic proteases via activation of *trypsinogen,* has only 6% of the activity found in the term newborn and 10% of adult activity. Reduced enzymatic activity and low gastric acidity may delay protein digestion, but usually only temporarily. Nevertheless, this potential delay has led to some use of partially hydrolyzed protein formulas in very preterm infants. **Such formulas may slightly reduce gastro-anal transit time (e.g., 10 vs. 12 hours), but these formulas do not have the total protein or mineral content needed for rapidly growing very preterm infants and should be used only with caution.**[38,180] After luminal hydrolysis, peptides are further hydrolyzed at the MVM. Some amino acids and oligopeptides are absorbed via transporters. Some peptides that are absorbed intact are hydrolyzed by intracellular peptidases that further aid in protein digestion. MVM and intracellular peptidases mature early in gestation.

Carbohydrate absorption is limited initially by a relative deficiency of lactase, which splits lactose into glucose and galactose. **Lactase in the infant of less than 34 weeks' gestational age is present at only about 30% of the activity found in the normal term infant, although lactose intolerance is rare in these infants, particularly when they are fed human milk.**[248] **Lactase functional activity increases with feeding and approaches term levels by 10 days after birth in most preterm infants.**[249] Human milk feedings increase lactase activity more than formulas. Twenty percent of dietary lactose may reach the colon in neonates. Lactose lowers fecal pH, a beneficial effect in that it promotes *Bifidobacterium* and *Lactobacillus* proliferation.[119] Lactose in mother's milk also promotes butyrate formation in the colon. Butyrate increases colonocyte proliferation and differentiation and tightens interepithelial junctions.

Preterm infants malabsorb 10% to 30% of dietary fat because of a small bile acid pool size and relative lack of pancreatic lipase.[170] Bile acid synthesis and reabsorption are lower in preterm infants than in term infants. Duodenal bile acid concentrations are usually low for a few weeks after very early preterm birth. Some compensation is provided by lingual and gastric lipases, as well as the lipase present in human milk. Combined with gastric lipase, milk bile salt–stimulated lipases (BSSLs) facilitate lipid hydrolysis and prepare intraluminal lipid for further cleavage by pancreatic enzymes. BSSLs are higher in milk of mothers delivering preterm than in those delivering at term.[111] Bile salts are not necessary for digestion or absorption of medium- and short-chain fatty acids. **Despite relative deficiencies in many enzymes important in nutrient processing, the preterm infant usually can digest and absorb complex nutrient mixtures such as human milk quite effectively.**

Postnatal Growth of Preterm Infants

After birth, usual nutritional regimens, even when provided more aggressively, fail to produce growth rates in preterm infants that mimic normal rates of intrauterine growth, the accepted goal of nutrition for the preterm infant.[82] **A variety of complications contribute to this growth failure, but the primary problem is that most preterm infants are fed less protein and calories immediately after birth than are needed to support normal fetal rates of protein accretion and body growth.** In addition, the preterm infant is exposed to environmental factors that increase energy expenditure, including low relative humidity and radiant and convective heat losses, as well as energy-consuming demands of breathing, resistance to gravity, and the processes of digestion, absorption, and synthesis of nutrients into body structure. Stress-induced hormones that are catabolic in sick infants, particularly corticosteroids and catecholamines, limit the production and action of anabolic growth factors, particularly insulin and IGFs, further preventing normal rates of growth and weight gain at rates comparable to those of healthier infants of the same gestational age.[225] Overall, however, **even in sick or physiologically unstable infants, the principal factor causing postnatal growth failure and unfavorable neurodevelopmental outcome is delayed and inadequate intake of protein and energy.**[82,88,90]

After birth, all infants lose excess extracellular salt and water. Term infants usually lose 5% to 8% of birth weight by the third day of life. In ELBW preterm infants (<1000 g birth weight), normal diuresis and common fluid management strategies to limit fluid overload over the first 10 to 14 days of life usually produce a net loss of body weight. Such infants may lose 8% to 15% of birth weight, though fluid management among institutions varies considerably. **Currently, mild fluid restriction that does not lead to dehydration appears safe and might decrease the incidence and/or severity of a patent ductus arteriosus (PDA), necrotizing enterocolitis (NEC), and bronchopulmonary dysplasia (BPD), and even reduce the risk of death.**[30,200] Relative fluid restriction during the later stages of enteral feeding can be accomplished in milk-fed infants by concentrating nutrients in milk with human milk fortifiers or preterm or postdischarge formula powder. Deficits accumulated daily during early neonatal life may take weeks to months to replenish. **Serial measurements of body length and head circumference are particularly useful in the newborn period because linear growth and head circumference represent lean mass growth and have the potential to help predict neurodevelopmental outcome.**[216] Employing validated methods, such as recumbent length boards, and training staff on correct technique will improve the validity of these measurements (Box 17.1).[72] More recent methods to assess body composition in the neonate include dual x-ray absorptiometry (DEXA), air displacement plethysmography, magnetic resonance imaging (MRI), anthropometric prediction equations, and isotope dilution, all of which partition new tissue accrual into water, fat, and lean body mass components.[79] More sophisticated assessment of body composition would define needs for additional specific nutrients (protein, lipids, carbohydrates) for body growth (even during the early postnatal period of fluctuating water weight). However, these methods are not usually available for routine clinical use and are used primarily as research tools.[229] **Thus assessment of postnatal growth is limited to following the trajectories of height, weight, and head circumference and calculating BMI or Ponderal index (weight in grams × 100/length in centimeters^3)** (Fig. 17.2). Recent studies demonstrate that BMI correlates with body fat composition, though with limited accuracy.[95,139,254] Improving the capacity to accurately assess body composition is fundamental for determining optimal nutrition, because with current feeding practices and nutritional regimens, preterm infants develop less lean tissue than the normally growing fetus in utero. Body fat content varies among studies, from similar fat mass compared with infants born at term to excess body fat, with the excess distributed more to the intra-abdominal region.[134]

Assessment of Growth and Nutritional Status

The generally accepted goal of postnatal nutrition for preterm infants is to achieve and maintain the normal rate of intrauterine growth (Fig. 17.3). Many growth curves have been developed from anthropometric measurements taken at birth in populations of infants born at different gestational ages.[93,201] The most recent reference growth charts are based on cross-sectional data from nearly 400,000 births in the United States[201] and from nearly 4 million births worldwide.[92] **Expected weight gain trajectories are remarkably consistent among many standard growth charts, and, on average, the expected weight gain in the appropriately growing preterm infant is approximately 15 to 20 g/kg/day.** Because preterm birth is not a normal outcome, cross-sectional anthropometric measurements obtained at birth may underestimate expected fetal growth rates.[50,142,206] The Intergrowth 21st study group and the World Health Organization have produced standard growth charts based on prospective serial ultrasound measurements of fetuses who were born to healthy women with low-risk pregnancies from across the world.[142,206] (Fig. 17.4). A subpopulation of infants from the Intergrowth 21st study who were born preterm was used to generate postnatal growth standards for preterm infants.[206,267] **Regardless of the growth chart used, slow growth rates and large losses in the change in both weight and length z-scores from birth to NICU discharge should be avoided as they are predictive of poor neurodevelopment.**[88,99,237,244,283]

Good methods are lacking to assess nutritional adequacy over time in very small infants. **Rates**

BOX 17.1 GROWTH MONITORING

1. *Weight* is subject to large variations based on fluctuations in fluid balance (e.g., presence or absence of edema, congestive heart failure, renal failure) and attached equipment (e.g., intravenous lines and boards, endotracheal tubes). Infant weight should be measured daily as follows:
   a. Use the same scale and weigh infant naked or using supportive weighing method as possible. Supportive weighing, or swaddled weights, help ensure an infant's physiologic and behavioral stability during the weighing procedure. Remove "attached" equipment if possible, or weigh similar items separately and subtract from total weight. Swaddled weights are equal to the naked weight after the weight of the diaper and blanket are subtracted. Unswaddled weights still can be used to improve accuracy for very small infants or if swaddling puts the infant at risk or interferes with the infant's care needs. In-bed scales are useful for ELBW infants or infants who become unstable with handling. An electronic scale that averages several measurements reduces movement artifact and may be useful for active infants.
   b. Reference standards for the weights of nursery equipment (e.g., diapers, intravenous boards, tubing, endotracheal tubes) should be available for nursery use.
   c. Weigh the infant at the same time daily, preferably before a feeding.
   d. Record the infant's weight, the time of weight measurement, and the scale used on the chart. Record energy (calories) and fluid intake on the same chart. This information combined with biochemical parameters (e.g., serum electrolytes, hemoglobin, albumin) and the physical examination provides the best overview of the infant's nutritional status. Once weekly, a daily weight should be plotted on the appropriate preterm or term growth chart. Weekly review of the infant's weight change provides useful information on trends in overall growth or weight loss that may be overlooked in the daily charting.
2. *Crown-heel length and head circumference* are measured and recorded on admission and at least weekly thereafter. Accurate length measurements are difficult to obtain without special equipment, such as a length board, but accuracy can be improved by repeated measurements and use of the tonic-neck reflex to straighten the hip and knee. Length and head circumference monitoring are just as important as, if not more important than, weight measurements. Increase in length reflects lean mass growth, and head circumference is used as an indicator of brain growth. Both measurements are predictors of neurodevelopmental outcome.[216,228]
   a. To measure the crown-heel length, two people are required for measuring patients using the statiometer: one registered nurse (RN) and one assistant. The assistant may be another RN, another NICU care team member, or a parent. Position the infant supine on the board with his or her head at the stationary head piece and the feet facing the movable foot piece. The assistant positions infant's head against the head piece by securing the head and shoulders between his or her hands. The top of the patient's head should touch the stationary head piece. The eyes should be facing straight up. Avoid hyperextension of the patient's neck. The RN straightens the infant's body along the center of the board. Apply gentle pressure to patient's knees, and hold the legs in place. Using a free hand, slide the foot piece until it is positioned firmly against the infant's heels. The toes should point directly up. Measurements with one lower limb extended may result in less patient discomfort than when both lower limbs are extended.[214] Repeat three times.
   b. Head circumference is obtained using a paper or soft tape measure. Record the largest measurement obtained with the tape placed over the frontal, parietal, and occipital prominences.
3. *The Ponderal index* (or weight-length index; see Fig. 17.2) is used to assess "quality" of growth. The Ponderal index is calculated as the weight in grams multiplied by 100, divided by the cube of the length in centimeters. True organ growth and tissue accretion are accompanied by increases in both weight and length and can be evaluated partly using the Ponderal index.
4. *Biochemical monitoring* of the growing infant may include periodic measurement of serum electrolytes, calcium, phosphorus, alkaline phosphatase, total protein, albumin, and hemoglobin. These data can be used to help prevent specific deficiencies in the diet, such as hyponatremia in preterm infants with excessive renal solute losses or hypophosphatemia with increased alkaline phosphatase as seen in rickets and osteopenia.

of change in anthropometric measurements provide some retrospective information, but they do not specify what an infant needs to maintain a normal growth rate (see Box 17.1). Too often, growth charts simply document continuing and, all too often, worsening growth, highlighting the failure to provide adequate nutrition during the previous days to weeks. Indirect calorimetry offers some advantage for determining at least the energy requirements for growth, but instruments that are clinically practical and sufficiently accurate to quantify nutrient

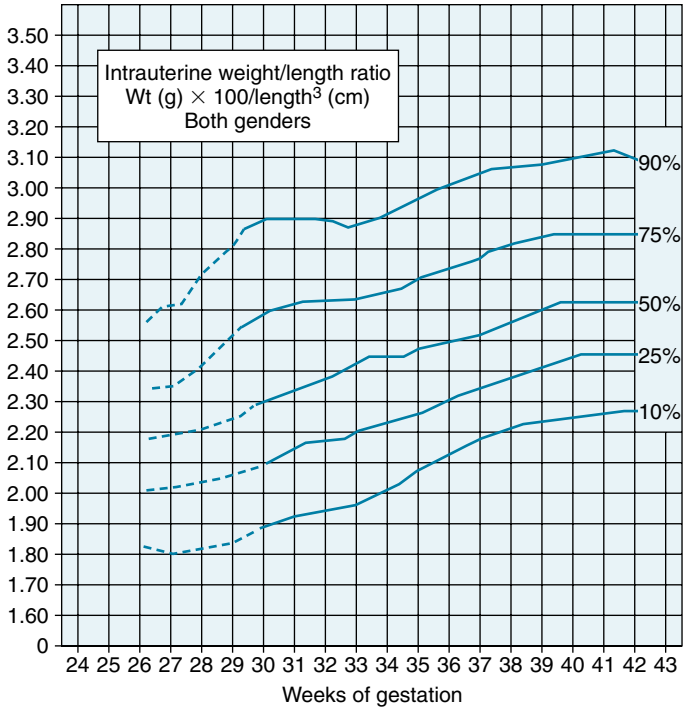

FIGURE 17.2 Ponderal index. (From Lubchenco L, Hansman C, Boyd E. Intrauterine growth in length and head circumference as estimated from live birth at gestational ages from 26 to 42 weeks. Reproduced with permission from *Pediatrics* 1966;37:403–408. © American Academy of Pediatrics.)

metabolism in tiny infants are not yet available. Similarly, application of stable isotope methodology to measure utilization and oxidation rates of individual nutrients remains confined to research studies in large medical centers with sophisticated mass spectrometry facilities. Evaluation of an individual infant's immediate nutrient requirements and responses to the administration of different mixtures and amounts of nutrients remains an elusive but still necessary goal.

NUTRITIONAL REQUIREMENTS FOR ENTERAL NUTRITION

Nutritional requirements should be considered in general categories: energy (or calories), protein, carbohydrate, fats, minerals, and vitamins. Water requirements and limits must also be considered when designing nutrition support strategies. The source, complexity, and constituents of these nutrients are important, as well as the route of administration. **Box 17.2 lists commonly used nutritional conversion factors and formulas.** See Chapter 16 for parenteral nutrition and Chapter 18 for breastfeeding.

Energy

Energy is necessary for all vital functions of the body at the molecular, cellular, organ, and systemic levels. **Preterm infants have minimum energy requirements for basal metabolism and growth, but also have requirements for unique physiology and metabolism that influence energy expenditure.** These include their smaller body size with increased surface area, postnatal age, physical activity, dietary intake, variable environmental temperatures, energy losses in the stool and urine, and clinical conditions and diseases, as well as changes in body composition. **Both energy and protein are necessary to produce normal rates of growth.** Carbohydrates (primarily glucose) are principle sources of energy for the brain and heart until lipid oxidation develops over several days to weeks after birth.[113] **Many preterm infants are energy deficient early in their postnatal life. This is largely a result of insufficient amounts of glucose and lipid with early intravenous (IV) nutrition and, later, energy deficits as IV nutrition is weaned before enteral nutrition has been increased sufficiently to meet energy requirements.** Thus cumulative energy deficiencies (and protein) are common and may contribute to slower postnatal growth rates.[82,115]

BOX 17.2 COMMONLY USED CONVERSION FACTORS AND FORMULAS

Energy
- 1 kcal = 4.184 kJ

Gross energy (kcal/g)
- Protein = 5.65
- Carbohydrate = 3.95
- Fat = 9.25

Metabolizable energy (kcal/g)
- Protein = 4
- Carbohydrate = 4
- Fat = 9

Protein
- Total protein (g/dL) = total nitrogen (g/dL) × 6.25

Vitamins
- 1 International unit vitamin A = 0.3 retinol equivalent = 0.3 mcg retinol = 1.8 mcg beta-carotene
- 400 International units vitamin D = 10 mcg vitamin D
- 1 International unit vitamin E = 1 mg DL-α-tocopherol

Minerals
- 1 mEq Na = 1 mmol Na = 23 mg Na
- 1 mEq K = 1 mmol K = 39 mg K
- 1 mEq Cl = 1 mmol Cl = 35 mg Cl
- 2 mEq Ca = 1 mmol Ca = 40 mg Ca
- 1 mmol P = 31 mg P
- Osmolarity (mOsm/L) = Osmolality (mOsm/kg H_2O) × kg H_2O/L solution
- Renal solute load (mOsm/dL) = [Protein (g/dL)] × 4 + [Na + K + Cl (mEq/dL)]
- Potential renal solute load (mOsm/dL) = [Protein (g/dL)] × 5.7 + [Na + K + Cl (mEq/dL)] + [P (mg/dL)/31]

Energy requirements are determined by an infant's total energy expenditure, energy excretion, and energy stored in new tissue as growth. Total energy expenditure can be subdivided into contributions of basal metabolic rate, activity, thermoregulation, and the energy costs of digestion and metabolism. Energy excretion is composed of fecal and urinary losses, as well as heat lost by radiation and evaporation. **Caring for and feeding infants under thermoneutral temperature conditions in humidified incubators, starting at admission to the NICU, substantially decreases energy expenditure in preterm infants. Reducing unnecessary care episodes to keep the incubator temperature and humidity constant and exposing the infant's skin when under radiant warmers helps ensure maintenance of thermoneutral conditions.** Estimates of energy requirements for growing preterm infants are shown in Table 17.2. The large range of these estimates reflects the variability of infant activity and environmental conditions. In general, the infant's muscle activity does not contribute much to total energy expenditure.[261] Most preterm infants also are tightly swaddled and do not move much.[120]

Caloric requirements for the healthy term breastfed infant average 90 to 100 kcal/kg/day.[116] Formula-fed term infants often receive more, up 100 to 110 kcal/kg/day, because of the greater caloric content of term formula, especially in comparison with breast milk, and particularly as the energy content of milk declines over longer periods of lactation. Concern that formulas had less efficient nutrient absorption from the GI tract contributed to formula manufacturers ensuring higher energy contents. **The higher energy content of formula, paired with volume intakes that are often higher with bottle feeding, can lead to greater fat mass gain over the first few months of life in formula-fed term infants.** More recently, energy content in some term formulas has been reduced to 19 kcal/oz to prevent excess fat mass accumulation and to match the energy intake (both fat and carbohydrate) of breastfed infants.

Caloric requirements are 110 to 130 kcal/kg/day for enterally fed very-low-birth-weight (VLBW) preterm infants and 85 to 95 kcal/kg/day for parenterally fed VLBW preterm infants because of better efficiency.[113] **Increased energy requirements can be anticipated during sepsis, acute and chronic respiratory illness, and recovery from surgery (Fig. 17.5). Daily caloric intake should be calculated for each infant in the NICU. A useful approach for calculating caloric intake is shown in Box 17.3.**

Protein

Protein accretion (net protein balance) is fundamental for normal growth. The amounts and types of protein necessary for optimal growth in preterm infants have been difficult to establish. Metabolic balance studies, fetal animal protein and amino acid metabolism, and human fetal body composition growth studies support a **need for higher protein intakes in the growing preterm infant**

than in the term infant. Throughout the normal period of breastfeeding, the concentration of protein in human milk decreases; however, the preterm infant's need for protein continues to be higher than in the term infant.[17] Human milk is highly variable in its protein and lipid concentrations.[78] Unfortified human milk is not adequate to meet the recommended goals of 3.5 to 4 g/kg/day for preterm infants because of their higher fractional protein accretion rates.[7,14,55]

TABLE 17.2 ESTIMATED DAILY ENERGY REQUIREMENT (kcal/kg) FOR ENTERALLY FED PRETERM INFANTS

FACTOR	AMERICAN ACADEMY OF PEDIATRICS	EUROPEAN SOCIETY OF GASTROENTEROLOGY AND NUTRITION	RANGE
	ENERGY EXPENDITURE

FIGURE 17.5 Daily nutritional requirements and changes with illness. *CHD,* Congenital heart disease; *CHF,* congestive heart failure; *CLD,* chronic lung disease; *IUGR,* intrauterine growth restriction; *NEC,* necrotizing enterocolitis; *RDS,* respiratory distress syndrome; *SBS,* short bowel syndrome. (Modified from Thureen PJ, Hay WW Jr. Conditions in preterm infants requiring special nutritional management. In: Tsang R, Lucas A, Uauy R, Zlotkin S, eds. *Nutritional Needs of the Preterm Infant: Scientific Basis and Practical Guidelines*. Baltimore, MD: Williams & Wilkins; 1993.)

In one study, preterm infants receiving protein and energy supplementation during enteral feedings had increased gains in length and head circumference in relation to increased protein intake. In the same study, extra energy (149 kcal/kg/day) increased primarily weight and triceps skinfold thickness, demonstrating the need for protein to grow bone, brain, and lean body mass, whereas excess energy leads primarily to increased fat deposition (Fig. 17.6).[136,137] These benefits unique to protein and energy have since been supported by Cochrane reviews of the literature.[94,149,150]

Preterm infants, especially those who develop growth failure in the NICU, are at risk for abnormal neurodevelopment.[98] Insufficient nutrition in the preterm infant, principally of protein, results in growth restriction of the brain (neuronal number, axonal length, dendrite growth, and synapse formation) **and deficits in later behavioral** (interactive behavior) **and cognitive outcomes** (learning and memory).[41,100] When protein and energy intake is inadequate, long-term benefits to developmental outcome with particular feeding strategies are not observed.[250,251] **Preterm infants maintained on diets fortified with protein and energy, however, have shown improved brain growth** (larger brain regions shown by MRI studies) across a broad range of gestation, **and improved neurodevelopmental test scores in early life.[35,240] Increased provision of protein and calories during the first week of life uniquely increases fat-free mass gains, but not fat mass gains (which happen more commonly**

BOX 17.3 CALCULATING DAILY CALORIC INTAKE (kcal/kg/day)

Conversion Factors

20 kcal/oz = 0.67 kcal/mL
24 kcal/oz = 0.80 kcal/mL
1 kcal = 1 calorie
1 oz = 30 mL

Calculation

1. Add total daily feeding intake (in mL).
2. Divide total intake (mL) by the infant's weight (kg). This equals enteral intake in mL/kg/day.
3. Multiply mL/kg/day intake by kcal per ounce of feeding.
4. Divide by 30 mL.
   This equals enteral intake in kcal/kg/day.

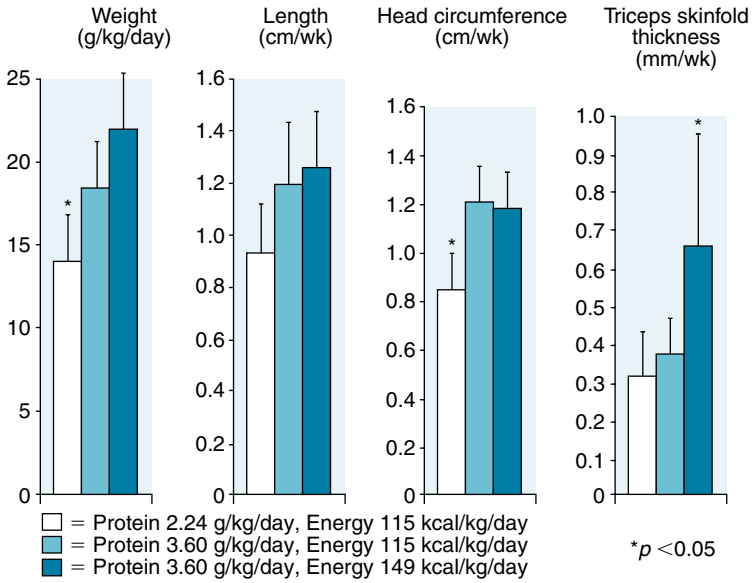

FIGURE 17.6 Growth rates with varying protein and energy intakes. (From Kashyap S, Schulze KF, Forsyth M, et al. Growth nutrient retention and metabolic response in low-birth-weight infants fed varying intakes of protein and energy. *J Pediatr.* 1988;113:713–721; Kennaugh JM, Hay WW Jr. Nutrition of the fetus and newborn. *West J Med.* 1987;147:435–448.)

with later periods of high energy intakes along with the protein).[227] Some evidence also indicates that longer periods of maintaining higher protein intakes will increase brain growth.[219] Larger total brain tissue, white matter, and cerebellar volumes at term-equivalent age are associated with better neurodevelopment in infants born moderately and late preterm. Brain volumes may be an important marker for neurodevelopmental deficits described in moderate and late preterm children.[59]

Neurodevelopmental outcome in preterm infants is unequivocally improved when they are fed human milk.[165] **Most studies indicate that such development is supported better when mature milk or donor milk is supplemented with protein and energy.** Improvements in neurodevelopmental outcome extend into adolescence. This was demonstrated in 17-year old former preterm infants whose brain size, caudate nucleus volume, and intelligence quotient (IQ) were directly associated with protein and energy intake during the postnatal period.[121,124,125] The slower weight gain of preterm infants fed exclusively with breast milk appears to be caused by a deficit in lean mass, likely reflecting lower protein intake. Whether this pattern persists into childhood, is altered by breast milk fortification or later diet, or relates to functional outcomes are important research questions.[162] **Higher protein intakes have been shown to lead to greater length gain. Linear growth is associated with improved neurodevelopment,** including increased cognitive, language, and motor scores, higher IQs, and less cerebral palsy.[28,155,226] **Gains in fat-free mass also are associated with improved neurodevelopment,** including higher motor and cognitive scores, faster speed of brain processing and improved working memory, and faster speed of processing and IQ in preschool.[215,227,239] A current challenge in nourishing the preterm infant is that higher energy intakes required to achieve linear growth also resulted in increased fat mass, a risk for later obesity.[27,47]

Human milk from an infant's own mother is unique and the preferred source of protein for that newborn. There are times when mother's own milk is not available. In such situations, **donor human milk (DHM) is a valid alternative.** DHM is a viable substitute when obtained from established milk banks that follow protocols established by the Human Milk Banking Association of North America (www.hmbana.org).[34,115] Human milk contains whey-predominant protein (whey:casein ratio of 70-80:30-20), whereas cow's milk has a whey:casein ratio of 18:82. Whey protein is particularly rich in essential and conditionally essential amino acids. **Milk and colostrum expressed from mothers of preterm infants is higher in protein than milk from mothers of term infants, but both have higher protein concentrations at the onset of lactation than later during full or mature lactation.**[222] **Nonetheless, fortification of preterm maternal milk with protein (and calcium, phosphorus, sodium, potassium, and lipid) is necessary to promote growth rates approximating those of normal human fetuses, particularly in ELBW and VLBW preterm infants (Table 17.3).**[4,233] Products to fortify human milk commonly used in US NICUs include Enfamil Human Milk Fortifier (Mead Johnson Nutritionals, Evansville, IN) and Similac Human Milk Fortifier (Abbott Nutrition, Columbus, OH), which provide an additional 1.4 g/dL of protein. Current human milk fortifiers contain partially hydrolyzed protein formulations to improve digestion, improve absorption, and reduce the risk of bovine protein-induced inflammation in the intestine. A human milk–based fortifier, Prolact+ H^2MF (Prolacta Bioscience, Monrovia, CA), also is available. Recent studies indicate that an exclusive human milk–based diet for preterm infants reduces the risk of NEC.[168,211]

A liquid protein supplement may be required to meet protein requirements in preterm infants.[166,181] **Enteral protein intakes of 3.2 to 4.2 g/kg/day are recommended for preterm infants born at 29 to 34 weeks of gestation. However, enteral protein requirements are 4.0 to 4.5 g/kg/day for less than 29-week ELBW infants** to meet the higher protein synthesis and growth requirements at this stage of gestation and to compensate for accumulated protein deficits and stool losses. From a practical perspective, a rough estimate for human milk protein content is ~1.4 g/dL at postnatal week 2 to 3 and ~1.1 g/dL at postnatal week 4 and beyond. Thus, a milk intake of 150 to 160 mL/kg/day of 24 kcal/oz feedings would provide 4.2 to 4.5 g protein/kg/day at week 2 to 3, but only 3.8 to 4.0 g protein/kg/day at week 4 and beyond, which would not support optimal protein balance and lean body growth. A reasonable approach, therefore, would be to supplement ELBW infants with liquid protein, which would add 0.45 g protein/kg/day. **Liquid protein supplementation**

BOX 17.4 INDICATIONS FOR USING HIGH-PROTEIN PRETERM FORMULAS

- Weight <1500 g
- Fluid-/volume-restricted infants
- Promotion of wound healing
- Cumulative deficit of protein intake
- Inadequate growth in length and/or head circumference
- Unfortified human milk feeds (e.g., direct breastfeeding or use of donor milk)

should be considered in infants less than 1000 to 1250 g after they reach approximately 24 weeks and day of life 21 to increase enteral protein delivery to the higher end of the protein goals. It may be added sooner with DHM because of the even lower donor maternal milk protein, or if there are concerns for poor linear growth. **Liquid protein supplementation should be stopped at 34 to 35 weeks when protein requirements decline. When human milk is not available, "high-protein" preterm formulas are available that contain higher protein contents than standard preterm formulas (3.3 to 3.6 g/100 kcal) and are recommended to increase protein delivery for ELBW infants[48] (see Table 17.3) (Box 17.4). Higher BUN values are often found in such infants, but this should not indicate excess protein intake, as it is an appropriate metabolic response of increased protein oxidation producing ammonia and hepatic detoxification of ammonia to urea.**[7,146]

The amino acid profile in the newborn diet is as important as the amount of protein provided. **Growth rate of lean body mass is determined directly by the intake of the essential amino acids.** Conditionally, or developmentally, essential amino acids (those that are uniquely required in larger amounts at certain developmental stages and cannot be synthesized at sufficient rates for requirements) also are important to the infant, especially if preterm. Normal growth, energy metabolism, and immune function depend on appropriate availability of these amino acids. Particularly in the rapidly growing infant, growth requirements may not be met by the relatively limited intake of essential amino acids common with most current nutritional regimens or by the limited biosynthesis of conditionally essential amino acids.

Fat

Human neonates are unique among neonatal mammals in having a relatively high white fat content of 12% to 18% of body weight at term. The term infant also has stores of brown fat, which are necessary for neonatal thermogenesis. **In utero fat deposition occurs predominantly during the last 12 to 14 weeks of gestation,** and fat accretion in adipose tissue adds increasingly large caloric requirements to the lean tissue growth. **Infants born preterm before fat deposition has occurred have insufficient fat stores for use as energy and for thermogenesis.** Dietary fats also are important to sustain growth. Once protein intake is sufficient to promote net lean body accretion, however, additional energy primarily produces more body fat, which increases almost linearly at energy intakes greater than 80 to 90 kcal/kg/day in normal, healthy preterm infants. **Rapid gains in adiposity have the potential to produce later-life obesity, an increasingly recognized risk of excessive energy intake.**[113]

Dietary fats also provide essential fatty acids (EFAs) and promote the absorption of fat-soluble vitamins. Newborn infants absorb fat less efficiently than older children. Preterm infants demonstrate even greater deficiencies in fat digestion and metabolism. Pancreatic lipase and bile acids are less available for fat digestion and absorption. Lingual and gastric lipases, present in greater amounts in term newborn oral-pharyngeal secretions than in the preterm infant, compensate for deficient pancreatic lipase, as does mammary gland lipase if the infant is receiving breast milk, but even these are reduced in the preterm infant. **Current recommended intakes for dietary fat consist of 40% to 52% of total calories (4.4 to 5.7 g/100 kcal).**

LC-PUFAs are essential for normal growth and development, particularly of the retina and brain (especially affecting cognition). LC-PUFA supplementation, therefore, has been a topic of much discussion and research in recent years. Of particular interest are the n-3 and n-6 EFAs, alpha-linolenic acid (ALA) and linoleic acid (LA), and their metabolites, docosahexaenoic acid (DHA) and arachidonic acid (ARA), respectively.[171] **Both term and preterm human milk contain considerable quantities of ALA. The term infant can synthesize DHA from its precursor ALA, but whether the synthesized amount is sufficient**

for growth and development in preterm infants remains uncertain. Human milk also contains preformed LC-PUFAs, but the DHA content of human milk is highly variable, ranging from ~0.08% to ~0.2% in the US, to ~0.3% in other parts of the world and in formulas.[20] Nevertheless, **current diets for very preterm infants do not provide enough EFA to match normal fetal development.** For example, fetal white adipose tissue accumulation of n-3 fatty acids during the last trimester is about 45 to 65 mg/day, mostly as 22:6n-3 or DHA. Human milk has on average 3.7 g fat/dL with 0.2% to 0.4% of fatty acids as 22:6n-3, so a 1-kg preterm infant fed at full enteral feeds of 180 mL/day would get only 13 to 25 mg 22:6n-3/day, clearly below normal in utero accretion rates. As a result, **the current diet for preterm infants is deficient in DHA, but the long-term significance of this deficiency is not known, or how these infants would develop if fed to sufficiency.**[152]

In an effort to make formula more like human milk, manufacturers in the United States have added DHA and ARA to both term and preterm infant formulas. This also has made clinical cases of EFA deficiency relatively rare. When severe and prolonged enough, EFA deficiency can lead to a clinical syndrome consisting of dermatitis (especially in the perianal region), thrombocytopenia, infection, and failure to thrive. The metabolic profile is characterized by an increased triene/tetraene ratio (increased nonessential trienoic:ETA 20:3ω9 to decreased essential tetraenoic:AA 20:4ω6).[109]

LC-PUFA supplementation is thought to be safe for both term and preterm infants.[91,96,122,147] **The evidence for long-term benefit, however, particularly for term infants, has been mixed.**[117] A recent Cochrane review concluded that the majority of randomized controlled trials have not shown benefit nor harm of LC-PUFA supplementation on the neurodevelopmental outcomes of term infants.[132] **For preterm infants, in whom PUFAs are particularly important for growth, brain, and visual development and who have not had the opportunity for late gestation accumulation of fats, there may be benefit and little risk with supplementation.**[96,97,145,235] A recent systematic analysis of the literature found a trend for LC-PUFAs to reduce the risk of BPD and NEC.[281] However, similar to LC-PUFA in term infants, the most recent Cochrane review concluded that no clear long-term benefits or harms were demonstrated for preterm infants receiving LC-PUFA–supplemented formula.[184]

Some fats (e.g., EFAs) are essential for normal infant growth.[145] **The amount of medium-chain triglycerides (MCTs) is also important for fat nutrition because of their greater absorptive capacity, especially in the underdeveloped GI tract of preterm infants.** MCTs do not require bile salts for absorption and can be directly absorbed into the portal venous circulation. This offers theoretical advantages for the preterm infant, although there is little evidence that inclusion of MCTs improves energy or protein/nitrogen absorption or retention, or growth of the healthy preterm infant.[273] The content of MCTs varies considerably among current feedings for preterm and term infants: expressed human milk, 2%; fortified human milk, 2% to 18%; preterm formula, 40%; and term formula, 8%. The considerable variability in milk MCT content parallels that of fat content of human milk and occurs because of interindividual variation and changes in milk fat content during the day, throughout lactation, and within one feeding (foremilk to hind milk). MCTs do improve fat absorption and energy intake in infants with hepatic dysfunction or short bowel syndromes. Excess MCTs can lead to diarrhea and dicarboxylic acid excretion.

Carbohydrates

Carbohydrate reserves begin to accumulate as glycogen in the developing fetus as early as the start of the second trimester. Most of this glycogen (as much as 90% of total body glycogen in term infants) serves local cellular needs in different organs, whereas hepatic glycogen specifically provides glucose for other glucose-dependent tissues, primarily the brain. Immediately after birth, with cessation of glucose supply from the placenta, the neonate must use stored glycogen for energy. **The newborn can exhaust the supply of stored glucose from the liver within 12 hours of birth under severely stressful conditions** (e.g., hypoxia, hypotension, increased catecholamine and glucagon release) **if milk/formula or IV glucose is not provided. The normal glucose utilization rate in the term newborn is 3 to 5 mg/kg/min, but slightly higher (5 to 7 mg/kg/min) in preterm infants. The brain accounts for most of the glucose used in the whole body, especially in preterm and asymmetrically growth-restricted infants, who have a larger-than-normal brain:body-weight ratio.**

The predominant carbohydrate in human milk is lactose, a disaccharide composed of glucose and galactose. **Glucose has a central role in energy metabolism.** Galactose provides 50% of the calories derived from lactose; its major metabolic role is in energy storage, because the newborn liver readily incorporates galactose from the portal circulation into hepatic glycogen.

Provision of 40% to 50% of total caloric intake as carbohydrate (10 to 12 g/kg/day) prevents breakdown of fat and oxidation of lipids that produce ketone bodies. Ketones can substitute for glucose for energy production, particularly in the brain, when glucose is limited and hypoglycemia develops. **Carbohydrate generally is supplied as lactose in human milk or commercial formulas. Preterm formulas have reduced lactose content, 40% to 50% of the total carbohydrate, and human milk fortifiers provide little to no lactose.** If there are signs of lactose intolerance, such as frequent loose stools, abdominal distention, apparent cramping, or positive stool reducing substances (Clinitest), a lactose-free infant formula may be considered (Table 17.4). **Use of such lactose-free products should be reserved for those rare infants with clinically proven lactose intolerance.**

Vitamins

Vitamins are organic substances that are present in trace amounts in natural food sources and are essential for normal metabolism. **Lack of vitamins in the diet produces well-recognized deficiency states in children and adults, but the biological roles of many vitamins are not completely understood in preterm infants, and recognition of clinical deficiency states is difficult.** Certain vitamins have received close attention in neonatology, in particular vitamin C for its role in enhancing iron absorption from the GI tract, vitamin K for prevention of hemorrhagic disease of the newborn,[13] vitamin D for the prevention of rickets,[2] and vitamins A and E as antioxidants.[118] Vitamin E protects lipid-containing red blood cell membranes against oxidative injury, thus reducing hemolysis, and may prevent neonatal oxygen toxicity, including retinopathy of prematurity (ROP) and intraventricular hemorrhage (IVH). Vitamin A is essential for cell growth and differentiation of epithelial tissues, including those in the lung. **Preterm infants have low stores of vitamin A at birth, and preterm infants with lung disease have lower plasma vitamin A levels than those without lung disease. Supplementation has been shown in some studies to decrease chronic lung disease in ELBW infants.**[76] Vitamin A supplementation has not become standard practice, in part because of the need for repeated intramuscular injections, as absorption from the GI tract does not appear to be sufficient. **Infants with short bowel syndrome who have lost function of the terminal ileum should receive supplementation of the fat-soluble vitamins to avoid deficiency.**[110]

Because **vitamins have a central role in many metabolic processes, signs of vitamin deficiency can be nonspecific, such as lethargy, irritability, and poor growth.** Table 17.5 is a summary of the recommended vitamin intake for enterally fed infants. For comparison, the average vitamin content of term human milk and commercial infant formulas is included in Table 17.4. **Vitamins are generally given on a weight-specific basis, not a gestational age basis.** Routine supplementation of vitamins above the recommended doses is not advised because of possible toxicity and lack of clearly demonstrated benefits. For example, the recommended dose of vitamin D for preterm infants, once they have reached full enteral feeds and weigh more than 1500 g, is 400 IU/day, up to a maximum of 1000 IU/day.[2] **Higher doses (800 to 1000 IU per day) have been recommended for infants born extremely preterm or infants with short bowel syndrome, cholestasis, and long-term exposure to diuretics or corticosteroids. In ELBW very preterm infants, serum vitamin D concentrations should be measured once they are on full enteral feedings and starting to grow, and then repeated every 2 to 4 weeks to ensure that with or without vitamin D treatment, serum concentrations remain above a reasonable level** (>50 nmol/L). Excessive dosing, particularly noted in former ELBW extremely preterm infants and especially after discharge from the NICU and at home, can produce hypercalcemia, constipation, muscle weakness, and vomiting. In more severe cases, it damages the bones and kidneys. Infants on high-dose vitamin D should have their serum vitamin D concentration checked on discharge from the NICU and soon after in clinic to ensure that serum concentrations do not increase to dangerous levels when growth is slowing and milk or formula feedings are increased.

Minerals and Trace Elements

The content of minerals in human milk is the gold standard for mineral requirements in term infants. Mineral requirements for the preterm infant have been estimated from in utero accretion rates. **Preterm infants are relatively lacking in some important minerals (e.g., iron, calcium, zinc) because their accumulation occurs mostly in the third trimester.** Published recommendations for selected daily intakes in healthy, enterally fed preterm infants are shown in Tables 17.5 and 17.6.[143]

Trace mineral supplementation of human milk or use of an enriched preterm formula usually is necessary to achieve the recommended trace element requirements. Iron intake should be 2 to 4 mg/kg/day for both term and preterm infants who are enterally fed, but increased to 6 mg/kg/day for preterm infants with anemia of prematurity who are receiving recombinant erythropoietin. Risks of iron overload and toxicity (e.g., possible increased risk of ROP) increase with red cell transfusions. Iron supplementation often is delayed for 2 weeks after a transfusion, but timing is variable. **Formula-fed infants should receive only iron-fortified formula, beginning with the first formula feedings.**

Enteral absorption rates for both calcium and phosphorus are limited in preterm infants, but are relatively greater with milk feeding and calcium- and phosphorus-enriched preterm formulas. **Adequate enteral intake for term infants in the first 6 months of life is about 70 mg/kg/day of calcium and about 100 mg/day of phosphorus. The requirements for preterm infants are much higher because of more active bone formation and remodeling: 150 to 220 mg/kg/day for calcium and 60 to 140 mg/kg/day for phosphorus.** The ideal Ca:Phos ratio is 1.8:1–2:1 mg weight basis. **Fortification of human milk is necessary to ensure adequate intakes of calcium and phosphorus to preterm infants who are fed human milk, particularly with mature mother's milk**

and donor milk. Risk factors in preterm infants for calcium and phosphorus deficiency and subsequent rickets are: gestational age less than 27 weeks or birth weight less than 1000 g; long-term parenteral nutrition (>4 to 5 weeks); severe BPD requiring diuretics and fluid restriction; long-term steroid treatment; history of NEC; and intolerance to enteral formula or human milk. **Supplementation with calcium and phosphorus has been shown to decrease the incidence of metabolic bone disease (osteopenia) in preterm infants.**[2] Mineral supplementation of human milk or use of an enriched preterm formula (Table 17.7) usually is necessary to achieve the recommended mineral requirements.

COMPOSITION OF ENTERAL FEEDINGS

Human Milk

The ideal enteral diet for almost all term newborn infants is human milk,[16,247] **which provides sufficient energy, protein, fat, carbohydrate, micronutrients, and water for normal growth.** Contraindications to the use of human milk, which are rare, are found in Box 17.5. **The development of a beneficial intestinal flora, characterized by a large prevalence of bifidobacteria and lactobacilli, is strongly supported by human milk feedings.**[52,163,173,174] In addition, human milk, unlike formulas, provides a variety of antimicrobial factors that protect against infections, such as secretory immunoglobulins (IgA), leukocytes, complement, lactoferrin, and lysozyme.[193] **The provision of human milk is particularly important for the preterm infant to reduce the rate of NEC**[53,66,168] **and to promote immune development.**[160,257] Human milk also contains hormones and growth factors such as epidermal and nerve growth factors, IGF-1 and IGF-2, erythropoietin, prolactin, calcitonin, steroids, thyrotropin-releasing hormone, and thyroxine.[238] **These milk hormones and trophic factors play active roles in organ maturation, growth, and health.** Several essential and conditionally essential amino acids are present in high concentrations in human milk.[280]

The protein and fat components of human milk are readily digestible, and human milk contains large numbers of enzymes that aid in nutrient digestion and processing (e.g., lipase). Exclusive human milk feeding of infants at high risk for atopy or milk protein allergy may reduce the development of disease in infancy.[106,126,224] Furthermore, human milk is protective against the development of obesity in childhood and beyond.[276] **Preterm infants breastfed at discharge have less subnormal neurodevelopment at 2 to 5 years of age.**[236] These effects last into infancy,[269] childhood,[165] and even into adolescence.[123] Thus, as clearly stated by the American Academy of Pediatrics, **human milk is the recommended basis of nutrition for the preterm infant**[16]**: (1) all preterm infants *should* receive human milk; (2) human milk should be fortified with protein, minerals, and vitamins to ensure optimal nutrient intake for infants weighing less than 1500 g at birth**[282]**; and (3) pasteurized DHM, appropriately fortified, *should* be used if mother's own milk is unavailable or its use is contraindicated.**

The preterm infant will not grow at the normal rate of fetal growth on human milk alone, because of the special nutritional requirements addressed previously. In fact, the larger the fraction of total feeding provided by just human milk without supplementation, the greater the reduction in final weight at term gestational age.[65] **Recommended daily requirements for energy, protein, calcium, sodium, phosphorus, magnesium, iron, zinc, and several vitamins necessary to meet the normal rate of in utero growth usually will not be achieved in the growing "healthy" preterm infant who is fed with unsupplemented human milk.** The preterm infant with respiratory distress, infection, excessive heat losses, GI disorders, or surgical stress has even greater nutritional needs. Nonetheless, **milk from mothers of preterm infants has more protein and sodium than milk obtained at term and occasionally provides for adequate growth in larger and healthier preterm infants who have the capacity to take in large volumes, at times over 200 mL/kg/day. The lowest rates of NEC and possibly related sepsis have been found in preliminary studies with an exclusive breast milk diet** consisting of mother's milk and/or donor milk supplemented with human-milk–based fortifier (Prolacta Human Milk Fortifier, Prolacta, Monrovia, CA),[150,257] particularly compared with formula-fed infants.[74]

***Donor human milk* is a pasteurized product from accredited milk banks that is used when**

TABLE 17.7 MINERALS AND TRACE ELEMENTS IN NEONATAL NUTRITION

MINERAL OR ELEMENT	BIOLOGIC ROLE	DEFICIENCY STATE	RECOMMENDED INTAKE FOR GROWING PRETERM INFANTS
Sodium	Growth and tissue accretion, body fluid equilibrium, cellular energy, electrical charge balance	Poor growth, fluid imbalance, hypotension, neurologic dysfunction, lethargy, seizures	3–5 mEq/kg/day
Potassium	Growth and tissue accretion, acid-base balance, cellular energy, electrical charge balance	Myocardial damage, dysrhythmia, hypotonia, muscle weakness	2–3 mEq/kg/day
Chloride	Growth and tissue accretion, cellular energy, electrical charge balance	Failure to thrive, muscle weakness, alkalosis, vomiting	3–5 mEq/kg/day
Calcium	Bone and tooth formation, fat absorption, nerve conduction, muscle contraction	Osteomalacia, tetany, dysrhythmias, seizures	200 mg/kg/day
Phosphorus	Bone and tooth formation, energy transfer compounds	Rickets, neuropathy, weakness	100–140 mg/kg/day
Magnesium	Metalloenzymes, cellular electrical charge balance	Hypocalcemia, hypokalemia, diarrhea, tremor, arrhythmia	5–10 mg/kg/day
Iron	Hemoglobin formation, metalloenzymes	Anemia, apathy	2 mg/kg/day after 1 month of age
Zinc	Metalloenzymes, DNA-RNA synthesis, wound healing, host defenses	Growth restriction, dermatitis, alopecia, diarrhea, delayed wound healing, hypogonadism	1.2–1.5 mg/kg/day
Copper	Metalloenzymes, protein metabolism	Neuropathy, anemia, neutropenia, osteoporosis, depigmentation of hair and skin	100–200 mcg/kg/day
Manganese	Metalloenzymes, carbohydrate metabolism, antioxidants, hemostasis	Neurologic dysfunction, defects in lipid metabolism, reduced coagulants, growth restriction in animals	10–20 mcg/kg/day
Chromium	Carbohydrate metabolism, component of nucleic acids	Impaired glucose tolerance, impaired growth	2–4 mcg/kg/day
Selenium	Metalloenzymes, antioxidants	Cardiomyopathy, anemia, myositis	1.5–3 mcg/kg/day
Iodine	Thyroid hormone synthesis	Hypothyroidism, goiter, cretinism	1 mcg/kg/day
Molybdenum	Metalloenzymes	Neurologic and visual dysfunction, growth restriction in animals	2–3 mcg/kg/day

maternal milk is insufficient or unavailable, because of the multitude of benefits associated with the use of human milk in preterm infants.[15] Donor milk is pasteurized to prevent infection, but this removes most of the anti-infective properties of milk. Nevertheless, infection rates and NEC rates are much lower with donor milk than with formulas.[191] There may be differences in milk composition as well, especially in protein content, but also energy, lactose, and fat content. Differences are particularly marked between human milk donated by women later in lactation after having delivered term infants compared with milk expressed by mothers delivering preterm infants[275]

BOX 17.5 CONTRAINDICATIONS TO BREASTFEEDING AND USE OF MATERNAL EXPRESSED BREAST MILK

- Mothers who have untreated brucellosis
- Mothers who have human immunodeficiency virus (HIV) infection
- Mothers who are positive for human T-cell lymphotrophic virus type I or II
- Mothers who have untreated miliary tuberculosis, active herpes virus lesions on the breast, acute H1N1 influenza, or acute varicella (*Note:* Expressed milk can be used because there is no concern about these infectious organisms passing through the milk and breastfeeding can be resumed when a mother with tuberculosis is treated for a minimum of 2 weeks and is documented that she is no longer infectious.)
- Maternal drug abuse (e.g., narcotics, phencyclidine, cocaine, cannabis) (*Note:* This contraindication is relative; mothers who test positive for such drugs should be enrolled in drug reduction programs rather than stopping breastfeeding, particularly among mothers with preterm infants, in whom the advantages of mother's milk generally outweigh the risks of addiction and neurodevelopmental defects in the infant.)
- Infants who have galactosemia

From American Academy of Pediatrics. Section on Breastfeeding. Breastfeeding and the use of human milk. *Pediatrics* 2012;129:e827.

(see Chapter 18). Donor milk in the United States also is low in DHA, containing only 50% to 75% the amount of milk from women in other parts of the world whose natural diets include more fish and vegetable oils that contain ALA and DHA.[20] **Donor milk is an appropriate choice for VLBW preterm infants whose maternal milk is unavailable[64] with greater than 75% improvement in feeding tolerance,[42] lower risk of NEC, and comparable neurodevelopmental outcomes when compared with supplementation with preterm formula.[221,198]**

There also is a growing interest in the use of *probiotics,* principally *Lactobacillus* species and *Bifidobacterium,* to assist in colonization of the preterm infant's gut with bacteria that might promote a more normal gut flora, replenish such flora after antibiotic use, and reduce the risk of GI disorders associated with abnormal gut flora, principally NEC. Several international trials support the use of probiotics to reduce the risk of NEC. **Use of probiotics in individual institutions might be considered if the NEC rate, particularly of surgical NEC and/or death from NEC, is relatively high (greater than 2%) despite efforts to reduce the risk of NEC. Such efforts to reduce NEC include the use of exclusive breast milk feeding (mother's own or donor), restricted use of antibiotics (in both mother and infant), and promotion of early trophic or gut-priming feedings with colostrum or mother's milk or donor milk.** A recent multicenter collaborative United Kingdom (UK) trial[23] and an updated *Cochrane* meta-analysis[9] that included 24 trials from around the world showed that **there is a significant decrease in NEC and all-cause mortality rate with the use of probiotics.**[11] Probiotic preparations containing either lactobacilli alone or in combination with bifidobacteria were found to be effective. Length of stay was 3 to 4 days shorter. Although there remains a risk for probiotic-related sepsis, especially in the most vulnerable ELBW infants, this has only rarely been reported and only in case reports outside of the UK trials and those reported in the Cochrane review. Recommendations for developing local institutional protocols to use probiotics have been published.[258] However, one of the primary reasons routine use of probiotics in preterm infants is not more widespread is the lack of available preparations that are regulated by the U.S. Food and Drug Administration (FDA).

The nutritional composition of term human milk is compared with commercial term infant formulas in Table 17.4. The nutrient content of "mature" preterm human milk is compared with fortified preterm human milk and preterm formulas in Table 17.8. Use of commercially available supplements to human milk that provide additional energy, protein, vitamins, and minerals is recommended.[136] Nutrient composition of these fortifiers is shown in Table 17.3. Most of the new formulations of the commercially available fortifiers now use hydrolyzed cow's milk protein, which might lead to less GI intolerance and possibly less NEC.

Formulas

Cow's milk–derived formulas have been modeled after the composition of human milk to provide biologically available protein mixtures with appropriate protein:energy ratios for normal growth. In general, **formulas designed for term infants contain 19 to 20 kcal/oz and are adequate to meet the needs of term infants with an intact GI tract and "normal" fluid requirements.** A whey and casein mixture approximating that of human milk is preferred.

ARA, Arachidonic acid; *DHA,* docosahexaenoic acid; *MCT,* medium-chain triglycerides.

Preterm formulas contain whey:casein ratios of 60:40 and have higher protein contents than those of term formulas (2.4 g/100 mL in preterm formula versus 2 g/100 mL in term formula or human milk). Preterm formulas also contain less lactose as a carbohydrate source and substitute corn syrup solids for lactose to provide approximately 42% to 44% of the calories derived from this carbohydrate (largely sucrose). Preterm formulas provide some of the fat in the form of MCTs because of the ease with which they are absorbed. **Calcium (Ca) and phosphorus (P) content is increased, with a Ca:P ratio of 1.8 to 2:1, which provides for improved bone mineralization.** Other minerals and vitamins also are present in higher concentrations in preterm formulas to reflect the special nutritional needs of the VLBW infant. **Preterm formulas are available in 20, 24, and 30 kcal/oz preparations, with similar osmolalities and renal solute loads.** Newer generations of **high-protein preterm formulas containing approximately 2.8 g/100 mL may be indicated for VLBW preterm infants who are not growing well, have experienced a cumulative deficit of protein intake, have inadequate growth in length and/or head circumference, or are fluid/volume restricted.**[48]

Soy protein formulas should be reserved for term infants with galactosemia, severe lactose intolerance, hereditary lactase deficiency, vegan families, or those who have IgE-mediated cow's milk protein allergy. Soy-derived formulas should not be used for preterm infants because of the poorer quality of protein, lower digestibility and bioavailability, and lower calcium and zinc accretion rates seen with these formulas.[37] In addition, there are concerns for all infants about the concentrations of phytates, aluminum, and phytoestrogens that these formulas contain.[6,264] If necessary, a protein hydrolysate formula should be used for preterm infants with protein intolerance. **For term infants, formulas derived from protein hydrolysates should be reserved for infants who are allergic to cow's milk proteins and are not breastfed or do not tolerate soy-derived formulas. Soy formulas have no role in the prevention of atopic disease. In contrast, extensively hydrolyzed formulas may delay or prevent atopic dermatitis in infants at high risk who are not breastfed.**[106] **In general, families with a strong history of cow's milk protein allergy should be encouraged to breastfeed.** The compositions of partially, extensively, and completely hydrolyzed formulas are shown in Table 17.6.

Elemental formulas are used in infants with malabsorption, abnormal GI tracts, or severe protein allergy. The protein in these formulas is derived from free amino acids, 52% of the fat is from MCT oil, and many are lactose free. **Use of elemental formulas generally is indicated in the infant with severe liver disease and fat malabsorption, with short bowel syndrome (e.g., after NEC with surgical resection), or with dysmotility syndromes (e.g., in gastroschisis).** Occasionally, elemental formulas are useful after a severe episode of infectious gastroenteritis with mucosal injury and resulting protein or lactose intolerance. It is not **necessary to use an elemental formula in the routine care of VLBW infants. Formulas with extensively hydrolyzed proteins also have been introduced to treat GI disorders. Hydrolyzed protein formulas are generally well tolerated, but they do not lessen feeding intolerance or the rate of NEC and may result in slower weight gain.**[179,195,243] A variety of other modified formulas are available for infants with special nutritional needs because of inherited enzyme deficiencies.

Caloric delivery and nutritional support can be maintained by increasing the caloric density of feedings when feeding volumes cannot be tolerated or fluid intake must be limited. This can be done by **adding human milk fortifiers to the milk or formula to achieve acceptable concentrations and intakes of nutrients. Liquid formula concentrates, including liquid protein modular, also are used to increase the caloric density of infant feedings. Powdered infant formulas should *not* be used for feeding or fortification in hospitalized newborns in an intensive care unit,** unless no alternative is available, **because of information linking *Cronobacter sakazakii* infections in neonates to the use of powdered infant formulas** (FDA recommendation, 4-11-02). Caloric densities of greater than 24 kcal/oz can be achieved with fortification. However, the cumulative effect of additives to milk, including human milk fortifiers, liquid formula, multivitamins, iron, and sodium chloride supplements, can increase the osmolality of the multiply supplemented milk above the recommended threshold of 450 mOsm/kg in preterm formulas. This **increase of osmolality can be associated with feeding intolerance in the form of reflux, dysphagia, and/or slowed gastric or intestinal motility.**[159] Therefore careful monitoring of

feeding tolerance, electrolytes, fluid balance, and renal function is necessary on a high–caloric density feeding regimen. **The distribution of calories should maintain a balance of protein, fat, and carbohydrate at about 10%, 45%, and 45%, respectively.**

FEEDING TECHNIQUES

Gavage Feeding

Gavage feedings are indicated in infants requiring endotracheal intubation, continuous positive airway pressure (CPAP), or those with an immature, weak, or absent suck, swallow, or gag reflex (Box 17.6). Most infants tolerate intermittent feedings delivered slowly over 30 to 60 minutes, commonly termed *slow bolus feedings*. Studies indicate that such an intermittent "slow" infusion (e.g., 3 hours of volume given over 1 hour out of 3) improves gastric emptying and duodenal motility.[21,80] **Intermittent feedings are given every 2 hours for infants weighing less than 1250 g and every 3 hours for infants weighing 1250 g or more.**[81,86] **Some institutions use continuous feedings for infants recovering from NEC or infants with short bowel syndrome, congenital heart disease, or intolerance of bolus feedings.** However, a summary of randomized controlled trials did not find consistent differences regarding the effectiveness of continuous versus intermittent bolus nasogastric (NG) feedings.[220] **In addition, extended infusion times and pump position may lead to significant (up to 50%) fat and calcium losses when gavage feeding human milk.** Increased exposure of milk to plastic in the form of extension tubing and milk transfer systems, as well as the syringe design, also can contribute to these losses. **Fat and calcium losses are higher with continuous feeding compared with intermittent bolus feeding.**[57] **Positioning electric syringes horizontally or with the tip angled upward, minimizing the length of extension tubing, streamlining feed preparation, and shortening infusion time as medically appropriate can mitigate these losses.**

Regardless of feeding method, gavage tube position must be checked carefully using auscultation over the stomach before every feed. Bedside testing of gastric aspirate pH is often performed on placement of a gavage tube.[197] **If the pH does not confirm gastric position, an abdominal radiograph can be considered to confirm placement.**

For most infants, intragastric feedings are preferred to transpyloric feedings. Current data available do not provide any evidence of benefit of transpyloric feeding for preterm infants, and some evidence for harm exists, including a higher risk of GI disturbances and mortality.[272] **Even when indicated because of severe GER with aspiration, transpyloric feedings have additional complications, including malabsorption and diarrhea, altered gut microbiome, and intestinal perforations requiring surgery. Use of transpyloric feeding should be restricted to short-term use in those infants who cannot tolerate gastric feedings because of excessive GER with aspiration, pneumonia, and apnea.**

Oral Feeding

Development of appropriate neuromuscular coordination is necessary to successfully initiate oral feedings. Criteria for initiating oral feeding must be individualized because components of sucking, swallowing, and respiration and their coordinated activity mature at different rates and times in preterm infants.[12] **Box 17.7 provides an algorithm for oral feeding readiness in those infants greater than or equal to 34 weeks requiring heated high flow nasal cannula or CPAP.** In general, coordination of suck, swallow, and breathing emerges at about 34 weeks of corrected gestational age (range 32 to 36 weeks).[46] **Aspiration is a serious risk in an infant of any gestational age who does not have a neurologically mature swallow, gag, or cough reflex. Tachypneic infants with labored respirations also are at increased risk for aspiration; thus oral feeding usually is not possible unless the respiratory rate is less than 60 breaths/min.**

Use of different nipple shapes and sizes with variable flow rates combined with bottle selection enables infant-driven flow and facilitates progression to safe oral feeding.[204] **Nipple selection is tailored to correspond with infant maturity and underlying medical complexity. Slower flow rates are recommended for the infant with a more immature feeding pattern. As the infant matures and underlying medical issues resolve, the infant can progress to a nipple with a faster flow rate.**

BOX 17.6 GAVAGE FEEDING GUIDELINES

Equipment

1. Breastmilk/formula in syringe (4-hour amount, or unit protocol, maximum)
2. Tape, optional transparent dressing
3. Lubricant, optional
4. Stethoscope
5. For intermittent feeding: infant feeding set with syringe, medicine cup, 4-Fr to 8-Fr gavage tube
6. For indwelling feeding tubes: infant less than 1 kg, 4-Fr tube; greater than 1 kg, 5-Fr to 6-Fr tube (tube size may also depend on placement [i.e., oral versus nasal], amount of feeding, and rate of delivery of feeding). Short-term feeding tube (generally made of polyvinyl chloride [PVC]) should be changed every 24 to 72 hours. Long-term feeding tube (made of polyurethane) should be changed at least once every week. *Note:* Always follow manufacturer's recommendations.
7. Syringe pump and extension tubing as needed

Feeding Tube Insertion

1. Wash hands, and assemble equipment in a clean area.
2. Measure for tube placement by placing tip of feeding tube at the tip of nose, draw to base of ear, then to halfway between the xiphoid process and the umbilicus.[209]
3. Mark tube with indelible ink pen to indicate the distance from the tip of the tube to the corner of the mouth or edge of the naris.
4. Insert tube (swaddling the infant may help with tolerance of this procedure). NEVER FORCE THE TUBE.
   Oral placement (usually preferred for infants less than 1 kg, those on nasal CPAP or ventilator, those with high oxygen need, or those with excoriated nares): insert tip into the oropharynx, gently pushing the tube in a downward arc into the esophagus until reaching the premeasured mark.
   Nasal placement (generally preferred for infants greater than 1 kg with mature or strong gag reflex and infants who are breastfeeding or nippling): moisten tip with water or lubricant. Insert tip gently into one nostril and advance slowly as above.
5. Gastric tube tip placement is verified by auscultation or abdominal radiograph or pH measurement of gastric aspirates. The tube landmark should be checked with every caregiving procedure to determine that it is still visible and at the correct location.
6. Soft Silastic tubes are generally used for transpyloric feedings and require the use of a stylet for insertion. The tube must be inspected visually and by flushing with water before insertion to ensure that it has not been perforated by the stylet. The stylet is removed after insertion and is stored in package by the bedside. Tip placement usually is verified by radiographic imaging.

Securing Feeding Tube

1. Intermittent feeding tubes can be taped to the cheek.
2. Indwelling tubes must be taped securely to the face, leaving the landmark visible. For tubes placed nasally, a narrow piece of tape may be placed along the tubing on the upper lip, with a transparent dressing applied over the tube on the cheek.

Feeding

1. Aspirate entire stomach contents to assess quantity, color, and appearance.
2. To prevent loss of electrolytes, slowly return aspirate to the stomach. Exceptions to this include aspirates that are bloody or "coffee ground," green or bright yellow, or fecal appearing or contain large amounts of mucus. Do not refeed, and discuss the feeding plan with the physician or practitioner. Also report aspirates of undigested formula if the amount is more than one-half of the feeding or occurs more than once, or if there is a change in abdominal assessment. Reducing the feeding by the amount of the refed aspirate is recommended for one or two feedings.
3. Instill human milk or formula via intermittent gavage feeding:
   Detach the syringe from the feeding tube, and remove the plunger; reattach the syringe to the feeding tube. Pour the predetermined amount of milk into the syringe. Flow may begin spontaneously or require a gentle nudge from the plunger. Allow the feeding to run in slowly by gravity. Never push a feeding. The higher the syringe is held, the faster the feeding will flow (about 8 inches is ideal). For most infants, a feeding should run in over 30 minutes. Gavage sets may be rinsed carefully and used for up to 24 hours unless labeled "single use only" or manufacturer's directions indicate otherwise.
4. Intermittent gavage feeding via indwelling feeding tube:
   Check aspirate, and feed as above. When feeding is complete, instill 1 to 2 mL sterile water to clear tubing of residual food, and cap or close off the tube by attaching the syringe with the plunger.
5. Continuous drip feedings via indwelling feeding tube:
   Check feeding tube placement and feeding residuals every 2 to 4 hours using the stopcock, which is placed between the feeding tube and the extension tubing. Check the ink landmark on the feeding tube hourly to ensure proper placement of the tube. Prepare up to 4 hours of breast milk or formula (or amount according to institutional studies of bacterial growth). Fill the syringe with a predetermined feeding amount plus enough to prime the extension tubing. Place the syringe into the syringe pump, and program it to deliver feeding at the desired rate. To help prevent loss of milk fat by settling, place the syringe in an upward vertical position and use minibore tubing.

Care, Assessment, and Documentation

1. Assess the infant's tolerance of feeding tube placement. If gagging occurs, attempt to insert the tube down one side of the oropharynx rather than down the middle. If the infant becomes apneic, bradycardic, or cyanotic during feeding tube placement, pause to allow recovery, or remove the tube and allow the infant to rest before trying again. If these symptoms occur during the feeding, stop the feeding by lowering the syringe or stopping the pump. If recovery occurs quickly, resume feeding slowly and observe. If distress continues or recurs, stop feeding and inform the physician or practitioner.
2. Change short-term (PVC) feeding tube every 24 to 72 hours (or manufacturer's recommendations).
3. Change long-term nasal feeding tube (polyurethane) to opposite nostril weekly. Discard and replace tube after 4 weeks (or manufacturer's recommendations).
4. Document all details of the feeding and the infant's tolerance, proper placement of the indwelling feeding tube, and when feeding tube or equipment is to be changed.

BOX 17.7 ALGORITHM TO ASSESS ORAL FEEDING READINESS FOR INFANTS ≥34 WEEKS REQUIRING HEATED HIGH-FLOW NASAL CANNULA OR NASAL CONTINUOUS POSITIVE AIRWAY PRESSURE

Criteria to Initiate Oral Feeding

1. The infant is showing oral feeding cues defined as the ability to:
   a. Manage oral secretions.
   b. Suck pacifier without desaturation, choking, or requiring increased Fio_2.
   c. Root and bring hands to mouth.
   d. Come to an alert state before/or with cares.
2. The infant is on CPAP 5 cm H_2O or less; HFNC 3 L/min or less
3. The infant has a sustained respiratory rate of <70 breaths/min.
4. The infant can be held in side-lying feeding position while sucking on a pacifier without desaturation or bradycardia.
5. The infant can tolerate tastes of breast milk or formula on a pacifier without desaturation or bradycardia.

Progression of Oral Feeding

1. For mothers who desire to breastfeed:
   a. Let the infant attempt breastfeeding on a pumped breast for 5 minutes, and assess for any sign of intolerance, including choking, desaturation, increased respiratory effort, bradycardia, and increased Fio_2 requirement.
   b. Increase time allowed at breast by 2- to 5-minute intervals.
2. For mothers who do not desire to breastfeed:
   a. Offer small amount (up to 10 mL) of donor human milk or formula in a bottle with a slow-flow nipple, only allowing 5 minutes to take that amount.
   b. Increase the amount of formula by 5 mL, and increase the limit of bottle feeding by 2 to 5 minutes.

CPAP, Continuous positive airway pressure; *HFNC*, high-flow nasal cannula.

Recent evidence has advocated the use of the semi-elevated side-lying (ESL) position when introducing bottle feedings to the preterm infant rather than the semi-elevated supine position (ESU). **ESL positioning better mimics the breastfeeding position, decreases flow of the milk because of decreased hydrostatic pressure, and allows for better coordination of breathing with swallowing**[60,103,207,208] (Fig. 17.7A). **As infants mature, they can be transitioned to ESU positioning. *Semi-demand, cue-based,* or *infant-driven* feedings result in an earlier attainment of full oral feedings in premature infants.**[141,157,176,245] Swallowing exercises, **including placement of a milk bolus (0.05 to 0.2 mL) on the tongue where the bolus rests before entering the pharynx, also facilitate the attainment of independent oral feeding.**[156] Gastrostomy tube placement may be necessary if oral feedings are not adequately established.

Coordination of sucking with breathing is the first lesson for the preterm infant. The ability to suck on a pacifier, fingers, or a gavage tube does not ensure the infant's ability to perform nutritive sucking. **An infant who is successful at oral feeding should exhibit an active suck, coordinated swallow with breathing, minimal fluid loss around the nipple, and completion of feeding within 15 to 30 minutes.**[246] Stress behaviors (e.g., increase or decrease in respiratory or heart rate, decreased oxygen saturation, color change, gagging, choking, emesis, fatigue, irritability, or a "panicked look") should be treated with a rest period or cessation of the feeding. **Provider *pacing* is important until the infant learns to self-pace feedings (see Table 13.13).** Strategies to facilitate oral feedings also include a relaxed caregiver, a quiet environment with subdued light, and a snugly wrapped infant (see Box 13.17) **A too-rapid change to oral feeding can result in insufficient nutrition and potential failure to gain weight appropriately, primarily because the infant tires with feeding and is unable to take a sufficient amount of food.** Diligent attention is warranted, and nipple feedings often have to be limited and gavage feedings continued to prevent dehydration and under-nutrition. Box 17.8 **provides infant-driven feeding scales for readiness score description, quality score description, and caregiver technique score description.**

FEEDING INTOLERANCE AND COMPLICATIONS

Assessment for signs of feeding intolerance is imperative; although some feeding complications are mild and respond to nursing interventions, others are more serious and require more intervention. **Feeding intolerance frequently is the first sign of illness (e.g., hypoxia, dyspnea, congestive**

FIGURE 17.7 The **(A)** semielevated side-lying (ESL) and **(B)** semielevated supine (ESU) positions when introducing bottle feedings to the preterm infant.

BOX 17.8 INFANT-DRIVEN FEEDING SCALES

Infant-Driven Feeding Scales (IDFS) help to determine infant readiness to nipple feed, quality of the feeding, and caregiver techniques used during the nipple feeding. These scales help caregivers determine if infants are ready to nipple feed, a way to assess the quality of the feeding, and what techniques are used to deliver that nipple feeding. The scales may help make nipple feeding more consistent among caregivers and promote feeding success.

Infant-Driven Feeding Scales (IDFS)—Readiness Score Description

1. Alert or fussy before care. Rooting and/or hands to mouth behavior. Good tone.
2. Alert once handled. Some rooting or takes pacifier. Adequate tone.
3. Briefly alert with care. No hunger behaviors. No change in tone.
4. Sleeping throughout care. No hunger cues. No change in tone.
5. Significant change in heart rate, respiratory rate, O_2 saturations/requirements, or work of breathing outside safe parameters.

If the infant receives a score of 1 or 2, the infant is ready to nipple feed. For any score higher than 2, the infant is gavage fed. The nurse would then reassess infant behavior at the next feeding. If nipple feeding readiness is determined, the next two scales are used to document quality of feeding and techniques used during feeding.

Infant-Driven Feeding Scales (IDFS)—Quality Score Description

1. Nipples with a strong coordinated suck, swallow, and breathing (SSB) throughout feed.
2. Nipples with a strong coordinated SSB but fatigues with progression.
3. Difficulty coordinating SSB despite consistent suck.
4. Nipples with a weak/inconsistent SSB. Little to no rhythm.
5. Unable to coordinate SSB pattern. Significant change in heart rate, respiratory rate, O_2 saturations/requirements, work of breathing outside safe parameters, or clinically unsafe swallow during feeding.

Continued

BOX 17.8 INFANT-DRIVEN FEEDING SCALES—CONT'D

Infant-Driven Feeding Scales (IDFS)—Caregiver Techniques Score Description

A. *Modified Side-lying:* Position infant in inclined side-lying position with head in midline to assist with bolus management.
B. *External Pacing:* Tip bottle downward/break seal at breast to remove or decrease the flow of liquid to facilitate SSB pattern.
C. *Specialty Nipple:* Use nipple other than standard for specific purpose (i.e., nipple shield, slow-flow, Haberman).
D. *Cheek Support:* Provide gentle unilateral support to improve intraoral pressure.
E. *Frequent Burping:* Burp infant based on behavioral cues, not on time or volume completed.
F. *Chin Support:* Provide gentle forward pressure on mandible to ensure effective latch/tongue stripping if small chin or wide jaw excursion.

From Waitzman KA, Ludwig SM, Nelson CLA. Contributing to content validity of the Infant-Driven Feeding Scales (IDFS). *Newborn Infant Nurs Rev.* 2014;14(3):88–91. Used with permission.

heart failure, sepsis, NEC). At first, such signs often are subtle; thus, the caregiver should be constantly aware of any change in the infant's overall condition and feeding tolerance.

Residuals

Traditional practice has been to aspirate the feeding tube before a feeding to measure a "residual," or to determine whether gastric emptying is adequate. Incompletely digested aspirates of less than 50% of the previous feeding, 2 to 4 mL/kg, or a 1-hour volume if on continuous feedings may be normal and generally should be refed to the infant. Increasing and persistent residuals in the context of abdominal distention and/or other signs of systemic illness should be further evaluated, as this can indicate ***feeding intolerance, intestinal obstruction, or early NEC.***[185] Recent evidence suggests that routinely checking for residuals in the context of a normal abdominal examination is unnecessary, even counterproductive if residuals are repeatedly not refed to the infant, and potentially harmful, as too high a negative pressure during the aspiration can damage the lining of the stomach.[161] Avoiding routine gastric residual volume before each feeding has been associated with earlier achievement of full enteral feeds in preterm infants.[234,262] An alternative to routine screening of residuals is to measure a prefeed abdominal girth, which also has been shown to decrease the time to reach full enteral feeds.[138,259] Placing the infant in the right lateral recumbent position prone aids in gastric emptying.[58] Because of gastric outlet sphincter incompetence, bile staining of gastric residuals is common in the very preterm infant. Frank blood, increasing bile in progressively increasing residual volumes, bilious emesis, and other signs of intestinal obstruction and/or NEC should be evaluated promptly.

Emesis

Infants with emesis should be evaluated for intestinal obstruction or diseases that produce ileus, such as NEC and sepsis. With persistent emesis or increasing amounts of bilious emesis, feedings should be withheld and the infant should be evaluated for sepsis, NEC, obstruction (including Hirschsprung's disease, malrotation, and midgut volvulus, with or without congenital bands, and microcolon in infants of diabetic mothers), metabolic disorders, or increased intracranial pressure. Postoperative emesis and abdominal distention may indicate a stricture, partial obstruction from subclinical continued NEC, or inflammatory abscess. Emesis also results from an overdistended stomach, severe GER, a poorly positioned feeding tube, gastric irritation from enterally administered medications, drug withdrawal, or overstimulation in a very small infant. Interventions include allowing the feeding to flow more slowly by instilling the feeding over a longer period, decreasing feeding volumes, prone positioning, giving medications at the end of the feeding, or modifying a stressful environment (see Chapter 13). Auscultation, pH testing of gastric aspirates, or abdominal radiographs should be used to assess feeding tube position.

GASTROESOPHAGEAL REFLUX

GER should be suspected in an infant with irritability, emesis, apnea and bradycardia,

respiratory deterioration, refusal to eat, or otherwise unexplained blood in the stools.[3] The use of histamine2 (H2) receptor blocker therapy and/or suppression of the H^+,K^+-ATPase enzyme system at the secretory surface of the gastric parietal cell for GER or feeding intolerance in infants is not supported by good evidence. H2 blockers have been implicated in neonatal sepsis for being permissive to pathologic organisms by eliminating the barrier function of gastric acid.[105] Studies have reported decreased NEC with the acidification of feedings,[202] and there is an association between use of H-2 blocker therapy and NEC.[108,212] Currently, use of such antacids is contraindicated for routine feeding practices.

Abdominal Distention

Abdominal distention with or without palpable or visible loops of bowel is a sign of poor gastric motility, ileus, constipation, or "gas." Variations in abdominal circumference of up to 1.5 cm can occur and, without other clinical signs of illness, may be normal. If the abdomen remains soft and nontender, prone positioning may be comforting, allowing gas and stool to pass. Persistent abdominal distention, pain with palpation, and discoloration of the overlying skin are signs of pathology (e.g., anatomic obstruction or inflammation) and require investigation. An abdominal x-ray examination is indicated in these patients. Abdominal girth is measured every 4 to 8 hours with paper or cloth tape around the abdomen at a consistent point marked on the abdomen to document increased distention.

Abdominal distention is a common complication in infants treated with CPAP.[129] These infants are prone to excess accumulation of air in their stomach and ultimately their intestines, which can present as visible bowel loops. This is a benign condition that can be alleviated by placement of an 8-Fr or larger orogastric (OG) tube to allow for continuous venting of gastric air.[40]

Diarrhea

Diarrhea, or frequent water-loss stools, indicates intolerance of the caloric density of feedings, transient lactase deficiency, use of highly osmotic medications, or other pathology, including, rarely, allergy. Stool culture for bacterial or viral pathogens and stool Clinitest should be performed if the infant also appears ill or if there is blood in the stools. In lactose malabsorption, short-term use of a non–lactose-containing formula or protein hydrolysate formula should result in return to normal stools.

Intermittent Rectal Bleeding/Food Protein–Induced Proctocolitis/ Eosinophilic Allergic Colitis

Asymptomatic and otherwise well newborns can pass stool noted to contain bright red blood. Pathologic factors including NEC, malrotation, Hirschsprung's disease, anal fissures, and blood clotting disorders should be investigated, as indicated. A short period of withholding feeds with supplemental IV fluids can be undertaken. Commonly, the cause is cow's milk protein. If pathology is ruled out, oral feedings can be resumed with a hypoallergenic formula or with mother's own milk after she has been on an elimination diet. The dairy elimination diet in the mother should continue for 2 weeks, but in severe cases up to 4 months, before the suspected allergen is reintroduced.[18,130]

Apnea and/or Bradycardia

Apnea and/or bradycardia frequently occur during or after feeding. These signs are the result of vagus nerve stimulation by the passage or presence of a feeding tube, gastric distention, or GER, or occur with abdominal distention and compromise of lung volumes or airway obstruction. Temporal associations between GER events and apnea/bradycardia events have been found in some studies, but not in other studies.[73,252] In most cases, it is actually the apnea that triggers GER by decreasing lower esophageal sphincter tone.[3] Interventions to decrease vagal stimulation include changing to an OG gavage tube, decreasing feeding volume, and feeding more slowly.

Poor Growth

Growth is an essential requirement for the preterm infant. When normal growth does not occur, all possible factors should be considered, but most commonly, the infant has not been

fed sufficient amounts of nutrition. If this is the case and the infant is not sick in some obvious way, then he or she should be fed more, primarily by increasing protein and energy delivery.[113] **Factors that increase caloric expenditure, such as thermal instability or overstimulation, should be considered as causes of growth failure. Preterm infants always should be cared for in a thermoneutral environment, wearing a hat or other form of head covering (because large amounts of heat are lost from the surface of the head). Additional clothing, bundling or wrapping in soft blankets, supportive positioning, and grouping of care and stimulation to conserve energy often help improve growth.**

Danger Signs

Progressively increasing abdominal distention, bilious emesis, and gross amounts of bile in the gastric aspirate can be signs of significant ileus, obstruction, or NEC. The presence of blood in the stools or gastric aspirate, a tense or tender abdomen, and abdominal wall erythema are more ominous signs of feeding intolerance and may indicate frank NEC (Box 17.9). The presence of these signs and symptoms warrants a careful physical examination and usually **further investigation including x-ray examinations. Feedings should be postponed while these signs and symptoms are being investigated. Other useful studies include a complete blood count with differential to evaluate extent of blood loss, presence of thrombocytopenia (a marker of necrotic bowel), and change in white blood cell count as evidence of infection.** Although feeding of human milk may help protect against developing NEC and 5% to 10% of cases of NEC occur in infants who have never been fed enterally, **NEC can occur in *any* infant. Abnormal abdominal distention or grossly bilious or bloody gastric aspirates should be investigated carefully regardless of feeding status.**

THE PRETERM INFANT

Much progress has been made in providing nutritional support for ELBW (<1000 g) and VLBW (<1500 g) preterm infants. The nutritional requirements of these very small infants are marked, unique, incompletely understood, and frequently inadequately provided for, despite improvements in both the quality and quantity of nutrients in currently used IV and enteral nutrient regimens (Box 17.10). Also, **many of these infants are growth restricted at birth. Thus their nutritional needs for normal rates of metabolism and growth are very likely to differ from those of normally grown infants.** Table 17.9 **shows enteral intake recommendations for stable, growing preterm infants.**

BOX 17.9 CRITICAL FINDINGS

Danger Signs Requiring Immediate Attention

1. Gross bile in the gastric aspirate with evidence of intestinal obstruction
2. Presence of blood in the stools or gastric aspirate
3. Tense or tender abdomen
4. Abdominal wall erythema
5. Unexplained anemia, thrombocytopenia, and neutropenia

BOX 17.10 SPECIAL NUTRITIONAL CONDITIONS IN EXTREMELY LOW-BIRTH-WEIGHT INFANTS

1. Minimal energy reserves (both carbohydrates and fat)
2. Intrinsically higher metabolic rate (greater relative mass of more metabolically active organs: brain, heart, liver)
3. Higher protein turnover rate (especially when growing)
4. Higher glucose needs for energy and brain metabolism
5. Higher lipid needs to match the in utero rate of fat deposition
6. Excessive evaporative rates (immature skin)
7. Occasionally very high urinary water and solute losses (depending on intake and renal maturation)
8. Low rates of gastrointestinal peristalsis
9. Limited production of gut digestive enzymes and growth factors
10. Higher incidence of stressful events (hypoxemia, respiratory distress, sepsis)
11. Metabolic effects of medications used frequently (steroids, antibiotics, sedatives, catecholamines)
12. Abnormal neurologic outcome if not fed adequately

Modified from Thureen PJ, Hay WW Jr. Conditions in preterm infants requiring special nutritional management. In: Tsang R, Lucas A, Uauy R, Zlotkin S, eds. *Nutritional Needs of the Preterm Infant: Scientific Basis and Practical Guidelines.* Baltimore, MD: Williams & Wilkins; 1993.

Enteral nutrient supply for preterm infants: commentary from the European Society for Pediatric Gastroenterology, Hepatology and Nutrition Committee on Nutrition. *J Pediatr Gastroenterol Nutr.* 2010;50:85.

§Aim = 400 international units/day.

In spite of increasingly aggressive in-hospital nutritional management, the majority of infants born preterm experience postnatal growth restriction during their NICU stay, in large part caused by inadequate nutrient intake.[61,69,87,90,255] In fact, the fraction of these infants who are small for gestational age at discharge is several-fold greater than the fraction at birth (Fig. 17.8).[89] **There is increasingly strong evidence that early nutritional support of preterm and growth-restricted infants can have lasting consequences for improved neurodevelopmental outcome.**[44,85,88] Such observations have important implications. First, we cannot now think of "early" nutrition of these small infants simply in terms of providing immediate nutrient needs just for metabolic maintenance (e.g., glucose to prevent hypoglycemia); we also must consider that early nutrition, both prenatally and postnatally, has biologic effects that have lasting or lifelong significance. Second, we can no longer regard nutritional practices in preterm infants as simply a matter of personal choice. The major impact of sufficient early nutritional support on long-term outcome should be a stimulus to new research that defines consistent approaches to the nutrition of preterm infants to optimize their future health and development.

Concerns about the safety of enteral feeding of preterm infants have frequently delayed the initiation of feedings, despite the fact that there

BOX 17.11 ADVANTAGES OF MINIMAL ENTERAL FEEDING

- No increase in incidence of necrotizing enterocolitis
- Decreased sepsis
- Decreased permeability of mucosa to foreign antigens
- Increased intestinal peptides and hormones
- Increased mucosal thickness and villi
- Maturation of intestinal motor activity
- Improved feeding tolerance
- Improved bone mineralization
- Earlier achievement of full enteral feedings
- Improved weight gain
- Shorter hospital stay
- Reduced requirement for supplemental oxygen

is little or no evidence that withholding enteral feeding decreases NEC.[187] Furthermore, the absence of enteral feeding leads to GI mucosal atrophy.[192] Evidence is accumulating that strongly supports early initiation (within the first 24 hours of life) of low-volume enteral feedings ("minimal enteral nutrition" or "trophic feeds" or "gut priming"), especially with human colostrum and milk. Minimal enteral feedings represent the administration of small feeds, less than 24 mL/kg/day, over a short but defined period (various feeding advancement protocols among different institutions define how many days to remain on minimal enteral nutrition before advancing to full enteral feeds) to promote GI development, motility, and function in the preterm infant. Enteral feedings are associated with surges in gut hormone production that mediate trophic effects on GI growth and mucosal maturation, including gastrin, enteroglucagon, motilin,[178] and lactase activity.[248] Animal studies have shown that minimal enteral feeding strategies trigger maturation of motor function in the intestine.[32,203] Absorption of nutrients is improved with increased amount and length of villous absorptive surface. Trophic feeding has been shown to improve energy intake, weight gain, head circumference gain, feeding tolerance, and time to reach full enteral feedings.[84,175,178] **The potential advantages of minimal enteral feeding are listed in Box 17.11. Nearly all studies support the use of minimal enteral feedings, although a recent *Cochrane* review could not define specific benefits or exclude harmful effects of minimal or trophic enteral feedings for VLBW infants.[188] Early trophic or gut priming feedings have not, however, increased the risk of NEC, particularly when mother's milk is used, and should be considered the standard of practice. Minimal enteral feedings should begin within the first day of life, range from 6 to 24 mL/kg/day, and be given every 4 to 6 hours for 2 to 5 days in VLBW infants.**

Although older studies indicated that rapid advances to large feeding volumes were poorly tolerated by preterm infants,[33] more recent evidence indicates that progressive feeding advances in both volume and concentration with supplements can proceed more promptly in most preterm infants.[56,135,148,231] A recent *Cochrane* review supported advancing feed volumes at daily increments of 30 to 40 mL/kg/day (compared with 15 to 24 mL/kg/day) in VLBW infants; however, applicability to ELBW infants is more limited.[186] **In the ELBW infant, greater attention should be paid to feeding tolerance, although larger, more mature infants certainly can develop serious feeding intolerance and, in some cases, even NEC.**

DOF, Day of feeds.

- Intake amounts presented as mL/kg/day.
- Gray shaded boxes represent minimal enteral feedings (trophic feedings).
- Patients may nipple bottle feeds up to the maximum feeding volume, or breastfeed as able. Patients should not initially be placed on ad lib nippling or advanced at higher volumes because of increased risk for feeding intolerance.
- Breast milk is preferred. Donor milk or formula is also acceptable if breast milk is not available or parental choice of formula.
- Infants deemed at higher risk (two or more risk factors) may have feeding amounts reduced or initiated at GI priming volumes with advancement as medically appropriate. *Perinatal risk factors* include 5-minute Apgar score <5, umbilical venous gas or infant's first blood gas with metabolic acidosis (pH <7.2, base deficit >10 mEq/L), nonreassuring fetal heart rate tracing as indication for delivery, asymmetric IUGR or IUGR with reversed or absent end-diastolic flow, monochorionic twin gestation with twin-to-twin transfusion syndrome, severe polycythemia with hyperviscosity.
- *Neonatal risk factors* include significant cardiovascular instability (chest compressions, vasoactive agent requirement, or multiple boluses of crystalloid or colloid), significant apnea (>1 per hour requiring intervention defined as vigorous stimulation with supplemental oxygen and bag-mask ventilation, any >4 per hour, or >6 total in 24 hours requiring intervention), symptomatic patent ductus arteriosus, antibiotic treatment >7 days, prolonged NPO status >7 days.

From K. Hendrickson, MS, RD, CNSC, CSP, in conjunction with NICU Quality Leadership, University of Colorado Health, Aurora, Colorado.

Once the infant is tolerating increasing amounts of enteral feeding (practice is variable, ranging from 20 to 100 mL/kg/day of enteral nutrition), breast milk can be fortified with the addition of human milk fortifiers (see Table 17.3). During this time, parenteral nutritional support is tapered to maintain from birth at least 3.5 g/kg/day protein, 30% to 54% of total calories from fat, and 40% to 60% of total calories from carbohydrate. A recent study showed that fortification as early as first initiation of enteral feeds (20 mL/kg/day) did not delay time to full enteral feeds and increased protein delivery as parenteral nutrition was weaned.[244] The transition from parenteral to enteral nutrition represents a critical period at which VLBW infants are at risk for progressive protein deficit and decreased growth velocity; thus earlier fortification of enteral feeds, if tolerated by the infant, may help to reduce this cumulative protein deficit.[182,241] Reasonable goals for time to achieving full enteral feedings of fortified human milk are 7 to 10 days in VLBW infants and about 2 weeks in ELBW infants. Table 17.10 contains guidelines reflecting a general approach to the advancement of enteral feedings.

Few randomized, controlled trials support any specific feeding strategy; however, several studies support that a defined feeding protocol that is strictly followed by an individual NICU, regardless of the details of the protocol, results in improved growth and reduced incidence of NEC and other morbidities.[71,101,213,256] The process of development and implementation of the

guideline requires reviewing current evidence and increased awareness of feeding tolerance and early signs of NEC by staff. Clinical judgment, however, should be used in following any feeding schedule for an individual patient.

Although most infants benefit from early enteral feeding, those who are asphyxiated with persistent hypoxemia and metabolic acidosis, hemodynamically unstable with a symptomatic PDA, hemodynamically unstable with sepsis, or with evidence of NEC should not be fed enterally. These infants should be managed with aggressive full parenteral nutrition. When infants are receiving indomethacin or ibuprofen for treatment of PDA, there is controversy about whether they should be fed.[169] However, some studies show that it is safe to provide at least minimal enteral feeds to neonates receiving pharmacologic therapy for PDA.[36,63,164]

Late-Preterm Infant

The late-preterm infant, born at $34^{0/7}$ to $36^{6/7}$ weeks of gestation, represents the population of preterm infants now accounting for more than 70% of all preterm births. Although generally these babies are larger and healthier than less mature newborns, NICU admission is frequent for feeding issues. **These infants have intact, functional digestive and absorptive functions, but motility and intestinal colonization may be delayed. Of particular clinical importance is the immaturity of oral motor tone, function, and neural integration. Infants born between 33 and 36 weeks of gestation may initially seem to feed well but cannot maintain successful feeding during the first week of life.** Poor feeding, therefore, is common in this group of babies, potentially contributing to problems of hypoglycemia, hyperbilirubinemia, and excessive postnatal weight loss (see Chapter 5). **The ideal nutrition for these infants, as with those infants born more preterm, is breast milk, preferably mother's own.** A significant amount of brain growth and development occurs between 34 and 40 weeks of gestation, including a 50% increase in cortical volume,[5] which could be compromised if suboptimal amounts of nutrition are delivered. Thus it is **reasonable even in such late-preterm infants to fortify mother's milk or donor human breast milk, or use preterm formulas, particularly if growth is compromised by illness and/or until the infant is taking full enteral feedings appropriate for a term infant.**[217]

THE INTRAUTERINE GROWTH–RESTRICTED INFANT

Many preterm infants have experienced IUGR and thus are born small for gestational age and preterm. Their nutritional needs for normal rates of metabolism and growth are very likely to differ from those of normally grown infants.[77] Nutritional support for the small-for-gestational-age infant requires separate consideration, because decreased size-for-dates occurs with various pathologic conditions or no pathology at all. Small size at birth is related to any number of diseases or abnormalities, both intrinsic and extrinsic to the fetus and newborn. Early events in gestation, including chromosomal and genetic abnormalities or early infection, can lead to symmetric growth restriction. In contrast, asymmetric growth restriction occurs in response to late placental insufficiency or other insults that restrict nutrient supply to the fetus. Many completely healthy and normal infants are constitutionally small. Complicating these issues is the fact that preterm infants often are growth restricted at birth (i.e., whatever led to IUGR also contributed to processes that caused or promoted preterm birth). **Such infants require more individualized management, because they may not tolerate advancing enteral feedings as well as normally grown infants and do not necessarily respond to increased nutrient intake with appropriate rates of growth.**[44,223]

In general, infants with IUGR are likely to have increased energy needs caused by low stores of energy, nutrients, and minerals.[39,77,190,230,263] **Hypoglycemia, hyperglycemia, and increased need for heat production are more likely in the early postnatal period in these infants than in their normally grown peers.**[31,279] **Infants with IUGR take longer to advance to full enteral feeds and have increased incidence of feeding intolerance and NEC.**[8,43] These problems require anticipatory nutritional monitoring and management. Early parenteral glucose, protein, and energy supplementation is necessary while a cautious advance of enteral feedings begins.[268] **Initiation of enteral feeds should not be delayed, however, as early initiation of enteral feeds in**

IUGR infants with prenatal absence or reversal of end-diastolic flow in the umbilical artery had earlier achievement of full enteral feeds with no increase in the incidence of NEC.[158]

CHANGES IN NUTRITIONAL REQUIREMENTS WITH ILLNESS

Studies in adult patients have shown dramatic changes in nutritional requirements depending on type of illness, degree of illness, surgery, and premorbid nutritional status. Although these changes are not well studied in neonates, preliminary data and clinical experience indicate that similar changes should be expected in ill infants. In fact, these patients have even greater nutritional needs because of requirements for growth and development. **The overriding observation from all studies, however, is that ELBW and VLBW preterm infants are underfed during the early postnatal period and that this undernutrition, combined with additional stresses from various diseases, increases the risk for long-term adverse neurologic sequelae.**[228] The value of achieving a specific body composition and growth rate is less certain. There remains a critical need for determining the right quality, as well as quantity, of nutrients for these infants. **The effects of common disease states on the nutrient requirements in preterm and term infants are shown in** Fig. 17.5.

Acute and chronic respiratory diseases are the most common illnesses in neonates. **Acute respiratory problems, such as respiratory distress syndrome, pneumonia, and aspiration, all increase the infant's metabolic needs for energy and protein. Energy requirements are met by increasing carbohydrate and fat delivery.** However, the metabolism of excessive carbohydrate feeding (>12.5 mg/kg/min) may be detrimental to pulmonary status by increasing oxygen consumption and carbon dioxide production, increasing respiratory work, and adding to respiratory failure. **Lipid is a good alternative source of concentrated energy because its metabolism has a lower respiratory quotient and produces less carbon dioxide. Lipids provide dense calories for volume and prevent essential fatty acid deficiency. Protein wasting and catabolism with illness increase the infant's requirement for exogenous support.** Adequate provision of amino acids, especially branched-chain amino acids, prevents catabolism of body protein stores, including respiratory and diaphragmatic muscle protein, and may improve minute ventilation by decreasing carbon dioxide production.

Infants with chronic lung disease and BPD present difficult nutritional problems.[75,189] **Poor nutrition is associated with abnormal lung development, increased toxic effects of oxygen, decreased surfactant production, and increased risk for infection.** Although energy and metabolic demands are increased in these patients, many routine management strategies make the disease process worse. When too much energy is delivered, this can lead to excess adiposity and inflammatory organ (heart and liver) fat deposition. **Excessive fluid volumes increase pulmonary edema and contribute to lung injury. Increased work of breathing limits intake. Steroid therapy and chronic disease have negative effects on protein balance. Diuretic use can waste calcium and potassium.** Feeding ELBW preterm infants with severe respiratory distress and respiratory insufficiency with higher protein-to-energy ratio diets starting with IV nutrition at birth and continuing with enteral feeding is more appropriate and is associated with reduced risk of BPD.[144]

Congenital heart disease, **especially when accompanied by cyanosis or congestive heart failure, significantly impairs nutritional status and growth. These infants have increased *basal metabolic needs* and experience the additional catabolic stress of early surgery.** Nutritional management also is complicated by underlying hypoxemia, diuretic therapy, respiratory distress, malabsorption, and variable fluid balance. Mineral derangement is common postoperatively with diuretic therapy and suboptimal intake. Iron supplementation is necessary to provide for increased erythropoiesis with chronic hypoxemia.

Undernutrition and malnutrition increase the risk of infections, including sepsis. **Good nutritional status can decrease the risk for infection and sepsis, as well as improve recovery in neonates.** Normal immune response depends on adequate protein, energy, micronutrients, and trace elements. Although not well studied in this population, it appears that the **metabolic requirements of septic infants, especially for energy and amino acids, are different from the requirements of otherwise similar, but uninfected, infants.**[225]

The infant with NEC or short bowel syndrome **is at additional risk for malnutrition because of malabsorption and increased nutrient losses. During the acute NEC illness, these infants must receive adequate parenteral nutrition, particularly emphasizing protein to counter the catabolic condition from stress hormones such as cortisol.** Recovery needs to be supported by gradual increases in enteral nutrition and slowly decreasing parenteral supplementation. Of particular concern are excessive water losses with electrolyte imbalance and malabsorption of fats and fat-soluble vitamins. **Infants with short bowel syndrome need to have enteral feeding advanced as soon as possible to avoid total parenteral nutrition (TPN)-related cholestasis.**

Any infant recovering from severe *perinatal hypoxic-ischemic injury* or "asphyxia" with significant evidence of shock (low blood pressure, poor circulation, and metabolic acidosis) should probably not receive enteral feedings for 24 to 72 hours to allow recovery of the bowel from the ischemic injury. Infants with moderate forms of hypoxia-ischemia probably can be given minimal enteral feedings with mother's colostrum or breast milk as soon as the infant is stable in terms of circulation and oxygenation. Minimal enteral feedings potentially could improve gut development after injury and colonize the gut with a more favorable microbiome.

Neonates who have undergone surgery **are at increased risk for nutritional deficiencies resulting from the stresses of illness and surgery and possible abnormal nutrient and water losses.** In these infants, enteral feedings are preferred because they preserve the integrity of the intestinal mucosa and promote continued development of the GI tract. **After a surgical procedure, the infant is often nil per os (NPO) status for 3 to 14 days until the return of intestinal motility and function** (e.g., stooling, lack of abdominal distention, decreased gastric aspirates, absence of bilious aspirates). The method of feeding chosen, rapidity of feeding advancement, formula composition, and type of feeding depend on the infant's general medical condition, GI function, and type of surgery. The choice of formula for the postsurgical neonate depends on bowel integrity. An infant recovering from mild NEC may be started on human milk or regular formula. **With serious or surgically treated NEC, human milk is preferred, but an elemental or protein hydrolysate formula may be used** with MCTs for easily absorbed lipids and glucose polymers for more easily absorbed carbohydrates, as long as they do not produce too high an osmolality in the feeding mixture.

DEVELOPMENTAL SUPPORT

Developmentally supportive feeding is extremely important. Preterm birth resulting in delayed introduction of oral feeding skills, surgical interventions for congenital or genetic abnormalities necessitating alternative feeding methods such as gastrostomy tube feedings, and prolonged interruption of normal feeding patterns for delayed postnatal adaptation in infants with hypoxic-ischemic injuries or early NEC and sepsis, are all examples of the impact that hospitalization can have on patients and their families.[67]

Being aware of the impact that prolonged hospitalization can have on feeding is the first step in being able to provide support and guidance to families of fragile infants. **By using a team approach, the family can help support their infant in attaining and strengthening feeding skills in preparation for discharge** and hopefully prevent or minimize long-term feeding difficulties that often are associated with an extended hospital stay, such as loss of feeding skills and feeding aversion issues.

A *supportive feeding team* should include the parents, physicians, nurse practitioners, lactation specialists, dietitians, occupational and physical therapists, developmental specialists, and nursing staff educated in the developmental support of infants with specialized feeding needs. This support should start as soon as an infant is admitted and continue beyond discharge to promote the best possible outcome with regard to feeding ability.

FAMILY SUPPORT

Parents of the NICU patient may feel overwhelmed by their infant's illness, appearance, and uncertain future. **Loss of control of the infant's care and unclear parental roles make bonding difficult and add to feelings of helplessness, frustration, and isolation.** All members of the health care team must be supportive and facilitate the parents as caregivers. **Parent education about early feeding**

practices in the nursery and anticipated infant growth and development facilitates care by parents. Feeding is an excellent way to involve parents in their infant's care. Parents should be involved in discussions of feeding practices and food choices. **Scheduling oral feedings for parent visits enables active participation in their infant's care. During gavage feedings, parents should be encouraged to hold their infant and support the pacifier to encourage nonnutritive sucking.** Frequent communication about the ups and downs of feeding the sick newborn, as well as weekly progress updates on growth charts, is helpful.

A mother's ability to provide breast milk remains the one aspect of care that she alone can do for her infant. Preterm birth and prolonged illness, as well as the inability to breastfeed the infant directly, are major barriers to successful breastfeeding. **Lactation support in the NICU increases mothers' success at maintaining lactation through discharge from the NICU.** Guidelines for expression and collection of human breast milk, gavage feeding of human milk, and identification of oral feeding readiness all are essential elements of lactation support and success (see Chapter 18).

FEEDING THE PRETERM INFANT AFTER HOSPITAL DISCHARGE

Many preterm infants are still preterm when they are discharged from the NICU, and most are small for their corrected gestational age (i.e., they are growth restricted) and at significant risk for further growth failure in the postdischarge period.[89,151] These infants require continued attention to nutritional support after hospital discharge.[153,199] **Mother's own milk should be used exclusively for the first 6 months of life, with continuation of breastfeeding for 1 year or longer as mutually desired by the mother and infant.**[143] However, postdischarge feeding practices, including the questions of whether and when and how to fortify human milk, vary widely because evidence is conflicting.

For VLBW, formula-fed preterm infants who are of subnormal weight and especially length and head circumference at the time of discharge, expert consensus guidelines support the use of postdischarge transitional formula and close nutritional follow-up.[153,196] These products are intermediate between preterm and term formulas in their energy, protein, calcium, phosphorus, vitamin, and mineral contents (see Table 17.7 for nutritional composition). **These recommendations are supported by some evidence that has shown that providing preterm infants with a formula containing higher protein and energy contents after discharge results in improved growth.**[277] Furthermore, use of a transitional formula for 3 to perhaps as long as 6 months after discharge increases lean mass without increasing percent body fat at 1 year and decreases body fat, truncal fat, and fasting insulin concentrations at 2 years.[70,218] However, few trials have assessed neurodevelopmental outcomes, and those that have do not detect any significant differences in developmental indices at 18 months' corrected age.[24,278] **Thus preterm infants discharged home with a normal weight for postmenstrual age could be fed similarly to term infants of similar gestational age.**[196]

Guidance on how to feed the breastfed preterm infant is scarce. Limited available data do not provide convincing evidence that multinutrient fortified breast milk compared with unfortified breast milk after hospital discharge affects important outcomes, with the exception of a small but significant effect on length at 12 months of age.[277] However, **preterm infants fed their own mother's milk for prolonged periods without fortification, and especially those receiving donor milk with limited fortification, often accrue the greatest nutritional deficits by discharge and are at continued risk of growth deficiencies postdischarge.**[199] Traditionally, mother's milk (22 to 24 kcal/oz) has been fortified with powdered transitional formula, but added nutrition with this method is negligible.[107] **If growth is suboptimal at the time of discharge or in the immediate postdischarge period, consideration can be given to either providing supplemental human milk fortifier in limited amounts or setting a minimum amount of transitional formula feeds to augment breastfeeding until adequate growth is achieved.** Close follow-up by a dietician is recommended. There also are many examples of **former preterm infants growing quite well with increased milk intake from their own mother. Such infants often can take in as much as 200 to 250 mL/kg/day. Prolonged breastfeeding also directly correlates with better neurodevelopmental outcomes.**[25,26,127]

Preterm infants with significant chronic lung disease or other chronic conditions that might increase energy expenditure are likely to need increased protein and energy delivery after discharge to maintain adequate growth. For all preterm infants, attention should be paid to other possible nutrient deficiencies including calcium, phosphorus, iron, vitamins, and LC-PUFAs. **Feeding post-discharge preterm formulas or breast milk with higher concentrations of calcium and phosphorus results in improved bone mineralization.[154] All preterm infants also should receive iron supplementation and close surveillance of iron status.[22] Regardless of milk type, demand feeding should be initiated before discharge to document adequate growth on the chosen feeding regimen. Close monitoring of growth (weight, length, and head circumference for age, indices of body proportionality) and feeding intake should be performed at discharge and regularly after discharge using appropriate growth curves.**

18 BREASTFEEDING THE NEONATE WITH SPECIAL NEEDS

SANDRA L. GARDNER, RUTH A. LAWRENCE, AND ROBERT M. LAWRENCE

Human milk has been recognized as the gold standard for infant nutrition for centuries. Published studies from 1918 on have confirmed that problems develop when human milk is replaced with artificial formulas made from the milk of other species. **Milk of other species that is fed to human infants has been known to contribute to increased infant mortality risk.** Over the years, increasing research has confirmed the presence of anti-infective properties of human milk that protect against infections of the gastrointestinal tract, the upper and lower respiratory tracts, and the urinary tract, as well as against otitis media, bacteremia, bacterial meningitis, botulism, and necrotizing enterocolitis (NEC), leading to lower infant mortality rates.[10,233] In numerous studies, human milk also has been shown to have a protective effect against sudden infant death syndrome, type 1 and type 2 diabetes, obesity, Crohn's disease, ulcerative colitis, lymphoma, childhood leukemia, allergic diseases, asthma, chronic digestive disorders, heart disease, hyperactivity, and hypertension.[154,245] Breastfeeding also enhances cognitive and visual development and neurodevelopment.[27,152,256] Studies show less of a pain response in full-term infants undergoing heel lance when they were breastfed before, during, and after the procedure. **Breastfeeding as a nonpharmacologic intervention for procedure-related neonatal pain is highly recommended**[361] (see Chapter 12). **In preterm infants, human milk provides both short-term and long-term advantages (Table 18.1) in a dose-dependent relationship; the more breast milk the preterm infant receives, the more benefits he or she receives.**[297,301,334,337,387]

Because of a lack of experience and knowledge about breastfeeding, a new mother who is discharged early (24 to 48 hours) from the hospital may find it challenging to initiate breastfeeding for her healthy newborn infant. The mother of a newborn with special needs, such as a preterm infant, a sick term newborn, or an infant with a congenital anomaly, may have even more difficulty in establishing breastfeeding because of the stress of separation and concerns about the infant's well-being (see Chapter 29). The tremendous benefits of providing human milk for all infants, but especially the premature infant, outweigh any apparent difficulties. In 2015, the Centers for Disease Control and Prevention (CDC) found a racial disparity in human milk use in neonatal intensive care units (NICUs) in the United States.[41] Although 80% of infants in reporting NICUs received mother's own breast milk and 10% of infants received donor milk, when NICUs serving a higher percentage of black residents were examined, 72% of their infants received mother's own milk and only 5% received donor milk.[41] **Human milk feedings (i.e., mother's own milk; donor human milk) need to be a priority for all preterm infants in NICUs.**[10,121,297,301]

Healthy People 2020,[445] the health policy statement for the United States, states the following goal about breastfeeding: 81.9% of women breastfeeding in the early postpartum period, at least 60.6% still breastfeeding their infant at 6 months, and 34.1% breastfeeding their infant at 1 year of age. A report published by the Institute of Medicine,[197] the American Academy of Pediatrics (AAP) Section on Breast Feeding,[10] the Academy of Breastfeeding Medicine (ABM),[73] and the U.S. Surgeon General's *Call to Action to Support Breastfeeding*[441] states that **(1) all infants in the**

BLUE type highlights content that is particularly applicable to clinical settings.

TABLE 18.1 ADVANTAGES OF BREASTFEEDING AND HUMAN MILK INTAKE FOR PRETERM INFANTS[295,297,387,433]

BENEFIT	COMMENT
Protection from NEC*	Formula-fed infants developed NEC 6–10 times more often than infants receiving only human milk. Infants ≥30 weeks' gestational age: incidence of NEC 20 times more in formula-fed than in human milk–fed infants. Lower incidence of intestinal perforation and less severity of NEC with human milk intake before NEC. Dose-dependent relationship among human milk intake, reduced risk for NEC, and cost savings (each additional mL/kg/day) of human milk in first 2 weeks of life decreased costs. Exclusive human milk diet fortified with human milk fortifier significantly lowers rates of NEC, severity of NEC, and cost when compared with human milk or formula diet fortified with bovine-based fortifier.[17,420]
Protection from infection or sepsis†	Lowered infection and severity of infections in hospitalized ELBW, VLBW, or LBW infants fed human milk,[334,388,393] resulting in shortened LOS. Skin-to-skin care customizes human milk by production of antibodies against NICU-specific pathogens.[367] Lower intestinal permeability with human milk vs. formula feedings; >75% human milk intake resulted in 3.8-fold lower intestinal permeability compared with <25% or no human milk intake.[425] A dose-response relationship between consumption of human milk and sepsis: every 10-mL/kg/day increase in human milk consumption decreased the risk of sepsis by 19%.[334] Use of mother's milk for oral care of ventilated premature infants was not associated with decrease in ventilator days, LOS; reduced positive tracheal aspirates/positive blood cultures not statistically significant.[426]
Increased feeding tolerance[90,393]	Decreased protection if formula feeding added to human milk feedings. Increased rehospitalization: sevenfold for formula-fed infants compared with 0–1 for infants who are breastfed (both partially and completely). Possible to achieve complete enteral feedings by 6 weeks of age in VLBW infants fed own mother's milk (compared with VLBW infants fed donor milk or formula).[255] Formula-fed infants: increased vomiting, gastric residuals, and longer time to achieve complete enteral feedings.[255]
Earlier attainment of full enteral feedings,[171] which is associated with a significant reduction in late-onset sepsis among extremely premature infants[372]	Preterm infants ≤1250 g receiving at least 50% human milk attained earlier full enteral feedings. Any bovine-based enteral intake in extremely preterm infants results in a longer time to full enteral feedings.[171]
Decreased risk for later allergy	Lower incidence of allergic symptoms (especially eczema) at 18 months in human milk–fed preterm infants.[254]
Improved retinal function[388]	Better retinal function, depending on omega-3 fatty acid concentration (found in human milk, but not previously in formula) in enteral feedings. Less ROP and less severe ROP in human milk–fed compared with formula-fed infants.[270,415,479]
Improved neurocognitive development‡ and brain growth[27,37]	Long-term advantages: higher intelligence quotients at 30 months,[455] and 7–8 years of age;[27] better development at 18–24 months of age;[152,256,454] and better behavioral scores (orientation/engagement, motor regulation, and total scores).[454] Better academic achievement, motor function, and working memory at 7 years of age.[27] Higher IQ and better neurocognitive abilities in adulthood.[384] Increased white matter microstructural organization in the cerebrum and cerebellum.[323] Supplementation with long-chain fatty acids (added to breast milk/formula) significantly improves neurodevelopment at 1–3 years of age.[459] Dose-dependent association between better cognitive scores at 20 months' CA in VLBW infants[337]
Suppression of oxidative stress	Reduced incidence of BPD/CLD in a dose-dependent relationship:[131,170,389,393,415,454] 9.5% reduction in BPD/CLD for every 10% increase in own mother's milk dose; cost savings for every BPD/CLD case prevented.[335] Anti-inflammatory and antioxidant properties of human milk may protect premature infants from white matter injury.[90,232]

Continued

TABLE 18.1 ADVANTAGES OF BREASTFEEDING AND HUMAN MILK INTAKE FOR PRETERM INFANTS[295,297,387,433] — CONT'D

BENEFIT	COMMENT
Reduced health care costs[205,254]	A dose-response relationship between consumption of human milk and cost savings: NICU costs lowest in VLBW infants with the highest intake of human milk in the first 28 days of life.[334] Lower risk of NEC and sepsis (see above). Earlier attainment of full enteral feedings (see above). Shorter LOS.[389,393] Fewer hospital admissions up to 30 months of age.[454]
Reduced heart disease in later life and features predictive of metabolic syndrome[401]	Lower cardiorespiratory levels and LDL to HDL ratios in adolescents born premature who were fed human milk.

Modified from Meier P, Brown L. Breast feeding for mothers and low birth weight infants. *Nurs Clin North Am.* 1996;31:351.

United States should be breastfed, (2) "human milk is uniquely superior for infant feeding,"[197] (3) "infants should be exclusively breastfed for 5 to 6 months,"[10] and (4) "breastfeeding is the ideal method of feeding and nurturing infants."[441] The policy statement by the AAP provides additional recommendations for high-risk infants, including preterm infants. It states that the "hospitals and physicians should recommend human milk for premature and other high-risk infants either by direct breastfeeding or using the mother's own expressed milk." The statement continues by recognizing that maternal support and education, mother-infant skin-to-skin contact, and direct breastfeeding as early as possible are keys to success. State-by-state breastfeeding data on the percentage and length of breastfeeding are available from the CDC in its Breastfeeding Report Card.[66] In 2018, the CDC reported that over one-half of the breastfeeding goals for *Healthy People 2020* had been met by the 2015 data: 83.2% of mothers in the United States breastfed their infants after birth, 57.6% were breastfed at 6 months of age, and 35.9% were still breastfeeding at 1 year.[66]

In 2018, the United Nations International Children's Emergency Fund (UNICEF) and the World Health Organization (WHO) published a revised 10 steps for the Baby-Friendly Hospital Initiative to protect, promote, and support breastfeeding.[439] Although the initial Baby-Friendly steps were intended for full-term healthy newborns and their families, **the revised 10 steps (Box 18.1) are intended to be applied to premature and sick babies as well as healthy breastfeeding neonates.**[439] Quality improvement strategies[332] using 10 steps for promoting breastfeeding for very-low-birth-weight (VLBW)[134] infants and a multidisciplinary approach[35] both significantly improved the rate of breastfeeding with mother's own milk in the NICU at initiation of feedings and at NICU discharge for VLBW infants. Before the start of the World Breastfeeding Conference in 2018, UNICEF and the WHO issued a report that **globally, only 2 of 5 newborns breastfeed in the first hour of life.**[440] Initiation of **breastfeeding later than the first hour of life increases the risk of neonatal mortality by 33%, and initiation after 24 hours of life increases the risk by 50%.**[440]

The goal of this chapter is to give the health care provider the skill and knowledge to support the breastfeeding dyad, especially when it involves the neonate with special needs.

BOX 18.1 REVISED TEN STEPS TO SUCCESSFUL BREASTFEEDING

Critical Management Procedures

1a. Comply fully with the *International Code of Marketing of Breastmilk Substitutes* and relevant World Health Assembly resolutions
1b. Have a written infant feeding policy that is routinely communicated to staff and parents
1c. Establish ongoing monitoring and data-management systems
2. Ensure that staff have sufficient knowledge, competence and skills to support breastfeeding

Key Clinical Practices

3. Discuss the importance of breastfeeding with pregnant women and their families
4. Facilitate immediate and uninterrupted skin-to-skin contact and support mothers to initiate breastfeeding as soon as possible after birth
5. Support mothers to initiate and maintain breastfeeding and manage common difficulties
6. Do not provide breastfed newborns any food or fluids other than breast milk, unless medically indicated
7. Enable mothers and their infants to remain together and to practice rooming-in 24 hours a day
8. Support mothers to recognize and respond to their infant's cues for feeding
9. Counsel mothers on the use and risks of feeding bottles, teats and pacifiers
10. Coordinate discharge so that parents and their infants have timely access to ongoing support and care.

From United Nations International Children's Emergency Fund (UNICEF) and the World Health Organization (WHO). *Implementation Guide: Protecting, Promoting and Supporting Breastfeeding in Facilities Providing Maternity and Newborn Services: The Revised Baby-Friendly Hospital Initiative.* Geneva, Switzerland: WHO Document Production Service; 2018:17.

PHYSIOLOGY OF BREASTFEEDING

Nutritional Value of Breast Milk

The components of breast milk vary with the (1) stage of lactation, (2) time of day, (3) sampling time during a feeding, and (4) extremes of maternal nutrition. In addition, there is variation among individual mothers, especially related to their age and gravity.[245,310,311]

***Colostrum* is produced immediately at delivery and within 5 days gradually changes to transitional milk with increased lactose and finally mature milk by 2 weeks** with an increasing concentration of fat. Colostrum contains higher ash content and higher concentrations of sodium, potassium, chloride, protein, fat-soluble vitamins, amino acids, and minerals than does mature milk. Colostrum has a lower fat content, especially of lauric and myristic acids, than does mature milk. Novel bioactive substances (i.e., irisin, adropin, copeptin) in colostrum may assist the neonate in postnatal adaptation related to thermoregulation, vascular adaptation, glucose metabolism, lung function, and fluid homeostasis.[46] This milk is yellowish, thick, and rich in antibodies, has a specific gravity between 1.040 and 1.060, and contains 67 kcal/dL. During the first day of life, full-term healthy breastfeeding neonates ingest a total of 15 mL (±11 mL) divided among 10 feeding sessions.[386] Multiparas and women who have previously breastfed have more colostrum during the first few days than do women who have not.

***Transitional milk* is produced between 7 and 10 days postpartum,** remains high in protein and fat,[114] and has a dramatic increase in water content compared with colostrum. Among mothers, the high variability of transitional milk accounts for 67 to 75 kcal/dL.

***Mature milk* is produced after 10 days postpartum** and contains 75 kcal/dL. The fat and energy content of mature milk at 30 days after birth is lower when compared with transitional milk.[114] Maternal factors such as age, diet-controlled gestational diabetes, and higher postpregnancy BMI levels, as well as the level of prematurity significantly affect breast milk's macronutrients and energy.[114,235] By the second week of life, maternal milk production averages about 30 mL/hr (i.e., 750 to 800 mL/day). During a feeding, the relative content of protein and the absolute content of fat increases. Morning feedings have a higher fat content than do afternoon and evening feedings. **Foremilk is lower in fat and energy content than hindmilk.** Severely malnourished mothers have been shown to produce less milk, and water-soluble vitamins may be affected by deficient diets, as may occur in strict vegetarians.

Human Milk Versus Cow's Milk

Cow's milk differs significantly from human milk. Cow's milk has 18 parts whey to 82 parts casein, whereas human milk has 60 parts whey to 40

parts casein. Casein is composed of proteins with ester-bound phosphate, high proline content, and low solubility at a pH of 4 to 5. Casein forms curd by combining with calcium caseinate and calcium phosphate. The cysteine and taurine content is low in cow's milk but high in human milk, whereas the methionine content is high in cow's milk and low in human milk (the human infant lacks the enzyme to digest methionine). Human milk also has lower levels of aromatic amino acids, phenylalanine, and tyrosine. Human milk contains 6.8 g/dL of lactose, and cow's milk contains 4.9 g/dL of lactose. Sodium, phosphorus, calcium, magnesium, citrate, and total ash content are higher in cow's milk, but potassium and the calcium:phosphorus ratio is higher in human milk. Formula attempts to mimic human milk but still lacks cholesterol, omega-3 fatty acids, enzymes, antibodies, lactoferrin, and other protective anti-infective properties.

Human milk contains more iron than unsupplemented cow's milk but less iron than supplemented cow's milk. **Only 10% of iron is absorbed from formula, whereas about 80% is absorbed from human milk.** Iron in formula encourages the growth of *Escherichia coli* and inactivates lactoferrin. Cow's milk has a mean pH of 6.8, osmolality of 350 mOsm, and 221 mOsm renal osmolar load. Human milk has a mean pH of 7.1, osmolality of 286 mOsm, and 79 mOsm renal osmolar load.

Cow's milk forms indigestible curds much more easily and thus delays gastric emptying. The newborn cannot handle certain proteins well because cow's milk lacks specific enzymes necessary for metabolism. These enzymes are readily available in human milk. **However, 95% of human milk protein is nutritionally available to term infants, whereas the gastrointestinal immaturity of the preterm infant enables four to six times higher daily losses of human milk protein if human milk is pasteurized or has cow's milk–based fortifier added.** Some human milk proteins are immunoglobulins, which have a protective effect on the gut and are preserved by antiproteases from being digested (i.e., are found in stool). In VLBW infants, the antiproteases persist so there are more immunoglobulins and lactoferrin in the stool early on (i.e., six and four times more immunoglobulin A [IgA] and lactoferrin, respectively). This is a function of the milk of mothers who deliver prematurely, not a deficiency of the VLBW gut. **Iron is more bioavailable in human milk, and iron absorption from human milk is more efficient,** but cow's milk has a higher concentration of zinc and contains more fluorine than does human milk. Human milk, however, contains a ligand specific to zinc absorption, and thus more zinc actually is absorbed and used. Human milk has been used as a therapy for zinc deficiency (see Chapter 17 for other human milk components).

Preterm Versus Term Breast Milk

Significant evidence exists that **there are many differences in the breast milk that a mother produces when she has a preterm infant compared with the breast milk produced for a term infant**[231,273,296,431]: (1) preterm breast milk has an increased protein content that decreases over the first month of lactation; (2) the types of protein, predominantly whey, have a more physiologic balance of amino acids and contain many anti-infective properties; (3) preterm breast milk has higher concentrations of immune proteins; (4) the lipid content in preterm breast milk is more specific for the preterm neonate (i.e., an increased supply of medium-chain to intermediate-chain fatty acids); (5) lactose, the major carbohydrate in breast milk, increases in the first month of lactation and is easily absorbed by preterm infants; (6) docosahexaenoic acid (DHA) and arachidonic acid (ARA) concentrations are similar to full-term breast milk and significantly decrease over the first month of lactation[157,368]; and (7) IgA concentrations are higher (see Chapter 17 for a comparison of preterm and term breast milk). Colostrum from mothers of extremely preterm infants (i.e., 24 to 27 weeks' gestational age) contains significantly lower concentrations of lactose and glucose and higher concentrations of cytokines and immunoglobulins than does mature milk.[305] **By 5 to 7 weeks postpartum, preterm milk changes to resemble term milk, independent of gestational age at premature birth.**[421] A recent study of 40 premature infants given bovine colostrum to supplement mother's own milk in the first 2 weeks of life found that those infants receiving bovine colostrum had increased enteral protein intake.[207] A larger RCT to test the safety and efficacy is needed.

Recent studies of the composition of preterm mother's milk found that mature preterm milk contains more stem cells and immune proteins than preterm colostrum[47,209] and term mother's milk during the first month of life.[163,431] Mother's milk

of premature boys had significantly more sIgA than the breast milk for premature girls; the levels of immune components decrease over time.[163]

In the NICU, four critical exposure periods for premature infants to human milk have been identified: (1) colostrum in the transition from intrauterine to extrauterine life, (2) transition from colostrum to mature milk in the first month of life, (3) the amount of human milk feeding throughout the NICU stay, and (4) human milk feeding after discharge.[295] Colostrum is rich in bioactive factors that promote growth and maturation, as well as protection of the immature intestinal tract of infants.[295,297,431] Mothers of the least mature preterm infants produce the most protective colostrum and produce colostrum for a longer period to protect their vulnerable offspring.[295,431]

The Immunologic Value of Breast Milk

Because human milk protects neonates through its many anti-infective properties, breastfed infants have decreased morbidity compared with bottle-fed infants.[159,306] **The immunologic benefits of human milk depend on dose, duration, and exclusivity.**[173] The main defense factors in human milk are (1) antimicrobial agents, (2) anti-inflammatory factors, and (3) immunomodulators and leukocytes. In addition to providing protective agents, the components in human milk also modulate the development of the newborn's own immune functions.[159] Bacteria in mother's milk and on her areola seed her infant's gastrointestinal system and establish the infant's gut microbiome.[328] **Through breastfeeding, 30% of the beneficial bacteria are provided by breast milk and 10% by skin flora on the maternal nipple.**[328] Formula feeding, as well as cesarean delivery and antibiotic therapy, significantly alter the infant's gut microbiome.[473] **The premature infant is born with an immature immune system, and the provision of human milk reduces the risk of immune system conditions such as infection, inflammation, and allergies.**[250] Bioactive factors in human milk and their functions are listed in Table 18.2.

TABLE 18.2 BIOACTIVE FACTORS IN HUMAN MILK

COMPONENT	FUNCTION
	ANTIBODIES
Secretory IgA (sIgA)	Attaches to mucosal epithelium of the digestive tract, thus preventing attachment of pathogens,[237,371] sIgA against enteric, respiratory, and viral pathogens, as well as specific pathogens to which the mother has been exposed; highest concentration in colostrum peaks during first 3–4 days postpartum; present in mature milk through first year of life.[387] Lower sIgA concentrations in very preterm infant's mother's colostrum than in term colostrum.[65] Antiallergic properties: inhibits absorption of macromolecular antigens from neonatal small intestine.
	MAJOR NUTRIENTS
Protein	
sIgA, IgM, IgG	Immune protection.
Lactoferrin	Higher levels at birth (in colostrum) and at 30 days in premature infants, higher levels at lower birth weights[435] and gestational ages,[6] compared with full-term infants.[296] Higher levels of commensal bacteria in neonatal gut associated with higher lactoferrin levels; may contribute to immunologic maturation and neonatal well-being.[261] Binds iron, thwarts growth of pathogens (e.g., bactericidal, antiviral), modulates cytokine function, and is anti-inflammatory; highest levels in colostrum; present in mature milk throughout first year of life.[237] May attenuate iron-induced oxidation products in preterm infants.[356] Enteral lactoferrin supplementation decreases late-onset sepsis and NEC stages 2 and 3 in preterm infants without adverse effects.[326]

Continued

TABLE 18.2 BIOACTIVE FACTORS IN HUMAN MILK—CONT'D

MAJOR NUTRIENTS	
Lysozyme	Destroys pathogens (e.g., gram-positive and few gram-negative bacteria) by cell wall lysis; human milk contains 300 times the concentration of cow's milk; concentration increases with prolonged lactation.[371] Higher concentrations in preterm breast milk.[431]
Casein	Inhibits microbial adhesion to mucous membranes of respiratory and gastrointestinal tracts. Promotes growth of *Lactobacillus bifidus,* the normal intestinal flora for breastfed infants, and inhibits pathogens[252]; by 1 month of age, *Bifidobacterium* level in infants fed human milk is 10 times that of formula-fed infants.
Adiponectin	Regulates metabolism; possible protection against obesity, by influencing development of body composition.[160]
Fibronectin	Enhances antimicrobial activity of macrophages[371]; assists in repair of intestinal tissue damage by immune reactions.
Carbohydrate	
Oligosaccharides	Bind to microorganisms (microbial ligands), thus preventing pathogens from attaching to respiratory mucosal surfaces.[387] Antimicrobial and antibiofilm properties against *Group B Streptococcus.*[2]
Glycoconjugates mucin and lactadherin	Microbial and viral ligands.[93] Provide receptor site binding for organisms so that the organism is made less harmful or passes from the body in the stool.[371] Lower levels of lactadherin in milk of mothers of very preterm infants.
Fat	
FFAs	Disrupt and destroy lipid-enveloped virus, bacteria, and protozoa.[177] Obese mothers have a proinflammatory fatty acid profile; decreased concentrations of fatty acids and carotenoids influence early visual and neurodevelopment.[327]
MINOR NUTRIENTS	
Nucleotides	Enhance T-cell maturation, antibody response to vaccines, intestinal maturation, repair after diarrhea, and natural killer cell activity; promote growth of *Lactobacillus bifidus.*
Vitamins	
A, C, E, D	Anti-inflammatory: scavenges oxygen radicals. Vitamin D content of breast milk is 25 IU/L or less. For prevention of rickets and vitamin D deficiency, all breastfed infants should be given supplemental vitamin D (e.g., 400 IU/day) beginning in the first few days of life.[312,458]
Enzymes	
Amylase	Digestion of polysaccharides.
Bile salt–dependent lipase	Production of FFAs with antibacterial/protozoan activity. Assists with fat digestion.
Catalase	Anti-inflammatory: degrades H_2O_2.
Glutathione peroxidase	Anti-inflammatory: prevents lipid peroxidation.
Lipase	Breaks down triacylglycerols.
PAF acetyl hydrolase	Degrades PAF, a potent cause of ulceration; protects against necrotizing enterocolitis.
GROWTH FACTORS (HIGHER AMOUNTS OF ALL GROWTH FACTORS IN COLOSTRUM COMPARED WITH MATURE MILK)[310]	
Epithelial growth factors	Enhances maturation of gut epithelial barrier, limiting penetration by foreign antigens, thus decreasing immune stimulation.[371]
Fibroblast growth factor 21	Enhances nutrient absorption and intestinal function.[140] Contributes to improved growth and metabolic profile.

TABLE 18.2 BIOACTIVE FACTORS IN HUMAN MILK—CONT'D

GROWTH FACTORS (HIGHER AMOUNTS OF ALL GROWTH FACTORS IN COLOSTRUM COMPARED WITH MATURE MILK)[310]	
Transforming growth factors	Higher concentrations in extremely preterm infant's mother's colostrum than in term colostrum.[65,431] Alpha: promotes epithelial cell growth. Beta: suppresses lymphocyte function: anti-inflammatory; prevents allergic reaction.
Angiopoietins	Necessary for vessel growth and maturation.[474]
HORMONES	
Prolactin	Enhances B- and T-lymphocyte development; affects differentiation of intestinal lymphoid tissue.
Cortisol, thyroxine, insulin	Promotes maturation of neonatal intestine and development of intestinal host-defense mechanisms.
Erythropoietin	Influences erythropoiesis, gut maturation, apoptosis, neurodevelopment, and immunity.[390] Risk of mother-to-child transmission of HIV inversely related to erythropoietin levels in mother's breast milk.[16]
Leptin	Lower concentration than in plasma. Higher concentration in human milk reflects higher maternal BMI.[235] May contribute to mediating the association between maternal and infant body composition[102] and appetite programming of breastfed infants.[235]
Peptide hormones: adropin, copeptin, irisin, preptin	Present in colostrum; may assist in postnatal adaptation related to thermoregulation, vascular adaptation, glucose metabolism, lung function, and fluid homeostasis.[46]
CELLS	
B lymphocytes	Synthesize IgA and other antibodies targeted against specific pathogens.
Macrophages	90% of cells in breast milk; phagocytize microorganisms and kill bacteria in neonatal intestine; produce lysozyme, lactoferrin, and complement.
Neutrophils	Phagocytize bacteria in neonatal gastrointestinal tract.
T lymphocytes	Phagocytosis against organisms in gastrointestinal tract; mobilize other host defenses; antigens introduced into maternal respiratory and/or gastrointestinal systems stimulate development of antibodies in breast milk; incorporation into neonatal tissue bestows short-term adoptive immunity.[246]
Cytokines	Modulate functions and maturation of immune system.
Proinflammatory: interleukins 1-beta, 6, 8, 12; interferon-gamma; tumor necrosis factor–alpha	Enhances inflammation. Higher levels of interleukin-6 and lower levels of interleukin 8/10 and TNF-α in colostrum after preterm birth.[65] Interleukin-8 levels decline with stage of lactation; no significant difference in concentration between premature and term mother's milk.[346]
Anti-inflammatory: interleukin 10; tumor growth factor–beta	Suppresses function of macrophages, natural killer cells, and T cells.

BMI, Body mass index; *FFA,* free fatty acid; *HIV,* human immunodeficiency virus; *Ig,* immunoglobulin; *IU,* International unit; *NEC,* necrotizing enterocolitis; *PAF,* platelet-activating factor; *sIgA,* secretory immunoglobulin A; *TNF-α,* tumor necrosis factor-α; *TGF-β,* transforming growth factor-β.
Modified from Hamosh B. Bioactive factors in human milk. *Pediatr Clin North Am.* 2001;48:69.

The highest concentration of immunoprotective factors is found in colostrum, which should be pumped, preserved, and fed to a neonate with special needs.[177] **Pumped milk should be labeled chronologically so that it is fed to preterm infants in the same sequence in which it was collected. In this fashion, the preterm infant receives the high concentration of protective qualities that have been shown to protect the gastrointestinal and respiratory systems. Clinical guidelines for colostrum feeding in the NICU are presented in** Box 18.2.[295]

BOX 18.2 CLINICAL GUIDELINES FOR COLOSTRUM FEEDING IN THE NICU

- Colostrum should be the first feeding received by the newborn infant.
- Colostrum may be used for minimal enteral nutrition (trophic feeds).
- Colostrum can be safely administered to the oropharynx either before or with minimal enteral nutrition.
- Give exclusive colostrum feedings for the first 3 to 4 days; then alternate colostrum with fresh mature human milk (to protect the infant from NICU organisms through the enteromammary pathway).
- Store colostrum in small, sterile, food-grade containers that are easy to recognize in the refrigerator/freezer.
- Number the colostrum containers in the order of pumping; feed to baby in the order of pumping.
- Dilute small, expressed drops of colostrum with 1 to 2 mL of sterile water so that drops of colostrum are removed from container and/or to achieve desired feeding volume. Dilution of colostrum is not necessary for any other reason.
- Do not mix colostrum with formula or fortifier.
- Pumping colostrum may be facilitated by a combination of hand expression and breast pumping.
- Avoid formula feeding during the introduction and advancement of colostrum. Formula may exert a separate detrimental effect on gastrointestinal integrity during this critical time.

Modified from Meier PP, Engstrom JL, Patel AL, et al. Improving the use of human milk during and after the NICU stay. *Clin Perinatol* 2010;37:217.

Providing colostrum to the oral cavity of the preterm infant stimulates the development and response of the neonate's own immune system. A pilot study of 5 extremely low-birthweight (ELBW) infants (mean birth weight 657 g and mean gestational age 25.5 weeks) receiving 0.2 mL of oral colostrum every 2 hours for 48 hours beginning at 48 hours of age found that the colostrum was easy to administer, inexpensive, and well tolerated.[369] In 48 extremely preterm infants (<28 weeks of gestation), oral colostrum resulted in increased levels of immune protective factors (i.e., secretory immunoglobulin A and lactoferrin) and an inhibition of proinflammatory cytokines.[249] Another study compared administration of colostrum to the buccal pouch of VLBW infants every 2 hours for 48 hours with standard NICU care. At 48 and 96 hours, there was a marked change in the oral microbiota between the two groups.[408] **Oropharyngeal colostrum is safe and associated with higher rates of breast milk feeding in the NICU and through discharge.**[407] A 5-year, multicenter, double-blind, randomized controlled trial to evaluate the safety and efficacy of oropharyngeal mother's milk on the incidence of late-onset sepsis, NEC, and death in a large cohort of extremely premature infants is ongoing.[370] Box 18.3 is an adapted protocol for oral care with colostrum.

BOX 18.3 ORAL CARE WITH COLOSTRUM[146,295]

Teach the mother hand expression, and place colostrum in small breast milk containers.
Use fresh colostrum if possible; otherwise, refrigerated/frozen colostrum can be used.
Use colostrum in the order that it was pumped.
Using universal precautions, saturate a sterile cotton swab with colostrum (about 0.2 mL).
Before feeds or with scheduled cares if on nothing-by-mouth status: Parent/nurse paints the tongue, gums, and cheeks with colostrum.
Document.

Enteral intake in the first month of life constitutes the second critical period when benefits listed in Table 18.1 **are seen in VLBW and ELBW preterm infants in a dose-dependent relationship to human milk intake.**[295,337] The normal microflora found in the neonatal gastrointestinal tract is the first line of defense against many pathogenic bacteria. After birth, the first exposure of the neonatal gut is to the maternal vaginal flora, and colonization continues with development of an environment of flora by 1 week of age. Colonization of the gastrointestinal tract of preterm and sick neonates is altered by cesarean birth, antibiotics, delayed enteral feeding, separation from the mother, and presence in an NICU. **With breastfeeding or provision of breast milk, containing both prebiotics and probiotics, the dominant flora are *Bifidobacterium* and *Lactobacillus,* which suppress pathogens.** Breast milk has been shown to be effective in reducing the colonization with *Klebsiella, Enterobacter,* and *Citrobacter.*[125] In addition, paracellular pathways between enterocytes in the preterm infant's intestine are closed, thus inhibiting the passage of bacteria and toxins from gut lumen to the bowel wall. When infants are provided formula, the growth of bifidobacteria is very slow, and there is only one-tenth the concentration at the end of the first week compared with that in infants fed breast milk. During this critical period, even small amounts of formula interrupt both of these processes.[295]

There are conflicting results from research as to whether reduction of anti-infective activity occurs with the use of breast milk fortifier. Older studies showed that fortifier does not decrease anti-infective properties of human milk,[179,246,389] whereas a more recent study showed that human milk fortifier with iron reduced the bacteriostatic action of the fortified breast milk against *E. coli,* in vitro.[59] Continued surveillance in the use of fortifiers is recommended.[389]

The fourth critical period of human milk intake for preterm infants is the total amount and/or exclusive human milk feeding during their NICU stay.[295] Research shows that extremely premature infants (i.e., ELBW, VLBW) exhibit benefits of human milk intake listed in Table 18.1 based on their total intake of human milk. Those infants with the highest doses benefited most in both short- and long-term outcomes.[28,388,389,396,454,455] A recent study of pumping practices among[129] mothers in two NICUs found that only 50% of their infants exclusively received their mother's own breast milk and that two-thirds of the mothers had inadequate expression practices (i.e., ≤6 times/day).[196] **The goal of breast pumping is to establish a full milk supply (≥500 mL/day) by the end of the neonate's first 2 weeks of life.**[189] Attaining a full milk supply by 14 days is the strongest indicator of VLBW infants receiving own mother's milk at NICU discharge.[188]

Banked human milk (donor milk) can be used if the mother is unable or unwilling to provide sufficient quantities of breast milk.[10,121] Human milk banks in the United States have rigorous guidelines for donations and adhere to strict quality controls.[10]

Normal Lactation

Breast development during pregnancy is stimulated by luteal and placental hormones—lactogen, prolactin, and chorionic gonadotropin.[315] Production of breast milk depends on both mammogenesis and lactogenesis. Mammogenesis is the growth and development of the glandular tissue of the breast and the differentiation of secretory epithelial cells or lactocytes during pregnancy.[181] **Estrogen stimulates growth of the milk collection (ductal) system, whereas progesterone stimulates growth of the milk production system.** These hormones, however, inhibit the initiation of breast milk production in significant quantity. With the birth of the infant, the hormones of pregnancy decline abruptly when the placenta is delivered, permitting the initiation of milk secretion. There is some speculation that mammogenesis and lactogenesis stage I may be truncated with the birth of preterm infants, especially the VLBW premature infant. In addition, cesarean delivery may affect lactogenesis stage II as it affects the hormone balance stimulated by labor. Breast growth varies greatly during pregnancy, and it is unclear how much breast tissue is necessary to support full lactation. Many factors other than breast size affect milk production, such as stress and fatigue, both of which are increased when a preterm infant is born.

If a woman aborts as early as 16 weeks, her breasts secrete colostrum; therefore mothers are prepared to breastfeed any viable infant.[245]

Estrogen and progesterone function as inhibitors to actual milk production because they inhibit the breast receptors for prolactin. Therefore stimulation of the breast before delivery does not create milk but may induce uterine contractions because oxytocin is released. Once the infant and placenta are delivered, stimulation of the nipple becomes effective in producing milk.

Stimulating the nipple by the infant's sucking action causes an increase in the prolactin released in the bloodstream and induces the synthesis and release of oxytocin, which is initiated by nipple stimulation and other sensory pathways (Fig. 18.1). The amount of prolactin is directly related to the quantity and quality of nipple stimulation; because prolactin stimulates the synthesis and secretion of milk, the surges in prolactin levels are related to the quantity of milk. **A decrease in the quality of stimulation causes a decrease in prolactin surges and thus a decrease in milk production.** Studies show that **overweight/obese mothers have a diminished prolactin response to infant sucking** (e.g., less milk production) in the first postpartum week.[359] **The prevalence of delayed milk production among obese mothers in a recent study was 57.9% with milk "coming in" delayed until the sixth day of life.**[350] These mothers may benefit from earlier lactation counseling and support that will enable them to continue breastfeeding and prevent their infants from excessive weight loss and formula supplementation.[350,359,405]

Adequate prolactin secretion controls the maintenance of milk supply. The sooner the infant nurses, the sooner the milk comes in and becomes established. Initially, production of milk is on a more consistent basis because the basal level of prolactin is very high immediately after birth. Maintenance of milk depends on adequate stimulation of the breast and removal of milk on

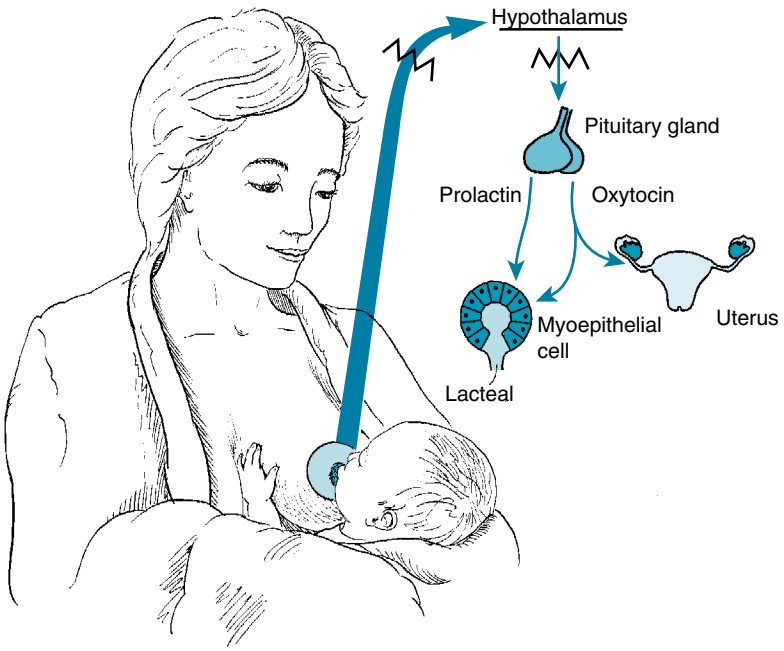

FIGURE 18.1 Ejection reflex arc, or letdown reflex. Infant suckling stimulates mechanoreceptors in the mother's nipple and areola that send the stimuli along the nerve pathways to the hypothalamus. Stimulation of the posterior pituitary gland releases oxytocin that (1) stimulates myoepithelial cells of the breast to contract and eject milk and (2) stimulates the uterus to contract. Stimulation of the anterior pituitary gland releases prolactin, which is responsible for milk production in mammary alveoli. (Modified from Lawrence RA, Lawrence RM. *Breast Feeding: A Guide for the Medical Profession.* 5th ed. St Louis, MO: Mosby; 1999.)

a regular and frequent basis. By the second week of lactation, 92% of mothers of healthy term neonates are producing *at least* 440 mL/day of breast milk for their infants.[221,222] Initially, a newborn needs to nurse for a longer time to stimulate milk production and letdown. As the infant grows, sucking becomes more efficient, with the infant stimulating sequential letdowns early in the nursing period, thereby shortening the length of nursing. Establishing a generous milk supply is critical in long-term maintenance. **Research has demonstrated that for mothers who are separated from their infants, pumping both breasts simultaneously stimulates a higher prolactin surge with increased milk supply than pumping one breast at a time.**[206]

PSYCHOLOGICAL VALUES OF BREASTFEEDING

The short-term advantage of breastfeeding is early mother-infant contact. The en face position of breastfeeding enhances this contact. During the first 1 to 2 hours after birth, the infant's sucking and touching of the mother's areola increases maternal attentiveness to the baby's needs for at least the first week of life. Because several studies show that maternal analgesia alters the infant's initial breastfeeding behavior, the mother's behavior may also be altered. Early contact—whether by breastfeeding or another physical means—sometimes must be delayed or modified in a sick neonate. **Prolactin and oxytocin affect the initiation of maternal behavior and are involved in stress management in humans.** Oxytocin has been shown to reduce depression and anxiety in lactating mothers compared with nonlactating mothers.[282] Feldman and Eidelman found that providing breast milk functions to initiate a more optimal bonding process between mothers and their premature infants by operating on physiologic, behavioral, and representational (mood) systems.[126] **Maternal depression as measured by the Beck Depression Inventory was reduced significantly when mothers provided more than 75% of breast milk nutrition for their**

preterm infant.[126] Two more recent studies also show that breastfeeding is associated with a reduced risk of postpartum depression that is maintained over the first 4 months of the postpartum period.[175,423]

The long-term psychological effect for the mother of unrestricted nursing is a more even mood cycle as a result of elevated prolactin, oxytocin, and endorphin levels,[445] which enhance coping mechanisms associated with caring for a new family member by diminishing maternal stress responses to physical, intrapersonal, or interpersonal stress.[164] Providing her own milk, including pumping and gavaging breast milk and eventual feeding at the breast, enhances maternal attachment and maternal behaviors[164,216,427] and enables the mother to contribute to her infant's care[195] (see Chapter 29). Proximity of the mother and infant, as well as the infant's initial experience at the breast, contributes to maternal and infant regulation and the establishment of innate behaviors and emotional and social ties between the mother and infant.[429] Kavanaugh et al. described rewards to the mother from breastfeeding as follows[216]:

- Knowing that she is providing the healthiest nutrition
- Enhancing closeness between her and her preterm infant
- Perceiving her preterm infant's contentment and tranquility during breastfeeding
- Convenience for the mother
- Giving her a tangible claim to her preterm infant

All physicians and nurses who admit infants to the NICU should educate, encourage, support, and assist mothers who wish to breastfeed their infants.[295,303] Use of kangaroo care at birth (see Chapter 5) and in the NICU (see Chapter 13) facilitates early initiation of breastfeeding and increases maternal confidence, competence, and breastfeeding duration. If the infant is able to take oral nourishment, he or she can be breastfed at 1000 to 1200 g and about 28 weeks' gestational age (see Chapter 13, Table 13.2).

Neurobehavioral Development in Premature Infants

The positive impact of breastfeeding on neurobehavioral and cognitive development in infants has been posited for several decades. Two theories have been proposed to explain improved neurobehavioral development: nutritional content of breast milk that improves neurologic growth, and the effect of breastfeeding on the mother-infant relationship that indirectly supports cognitive development. Evidence continues to mount demonstrating positive effects of human milk in the preterm infant. Breastfeeding increases maternal responsiveness and higher levels of synchrony observed between mothers and preterm infants, hence leading to higher cognitive outcomes. A study of 86 preterm infants with a mean gestational age at birth of 30 weeks and an average birth weight of 1300 g found that the amount of breast milk provided made a significant impact on the neurodevelopment of the infant when assessed at 37 weeks and 6 months' corrected age. The preterm infants who received more than 75% of their nutrition from breast milk demonstrated a more mature neurodevelopmental profile at 37 weeks' corrected age and higher mental and psychomotor skills at 6 months' corrected age.[126] An observational cohort study of the relationship between breastfeeding, early weight gain, and neurodevelopment resulted in an "apparent breastfeeding paradox."[377] In the studied cohorts, only 16% and 19% of very preterm infants breastfed at discharge from the NICU. On follow-up, the breastfed infants' initial weight gain was characterized as "suboptimal," but their neurodevelopmental outcomes were more favorable than the very preterm infants who were not breastfed.[377]

FACILITATING SUCCESSFUL BREASTFEEDING

Although breastfeeding is a normal, natural function, it is not a reflex but, rather, a highly complex interaction and interdependence between mother and infant. To be successful, the breastfeeding dyad must synchronize their behavior and physiology and receive support from their environment. Delayed breastfeeding may be as successful as immediate feeding when (1) problems are prevented, (2) the mother receives support and encouragement in maintaining her milk supply, and (3) everyone is patient and knowledgeable about teaching the infant to suckle. Initiating breastfeeding as early

as possible is important to prevent problems. Thorough evaluation of the effectiveness of the nursing couple is important in achieving adequate nutrition and breastfeeding success. Knowledgeable health care providers and licensed, certified lactation consultants, where available, can perform these evaluations.[348] **Development of an evidence-based and mother-friendly breastfeeding service has been shown to dramatically improve the volume of mother's milk that is available and to prolong the duration of milk provision for preterm infants.**[297]

Sucking

Sucking is a primitive reflex appearing as early as 15 to 16 weeks of gestation. **Although isolated components of feeding behaviors (e.g., root, suck, swallow, gag) are all present early in gestation, they are not effectively coordinated for bottle feedings before 32 to 34 weeks' gestational age (see Chapter 13, Table 13.2).** The infant can coordinate suck and swallow while breastfeeding as early as 28 weeks of gestation. Two distinct types of sucking, nonnutritive and nutritive, develop in the human infant.

Nonnutritive Sucking

Nonnutritive sucking (NNS) is sucking activity in which no fluid or nutrition is delivered to the infant. Characterized by short bursts of rapid motion, pauses, and few swallows, NNS has a stabilizing effect on physiologic responses (i.e., better oxygenation; quieter, more restful behavior; decreased tension; increased insulin and gastrin secretion that may stimulate digestion and storage of nutrients; and improved readiness for oral feedings) (see Chapter 13). Because there is no bolus of fluid to swallow, NNS results in an alternation of inspiration and expiration without the regular apneic periods of nutritive sucking. However, even in NNS when the occasional swallow of saliva is necessary, there is a maturational progression of swallow-breathe interaction from central apnea to obstructive apnea to attenuated breathing.[365] A sensorized pacifier has been developed to give a complete pressure profile of sucking patterns with NNS and possibly used to monitor sucking skills of premature infants.[158]

Nutritive Sucking

Nutritive sucking, used by an infant when fluid or nutrition is available, is characterized by an organized, rhythmic pattern that is about one-half the rate of NNS (i.e., one per second). During nutritive sucking, each milk expression is followed by a reflexive swallow and an occasional brief pause. In a term neonate, rates of sucking range from 40 to 60/min. Nutritive sucking provides the neonate with positive reinforcement, which encourages a steady level of behavior. A variety of factors affect nutritive sucking, including maternal anesthesia and/or analgesia, length of labor, type of delivery, gestational age, birth weight, age (in hours), severity of illness, infant state, type of fluid, disorders of the central nervous system, and individual variations.★

Although nutritive sucking is associated with faster heart rate (when bottle feeding), little information is available describing energy requirements of nutritive sucking. The findings of one study suggest that, during bottle feeding, preterm infants expend significantly less energy to suck the same volume than do full-term infants.[202] **Bottle feeding requires *more* energy than breastfeeding in all infants.**[202]

Two patterns of nutritive sucking have been identified: continuous sucking and intermittent sucking.[269] ***Continuous sucking* occurs at the beginning of bottle feeding, when the suck is strong and continuous for at least 30 seconds.**[266,269] ***Intermittent sucking,* an alternation of sucking bursts with periods of pause/no sucking,**[266,269] **occurs first during breastfeeding, followed by continuous sucking (with breast milk letdown).**[268,289] **Breathing and oxygenation are affected more during continuous sucking than during intermittent sucking,**[428] even in full-term infants who can exhibit apnea and bradycardia with feeding.[265]

An increasing level of organization of nutritive sucking occurs with increasing gestational age, maturity, and experience.†

Preterm sucking patterns exhibit a higher sucking-to-breathing ratio (2:1 to 4:1) than the well-coordinated ratio of full-term newborns (e.g., 1:1).[342] By 32 to 34 weeks' postconceptual

★References 49, 135, 241, 268, 278, 282, 283, 319, 342, 400
†References 135, 241, 268, 278, 282, 283, 319, 342, 400

age (PCA), there is a change in sucking bursts (i.e., increase in number of sucks, number of suck bursts, and pressure; decrease in time between sucking bursts). This developmental maturation enables nutritive sucking to take less time and is less tiring. For infants having feeding difficulties or a preterm infant who is not progressing as expected in feeding ability, there is a quantitative instrument, the Medoff-Cooper Nutritive Sucking Apparatus (M-CNSA), that provides a continuous record of the negative pressure generated during a 5-minute feeding assessment. The M-CNSA augments clinical evaluation as it objectively measures nutritive sucking parameters and enhances clinical decision making.[461]

Nutritive sucking requires coordination between sucking, swallowing, and breathing. During coordinated sucking bursts, suck-swallow-breathing occurs in a 1 sec:1 sec:1 sec sequential pattern. Recent research has found highly variable suck-swallow-breathe patterns ranging from 1:1:1 to 12:1:14.[382,383] The lack of a coordinated suck-swallow-breathe ratio of 1:1:1 contributes to a preterm infant's apnea with feeding, a reflexive protection of the airway.[268,348,365,428] Although suck-swallow is achieved by 32 weeks of gestation,[284] respiration may still not be well coordinated, so the preterm infant may develop apneic episodes with bottle feeding.[348,365,428] With increasing PCA and neuromuscular maturity, *consistent* coordination of suck-swallow-breathe (with bottle feeding) occurs by 35 to 37 weeks' PCA.[135]

Sucking patterns of full-term, preterm, and preterm infants with bronchopulmonary dysplasia (BPD) have recently been studied. **All full-term infants had a normal sucking pattern soon after birth, but bottle feeding was found to contribute to arrhythmic sucking over a 10-week period after birth.[96]** Small-for-gestational-age (SGA) preterm infants were found to develop normal sucking patterns later than appropriate-for-gestational-age (AGA) preterm infants; **by term-equivalent, no SGA infants and 38% of AGA preterm infants had normal sucking behaviors.[97]** Abnormal sucking in the SGA infants included incoordination and dysfunctional sucking patterns. Compared with preterm infants without BPD, those with BPD had more incoordination of sucking, swallowing, and breathing (36% vs. 15%).[98]

A randomized study of early introduction of oral (bottle) feeding (e.g., within 48 hours of full tube feedings) found the following[400]:

- Transition time to all oral feedings was significantly shorter.
- Oral feeding was introduced 2.6 weeks earlier.
- Total oral feeding was achieved at earlier postmenstrual age (PMA) (e.g., 54% of 33-week-PMA infants vs. 12.5% of control group infants).
- Weight gain and discharge weights were similar in both groups.
- Episodes of feeding-related bradycardia and desaturations were similar for both groups.
- The early feeding group was discharged 10 days earlier than the control group.

In this study and others, researchers postulate that **feeding opportunities in young infants provide them with practice and *experiential* opportunities to develop their oral motor skills and coordination of suck-swallow-breathe.[133,276,400]**

Human nutritive sucking is composed of five separate yet interrelated processes: rooting, orienting, sucking, expressing, and swallowing (Fig. 18.2).[40] *Rooting,* the tactile stimulating of the infant's face and lips, elicits the head to turn toward the stimulus. Stimulation of the center of the lower lip enables the infant to root by coming forward extending the tongue, drawing in the nipple and areola, and latching on, rather than turning the head to one side. *Orienting,* or *latching on,* occurs when the tongue draws the nipple and areola into an elongated teat and compresses it against the hard palate (Fig. 18.3).

Sucking, the application of negative pressure in the infant's mouth with lowering of the tongue/mandible, elongates the nipple and transfers milk from the breast.[116,304,357] At the beginning of breastfeeding, a strong suction stretches and shapes the nipple, but only moderate suction is necessary to maintain adequate grasp of the nipple.[60] During the feeding, occasional bursts of sucking enable milk to be expressed. *Expressing* milk occurs when negative pressure is applied to the breast with closure of the mandible that compresses milk ducts, slowing or stopping milk flow allowing for safe swallowing and breathing[116,141,357] (Fig. 18.4). The lips should be flanged out to create a seal.

Swallowing milk occurs as peristaltic motion of the posterior pharynx (reflexive swallowing) and

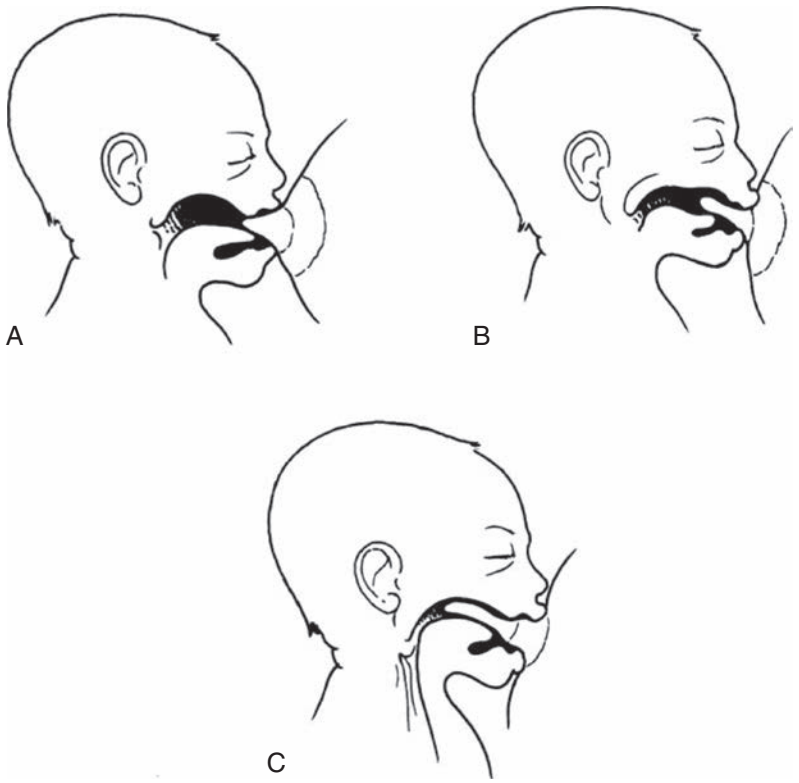

FIGURE 18.2 Normal suckling. **A,** As the infant grasps the breast, the tongue moves forward to draw in the nipple. **B,** The nipple and areola move toward the palate as the glottis still permits breathing. **C,** The tongue moves along the nipple, pressing it against the hard palate and creating pressure. Ductules under the areola are milked, and flow begins as a result of peristaltic movement of the tongue. The glotis closes. Swallow follows. (From Lawrence RA, Lawrence RM. *Breast Feeding: A Guide for the Medical Profession.* 8th ed. Philadelphia, PA: Elsevier; 2016.)

propulsion of milk down the esophagus. These peristaltic motions coordinate suck and swallow so breastfeeding infants do not choke, unless the letdown reflex is excessive. Swallowing milk also inhibits respiration (thus protecting the airway), and reflexively initiates the expression cycle of jaw and tongue movements. Therefore nutritive sucking is primarily expression and swallowing of milk. During nursing, just enough suction to keep the nipple in proper position is used, even during the expressive phase of sucking. **Breastfeeding is an infant-regulated system; milk flow depends on active sucking by the infant. When an infant pauses to regain physiologic stability, the flow of milk from the breast ceases.**

Ultrasonographic studies[145] of full-term infants' breastfeeding note (1) an elongation to twice the resting size of the maternal nipple[358]; (2) the formation of a passive seal by the neonate's oral cavity[358]; (3) milk ejection coinciding with the downstroke of the tongue and jaw, creating negative pressure by oral cavity enlargement[358]; (4) multiple milk ejections during breastfeeding that may not be sensed by the mother[358]; and (5) milk ejection characteristics that are consistent within women during different breastfeeding and pumping sessions,[138] as well as across consecutive lactations.[139]

Artificial nipples have also been shown to vary in their rate of milk flow.[262,264,266] Nipple hole size, rather than the type of nipple,[262,267] has been found to be the major determinant of the variability in

milk flow.[264] With an artificial nipple, fluid flows into the posterior oropharynx by gravity (Fig. 18.5). Artificial nipples and bottles are gravity-regulated systems requiring the infant to actively inhibit milk flow to permit swallowing and breathing. In an attempt to regulate milk flow and prevent choking or gagging, infants may clench their jaws or obstruct the nipples' holes with their tongues in a thrusting motion. Orthodontic nipples result in physiologic stability and more effective feeding behavior in some infants.[109] A study comparing breastfeeding and bottle feeding with two delivery systems (soft-walled and rigid-walled bottles/nipples) found better coordination of suck-swallow-breathing, better oxygen saturations, and a feeding pattern more like breastfeeding when the soft-walled system was used.[155]

FIGURE 18.3 Latch-on response. In response to stimulating the infant's lower lip with the nipple, the mouth opens wide. This response has been called the *oral searching reflex*. It is part of the circumoral rooting reflex. (From Righard L, Alde MO. Sucking technique and its effect on success of breastfeeding, *Birth* 1992;19:185; Lawrence RA, Lawrence RM. *Breast Feeding: A Guide for the Medical Profession*. 8th ed. Philadelphia, PA: Elsevier; 2016.)

An RCT of a novel feeding nipple that only allows milk to flow when a preterm infant creates a vacuum showed that length of stay in the NICU was shorter, and less formula was fed at discharge to infants using the novel nipple.[399] A more recent study of the new nipple found tongue actions the same as those used in breastfeeding, with a higher volume of milk intake while using an intraoral vacuum that was lower than the pressure used in breastfeeding.[144] With further research, this system could be used to provide supplementary oral feedings when the premature infant's mother is unavailable and may assist the preterm infant in learning the sucking dynamics necessary for successful breastfeeding.[144]

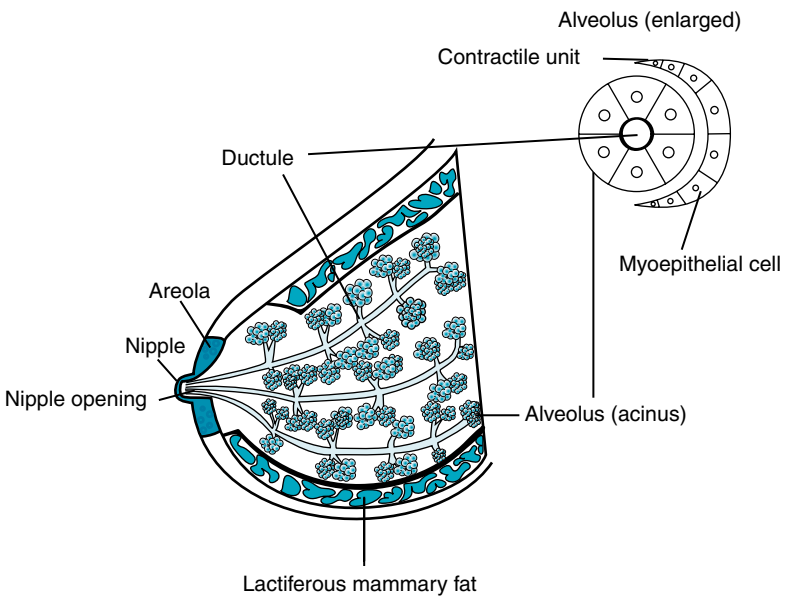

FIGURE 18.4 Structure of human breast during lactation based on ultrasound findings. (Redrawn from Ramsey DT, Kent JC, Hartmann RA, et al. Anatomy of the lactating breast redefined with ultrasound imaging. *J Anat*. 2005;206:525. With permission from Wiley-Blackwell Publishing.)

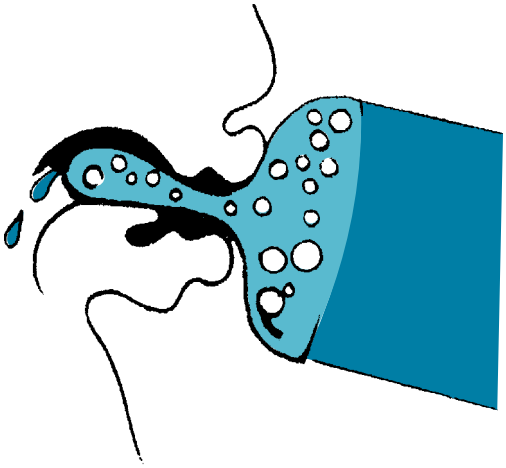

FIGURE 18.5 Artificial nipple. Infant sucking on artificial nipple, which fills the mouth and thus prevents tongue action and provides flow without tongue movements. Flow occurs even if the lips are not tight around the rubber hub. (From Lawrence RA, Lawrence RM. *Breast Feeding: A Guide for the Medical Profession*. 8th ed. Philadelphia, PA: Elsevier; 2016.)

PREVENTION OF BREASTFEEDING PROBLEMS

Problems with breastfeeding may be with the mother or with the neonate or may arise from a combination of problems in the dyad. Lack of information about common problems in the early weeks of breastfeeding is a common reason for breastfeeding failure.[108,410] In descriptive studies addressing breastfeeding problems, mothers frequently identified concerns related to sore nipples, breast discomfort, and inadequate milk supply.[57,108] Breastfeeding problems should be prevented. To solve a breastfeeding problem, the mother must be observed feeding the infant.

Maternal Problems

INADEQUATE MILK SUPPLY

An inadequate milk supply is production *of less than* 440 mL/day by the 11th day of lactation.[221,222] Breast milk production in the first 4 weeks after birth in healthy, full-term infants shows a high frequency of inadequate milk production: (1) two-thirds of mothers produced less than 440 mL/day between days 11 and 13, and (2) one-third of mothers between days 14 and 28 produced less than 440 mL/day.[221] **Assessment for adequate milk supply is essential to assist mothers in correcting low supply early in lactation and preventing early cessation of breastfeeding.**

Inadequate milk supply, a major problem for both the mother and infant, is the most commonly cited reason for discontinuation of breastfeeding in the NICU and after discharge.[57,185,215,287,452] Predictors of maternal perception of inadequate milk supply at 8 to 12 weeks postpartum (after preterm birth) include inadequate milk supply at 6 weeks postpartum, unemployment, and infant hospital discharge after postpartum day 42.[185] **Initially, some neonates with special needs are unable to breastfeed. In this common situation, the most compelling breastfeeding issue is establishing an adequate milk supply without the neonate's assistance[184,295] (Table 18.3). Preterm mothers are three times more likely to produce an inadequate milk supply at 6 weeks than are full-term mothers.[184] Because low milk volume in the first week of life is related to continued low production,[184] developing a very early program of education and support for the mother will help her establish an early milk supply and prevent low milk volume.**

Initiating, establishing, and maintaining a milk supply must be accomplished mechanically when the infant is unable to breastfeed. Because milk production depends on adequate and frequent expression, maternal education is the key to establishing an adequate supply (see Table 18.3). Mothers should be encouraged to provide their milk for their compromised infants and should be educated about the benefits of human milk feedings for their fragile infant so they are able to make an informed choice and decision.[288,297,303,410] A parent-focused video about the importance of human milk and the science that supports human milk as the best source of nutrition is available.[378]

The mother who wants to or is willing to breastfeed should be instructed about initiating and maintaining a milk supply until the infant can breastfeed. In general, instruction includes information about pumping, which is individualized to the mother's situation. **Milk production through pumping should be encouraged early and regularly to (1) collect colostrum, which is rich in anti-infective properties; (2) ease the initial engorgement associated with lack of regular stimulation and**

TABLE 18.3 CRITICAL FINDINGS FACTORS THAT INFLUENCE THE MOTHER'S MILK SUPPLY AND SUCCESSFUL BREASTFEEDING OF THE PRETERM INFANT

ENHANCES	REDUCES	COMMENTS
Early skin-to-skin contact regardless of method of delivery[172,242]; early initiation of pumping,[329] preferably with a double-pumping setup and breast massage[206,412]	Immediate separation at birth, delayed initiation of pumping (associated with cesarean birth, male gender, higher gestational age at birth, poor maternal psychological well-being, and previous NICU experience)[196] or feeding at the breast[45,313]	If possible, initiate within 1–2 hr of birth (first hour after birth for mothers of VLBW preterm infants)[329]; pumping both breasts simultaneously is associated with higher prolactin levels, milk yield, fat concentration, and maternal preference.[206,295] Provide volume-based containers for storing milk from each pumping episode.[295]
Frequent milk expression with complete breast emptying at each session	Failure to express frequently or incomplete emptying of the breasts	5–8 expressions/day (every 3–4 hr)[188,412]: duration of pumping >100 min/day (about 15–20 min with double-pump setup); longest nonpumping interval <6 hr. Maintain a pumping log.[412] A password-protected website with educational information and ability to track pumping volumes actively involves mothers.[36]
Rest, relaxation, and stress management (see Chapters 29 and 30)	Fatigue, anxiety, stress (i.e., maternal illness; stress, noise and lack of privacy in NICU; return to work; more commitments in and outside the home; maternal dislike of breastfeeding)[45,313]	Inverse relationship between maternal anxiety scores and milk volume for mothers of preterm infants; uninterrupted sleep of at least 6 hr.[245,445] Privacy for breast pumping: 55% of mothers preferred to pump at home for more privacy; more mothers pumped in their preterm infant's single-family room.[110]
Adequate nutrition	Inadequate nutrition	At least 60% of recommended daily allowances produces milk of adequate quantity and quality to promote infant growth.[68]
MEDICATIONS		
Use of galactogogues[51] (metoclopramide, oxytocin, reserpine, phenothiazines, domperidone[167])	Bromocriptine, antihistamine, oral contraceptives (especially estrogen and progesterone combination)	Knowledge of maternal medication use enables effective counseling. More pump-dependent mothers achieved a 50% increase in human milk volume with the use of domperidone.[20]
HERB		
Fenugreek		Two or three capsules two or three times per day; maternal diarrhea; lowers blood glucose; may increase asthma symptoms; maple syrup smell to sweat, urine, milk; colic.[173] Less weight loss and greater milk volume at 3 days of age in infants whose mothers took fenugreek.[436]
Positive feedback to mother regarding infant growth;[63] infant's condition improving	Worsening infant's condition	Mothers report feeling rewarded by infant's growth while receiving expressed mother's milk by gavage[287]; Mothers continue to provide breast milk when preterm infant has good growth velocity.[63]
Educate mothers about fortification and why it is necessary with premature infants.	Mother thinks fortification of her milk needed because her milk is not "good enough"	Parents understand how mother's milk changes and special needs of preterm infants for growth.
Skin-to-skin contact (kangaroo care)[86,248,412] in the NICU	Parental separation	Maternal reinforcement of lactation, maternal behaviors, confidence, and attachment; ensures maternal exposure to pathogens in NICU so that her immune system is stimulated to produce environmentally specific antibodies that are passed in maternal milk and protect the preterm infant.

Continued

TABLE 18.3 CRITICAL FINDINGS FACTORS THAT INFLUENCE THE MOTHER'S MILK SUPPLY AND SUCCESSFUL BREASTFEEDING OF THE PRETERM INFANT—CONT'D

Educational information (e.g., video, brochure) readily available for both mothers and fathers [73,406,412,422] of preterm infants within the first 24 hr after birth[422]	No verbal or written information for parents; conflicting opinions and advice about breastfeeding[288,295]	Decision about type of pump, frequency; written instructions on collection and storage per NICU protocol; information about maternal rest, fluid intake, and nutrition. Positive effects of breastfeeding, advantages of human milk to preterm infant; how to interpret infant cues and behaviors.[245,317]
Knowledgeable professional care providers (e.g., primary nurses, lactation specialists, physicians, peer support) who educate, support, and assist[73,132] through consistent, practical advice[248,288,295]	Nonsupportive care providers and/or inconsistent advice and information; no alignment between NICU routines and parents' needs	Prevention of maternal problems (e.g., inadequate supply,[45] sore nipples,[45] engorgement)[29] through self-education and professional interaction and education enhances success and prevents discontinuation of breastfeeding.
Initiation of breastfeeding before bottle feeding	Initiation of bottle feeding before breastfeeding[45] Small size, fragility, medical complications of premature infant[313]	Early breastfeeding is less stressful than early bottle feeding[135,285–287,289,471] because of difference in the patterns of sucking and breathing; during bottle feedings, preterm infants alternate short bursts of sucking with breathing and do not breathe within sucking bursts; during breastfeeding, breathing is integrated within sucking bursts.[286] Test weighing (i.e., weighing before and after breastfeeding, with differences in weight representing milk intake [1 g = 1 mL]) using electronic scales is a reliable method of documenting milk intake in preterm infants.[291,295] For specific problems, maximizing milk intake may be assisted by lactational support devices (i.e., nipple shields; lactation supplementer) and/or breast pump stimulation of the opposite breast during infant feeding.[245,287,295]
Simultaneous feeding and caregiving schedules for multiples (see Chapter 13)		For multiples: Introduce simultaneous feeding as soon as possible, encourage maternal independence with position suggestions, comfort measures, experimenting, and verbalizing what mother needs or wants.[318] Need for privacy, taking babies out of NICU, rooming-in with father to assist with care and feeding.[318] Lactation support devices and/or breast pump stimulation of the opposite breast during infant feeding.[388]

NICU, Neonatal intensive care unit.
Modified from Schanler R, Hurst N. Human milk for the hospitalized preterm infant. *Semin Perinatol.* 1994;18:476.

maintain continued stimuli to produce milk; (3) provide quality nutrition for the neonate; and (4) alleviate concerns about available volume once the infant begins breastfeeding. The early postpartum period in the hospital is the optimal time to teach pumping methods, while support and encouragement are readily available.

BREAST DISCOMFORT

Maternal problems include engorgement, painful nipples, and cracked nipples. A primipara is at high risk for developing engorgement. Frequent emptying of the breast is the best prevention.

Engorgement occurring in the early postpartum period is characterized by general breast

swelling, usually in both breasts in a well, afebrile woman. A little engorgement is normal. Areolar engorgement blocks the nipple and makes grasping the areola difficult for the infant. **Gentle breast massage and manual expression of a small amount of milk soften the areola so the infant is able to "latch on."** When the body of the breasts and the areolae become excessively engorged and painful, **the goal of management is to make the mother comfortable so that nursing may continue. Supporting the breasts is crucial, and the mother should wear a well-fitting but adjustable brassiere 24 hours a day.**[245] **Applying cold packs between nursing decreases pain and swelling. Pain relievers also may be prescribed. In a recent study, application of herbal compresses relieved the pain of engorgement better than hot compresses.**[223] **Applying heat (packs or a warm shower) and expressing some milk before feeding help initiate milk flow. A nursing infant, manual expression, or an effective pump helps initiate and maintain milk flow.** Breast massage before and during breast pumping/feeding also facilitates milk flow. Therapeutic breast massage in lactation (TBML) is effective in reducing the breast pain of engorgement and for management of future episodes.[469]

Prenatal stimulation of the nipple by pulling or rolling (to toughen it for breastfeeding) is not recommended because of the possibility of initiating uterine contractions and premature labor.[245]

Nipple pain occurs by the seventh postpartum day in 9.6% of breastfeeding women, with primiparity being a predisposing factor. Causes of nipple pain include (1) inappropriate positioning and latching (72.3%); (2) ankyloglossia (tongue-tie) (23.2%); and oversupply of milk (4.4%).[352] Other causes of nipple pain include infection, flat/inverted nipples, mastitis, vasospasm, and neonatal palatal anomaly.[220] With prompt recognition and appropriate interventions, recovery occurs within 2 weeks and does not reduce exclusive breastfeeding rates.[352]

Breastfeeding should *not* be painful. When it is, the problem is most often an incorrect latch. Sore nipples are another major discomfort and concern for the new mother. The initial grasp of the nipple by the infant or with pumping can be uncomfortable. **Poor positioning of the infant, however, can cause painful and eventually cracked nipples. Prevention and treatment involve educating the mother about careful positioning of the infant facing the mother, looking directly at the breast, and tummy-to-tummy with her (Fig. 18.6). Changing the infant's position on the nipple at different feedings is helpful.**

FIGURE 18.6 Proper positioning for breastfeeding infant tummy-to-tummy facing the mother.

Positioning the infant correctly at the breast assists in the prevention of sore nipples. There are three common positions that can be used with breastfeeding: the cradle hold (see Fig. 18.6), the football hold (Fig. 18.7), and lying down. Initially, the cradle or football hold allows the most control for the mother and infant to learn breastfeeding. Breastfeeding in the lying-down position becomes easier once latch-on techniques are developed.

Nipple care involves keeping nipples clean and dry. Clear water (no soap or alcohol) is all that is necessary to keep the nipples clean. Drying nipples well, not using plastic nursing pads, and exposing nipples to air and dry heat (sunlight, light bulb, sauna, or a low setting on a hair dryer) are comforting. **Using ointments may be helpful, especially**

FIGURE 18.7 Football hold in breastfeeding. Pillows may be used for support.

in dry climates. If used, a small amount (i.e., one drop) should be gently massaged into the nipple after the feeding. Purified lanolin (if there is no allergy to wool), A&D ointment, or vitamin E may be used to treat, but will not prevent, sore nipples. An RCT comparing the use of hydrogel dressings with lanolin ointment in the prevention and treatment of sore nipples found a greater reduction in pain, no infections, and earlier discontinuation of therapy in the hydrogel dressing group.[105] A more recent RCT found maternal satisfaction with use of lanolin, but its use did not reduce nipple pain or improve breastfeeding outcomes.[200] Combining treatment with breast milk and a breast shell was more effective than using lanolin for nipple trauma and pain.[450] The most recent Cochrane review states that **applying nothing to painful nipples or treatment with expressed breast milk (EBM) may be equally or more beneficial than ointments such as lanolin.**[103]

Severe and/or persistent nipple pain may be caused by a bacterial or yeast infection, which should be promptly treated. Yeast infection of the breast (Table 18.4) **manifests as a burning sensation in the nipples, stabbing pain throughout the breast, and edema/shiny skin or flaking skin on the nipple/areola.**[307] A significant risk factor for yeast infections of the breast and oral thrush in the baby is the use of bottles in the early postpartum period.[236] In one study, yeast infection was associated with cessation of breastfeeding (in 65% of infected mothers) by 9 weeks postpartum because of pain with feeding.[307]

Another recognized cause of nipple pain is **Raynaud's phenomenon of the nipple,** which is often misdiagnosed and mistreated as a yeast infection.[13] Twenty percent of childbearing-age women may have Raynaud's phenomenon, and symptoms are exacerbated by cold temperatures.[13] **Raynaud's phenomenon of the breast, associated with a history of breast surgery, is characterized by extreme or severe nipple pain with breastfeeding; nipple blanching, cyanosis, or erythema; and accompanying throbbing pain, burning, and paresthesia.** Treatment includes (1) preventing and/or decreasing exposure to cold and emotional stress, (2) avoiding vasoconstrictive drugs (e.g., nicotine), (3) using nifedipine for its vasodilator effects (see Table 18.7), and (4) including fish oil and evening primrose oil in the mother's diet.[245] **If the mother does not have Raynaud's of the fingers or toes, it is unlikely that she has it of the breast.**

In the past, nipple shields were not recommended because they are awkward for the mother, are confusing for the infant, and decrease milk production by 50%. Modern ultrathin nipple shields concentrate the immature (preterm or late preterm) infant's suction pressure in the tunnel of the shield, stimulate milk flow, and stimulate milk removal.[291,295] **Use of silicone nipple shields has been found to be a useful tool in treatment of sore nipples and latch-on problems and as a bridging technique to direct breastfeeding.**[410] One study showed that for preterm infants, use of a nipple shield increased breast milk intake and promoted longer duration of breastfeeding.[290] Although use of nipple shields is associated with weaker intraoral vacuum pressures, vacuum strength was not associated with milk intake, rather higher milk intake was caused by longer sucking.[142] **Breast pumping after use of nipple shields is necessary to express residual milk, maintain adequate milk supply, and obtain milk for supplemental feeding.**[297,410] Nipple shields are also helpful if the mother's nipple is too large for her infant's mouth. Use of nipple shields to facilitate and support breastfeeding is certainly preferable to cessation of breastfeeding.[77]

TABLE 18.4 PERINATAL COMPLICATIONS AND BREASTFEEDING

COMPLICATIONS	BREASTFEED YES	BREASTFEED NO	COMMENTS
MATERNAL COMPLICATIONS			
Cesarean delivery	X		Regional anesthesia enables contact and feeding in recovery room. Pain medication is best given after feeding so levels peak before next feeding. Use of breast pump (pressure of ~150 mm Hg) quickens onset of lactation, increases daytime milk supply, and improves maternal confidence.[478]
Pregnancy-induced hypertension	X		Preterm or small-for-gestational-age infants may be delivered, making delayed breastfeeding and pumping necessary. Maternal drugs may affect infant (see Table 18.7).
Venous thrombosis and pulmonary embolism	X		Depending on mother's ability; radioactive materials may be used for diagnosis, and pulmonary embolism anticoagulants may be used for therapy (see Table 18.7).
BACTERIAL INFECTIONS			
Urinary tract	X		Choice of antibiotics is important (see Table 18.7).
Mastitis[12]	X		Continued emptying of breast (i.e., nursing baby or breast pump), bed rest, antibiotic therapy that is safe for infant, application of heat and cold, and use of analgesics are therapeutic.
Sexually transmitted diseases	X		No contraindication once mother is treated appropriately.
Tuberculosis	X	X	Culture-positive mothers must be separated from their infants regardless of mode of feeding; may pump and provide breast milk because tubercle bacillus is not passed through milk but through respiratory contact.[246]
	X		After therapy, when it is safe for mother to contact infant, it is safe to breastfeed directly.
Diarrhea	X		Proper handwashing should be done and breastfeeding continued.
VIRAL INFECTIONS			
CMV	X		Both virus and protective antibodies occur in breast milk. Anti-CMV activity in breast milk from mothers of preterm infants that varies with stage of lactation and serologic maternal status.[106] Anti-CMV activity may attenuate CMV excreted in milk and reduce risk of maternal to neonatal transmission.[106] Incidence of acquired infection in preterm newborns at 4%, with 82% of those having CMV-positive breast milk[25] Freezing (for 72 hr)-thawing method effectively reduces CMV viral load in human milk of mothers of preterm infants.[191] Pasteurization, but m=not freeze-thawing, eradicates CMV from human milk. 8% of ELBW infants developed CMV after freeze-thawing[475]
Enterovirus	X		Maternal antibodies in breast milk protect infants from enteroviral infections, especially if the infant was breastfed for >2 weeks.[381]
Rubella	X		Isolate infected infant from other infants and susceptible personnel. Mother is not contagious postpartum and need not be isolated from infant. Rooming-in may be considered.

Continued

TABLE 18.4 PERINATAL COMPLICATIONS AND BREASTFEEDING—CONT'D

COMPLICATIONS	BREASTFEED YES	BREASTFEED NO	COMMENTS
Rubella immunization	X		There is no known adverse effect on infant.
HSV	X	X	May breastfeed if there is no active lesion on breast. Strict handwashing and covering of genital lesions is necessary. Rooming-in supports breastfeeding while isolating infant from others in nursery.
Varicella (chickenpox)	X	X	If mother has chickenpox within 6 days of delivery, isolate mother and do not allow her to breastfeed until she is no longer contagious. Infant should be separated regardless of mode of feeding.
Measles (rubeola)	X	X	If infant has measles, may isolate mother and infant together and allow breastfeeding. Mothers with postpartum measles have breastfed, and neonates have acquired mild disease. Secretory antibodies are probably present in milk in 45 hr. Mother exposed before delivery without active disease should be isolated from infant, because 50% of infants contract disease.
Hepatitis	X		Hepatitis A: may breastfeed as soon as mother receives gamma globulin.
	X		Hepatitis B antigen has been found in breast milk, but transmission by this route is not well documented. Both infants of chronic HBsAg carriers and those with acute hepatitis should receive high-titer hepatitis B immunoglobulin and hepatitis vaccine, and breastfeeding is permitted.
	X		Hepatitis C virus (HCV) infection rate is 4% in both breastfed and bottle-fed infants; breastfeeding permitted: HCV-positive women do not increase the infection risk to their infants.
HIV, AIDS	X		WHO recommends that mothers who receive ARV therapy while breastfeeding should: (1) exclusively breastfeed for the first 6 months, (2) introduce complementary foods and continue breastfeeding after the first 6 months, (3) if not exclusively breastfeeding or breastfeeding for less than 12 months, mixed feeding is acceptable with ARV therapy, and (4) breastfeed for 12–24 months.[472]
Human T-cell leukemia virus type I (HTLV-I) or type II (HTLV-II)		X	Infected lymphocytes found in breast milk; unknown if able to cause disease. Current US position: breastfeeding is contraindicated.[9,10]
West Nile virus	X		Transmission through human milk occurs but is rare;[186] breastfeeding recommended by CDC.[69]
Zika virus	X		Virus transmitted through breast milk and infected a newborn.[38] After third-trimester Zika infection, virus persists in breast milk (33 days after maternal infection; 9 days after delivery)[409] CDC recommends breastfeeding in Zika areas because benefits outweigh risks, and no reports of health problems in infants breastfed from a mother with infection.[70]
PARASITIC INFECTIONS			
Toxoplasmosis	X		No transmission of toxoplasmosis has been demonstrated in humans. Antibodies are present in breast milk.
FUNGAL INFECTIONS			
Candida albicans infection of the nipple/breast	X		Antifungal topical medication (nystatin) for the mother and simultaneous oral nystatin for the infant. Persistent yeast infections are treated with oral fluconazole (see Table 18.7).

TABLE 18.4 PERINATAL COMPLICATIONS AND BREASTFEEDING—CONT'D

COMPLICATIONS	BREASTFEED YES	BREASTFEED NO	COMMENTS
OTHER INFECTIONS			
Trichomoniasis		X	Metronidazole is contraindicated for infant; milk may be pumped and discarded until therapy is completed. Mother's dose can be modified so she can pump and discard milk for 24–48 hr.
OTHER MATERNAL COMPLICATIONS			
Anemia	X		Severe maternal anemia, but not mild to moderate anemia, adversely affects the iron status of breast milk. Maternal nutritional status significantly influences fetal iron status but not breast milk iron content.[236]
Diabetes	X		Lactation is antidiabetogenic. Lactosuria must be differentiated from glycosuria.
Thyroid disease	X	X	Radioisotopes and thiouracil are found in breast milk and may adversely affect infant. Mother who is taking propylthiouracil can breastfeed. Neither hypothyroidism nor hyperthyroidism is contraindication alone.
Cystic fibrosis	X	X	May cause nutritional drain on mother. Milk composition is normal. The Cystic Fibrosis Association has guidelines for lactation.
Smoking	X	X	Nicotine interferes with letdown and is excreted in milk. Approximately 50% of women who cease smoking during pregnancy resume after birth.[362] Of mothers who smoke, breastfed infants are healthier than bottle-fed infants. Second-hand smoke increases the risk of SIDS and respiratory illnesses.
Opiate withdrawal	X		One small study. See "Methadone" in the "Other Substances" section in Table 18.7.
Bariatric surgery	X		Breast milk adequate in energy, macronutrients, and vitamin A during first 6 weeks of lactation.[203]
NEONATAL COMPLICATIONS			
Medical			
Diarrhea	X	X	Maintain breastfeeding in infectious diarrhea unless milk is source of infection. Congenital lactase deficiency is rare but requires lactose-free formula.
Respiratory disease	X	X	Breast milk by gavage may be used if infant's condition permits.
Galactosemia		X	Galactose (lactose)-free diet is required.
Inborn errors of metabolism (e.g., phenylketonuria)	X	X	Combination of breast milk and special formula may sometimes be used. Careful monitoring of blood and urine levels of the amino acid is required.
Acrodermatitis enteropathica	X		Low plasma zinc levels are corrected by human milk and zinc sulfate supplementation.
Down syndrome	X		Hypotonia and poor suck reflex contribute to poor letdown and inadequate supply. Proper positioning, manual expression to begin feeding, and supporting the breast so infant does not lose nipple are helpful. Support from another mother with an infant with Down syndrome is helpful.
Hypothyroidism	X		Enough T_3 may be ingested to avoid serious symptoms.
Hyperbilirubinemia	X		May have slightly higher bilirubin than bottle-fed infant. There is no evidence that supplements are beneficial (see Chapter 21).
Breast milk jaundice	X	X	Uncommon occurrence; diagnosis of exclusion; if all other causes are excluded, a temporary cessation of breast milk may be indicated (see Chapter 21).
Cystic fibrosis	X		Increased losses of and lower electrolyte content of breast milk may cause electrolyte imbalance, which is less likely than with formulas.
Sepsis/rule out sepsis	X		NICU admission for presumed early-onset sepsis caused by maternal chorioamnionitis is associated with reduction in discharge breastfeeding rates in asymptomatic term neonates.[395]

Continued

TABLE 18.4 PERINATAL COMPLICATIONS AND BREASTFEEDING—CONT'D

COMPLICATIONS	BREASTFEED YES	BREASTFEED NO	COMMENTS
Surgical			
Cleft lip and/or palate	X		Associated lesions, size, and position of defect influence successful feeding. Positioning and stabilizing breast in infant's mouth may help seal defect.[364] Consult plastic surgeon.
Gastrostomy	X		If gastrostomy feedings are used, expressed breast milk is appropriate.
Partial obstruction (meconium plug, ileus, Hirschsprung's disease)	X		If oral feedings are indicated, breast milk is feeding of choice because of digestibility and mild cathartic effect. After GI surgery, 100% breast milk diet associated with earlier full enteral feedings, shorter length of TPN use, and shorter LOS[396]
Necrotizing enterocolitis	X		Breastfeeding may be partially protective and may be used when feeding resumes.
Gastrointestinal bleeding	X		Most common cause is maternal bleeding from nipple. Perform Apt test to differentiate fetal from adult hemoglobin.
Central nervous system	X		Weak suck and uncoordinated suck and swallow may be problems; however, infants with malformations may breastfeed more effectively than bottle feed.
Omphalocele repair	X		If oral feedings are indicated, breast milk is feeding of choice because of digestibility.[411]
Congenital diaphragmatic hernia	X	X	Breastfeeding is deferred until surgery and ECMO are completed. Mother initiates pumping and storing until baby is able to have enteral nutrition.[413]

Flat or inverted nipples may be difficult for the infant to grasp and result in maternal engorgement, decreased milk supply, infant frustration, and suboptimal infant breastfeeding behavior (Fig. 18.8). Inverted nipples may be treated by using a breast pump to draw out the nipple before attempting to latch the baby onto the nipple.

Neonatal Problems

Ideally, no term or preterm infant who will be breastfed should ever be fed with an artificial nipple, but this is not always possible, especially for a sick premature infant who requires prolonged hospitalization. However, teaching a premature infant to suck often starts long before nutrition is obtained from a nipple. **When a premature infant is gavage fed, swabbing the cheeks, tongue, and gums with colostrum familiarizes the infant with the taste of mother's milk and provides oral immune therapy.[146] In addition, stable preterm infants who are gavage fed should be held for feedings and offered a pacifier, which may teach the infant to equate satiety with sucking. Using a pacifier provides NNS that calms and soothes the preterm infant and also provides the opportunity to develop sucking skill.** A recent study of preterm infants randomized to pacifier use versus no pacifier use in the NICU found significant advantages among those preterm infants using a pacifier: (1) shorter time to full transition to breastfeeding, (2) shorter time to discharge, (3) lower weight at full breastfeeding, (4) lower weight at discharge, and (5) better sucking skills.[217]

When the mother is present for gavage feeding, she can administer oral colostrum,[146] hold the infant, and offer the breast instead

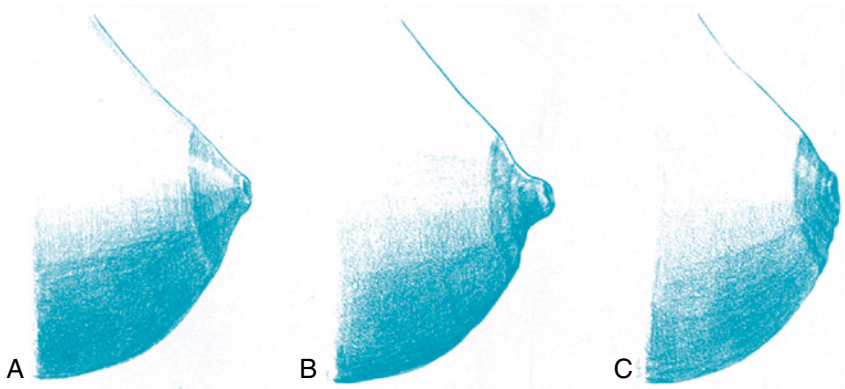

FIGURE 18.8 Inverted nipples. **A,** Normal and inverted nipples may look similar when the nipple is not stimulated. **B,** The normal nipple protrudes when stimulated. **C,** The inverted nipple retracts when stimulated. (Courtesy Jimmy Lynne Scholl Avery.)

of an artificial nipple. If it is necessary to avoid swallowing any fluid, the breast can be prepumped. **Placing the infant in direct skin-to-skin contact with the mother's breast enables nuzzling and licking behaviors and teaches that relief from hunger and the breastfeeding position are associated. Because increased stimulation creates an increased milk supply, it is possible to breastfeed multiple infants. In the early weeks, it is difficult and time-consuming, but eventually it can become faster and more convenient than bottle feeding. Two infants can be fed at the same time, in the cradle position or in the football hold position (Fig. 18.9).** A study of breastfeeding twins found that mothers preferred simultaneous feeding using the football hold (possibly because of the bias of the observers because not all mothers of twins agreed).[318] Infants should change breasts with each feeding because one may have a stronger suck than the other, and each breast should receive an equal amount of stimulation.

Understanding the mechanisms of sucking is essential to preventing, assessing, and intervening in neonatal sucking problems. Infants are born ready to suckle the breast.[96] Arrhythmic sucking has been found in full-term infants who bottle feed.[96] Nipple confusion describes the difficulty of infants who have been fed with artificial nipples before learning to breastfeed.[480] The infant who has learned to feed from a bottle nipple often sucks incorrectly at the breast, preventing milk flow.

The infant's confusion creates frustration and crying, which may inhibit milk letdown. The best means for preventing nipple confusion is to enable the infant to learn breastfeeding *before* bottle feeding is established[480] (see Table 18.3).

Assessment of the problem includes evaluating the method of feeding and possibly using alternative nutritional methods (gavage feedings) until the cause is determined. If the infant is bottle fed, choking may be a result of a soft nipple, a fast flow that the infant cannot control, or a nipple that is too long for the infant's (particularly the preterm infant's) mouth. If the mother is breastfeeding and the ejection is strong, the first rush of milk could cause choking, which may be prevented by manual expression of a small amount (several spurts) of milk before offering the nipple to the infant. Collins et al.[84] studied the effect of bottles, cups, and dummies (pacifiers) on breastfeeding in preterm infants using an RCT. Included in the study were 319 preterm neonates born at 23 to 34 weeks of gestation, with 303 included in the final analysis. The primary outcome measure was continuation of any breastfeeding on discharge home from the NICU. **The results demonstrated that there were no significant differences with the use of a pacifier.** However, infants randomized to cup feeds were more likely to be fully breastfed on discharge home but had a longer length of stay in the hospital (cup = 59 days; bottle = 48 days). Cup feeding did not show a difference in the incidence of any breastfeeding at discharge.

Studies of pacifier use and impact on breastfeeding in premature and term infants show conflicting results. **Howard et al.[192] found in a cohort of 750 healthy newborns that early use of a pacifier**

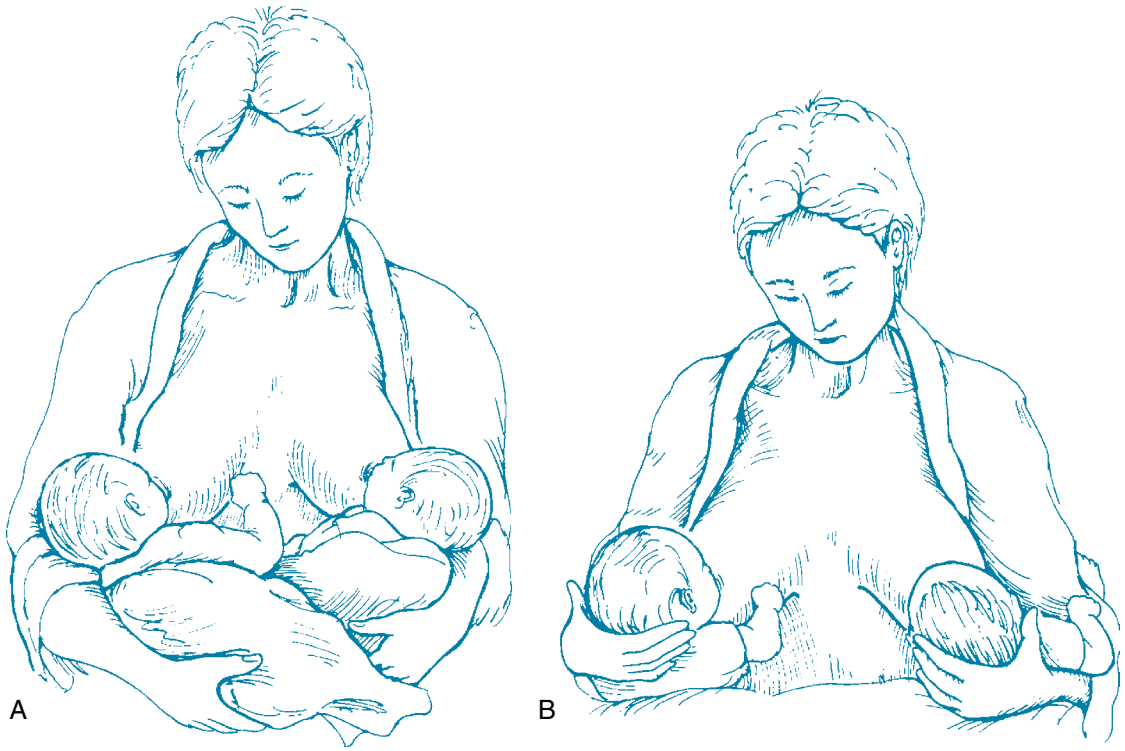

FIGURE 18.9 Breastfeeding twins. **A**, Cradle position. **B**, Football hold position.

did decrease success and duration of breastfeeding through 1 year. Another study of pacifier restriction in term newborns, without restriction of formula use, resulted in a drop of exclusive breastfeeding rates to 68% from 80% when pacifiers were routinely used.[213] Among new mothers with a high risk for postpartum depression, pacifier use may help protect against early breastfeeding cessation.[402] A secondary analysis of the CDC Pregnancy Risk Assessment Monitoring System (PRAMS) data from 10 states assessed the relationship between pacifier use in the hospital and breastfeeding (continuation and exclusivity).[211] **Pacifier use by neonates admitted to the NICU was not associated with less breastfeeding (duration and exclusivity), whereas pacifier use by neonates in the well-newborn nursery was independently associated with a decrease in breastfeeding and exclusive breastfeeding by 10 weeks of age.**[211] A Cochrane review of restricted pacifier use (from birth or after lactation was established) in healthy full-term infants found no significant effect on the prevalence or duration of exclusive or partial breastfeeding from birth to 4 months of age.[198] Benefits of NNS for preterm infants are listed in Chapter 13, Box 13.15.

The most recent Cochrane review of cup feeding newborn infants evaluated five studies of cup feeding versus bottle feeding for supplemental nutrition in breastfeeding infants.[129] The majority of studied infants were premature, so the recommendations are only for preterm infants. For late-preterm infants (LPIs), there may be some benefits on breastfeeding rates at 6 months of age. Although premature infants of younger gestational ages spent 10 more days in the hospital, more mature preterm infants who did not start cup feeding until 35 weeks of gestation did not have longer lengths of stay (both groups average a length of stay of 26 days). The reviewers also reported problems with the studies that may have included overreporting of breastfeeding exclusivity and compliance with supplemental feeding. Before larger RCTs are undertaken, the reviewers recommend that consideration of the issues of noncompliance with cup feeding, blinded outcome assessment, and 100% follow-up are needed.[129] Another recent

Cochrane review of 7 studies of low-to-moderate quality using cups, tubes, and nipples for supplementation of breastfeeding found that use of cups increased the extent and duration of breastfeeding.[85] The safety of cup feeding has not been established so that noncompliance with cup feeding may be the result of fear of aspiration by the neonate.

Some sucking problems result from the sequelae of perinatal events (e.g., low Apgar score, preterm low-birth-weight [LBW] infant, small-for-gestational-age [SGA] infant, large-for-gestational-age [LGA] infant, LPI, infant of a diabetic mother [IDM], and multiple births)[201] or from physical disorders (e.g., hyperbilirubinemia, hypoglycemia, cardiorespiratory conditions, sepsis, neuromotor/developmental problems, and structural abnormalities of the oral cavity)[98,245,259] and represent developmental delays. **These sucking difficulties require diagnostic evaluation of the underlying cause and appropriate intervention.**[245,259]

LPIs ($34^{0/7}$ to $36^{6/7}$ weeks' gestational age; see Chapter 5) are often poor feeders because of their developmental immaturity in coordination of suck-swallow-breathe and because they are awake less frequently, give fewer if any cues of readiness to feed, and are easily fatigued and fall asleep before a feeding is completed.[48,300,343] A retrospective review of factors predicting the time and age at which the LPI (32 to 36 weeks' gestational age) initiated and attained full oral feedings found that the median time to the first oral feeding was 1 day, and the median time to full oral feedings was 12 days.[199] In this study, no LPI attained full oral feeding before 33 (±3) weeks PMA, and factors such as gestational age, birth weight, medical conditions, and location of the NICUs was significantly associated with the time to first oral feeding and full oral feeding in 6 NICUs in Baby-Friendly accredited hospitals.[199]

Being an LPI or an early term infant is an independent risk factor for breastfeeding difficulties and lack of exclusive breastfeeding at 1 month and 4 months of age.[168,253,300,314] All of these problems contribute to poor stimulation of the breast, incomplete breast emptying, and inadequate milk production. While in the hospital, lactation assistance should focus on strategies to initiate and maintain maternal milk supply and provide adequate fluids and calories for the LPI. When supplementation is needed by the LPI, use of human milk rather than formula does not increase length of stay and supports breastfeeding until hospital discharge.[274] **Hallmarks of breastfeeding the LPI include proper positioning; use of breast pump, nursing supplementer (Fig. 18.10), or nipple shield; waking every 2 to 3 hours to feed (for 8 to 12 breastfeedings per day); use of skin-to-skin care; weights before and after breastfeeding; use of alternative methods of enteral nutrition; lactation support during hospitalization and after discharge, and peer support groups.**[39,48,62,150,212,253,300,343,360]

FIGURE 18.10 Lact-Aid Nursing Trainer. (Courtesy Lact-Aid International, Inc.)

Collaboratively creating a feeding plan with parents that they understand and are able to carry out at home is essential before discharge.[18,39,48,117,300] A Canadian study of LPIs and term infants found a longer hospital stay for LPIs, initial breastfeeding difficulties, and higher readmission rates by 4 months.[277] Although this study found earlier cessation of breastfeeding at 4 months,[277] another Canadian study, in the same region, found that being an LPI and readmission were not factors influencing the predominance of breastfeeding at 2 months, especially if parents had a positive encounter with a health care provider about breastfeeding.[281]

Maternal factors also contribute to breastfeeding problems with LPIs, but research shows contradictory results. One study showed that admission

of LPIs to the NICU was not associated with early breastfeeding cessation,[210] and another study showed that mothers of LPIs in the NICU were as likely to initiate breastfeeding but less likely to still be breastfeeding at 10 weeks postpartum.[178] In the first study, lower breastfeeding rates at 10 weeks was associated with being a single mother, having only a high-school education, and maternal obesity.[210] In the second study, mothers of LPIs in the NICU were less likely to breastfeed in the hospital, less likely to be told to feed on demand, and more likely given a breast pump while in the NICU.[178] A Swedish study found that higher maternal self-efficacy, measured by The Breastfeeding Self Efficacy Scale—Short Form (BSES-SF), was positively associated with exclusive breastfeeding of their LPI at 40 weeks, and 3 months corrected age.[149] Maternal breastfeeding self-efficacy and breastfeeding success of moderately and late preterm infants is being studied by a mixed-methods protocol in a family integrated care setting.[50]

Maternal emotional well-being is altered with a late-preterm birth and for the first month postpartum.[44] During both of these periods, mothers had elevated anxiety, depression, posttraumatic stress symptoms, and worry about their infant's health. Mothers were coping with their altered birth and postpartum experiences after giving birth earlier than planned. A more recent study corroborates these findings and found that **maternal distress over giving birth prematurely affected both initiation and duration of breastfeeding.**[477]

A Canadian quantitative and qualitative study about maternal and public health nurses' perceptions about breastfeeding LPIs found that 50% of the mothers (n = 61) breastfed their LPI after discharge.[107] Only 10 of these mothers exclusively breastfed their infants, and 51 partially breastfed. Qualitatively, three themes emerged from maternal interviews: **(1) significant difficulty with breastfeeding, (2) failing to recognize their infants' disorganized behavior and feeding distress, and (3) parental stress caused by their infants' multiple feeding issues.** Qualitatively, public health nurse interviews found corollary themes of challenges initiating and during breastfeeding as well as the need for breast stimulation during breastfeeding. This same research team followed these **mother-infant pairs for the first 2 months after birth of an LPI and found maternal depression and declining maternal confidence.**[349] **Declining maternal confidence was caused by (1) demanding needs of the LPI, (2) the ever-looming prospect of rehospitalization, and (3) interactions with public health nurses.**[349] In this cohort, maternal depression resulted in less maternal confidence when compared with nondepressed mothers. Multidisciplinary lactation teams of health care professionals with special education to assist mothers of LPIs are recommended.[434] Providing parental education and anticipatory guidance about the challenges of breastfeeding an LPI; providing ongoing support with initiation and continuation of breastfeeding; promoting maternal skills with the LPI; assisting mothers in their own self-care; and assisting mothers with strategies to support breastfeeding are all essential with this population of high-risk mothers and neonates.[107,349,434]

Some mothers may not establish or may have difficulty maintaining an adequate milk supply, yet infants with problems require an easily obtainable milk supply. **The Lact-Aid Nursing Trainer system (see Fig. 18.10) addresses a variety of breastfeeding problems, including sucking defects.**[21] EBM or formula is contained in a presterilized, disposable bag suspended between the mother's breasts by a cord, and the liquid is delivered by a thin, flexible tube attached to the bag. The end of the tube is placed against the mother's nipple to enable the infant to suckle the tube and nipple at the same time. **This device provides the correct rate of flow and volume of liquid that elicits the reflexes of swallowing and expression. The Lact-Aid trainer provides oral therapy and nutritional supplementation for the infant and the mammary stimulus necessary to enhance the mother's lactation.**[245] **It is effective in managing low milk production in the mother that has resulted from separation, delayed breastfeeding, poor technique, or other correctable problems, and the device gives nutritional and oral therapy to an infant who is slow in gaining weight or has a sucking dysfunction.**

CAUTION: To prevent the spread of serious infections, the Lact-Aid trainer should never be borrowed, rented, or loaned from another mother.

Problems with the letdown reflex may originate with the mother, the neonate, or both. Often, especially in breastfeeding a premature infant, this is because of fear of failure or a lack of privacy. Knowledge of the mechanisms of lactation can help the mother avoid a fear of failing. **Give the mother as much privacy and the least stressful**

environment possible when she is pumping her breasts and breastfeeding. If a mother experiences a weak or delayed letdown, she should massage the colostrum or milk down to the nipple before putting the infant to the breast. Infants with a poor suck, such as preterm infants or infants with Down syndrome or a neurologic deficit, understimulate the breast and do not trigger the letdown reflex. **Use of the Lact-Aid trainer provides oral therapy, improves these infants' sucking ability, and facilitates a successful nursing relationship. The breast also can be stimulated with a good pump between feedings to increase the milk supply.**

DATA COLLECTION AND INTERVENTION

Establishment of Breastfeeding

AVAILABLE FEEDING AND SUCKING NEONATE

Infants who have been admitted to the NICU often present a dilemma to care providers as to the most favorable time to begin putting the infant to the breast. Research shows that direct breastfeeding, especially for the first oral feeding in the NICU, is associated with an increase in (1) frequency of later breastfeeding, (2) duration of breast milk feedings, (3) success with breastfeeding in the hospital, and (4) breast milk feedings at discharge.[344] **A more recent study of direct breastfeeding as the first feeding in the NICU found a shorter time to transition to oral feedings, a younger age of attainment of full oral feedings, and earlier NICU discharge.**[419] Because combination human milk and formula feedings have been shown to result in earlier breastfeeding cessation, prompt initiation of breastfeeding in the NICU benefits the mother-infant breastfeeding dyad.[190] A randomized study of oral stimulation (15 minutes for at least 10 days before oral feeding) provided to preterm infants resulted in significantly higher breastfeeding rates (70% vs. 45.6%) at discharge.[23]

In the NICU, the infant's current physical status, plus considerations of nutrition and energy expenditure, helps determine the decision to initiate enteral feedings.[229] In a national survey, criteria used to determine readiness for oral feedings included the following: (1) 75% used gestational age (e.g., 34 weeks by 60%) or weight (e.g., 1500 g by 50%) and (2) infant behavioral cues (e.g., sucking behaviors).[397] Table 18.5 presents the research basis for readiness to initiate oral feedings. A more recent survey of enteral feeding practices found that gestational age was the leading criteria used to initiate feedings.[159] **Few empirical data support the contention that either weight or gestational age affects the ability of a preterm infant to suckle effectively because the suck and swallow will automatically be coordinated by the peristaltic motion at the breast.** In the earlier survey, a majority (85% to 93%) responded that bottle feeding is started first, before breastfeeding.[397] **Professional caregivers believe and teach parents that breastfeeding is too stressful and requires more energy and exertion than bottle feeding.**[462] Contrary to physiologic evidence, progression of nutritional support for the preterm infant has proceeded from intravenous fluids → total parenteral nutrition → gavage (continuous → intermittent) → bottle feeding (at 1500 to 1800 g or 34 to 35 weeks' PCA) → breastfeeding (after bottle feeding without distress). **Problems arising from this approach include the following*:**

- Delay in initial oral feedings and slower attainment of full oral feedings
- Establishment of a sucking method that may not easily transfer to breastfeeding (i.e., bottle feeding alone has been found to contribute to arrhythmic sucking in full-term infants)[96]
- Initiation of breastfeeding when discharge is imminent so the mother receives little, if any, breastfeeding assistance and support
- Each additional week of hospitalization reduces the likelihood of the infant transitioning to direct breastfeeding by 14%

An ***Early Feeding Skills (EFS) Assessment*** checklist has been developed to assess both oral feeding readiness and oral feeding skills in preterm infants.[429] To individualize interventions, an infant's developmental stage regarding specific feeding skills (e.g., the ability to remain engaged in feeding; to organize oral-motor functioning; to coordinate swallowing and breathing; and to maintain physiologic stability) is profiled. Content validity and intrarater and interrater reliability have been established. The EFS is being tested for predictive, concurrent, and construct validity.[429] Other tools to evaluate readiness for oral feedings are the Premature Infant Oral Motor Intervention (PIOMI) and the

TABLE 18.5 CRITICAL FINDINGS READINESS FOR INITIATION OF ORAL FEEDINGS: RESEARCH BASIS

BREASTFEEDING	CRITERIA	BOTTLE FEEDING
	←Gestational/ Postconceptual Age→ ←Weight→	
Preterm 28–32 weeks: Better able to coordinate suck, swallow, and breathing.[285,286,289]		**Preterm** 34–35 weeks: PCA is a developmental guideline—based on belief that sucking pattern is similar to that of full-terms*; infants may be ready at an earlier age (i.e., 28–34 weeks).[228,284] Coordination of respirations with sucking and swallowing is consistently achieved by infants >37 weeks PCA.[201,278,342,449]
<1500 g: Better able to coordinate suck, swallow, and breathing.[285–287,289]		1500–1800 g: Traditional criteria without research basis.
Full-Term Ultrasound study shows human nipple elongates to twice its resting length; neonatal cheeks act as a passive seal for the oral cavity. Sucking pressures of –50 to –155 mm Hg[351]; and –64 to –145 mm Hg.[143] Peak vacuum pressures highest at initiation of nutritive suck then decreases.[60] More milk removed with stronger vacuum and faster application rate[60]	←Mechanics of Sucking→	**Full-Term** Higher maximum pressure and number of sucks or bursts; greater suck widths and greater intake/suck. Able to alter sucking to accommodate nutrient composition, nipple, and hole size to minimize energy expenditure[268] and autoregulate milk flow by controlling pressure generated during sucking.[268] Regulates sucking pressure by coordination of various oral motor structures so that intraoral pressure is controlled to enable milk flow in a manageable fashion.
Preterm Sucking pressures of –2.5 to –15 mm Hg.[351] Generate intraoral pressure in same manner as term infants; higher milk intakes associated with longer, more efficient and a greater proportion of sucking during a feeding and not with vacuum strengths[142]		**Preterm** Burst width (interburst and intersuck width) similar to that of full-term infant.[202,282,283] At the beginning of a feeding, preterm infants generate weaker sucking pressure within the oral cavity that changes over time to pressures and duration in the same range as for term infants, because of neural maturation and sucking experience.
Full-Term 50% of feeding obtained in first 2 min; 80%–90% by 4 min; last 5 min, minimal obtained from each breast.[351]	←Energy Expenditure→	**Full-Term** 86% of feeding obtained in first 4 min of sucking.[241] Generate larger negative pressure with sucks with higher energy expenditure.[202] Able to alter sucking to accommodate nutrient composition, nipple and hole size to minimize energy expenditure[268] and autoregulate milk flow by controlling pressure generated during sucking.[268]

TABLE 18.5 CRITICAL FINDINGS READINESS FOR INITIATION OF ORAL FEEDINGS: RESEARCH BASIS—CONT'D

BREASTFEEDING	CRITERIA	BOTTLE FEEDING
Preterm After 34 weeks: 70%–80% of feeding ingested in first 6 min, then intake sluggish, rest periods increase; and sucking and nourishment decrease. At 36–37 weeks: Sucking standards are similar to those in mature neonate.[319] The younger the gestational age, the higher the variability.[319] Longer duration of breastfeeding than bottle feeding.[285,289] No differences in duration of breastfeeding versus bottle feeding. At 35 weeks' CA: Small volume of milk intake in same duration of feeding; fed less efficiently and with fewer suck bursts.[135]	←Energy Expenditure→	**Preterm** 40% of total volume ingested in first min, less energy to suck same volume as full-term infant.[202] Infants born 26–29 weeks' gestational age benefit from restricted milk flow (i.e., milk is obtained only with active sucking; no milk flows to infant by gravity or high-low nipples during rest periods). At initiation of oral feeding (with restricted milk flow), an intake of 1.5 mL/min and a proficiency of 30% (e.g., intake of 9 mL in first 5 min; intake of 30 mL in 20 min) are indicative of earlier attainment of full oral feeding.[241] Consumes an average of 2.6 mL/min of feeding.[342] At 35 weeks' CA: Greater volume of milk intake in same duration of feeding with more sucking bursts; fewer single sucks, better nipple seal.[135]
Preterm Skin temperature higher (than when bottle feeding) because of bodily contact with mother.[76,285,289] No temperature change before feeding (ac) or after feeding (pc).	←Temperature→	
Preterm Less weight gain after breastfeeding compared with bottle feeding.[174]	←Weight Gain→	**Preterm** No difference in weight gain between experimental self-demand feeding protocol and control group (standard care).[276]
	← Heart Rate→	**Preterm** Bradycardia occurred with bottle feeding but not breastfeeding; bradycardia possibly related to faster milk flow and interference with breathing;[285,289] apnea and bradycardia with bottle feeding in otherwise healthy preterm infants.[278]
Full-Term Swallowing occurs nonrandomly between breaths and does not interfere with breathing.[155] With age and experience become more efficient by extending suck bursts, pausing less, applying weaker vacuum levels and increased oxygen saturation and decreased heart rate.[383]	← Coordination of Suck, Swallow, and Breathing→	**Full-Term** Suck, swallow, breathe in a 1:1:1 pattern.[278] Alteration of breathing pattern—prolongation of expiration and shortening of inspiration.[269,289] No difference in sucking frequency or pressure when bottle feeding expressed milk or formula. Differences in sucking and/or breathing patterns attributed to nutrient delivery rather than nutrient composition.[267] Soft-walled delivery system results in significantly higher oxygen saturation, better coordination of suck-swallow-breathe, and feeding behaviors more like breastfeeding than use of hard-walled delivery system.[155]

Continued

TABLE 18.5 CRITICAL FINDINGS READINESS FOR INITIATION OF ORAL FEEDINGS: RESEARCH BASIS—CONT'D

BREASTFEEDING	CRITERIA	BOTTLE FEEDING
	← Coordination of Suck, Swallow, and Breathing→	
Preterm Different patterns of sucking bursts and better coordination, breathing is integrated within sucking bursts.[286]		**Preterm** Initial feedings at 32–34 weeks are characterized by periods of apneic suckle alternating with respirations; as PMA increases, the percentage of apneic swallows decreases and suck-swallow-breathing is more synchronized.[449] High-flow nipples result in apnea[268,394] or bradycardia.[262–264,266] Do not breathe within sucking bursts but in alternate short bursts of sucking with breathing.[289] Consistently achieved by infants 36–37 weeks' PCA.[449] Use of orthodontic nipples results in physiologic stability and effective feeding behavior in some preterm infants.[109] At 34 weeks' PCA, sucking pattern primarily expression component; with maturation, experience, endurance, and strength gains, there is a shift to more frequent use of term sucking pattern.[400] Not necessary to wait for full-term sucking pattern for successful oral feeding.[133,400]
Full-Term No desaturation with feeding.[176] 18% of pc saturations <90%.	← Oxygen Saturation→	**Full-Term** No desaturation with feeding[269] 29% of pc saturations <90%. More oxygen desaturations (<90%) than breastfeeding.[267]
Preterm No difference in oxygenation with breastfeeding versus bottle feeding;[285,289] no pc decline of oxygenation; oxygenation more stable than with bottle feeding—fewer desaturations.[109] Desaturations (<90%) in 21% of breastfeedings.[76] With BPD, saturation higher than with bottle feeding.[76]		**Preterm** Decreased oxygenation during initial sustained sucking, but oxygenation increased as sucking pattern modulated.[373] 32–36 weeks: Range of 94%–97% with feeding, with sucking decreased saturation from 2.5%–16% (range 80%–100%).[284] Fluctuations and sharper decrease in saturation with bottle feedings versus breastfeeding;[76,285,289,373] 10 min pc saturation 50% below baseline.[76] Desaturations (<90%) in 38% of bottle feeding.[76] Desaturation in VLBW infants at discharge: average of 10.8 events during feeding; 20% of feeding time with saturations less than 90% Behavioral cues of desaturation are unreliable; changes in breathing and sucking pauses to regulate breathing pattern and increase oxygenation may occur.
	←Hypercapnia→ (elevated P_{CO_2})	**Preterm** 34–35 weeks: Increased P_{CO_2} depresses sucking and swallowing so that respirations may supersede feeding in preterm infants with increased respiratory drive (e.g., BPD).

TABLE 18.5 CRITICAL FINDINGS READINESS FOR INITIATION OF ORAL FEEDINGS: RESEARCH BASIS—CONT'D

BREASTFEEDING	CRITERIA	BOTTLE FEEDING
Preterm 32 weeks: Increased feeding in active alert and quiet alert state.	**←Behavioral Cues→** ←Quiet alert→state before and during feedings associated with more successful feeding behaviors.[162,276,278,279] Offer pacifier for NNS ac to promote awake behavior at beginning of feeding.[342,348] NNS ac associated with better oral feeding ability.[40] ←NNS pattern of sucking develops before nutritive pattern; mature NNS pattern not reliable cue for readiness to orally feed.[241,342] ←Cues include[10,278,400]→ Oral behaviors—sucking on pacifier, fingers, feeding tube. Rooting reflex, hand-to-mouth behaviors, mouthing movements. Presence of gag reflex. ←*Behavioral State*→ Changes—arousal from sleep, quiet alert state ac.[279] Exhibits stability in autonomic, motor, and behavioral states. Able to self-regulate, interact, and tolerate outside stimuli.[278] ←Crying→fussing and demanding to feed—a late sign.	**Full-Term and Preterm** Motor behavior: Change in arm posture (flexion) with feeding.

*References 133, 241, 276, 278, 284, 342.

ac, before feeding; *BPD,* bronchopulmonary dysplasia; *CA,* corrected age; *NNS,* nonnutritive sucking; *pc,* after feeding; *PCA,* postconceptual age; *PMA,* postmenstrual age; *VLBW,* very-low-birth-weight.

Supporting Oral Feeding in Fragile Infants (SOFFI), which are briefly discussed in Chapter 13. The latest Cochrane review of RCTs or quasi-RCTs of instruments for assessing readiness to commence oral feeding in preterm infants concluded that there is no evidence that supports any instrument or that informs practice.[94] Recent research has found five genes involved in the essential developmental pathways for feeding readiness present in neonatal saliva.[225] Hunger signaling proteins in saliva are quantifiable and in the future may be used to assess oral feeding readiness in the premature neonate.[225]

Use of a breastfeeding protocol[418] without use of bottle feeding (either before breastfeeding or to supplement breastfeeding) is associated with the longest duration of breastfeeding. An RCT of this protocol in which nasogastric (NG) supplementation was compared with bottle feeding for a transition to feeding at the breast found that NG supplementation was associated with feeding from the breast at discharge, 3 days, 3 months, and 6 months compared with preterm infants supplemented with bottle feeding.[230] In this same study, earlier age at initiation of breastfeeding also was

associated with successful and longer duration of breastfeeding.[230] If the first oral feeding is direct-to-breast, preterm infants in the NICU are more likely to still be receiving breast milk at discharge.[63] Other protocols for transitioning from gavage to breast have been proposed but not tested in an NICU population. **After discharge from the NICU, mothers wean their preterm infants from the breast because of (1) infant resistance to latching on, (2) weak suck, (3) refusing the breast, and (4) difficulty with latch-on.**[183] **If the sucking pattern learned with bottle feeding impedes breastfeeding, health care providers should promote early, exclusive breastfeeding to prolong the duration of preterm breastfeeding after discharge.**[230,348,465]

Maturation of feeding skills depends on developmental changes in the infant's central nervous system coupled with experiential learning.★ "Successful infant feeding is a complex process that requires integration of physiologic function and neurobehavioral ability."[61] Experiential learning through a prefeeding oral stimulation program has been shown to improve preterm infants' sucking behaviors before actual oral feeding.[23] A recent randomized study of oral stimulation (15 minutes for at least 10 days before oral feeding) resulted in significantly higher breastfeeding rates (70% vs. 45.6%) at discharge.[23] **Studies show that preterm infants are able to breastfeed far earlier (less than 1500 g or 28 to 36 weeks' gestational age) than they can bottle feed.**[285-287,289,410] **VLBW infants (at 28.7 + 2.8 weeks' gestational age) who were fed their first oral feeding at their mother's breast were more likely to be receiving breast milk at discharge from the NICU.**[64] A comparison of studies of breastfeeding and bottle feeding shows less oxygen desaturation, warmer skin temperature, no bradycardia, and better coordination of sucking and breathing with breastfeeding compared with bottle feeding (see Table 18.5). According to these research data, **the ability of the preterm infant to breastfeed without alterations in homeostasis occurs *before* the ability to safely bottle feed.** Oxygenation is more stable with breastfeeding, because the type of sucking pattern (e.g., intermittent) and the flow of milk at the beginning of breastfeeding may be easier for the VLBW infant to control and regulate.[263,394] In VLBW infants, breathing is compromised (e.g., desaturations, increase in heart and respiratory rates) more during continuous sucking than during intermittent sucking.[394]

When an NG tube is in place, a VLBW infant has even poorer oxygenation, shallower breathing, and inability to increase tidal volume.[394] **The postfeeding period enables recovery of oxygen saturation and end-tidal CO_2 to the prefeeding levels.**[394]

Health care providers and parents should closely observe VLBW infants during the continuous sucking period (e.g., the first minute of bottle feeding,[428] **with letdown during breastfeeding) for apnea, oxygen desaturation, and heart rate changes. Recommendations for continuous sucking periods include (1) not allowing breathing pauses of more than 10 seconds, (2) monitoring oxygen saturation and heart rate for continuous sucking of more than 30 seconds, and (3) interrupting sucking by withdrawing the nipple for breathing pauses and desaturations.**[394] **Desaturations, especially in the first minute of bottle feeding, during the continuous sucking period, still occur in VLBW infants nearing discharge.**[428]

Skin-to-skin (kangaroo) care provides a safe, effective alternative method of caring for premature infants (see Chapters 5 and 13). Use of kangaroo care has been shown to improve lactation for mothers of preterm infants.[135,317,410] **During skin-to-skin contact, the infant may initiate NNS at the breast.**[297,412] **NNS time at the breast is used to accustom both the mother and baby to each other and the pleasant sensory stimuli at the breast. The smell of a premature infant's own mother's milk persistently decreases salivary cortisol levels, even after the breast milk odor has been removed.**[271] **NNS at the breast improves maternal letdown, enhances attachment and bonding, and shortens transition time to and lengthens the duration of breastfeeding.**[348,410] As the preterm infant matures, NNS is replaced by hunger cues, latching on, and effective nutritive sucking. Both AGA and SGA infants (700 to 2450 g) benefit from early (sometimes starting at birth) (see Chapter 5) and sustained breastfeeding as follows (see Chapter 13):

- More mothers breastfeed and are more confident.
- More frequent feedings are given.
- More milk is produced.
- Infants breastfeed longer (e.g., at 1 month after discharge, breastfeeding rates increased from 11% to 50%).
- There is less bradycardia than with gavage or bottle feeding.
- There is better weight gain and earlier discharge.

★References 133, 278, 319, 342, 348, 400, 410, 418

Both maternal and neonatal responses to breastfeeding should be monitored.[348,410] Adequate milk volume is available when the milk ejection (letdown) reflex occurs. Breast massage may assist in bringing down the milk, thus making it easier for the infant to obtain. Letdown may be felt by the mother or observed as a change in the rhythm of infant sucking and audible swallowing. After letdown is established, the infant expends little energy in sucking. He or she only needs to coordinate swallowing and breathing with an occasional burst of sucking. The nurse should be available during the initial breastfeeding to provide support to the mother, to ensure that the infant exhibits no signs of distress (e.g., color changes, bradycardia, oxygen desaturation, drop in temperature), and to provide guidance for the mother if the infant chokes with letdown. The nurse also needs to reinforce to the mother that the infant's sucking pattern will be a pattern of bursts and pauses. The pauses are present in all infants and provide rest periods for the infant.

The infant's respiratory status should be reviewed. Infants requiring supplemental oxygen can breastfeed. If the infant requires 35% oxygen or less, oxygen may be delivered through a nasal cannula to ensure adequate, consistent oxygenation. This will eliminate another source of concern for the mother: having to worry about juggling the blow-by oxygen line. If the infant has not been placed on a nasal cannula previously, the nurse should initiate the cannula and then assess oxygenation using a pulse oximeter before the feeding begins. The infant's temperature status requires review. Attention should be directed toward preventing hypothermia with infants who require significant thermal support. The infant should be swaddled, and a hat should be placed on his or her head to prevent heat loss.

Duration of breastfeeding should be based on cues of satiety, such as sucking cessation or falling asleep, or cues of physiologic instability or fatigue. Frequency of breastfeeding can be progressed, as can frequency of bottle feeding: from one breastfeeding per day to one per shift to every other breastfeeding. If the mother is available for this progression, bottle feeding may be deferred until breastfeeding is well established, or bottle feeding may be avoided altogether. When the infant is taking all nutrition orally, the mother can be encouraged to breastfeed as often as possible and institute an ad lib schedule.[288,410] If the mother is available, the infant should breastfeed as often as necessary, and supplementation should not be provided. However, if the breast milk supply is insufficient, using a Lact-Aid Nursing Trainer provides nutritional supplementation and mammary stimulation to increase maternal milk supply. Total intake should be estimated to ensure adequate calories.

If the infant weighs less than 1500 g, it is necessary to augment calories, protein, and calcium with human milk fortifiers (fortifiers made from human milk are preferred to cow's milk fortifiers) (see Chapter 17).[1,104,238,385] Advantages of an exclusive human milk diet are listed in Table 18.1. Exclusive use of human milk, fortified with human milk fortifier, results in less feeding intolerance[385] and lower rates and severity of NEC in extremely premature infants compared with the use of human milk or preterm infant formulas with bovine milk fortifier.[420] A standardized feeding protocol using an exclusive human milk diet and early fortification with human milk–based fortifier resulted in improved growth, significantly less NEC, and no effect on NEC of the early fortification in preterm infants less than or equal to 1250 g.[194] High protein intake of fortified human milk in preterm infants less than or equal to 1250 g resulted in less postnatal growth restriction and better neurologic outcomes at 24 months corrected age.[33] There are limited data to support multinutrient fortification of human milk after hospital discharge and little data to show that important outcomes are affected, including growth rate during infancy.[476] Fortification also interferes with feeding at the breast.[476]

Families and staff often fear that the infant will not get enough during a breastfeeding. This concern is especially predominant when infants have been hospitalized for prematurity and fluids and calories have been scrutinized closely. Health professionals should be sensitive to such concerns and refrain from employing methods such as weighing infants before and after feedings or using gavage tubes to attempt to determine the exact amount of breast milk ingested during the feeding. With today's electronic NICU scales, however, test weighing (before and after feeding) (see Table 18.3) is accurate, if necessary.[174,291,297] Test weighing reassures mothers (and professionals) that preterm infants are receiving adequate intake while nursing and is associated with a higher exclusive breastfeeding than merely estimating breastfeeding intake.[119,295]

Health care professionals should also focus on cues that can be used during and after hospitalization by both caregivers and the family.[174] These cues include the infant's satisfaction after the feeding (asleep or fussy), the frequency of feedings, voiding pattern (minimum of six to eight wet diapers per day, weighing diapers, and checking specific gravity), and palpation of the mother's breasts before and after feeding. Trends in weight gain also can demonstrate the success of the mother-infant dyad in breastfeeding.

A small infant may have difficulty taking a large nipple into the mouth. The mother should shape her nipple by compressing behind the areola to allow more of the nipple to be placed in the infant's mouth. The thumb and index finger or the first two fingers should be parallel to the infant's nose and chin. The breast must be soft enough to be compressed in this manner. The mother should hold the infant close for the comfort of both, with the infant's entire body, not just the head, turned toward the mother's body (see Fig. 18.6).

A nipple shield allows the infant to get a nipple in the mouth but increases the amount of sucking necessary to obtain milk and decreases the amount of stimulation received at the nipple. Supervised temporary use of silicone nipple shields has been found to be a successful bridging technique for the infant to transfer to direct breastfeeding (after only a few sessions of shield use).[290] Use of a nipple shield should be followed by breast pumping to express residual milk, maintain adequate milk supply, and obtain milk to freeze for supplemental feeding.

Because NNS does not stimulate prolactin secretion and milk production, infants should not be placed on an empty breast to feed. Without positive reinforcement (i.e., milk) for their efforts, infants soon learn that the breast does not give milk, become frustrated, and refuse to feed. The Lact-Aid Trainer may be used to initiate proper suckle and supplement intake in a small premature infant who is able to nurse (see the Prevention of Breastfeeding Problems section earlier in this chapter).

Supplementing breastfeedings with bottle-fed formula is inefficient in terms of energy and calories, because the infant expends energy, and thus calories, to feed twice. More energy-efficient and calorically efficient methods of initiating breastfeeding include offering smaller, more frequent feedings; supplementing by gavage feeding[100]; and using a lactation supplementing device. Breast milk fortifiers (see Chapter 17) should be used when the mother's milk is not nutritionally adequate for the infant's requirements.[104] Breast milk substitutes, such as donor milk, should be used when the mother does not provide sufficient volume; donor milk also needs fortification to meet the nutritional needs of VLBW premature infants[470] (see Chapter 17). A recent RCT showed that standard fortification of donor milk does not increase the incidence of NEC in preterm infants.[3]

UNAVAILABILITY OF A FEEDING OR SUCKING NEONATE

If premature birth or neonatal or maternal illness delays the onset of breastfeeding, the mother experiences a decrease in her milk production. Depending on how long breastfeeding has been delayed, mammary involution and the return of menstrual hormonal cycles may inhibit breastfeeding. A preterm infant or one who is ill may be weak and tire easily, and thus adequate lactation is not established.

If a neonate is unable to feed at the breast, breast milk must be produced through artificial stimulation of the breast. The mother should establish a regular routine of breast massage[206,410] and pumping soon after the infant's birth. A comfortable chair with armrests or a pillow often helps, and the mother should be assured of privacy during breastfeeding and breast pumping. It is often necessary for the care provider to help the mother start and to encourage her routine. Each breast should be pumped every 2 to 4 hours, preferably with a double pumping system to enhance milk supply.[206] Mothers should increase pumping time up to 15 to 20 minutes as the milk comes in, with the suction pressure increased as tolerated. At the beginning of pumping, mothers should awaken to pump at night to establish a good milk supply. Sleep and rest are necessary for good milk supply; however, the mother should not sleep when breasts are engorged because this will decrease the supply. Mothers should be advised that if their infant were with them, they would be feeding every 2 to 4 hours around the clock and therefore should develop that pattern to establish an adequate supply.

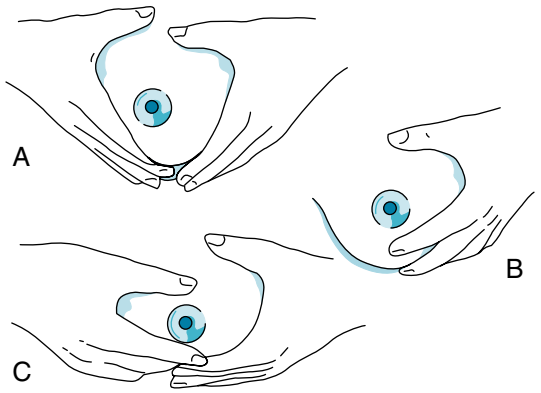

FIGURE 18.11 Breast massage. **A**, Place hands with palms toward the chest at the breast. Encircle the breast with the fingers and thumbs. **B** and **C**, Applying pressure, move hands forward, overlapping as they near the nipple. Stop posterior to the areola. Continue for 1 to 2 minutes or until milk is on nipple. Repeat on the opposite breast. (From Lawrence RA, Lawrence RM. *Breastfeeding: A Guide for the Medical Professional.* 6th ed. St Louis, MO: Mosby; 2005.)

CAUTION: Mothers should be counseled about the potential risks of using breast shells or breast pump kits that have been used by other women. Breast shells, breast pump kits, and lactation aids are intimate-care items and are meant for use with one mother and one baby. Breast pump attachments and collection devices must be appropriately cleaned.[67]

Induction Aids. Various induction aids using tactile and mechanical principles are available to assist the mother in lactating and relactating. Knowledge of the different systems and their advantages and disadvantages enables the health care provider to help the mother choose the most helpful aid.

Breast massage (gentle, tactile stimulus usually in a circular motion using increasing pressure) before breastfeeding or pumping may help unplug breast ducts and enable milk to flow more easily.

Breast massage during pumping provides the important tactile stimulation that is missing without the infant's nursing and facilitates prolactin release and milk yield.[245]

Hand Expression. Once the breast milk supply has been established, hand expression (Fig. 18.11) is the simplest and most cost-effective way to collect milk; however, prolactin secretion and milk yields are less than with a pulsatile breast pump.[481] Combining hand expression of colostrum and hands-on pumping results in greater milk production for pump-dependent mothers of preterm infants.[308] A comparison of exclusive hand expression versus electric breast pump expression in mothers of VLBW infants in an NICU found significantly lower cumulative daily breast milk production during the first 7 days postpartum in the hand expression group that lasted throughout the first 28 days.[257] Some mothers find hand expression esthetically unsatisfactory, and they should use other methods.

Mechanical Devices. Breast pumps work by application of negative pressure (e.g., −50 to −155 mm Hg) and compression in a suck-release pattern (e.g., rate of 40 to 50 suck-release cycles/min) by fitting the nipple cup (or flange) over the maternal nipple and areola.[299] Nonautomated or manual pumps are regulated by the number of times the mother manually exerts and releases pressure; they are best for occasional use. Automated pumps (battery, mini-electric, double electric, and hospital-grade) exert more negative pressure, permit the greatest number of cycles per minute, and are the pumps of choice for establishing and maintaining lactation for a preterm or sick infant.[299,410] Breast pumps that mimic the sucking pattern of the human infant result in greater amounts of pumped milk and are more efficient, comfortable, and convenient.[293,347] Automated pumps are available in the NICU and for home rental use. Health insurance (both public and private) may reimburse for pump rental.

Serum prolactin levels and increased milk yield more closely parallel those with natural infant sucking when an intermittent, pulsative pump is used.[481] Just as nursing twins simultaneously results in a greater prolactin response, pumping both breasts simultaneously is more convenient, provides higher prolactin release (and higher milk yield), and saves time.[481]

To increase milk supply when the infant is not nursing, the pump should be used frequently (see Table 18.3). Because the breast pump is not as efficient as the suckling infant (a healthy neonate removes ~80% of the total ingested breast milk volume in 4 minutes,[351] and an efficient breast pump removes 85% in 15 minutes[292]), the mother may find that tactile

stimulation and breast massage before initiating pumping help increase the milk supply. Looking at the infant's picture or listening to a recording of the infant's cry stimulates the mother's milk production with a pump.

Beginning on the low or normal pump setting and carefully breaking the suction at the breast with a finger will help prevent sore nipples. Painful engorgement is relieved by pumping each breast just enough to obtain relief. Nipple or areolar engorgement must be relieved so that the infant is able to grasp and suckle the nipple.

Lactoengineering.

To increase caloric density of EBM to improve growth/weight gain in VLBW infants, the pumping process can be altered to increase lipid content. Because the lipid content of hindmilk (e.g., milk expressed after letdown or later in the pumping session) is two to three times higher than the lipid content of foremilk, selectively feeding hindmilk to VLBW infants has been shown to increase growth and weight gain.[387] For VLBW infants with a consistent weight gain of less than 15 g/kg/day, hindmilk feedings may be initiated until a consistent weight gain of more than 30 g/kg/day is achieved.[446]

To express hindmilk, breast pumping is interrupted an average of 2 to 5 minutes after milk ejection has begun. This milk is collected and labeled "foremilk." Pumping is resumed until about 2 minutes after milk flow has ceased. This milk is placed in a separate container labeled "hindmilk." Another method of lactoengineering is to individualize the milk fractionation procedure by use of a "creamatocrit" that accurately estimates lipid and caloric content of EBM.[161,294] A small sample (<1.0 mL) of pumped breast milk is aliquoted into two capillary tubes that are sealed and centrifuged for 5 minutes. The lipid and cream layer rises to the top of the tubes and can be quantitated as a percentage of breast milk volume using a hematocrit reader and converted to estimates of lipid concentration and caloric density using published regression equations.[294] One study showed that mothers are able to cost-effectively and accurately perform creamatocrit assays; the mothers enjoyed the responsibility and increased involvement in their infant's care.[161] It is interesting to note that low-income mothers with fewer years of formal education and skilled rather than professional occupations were the most accurate in their performance of creamatocrits.

DONOR HUMAN MILK

Human milk banks that collect, store, and distribute milk to infants other than those of the donating mother exist around the world. This support is not available to some NICUs; others intentionally choose not to store or use donor milk.[26,330] In England, a wide variation in the use of donor milk was ascribed to clinical uncertainty.[26] The reservations about storing/using donor milk in the NICU generally involve lack of knowledge (i.e., advantages, concerns about adequate nutrition, safety, parental receptiveness, cost).[26,121,330] Parental reluctance to use donor milk for preterm or term infants correlates with education, ethnicity, religion, and a desire to have the infant receive only mother's milk because "donor milk is somebody else's milk."[54,122,224,355]

Recognition of human milk as the best nutrition for preterm infants has increased research into donor milk and the growing use of pasteurized donor human milk in NICUs worldwide.[10,121,330] One study showed a marked increase in the use of donor milk for preterm infants, especially in the first 2 weeks of life, from 8% to 77% in two urban US hospitals from 2006 to 2011.[101] There is also increasing use of donor human milk in larger, higher-level care NICUs that are in close proximity to a milk bank in the Midwest and western United States, in facilities with the highest rates of mothers' own milk feedings, and those participating in the Baby-Friendly Hospital Initiative.[330,339] Level 3 and 4 NICUs that participate in the Vermont Oxford Network and have a high number of VLBW admissions use more donor human milk.[169] According to the CDC, disparities exist in the provision of donor milk in NICUs where more black patients are cared for; less donor milk is used, which may be a result of hospital policies, personnel, distance from a milk bank, and/or lack of maternal knowledge.[41] **For preterm infants, use of donor milk dramatically increases human milk intake, decreases formula intake, does not alter the mother's milk intake,[101] and is associated with higher rates of exclusive breastfeeding of VLBW preterm infants at discharge.[121,331,432,466]** A systematic review of 10 studies of the use of donor milk in neonatal units found mostly positive effects.[464] However, one single-center study in the systematic review found less own mother's milk use on days 1 to 14 and 1 to 28 days of life.[123]

Use of donor milk is also increasing in well-baby, level 1 nurseries. A survey in Massachusetts found that 29% of birthing hospitals and 43% of hospitals served by a human milk bank used donor milk in the well-baby nurseries.[28] **Use of donor milk increased exclusive breastfeeding at discharge (77% vs. 56%).** Donor milk utilization for healthy term newborns in one academic center in Massachusetts increased from 0.4% to 4.7%, mainly for excessive weight loss/dehydration and parent/caregiver request.[392]

The WHO, UNICEF, AAP,[8] ABM,[73] European Society for Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN),[121] and World Association of Perinatal Medicine all endorse the use of donor human milk.[301] The increased use of donor milk has increased the importance and existence of human milk banks.[121,219,321] Adequate screening of human milk donors (for cytomegalovirus [CMV], human immunodeficiency virus [HIV], and other viruses) is essential **because of the possibility of milk-borne pathogens (e.g., CMV, HIV, herpes simplex virus, human papillomavirus, hepatitis B and C viruses).**[240,321] **All donor milk must be pasteurized, which eradicates bacteria with 93% of pooled samples sterile after pasteurization in one study.**[240] Milk banks ship human milk when necessary. A list of human milk banks is available at www.hmbana.org.

Donor human milk for use in the NICU should *only* be provided by a human milk bank.[10,121,321] Two studies of purchases of human milk from the Internet found microbial contamination[218] and milk arriving above the recommended frozen and refrigerated temperatures.[147,148] Seventy-four percent (74%) of the Internet milk was colonized with gram-negative bacteria or had too high an overall bacterial count.[218] No samples were HIV positive, but 21% of the Internet samples were positive for CMV DNA.[218] **Parents should be cautioned that human milk obtained without adequate screening, use of proper collection and storage techniques, and pasteurization poses an increased risk as a source of acquired infection for their preterm and/or medically compromised neonate.**[147,148,218]

For healthy term neonates, informal milk sharing should also *not* include Internet-based acquisition of human milk because the donors are unknown and the milk often arrives without proper storage and temperature. The ABM recommends that if human milk is shared for term healthy neonates that the donor be medically screened and that safe milk handling practices be used.[416] The ABM position statement provides guidance for health care providers to educate their patients about informal milk sharing.

Nutritional analysis of donor human milk may optimize its use in feeding of preterm infants[88,121] **(Box 18.4).** The nutritional composition of donor human milk is influenced by mammary gland maturity, stage of lactation that donor milk replaces or supplements the mother's own milk, and freezing and thawing.[296] In addition, the method of administration of donor human milk alters its nutritional content. When three feeding methods (bolus/gravity gavage; syringe pump gavage over 1 hour and 2 hours) were compared, lipid loss was significant in the timed feedings compared with the bolus method.[52]

Outcomes of premature infants fed donor human milk are compared with outcomes from mother's own milk and formula in Table 18.6. Use of donor breast milk to feed preterm infants and the resulting decrease in the incidence of NEC is a cost-effective and clinically effective strategy.[136,430] A recent meta-analysis of RCTs did not demonstrate that feeding very preterm infants their mother's milk supplemented with donor human milk decreased the incidence of BPD/CLD. However when a meta-analysis of observational studies was done by the same reviewers, **there was a reduction in BPD/CLD with mother's milk supplemented with donor human milk.**[453] **Use of donor human milk after birth in one study resulted in a decrease in BPD/CLD (36.1%) when compared with the preterm formula group (70.4%).**[227]

Reimbursement for donor milk varies among third-party payers and from state to state. Although the cost of donor milk to the hospital and families may be a barrier to wider use, pasteurized donor human milk is a low-cost intervention compared with other NICU interventions and has numerous short- and long-term benefits that are cost-effective.[8,55,414]

COMPLICATIONS OF BREASTFEEDING

Many complications other than prematurity may pose difficulties with breastfeeding. **Information on perinatal complications and breastfeeding**

BOX 18.4 NUTRITIONAL ANALYSIS OF DONOR HUMAN MILK COMPARED WITH MOTHER'S OWN MILK[121,298]

Differs from Mother's Own Milk

- Oligosaccharide amount and content[260]
- Lower protein levels[88]
- Pasteurization:
  - Decrease in cytokines, lactoferrin, lysozyme, leukocytes, lymphocytes, phosphatases, and growth factors[82,298,363]
  - Inactivation of maternal T and B cells, macrophages, neutrophils[82]
  - Reduction of secretory immunoglobulin A (sIgA) by 28% to 60%[82]
  - Reduction of immunoglobulin A and G by 33% to 40%[321]; reduction by 30% to 60%[4]
  - Reduction in minerals (Ca, P, K) and electrolytes (Na)[81]
  - Reduction in lysine and DHA[447]
  - Reduction in nutritional antioxidants by 18% to 53%[180]
  - Modest decrease in protein (6%) and fat (8%)[82]; reduction of fat absorption by infant recipient
  - Reduction in protein, fat, and carbohydrates[4]
  - Higher concentration of free fatty acids than in fresh milk[82]
  - Kills bacterial pathogens such as *Staphylococcus aureus, E. coli,* etc.
  - Inactivates cytomegalovirus
  - Slightly affects content of vitamins (A, D, E, B_2, and B_6); choline, niacin, and pantothenic acid[5]; significant reduction (10% to 20%) in vitamin D compounds[156]
  - Significantly decreases thiamine (25%), biotin (10%), and vitamin C (35%)[5]
  - Reduces nitrogen retention[5]
- After first year of lactation[340]:
  - Increased concentration of lysozyme
  - Decreased concentration of zinc and calcium

Similar to Mother's Own Milk

- Does not meet nutritional requirements of preterm infants; fortification required
- Pasteurization:
  - No decrease in cytokines, chemokines, and growth factors[165]
  - No change in long-chain polyunsaturated fatty acids (DHA/ARA),[22] monoglycerides/free fatty acids, and linoleic/alpha-linoleic acid[321]
  - No change in oligosaccharide amount and content[31]
  - No effect on protein, fat, and carbohydrate levels[82]
  - No difference in trace elements (Zn, Cu, Se, Mn, I, Fe, Mo, Br)[424] or Mg[81]
- After first year of lactation[340]:
  - Stable concentrations of protein, lactose, iron, copper, lactoferrin, and secretory immunoglobulin A (sIgA)

Br, Bromine; *Cu,* copper; *Fe,* iron; *I,* iodine; *Mn,* manganese; *Mo,* molybdenum; *Se,* selenium; *Zn,* zinc.

TABLE 18.6 OUTCOMES OF PREMATURE INFANTS FED DONOR HUMAN MILK*

	COMPARED WITH MOTHER'S OWN MILK	COMPARED WITH PRETERM FORMULA
Growth	Higher rates of SGA at discharge if received >75% donor milk[83] Slight and nonsignificant difference in growth[258] Similar growth[272,388] Slower regaining of birthweight and higher length and head circumference at discharge[113] Every 10% increase in donor human milk intake slowed growth velocity by 0.17g/kg/day and head circumference by 0.01cm/week[53]	Slower in-hospital rates of increase in weight gain but length and head circumference similar[258] Slower in-hospital rates of increase in weight gain, length, and head circumference;[87,227,354] and higher risk of NEC,[354] no significant difference in any of these parameters at 36 weeks' PMA[227] Slower growth[43,53,272] Slower growth in weight and head circumference[256] Very early fortification associated with significantly higher early extrauterine weight gain and head growth in VLBW infants.[153]
Feeding Tolerance	Slower initiation of breastfeeding by 2 weeks[112]	Better feeding tolerance[463] Shorter time to full enteral feeding[234] Same time to achieve full enteral feedings[91]

TABLE 18.6 OUTCOMES OF PREMATURE INFANTS FED DONOR HUMAN MILK* — CONT'D

	COMPARED WITH MOTHER'S OWN MILK	COMPARED WITH PRETERM FORMULA
Incidence of NEC	More NEC when compared with exclusive mother's milk group[388] Less NEC: 4.3% vs. 5.3%[404] Similar intestinal microbiome[333] Intestinal microbiome with a high number of *Enterobacteriales*[87]	Less NEC[17,89,280,354,420]: • Decreased by 79%[43] • 4–6.5 times less likely[280] • 3% vs. 21%[93] • Decreased by 2.6%[214] • 3.9% vs. 11%[430] • 2.8% vs. 38.9%[227] • 4.3% vs. 11.4%[404] Meta-analysis of four studies: not protective against surgical NEC[398]
Incidence of Infection	More infection when compared with exclusive mother's milk group[388] Similar intestinal microbiome as when fed mother's own milk[333]	No difference in incidence of serious infection, NEC, and mortality[89,388] Lower incidence of sepsis: 11% vs. 23%[234]
Length of Stay	Longer LOS when compared with exclusive mother's milk group[388]	No difference in LOS[388] Fewer days of TPN and nonsignificant decrease in LOS[93] Longer LOS[89,437] Less time receiving supplemental oxygen and mechanical ventilation[448]
Neurodevelopmental Outcomes	Lower cognition scores at 1 and 2 years of age[272]	Similar outcomes when unfortified donor milk group compared with preterm formula group[256] Better outcomes when donor milk group compared with term formula group[256] Less responsive at 37 weeks' PMA to inanimate stimuli[437] No significant developmental difference (cognitive, language, motor) at 18 months CA[113,256,320] Lower cognition scores at 1 and 2 years of age[272]
Cost-effectiveness		Costs to 18 months CA did not differ, but postdischarge costs lower in donor milk group[430] Exclusive human milk diet decreases LOS, shorter time to full feedings, and lower hospital and MD costs for extremely preterm and VLBW infants.[17]

CA, Corrected age; *LOS,* length of stay; *MD,* physician; *NEC,* necrotizing enterocolitis; *PMA,* postmenstrual age; *SGA,* small for gestational age; *TPN,* total parenteral nutrition; *VLBW,* very-low-birth weight.
Modified from Gardner SL. Current use of donor human milk in the NICU: "evidence-based practice." *NICU Curr.* 2017;7(1):1.

is shown in Table 18.4.[10,245] Because of the significant benefits of breast milk, infants with special needs should be encouraged and mothers should be assisted in breastfeeding. Many principles used with the preterm infant and other variations of feeding styles and techniques may help facilitate these infants and their mothers in enjoying a successful breastfeeding experience.

Consultation with or referral to a certified licensed lactation consultant or specialist also may be helpful.[348] Many NICUs have such an expert on their staff.

Misappropriation of Breast Milk

Misappropriation of breast milk (giving the wrong EBM to the wrong infant) does occur.

As a distillate of human blood, human milk may contain infectious bacteria (e.g., *Klebsiella, Streptococcus,* methicillin-resistant *Staphylococcus aureus*) and viruses (e.g., HIV, hepatitis virus, CMV, herpes virus) to which the infant given the wrong milk may be exposed. Both staff and parents involved in such an event experience psychological stress and anxiety.[111] Human milk has also been mistakenly administered by the intravenous instead of the enteral route, resulting in a range of consequences from no sequelae to death.[379] **Unit practices to prevent these occurrences include the following**[111,127,275,379]:

- **Ensure centralized milk preparation** with trained milk technicians.
- **Use tubing for enteral feedings** that is incompatible with intravenous tubing/connections.
- **Check milk containers for two identifiers.**
- **Have two nurses verify** the milk for administration; both nurses should sign that verification has occurred.
- **Have two nurses verify and sign** (that the milk has been verified) at transfer and at discharge.
- **Use commercial bar-coded devices.**

A quality improvement project in a large tertiary NICU resulted in a reduction of human milk administration errors over a 6-year period.[324] Using an electronic breast milk tracking system, the project reduced the total number of errors from 97.1/1000 bottles to 10.8/1000 bottles. Reduction of errors occurred in the following areas: (1) expired milk errors from 84/1000 bottles to 8.9; (2) preparation errors from 4.8/1000 bottles to 2.2; and (3) wrong-milk–to–wrong-infant from 8.3/1000 bottles to 2.0.[324] The quality improvement team concluded that the major contributors to their success were use of bedside scanners (rather than centralized scanners) and dedicated staff (i.e., milk technicians) rather than bedside nurses to handle milk.

Drugs in Breast Milk

Table 18.7 **provides information about specific drugs excreted in breast milk.**[245,380] **The most current and comprehensive information about the transfer of drugs and therapeutics into human milk is available at LactMed at www.toxnet.nlm.nih.gov.** Protein binding, degree of ionization, molecular weight, and solubility of drugs influence the passage of drugs into milk. Protein-bound drugs and drugs of large molecular weight (greater than 200) are less likely to pass into milk. Conversely, lipid-soluble drugs pass more easily into the milk. Because breast milk is slightly acidic compared with plasma, weakly alkaline compounds are present in equal or greater amounts in breast milk compared with plasma. Weakly acidic compounds have a higher concentration in plasma than in breast milk.

Several factors influence the drug effect on the infant. **Most drugs appear in milk, but drug levels usually do not exceed 1% to 2% of the ingested dose and do not depend on the milk volume.**[245] The clinical dose of a drug to the infant can be calculated by the following formula[173]:

$$\text{D} - \text{infant} = \text{Drug concentration in milk (at C} - \text{max, or C} - \text{av)} \times \text{Volume of milk ingested}$$

Drug transfers through breast milk may be minimized by feeding the infant before taking oral medications. Many variables, such as gastric emptying, pH, and effects of intestinal enzymes, affect absorption. Finally, the chronologic and gestational ages of the infant affect the maturity of the systems involved in excretion and detoxification (see Chapter 10).

PARENT TEACHING

Parent teaching has been discussed throughout this chapter because it is essential to a successful breastfeeding experience for both the mother and infant (Box 18.5). Postnatal education for parents about breastfeeding is significantly associated with improvement in knowledge, changed attitudes, and better exclusive breastfeeding rates at 6 months.[309]

Before a premature or sick infant is actually nursed at the breast, the colostrum and breast milk may have to be pumped and fed to the infant. If the mother's production is adequate, no supplementation is necessary. **Before collecting the mother's milk, perform the following:**

- Screen the mother (by history) for disease.
- Screen the mother (by history) for drugs that she has taken.
- Instruct the mother in sterile technique.

Proper collection and storage must be discussed with each family so that stored milk does not cause infections. Breast pumps can be a potential source of contamination, and therefore instructions on proper cleaning are paramount. After the death of a 29-week-old infant in an NICU as a result of a contaminated breast

TABLE 18.7 DRUGS EXCRETED IN BREAST MILK

DRUGS	BREAST MILK	CONSIDERATIONS IN INFANT
	ANALGESICS	
Heroin, codeine, meperidine, fentanyl, morphine, tramadol, pentazocine, oxycodone, dextropropoxyphene	Appears in variable amounts. FDA warning recommends against use of codeine and tramadol by breastfeeding women.[443] FDA warning[442] about mothers who rapidly metabolize codeine (because of a genetic predisposition), resulting in increased morphine levels in their breast milk and morphine overdose to breastfeeding infants. Mothers who rapidly metabolize codeine will become so sleepy that they are unable to care for themselves or their infant. Rapid metabolizers of codeine include (1) 1%–10% in whites; (2) 3% in blacks; (3) 1% in Asians and Hispanics; (4) 16%–28% in North Africans, Ethiopians, and Saudi Arabians; and (5) those positive for *CYP2D6* genotype with genetic testing.	Symptoms of depression and floppiness have been associated with these drugs.[208,239] Sleepiness, difficulty breastfeeding, limpness, hypotonia, and respiratory distress. Severe, life-threatening events (respiratory arrest) caused by morphine overdose have occurred.
Aspirin	Safe on a single-dose schedule, although it passes into milk in low concentration.	In a deliberate overdose, metabolic acidosis resulted from an accumulation in the infant; use cautiously because of the risk for Reye syndrome.
Acetaminophen	Appears in small amounts.	Well tolerated.
Ibuprofen	Appears in small amounts.	Well tolerated.
Sumatriptan succinate	Appears in small amounts.	Well tolerated.
	ANTIBIOTICS AND SULFA DRUGS	
Sulfa drugs	Appear in breast milk and may interfere with bilirubin binding in neonate; infants with G6PD deficiency may develop hemolysis.	Should not be used for breastfeeding mother in the first month if infant is jaundiced or if infant has G6PD deficiency.
Chloramphenicol	Appears in breast milk.	Contraindicated in nursing mother because infant may accumulate drug and develop "gray baby syndrome."
Penicillins (ampicillin, amoxicillin)	Small amounts in breast milk.	Disruption of gastrointestinal (GI) flora, allergic sensitization/reactions. Observe for thrush, diarrhea, and rash. Breast milk assists recolonization of normal gut flora.
Tetracycline	Appears in breast milk at 50% of serum level.	Infants may develop stained and mottled teeth when therapy exceeds 10 days; should be given only for life-threatening maternal infections. Discontinue breastfeeding during treatment.
	ANTIFUNGALS	
Metronidazole/tinidazole	Appears in breast milk in levels equal to serum levels.	Side effects include decreased appetite, vomiting, blood dyscrasia, and animal evidence of tumorigenesis. Mother's dose can be modified (e.g., 2 g single-dose therapy) so she can pump and discard milk for 24 hr.
Antimalarial (chloroquine)	Very small amounts appear in breast milk.	Observe for GI symptoms (vomiting, diarrhea); hypotension.

Continued

TABLE 18.7 DRUGS EXCRETED IN BREAST MILK—CONT'D

ANTIFUNGALS		
Cephalosporins (cephalexin, cephalothin)	Very small amounts appear in breast milk.	Rash and sensitization are possible. Also may affect bacterial flora—diarrhea, thrush.
Fluconazole (Diflucan)	Excreted into breast milk in small amounts (1% of the maternal dose; <5% of the therapeutic pediatric dose).	Considered safe for nursing infants.
Fluoroquinolones (levofloxacin, norfloxacin, ofloxacin, ciprofloxacin)	Varying levels in breast milk—use with caution.	Pseudomembranous colitis—observe for GI symptoms (vomiting, diarrhea). Tooth discoloration; phototoxicity. Arthropathy in animals.
ANTICHOLINERGICS		
Atropine, scopolamine, synthetic quaternary ammonium derivatives	Atropine appears, but quaternary ammonium derivatives do not appear in breast milk.	The neonate of nursing mother receiving atropine should be observed for tachycardia, constipation, and urinary retention.
Cimetidine	Appears in higher concentration than in serum.	No reported effects, although may suppress gastric activity, inhibit drug metabolism, and produce central nervous system stimulation. Use with caution until more information about antiandrogenic effects.
ANTICOAGULANTS		
Heparin and warfarin (Coumadin)	Do not appear in breast milk.	
ANTITHYROIDAL AGENTS		
Iodide	Passes into milk. May affect thyroid activity and cause goiters.	Not contraindicated during breastfeeding.
Thiouracil	Higher concentration in maternal milk than in blood.	Neonatal problems include suppression of thyroid activity and agranulocytosis. If breastfed, infant should be given thyroid supplement, and thyroid function should be followed.
Propylthiouracil	Appears in small amounts (<0.3% of maternal dose).	No reported effects on infant. Follow with T_3, T_4, and TSH.
ANTICONVULSANTS		
Phenobarbital, phenytoin, carbamazepine (Tegretol), and valproic acid (Depakene)	All appear in small amounts.	Sedation is possible, but rarely are clinical symptoms significant enough to cause adverse effects. Accumulation may occur because of long half-life of valproic acid.
Lamotrigine	Mean milk-to-plasma ratio 41.3% with a nonsignificant trend toward higher levels in breast milk 4 hr after maternal dose.[316]	Infant plasma concentrations were 18.3% of maternal plasma concentrations, with a theoretical infant dose of 0.51 mg/kg/day and a relative infant dose of 9.2%.[316] Mild thrombocytosis was the only adverse event noted.

TABLE 18.7 DRUGS EXCRETED IN BREAST MILK—CONT'D

CARDIOVASCULAR DRUGS		
Digoxin	Appears in small amounts.	Appears to be safe.
Reserpine	Appears in breast milk.	Symptoms include diarrhea, lethargy, nasal stuffiness, bradycardia, and respiratory difficulties; contraindicated in breastfeeding.
Propranolol, metoprolol, labetalol	Appear in breast milk in varying degrees; safest beta blockers with breastfeeding.	Observe for beta blockade—respiratory depression, bradycardia, or hypoglycemia.
Verapamil, diltiazem	Appear in varying amounts in breast milk.	Appear to be safe.
Nifedipine	90% of the dose unavailable for transfer to breast milk because of binding to plasma proteins.[13] Low levels (<1–10.3 mcg/L) appear in breast milk 1–3 hr after maternal dosing.[173]	Appears to be safe.
CATHARTICS		
Aloin, cascara sagrada, and anthraquinone preparations	Appear in breast milk.	Colic and diarrhea are possible side effects.
CONTRACEPTIVES		
Birth control pills (combined; progestin only; minipill)	Appear in breast milk with peak levels 2 hr after intake.	Combined: may alter the quality and quantity of milk—suppress lactation, shorter breastfeeding, and slower weight gain. Progestin only or minipill: no alteration of milk volume or infant weight gain. Avoid progestins in pump-dependent mothers of premature infants to avoid affecting milk supply.[295] Unknown long-term risk for cancer—no evidence in past 30 years.[245]
Medroxyprogesterone (Depo-Provera)	Increased prolactin levels before/after sucking.	No adverse effects—3-month injection (increased protein and quantity of milk); 6-month injection (increased quantity but decrease in protein, fat, calcium).[245]
Birth control implant (IMPLANON)	Small amount of hormone passes into breast milk. Best to delay implant until 4 weeks postpartum.	Small number of children studied for 3 years after breastfeeding—no effects on growth and development.
Barrier methods (diaphragm, condoms, foams, cervical cap)	No chemicals to be excreted into breast milk.	No effects on infant.
DIAGNOSTIC RADIOACTIVE COMPOUNDS		
^{66}Ga, ^{124}I, and ^{63}Cu	Appear for 24–48 hr.	Check half-life of specific compound. Pump and discard; then resume breastfeeding.
DIURETICS		
Hydrochlorothiazide	May suppress lactation.	Inadequate milk; no significant risks are present; compatible with breastfeeding.

Continued

TABLE 18.7 DRUGS EXCRETED IN BREAST MILK—CONT'D

IMMUNOSUPPRESSANT		
Azathioprine	One small study ($n = 10$ mothers; 31 breast milk samples) found small levels (1.2 and 7.6 ng/mL) of 6-mercaptopurine (6-MP) in breast milk samples at 3 and 6 hr, respectively, after azathioprine ingestion.	Potential risks of bone marrow suppression, increased risk for infections and pancreatitis. No signs of clinical immunosuppression in the small study.
PSYCHOTHERAPEUTIC AGENTS		
Lithium	Appears in breast milk; infant serum level is 10%–50% of mother's level.	Contraindicated in pregnancy because of the risk of congenital heart defects[336]; use controversial during lactation. Cyanosis, hypotonia, electrocardiogram changes. Evaluate lithium levels. Inhibits cyclic 3′,5′-AMP, a substance significant to brain growth.
	A small study ($n = 10$ mother/baby pairs) found the average breast milk concentration of lithium to be 0.35 mEq/L with an infant trough concentration of 0.16 mEq/L.[451]	Carefully selected mothers may breastfeed a healthy infant while taking lithium: (1) maternal mood stable, (2) simple medication regimen and/or monotherapy with lithium, and (3) a pediatrician collaborating to monitor the infant.[451]
Olanzapine	Small amount (1.02%). Avoid breastfeeding during peak levels within 5 hr after dose.[137]	No adverse effects. Monitor for drowsiness and sedation; developmental milestones, especially if combination antipsychotics used.
Haloperidol	Low levels in breast milk.	Monitor for drowsiness and sedation; developmental milestones, especially if combination antipsychotics used.
Risperidone	Low levels in breast milk.	Little data; another antipsychotic agent preferred during breastfeeding.
Phenothiazines	Appear in small amounts.	Evaluate each drug separately; observe for sedation.
Diazepam (Valium)	Appears in breast milk and may accumulate in infant because it is detoxified in liver.	Poor feeding, weight loss, hypoventilation, and drowsiness may be seen. Low incidence of toxicity and adverse events.
Tricyclic antidepressants (amitriptyline, nortriptyline, desipramine)	Appear in minimal amounts (<1%)	Careful considerations to select the safest for the infant. Nortriptyline may be the preferred choice.
Selective serotonin reuptake inhibitors (SSRIs) (fluoxetine, sertraline, paroxetine, citalopram, escitalopram)	Appear in varying amounts. Fluoxetine—high levels, highly lipid bound. Produces the highest proportion (22%) of infant levels that are elevated above 10% of the average maternal level.[34] Citalopram produces elevated levels in 17% of infants.[34]	SSRI intake does not alter milk supply, and untreated psychiatric illness does lower milk supply.[166] Sertraline and paroxetine have a better neonatal safety profile than other SSRIs.[322] Sertraline is the drug of choice after birth because plasma levels are low (<2 ng/mL),[460] and there are few side effects.[322] May alter short-term and/or long-term central nervous system development and function. Slower growth curve or weight gain with fluoxetine.[71] Most infants may continue breastfeeding when mother is treated with 20–40 mg daily.[118] Citalopram—minimize maternal dose to decrease elevated infant levels.[460] Paroxetine levels are also low.[460] Adverse effects include insomnia, restlessness, and constant crying that ceases when sertraline is used.[438] Escitalopram—somnolence and sedation in young infants.

TABLE 18.7 DRUGS EXCRETED IN BREAST MILK—CONT'D

PSYCHOTHERAPEUTIC AGENTS		
Serotonin-norepinephrine reuptake inhibitors (SNRIs) (duloxetine, venlafaxine, desvenlafaxine)	Appears in breast milk in low levels	Monitor for drowsiness, sedation, adequate weight gain, and developmental milestones, especially if combination antipsychotics used.
STIMULANTS		
Amphetamines (methamphetamine* MA)	Amphetamine concentration 3–7 times higher in breast milk than in maternal plasma on the 10th and 42nd days of life.[417] Half-life of smoked MA in breast milk is 11.3 and 40.3 hr.[78] MA disappears from breast milk approximately 24 hr after maternal urine MA is negative.[78]	Stimulation of the infant—poor sleeping patterns and irritability. Infant death and SIDS-like syndrome reported with methamphetamine intake of mother.[14] Small amounts of amphetamine in infant's urine.[417]
Caffeine	Appears in small amounts (<1%) but may accumulate in infant.	Symptoms include jitteriness, wakefulness, and irritability. May alter iron concentration in milk and iron deficiency anemia at 1 month of age.
Theophylline	Appears in moderate amounts.	Irritability, jitteriness, and wakefulness may be seen in infant.
Cocaine*	Appears in breast milk.	Cocaine intoxication: neurotoxicity (e.g., irritability, hyperactive reflexes, tremulousness, and mood lability), tachycardia and seizures have been reported (see Chapter 11).[72,75] Infant urine may be positive for cocaine for 60 hr after maternal use; delay breastfeeding to allow cocaine elimination (24–48 hr).[92]
OTHER SUBSTANCES		
Buprenorphine†	Appears in low concentrations; poor oral bioavailability of drug in infants.	Safe during breastfeeding.[80,362] Monitor for drowsiness, adequate weight gain, and developmental milestones. Observe for sedation and withdrawal symptoms.
Methadone†	Appears in breast milk, concentration low (range 21.0–46.2 ng/mL).[204] Peak methadone levels occur in 4 hr after oral administration; the maximum amount secreted into breast milk is approximately 2.2% of the mother's dose.[246]	Management depends on maternal dosing for methadone maintenance.[7] Observe for sedation and withdrawal. Studies have found that breast milk intake is associated with less neonatal abstinence syndrome (NAS) and less use of pharmacologic treatment, regardless of type of drugs and gestation.[79,80,204,362]
Naltrexone†	Minimally excreted into breast milk	Monitor for drowsiness, adequate weight gain, and developmental milestones. Observe for sedation and withdrawal symptoms.

Continued

TABLE 18.7 DRUGS EXCRETED IN BREAST MILK—CONT'D

OTHER SUBSTANCES		
Ethanol (alcohol)	Quick equilibration between serum and breast milk levels.	Large quantities associated with lethargy, drowsiness, and affected motor development. The deficit in motor development was not replicated in a study of 18-month-olds exposed to moderate alcohol use during breastfeeding.[251] May inhibit milk letdown reflex and suppress lactation. Avoid nursing within 2–3 hr of alcohol intake. Low levels of postpartum maternal alcohol use not associated with shorter duration of breastfeeding or adverse outcomes up to 12 months of age.[467]
Marijuana*	THC, the active ingredient in marijuana, appears in median concentration of 9.47 ng/mL; concentrations influenced by time of last use and for up to 6 hr after use.[32] Recommended to discontinue use while breastfeeding.[11]	THC, the active ingredient in marijuana, is absorbed and metabolized by the infant.[362] May decrease prolactin levels, milk supply, and motor development. Exposure to secondary smoke. Avoid breastfeeding for several hours after use.[245] Decreases motor development at 1 year of age;[19] other long-term effects on development are unknown.[11,58,362]
Nicotine	Appears in breast milk in proportion to number of cigarettes smoked and/or time from last cigarette.	Irritability; failure to thrive may result because of suppression of lactation. Effects of secondary smoke: increased incidence of upper respiratory infections, otitis media, bronchitis, pneumonia, and SIDS. Avoid smoking in the same room with the infant.
	Smoking reduces the transport of iodine into breast milk. Mothers should receive iodine supplement.[243]	Infants whose mothers smoke are at increased risk for iodine deficiency–induced brain damage if the mother does not receive iodine supplementation.[243]
Herbal tea mixtures (containing anise, fennel, licorice, galega) used to stimulate lactation (i.e., mother's milk tea)	Essential oils found in anise and fennel appear in breast milk.	Recent RCT found no adverse effects for 30 days of study or first year of life.[457]
Fenugreek	Appears in breast milk; milk has a maple syrup smell.	Urine may have a maple syrup smell.
Ginseng	No data on amount in breast milk.	May cause neonatal androgen effect and hirsutism.
Comfrey	No data on amount in breast milk; caution use in any form.	Associated with veno-occlusive disease and hepatotoxicity and is carcinogenic. Contraindicated in breastfeeding.

TABLE 18.7 DRUGS EXCRETED IN BREAST MILK—CONT'D

OTHER SUBSTANCES		
Silicone breast implants	Silicon in cow's milk has been shown to be 10 times higher and even higher in commercial infant formulas than in mothers with silicone implants.[391] Breastfeeding mothers with silicone implants are similar to mothers without implants with respect to levels of silicon in their blood and breast milk.[391]	No adverse effects.
RESPIRATORY DRUGS		
Inhalants (steroids—budesonide)	Lower levels of budesonide (mean ratio of 0.46) in milk than in maternal plasma.[124]	Negligible systemic exposure to inhaled corticosteroids[124]: Mean infant dose 0.3% of daily maternal dose; average infant plasma concentration 1/600th of maternal plasma concentration.

*Drug of abuse; contraindicated during breastfeeding—hazardous to both the mother and infant.
†Food and Drug Administration–approved drug for opiate withdrawal.
3′,5′-AMP, 3′,5′-Adenosine monophosphate; *FDA,* Food and Drug Administration; *G6PD,* glucose-6-phosphate dehydrogenase; *SIDS,* sudden infant death syndrome; T_3, triiodothyronine; T_4, thyroxine; *TSH,* thyroid-stimulating hormone.

BOX 18.5 PARENT/CAREGIVER TEACHING KEY POINTS FOR SUCCESSFUL BREASTFEEDING

- Breast milk is the best milk for preterm or sick neonates. Teach parents the benefits and advantages of breast milk for their infant(s).
- Teach parents how to interpret their infant's cues/behaviors of self-regulation and stress (see Chapter 13), hunger, and satiety.
- Teach parents proper collection/storage/transport of pumped breast milk; teach proper care and cleaning of breast pump supplies to prevent infection.
- Teach mothers self-care: need for rest, diet, and fluid intake for lactation.
- Provide anticipatory guidance about pumping and a dwindling milk supply (see Fig. 18.12). Teach parents realistic expectations for the first feeding at the breast and that breastfeeding is a learned behavior for both mother and the preterm or sick infant.
- Provide positive feedback, support, and encouragement to the mother for pumping and with feeding at the breast.
- Teach parents the importance of their involvement in their infant's care, especially in skin-to-skin (kangaroo) care and its benefits for both the mother and preterm infant.

pump,[42] new guidelines for cleaning pumps have been released by the CDC.[67] A written handout of pumping, storing, and thawing practices is helpful. Often the mother pumps and collects the milk, and the father transports it to the NICU (see Chapter 29). In addition, fathers assist with pumping, assume more daily domestic duties, and provide moral support to pumping mothers.[406] **Methods of treatment and storage are listed in Box 18.6.**

Rewarming techniques include (1) placing frozen milk in a room-temperature water bath, in a hot-water bath, in a microwave oven, or under cold running water and then tepid water or (2) using commercially available devices. Slow room-temperature rewarming is a concern because of bacterial overgrowth, especially if thawing is prolonged. Most nurseries use room-temperature water bath rewarming to avoid exposure to the high temperatures of the hot-water bath and the microwave. Microwaving is contraindicated—*never* use microwave heating of breast milk because of the destruction of anti-infective properties (e.g., lysozyme and secretory IgA), resulting in an overgrowth of

BOX 18.6 TREATMENT AND STORAGE OF BREAST MILK

Treatment

1. Heat: Significant loss of lysozyme, lactoferrin, immunoglobulins, lactoperoxidase, lymphocyte function, complement, phagocytosis, and macromolecules may occur. Fat content altered (approximately 13%) by milk sterilization.[10] Pasteurization (Holder method: 62.5° C for 30 minutes)[140] does not alter fatty acid composition, but fat absorption by small preterm infants may be reduced from inactivation of bile salt lipase.[237]
2. Lyophilization: Effects are similar to those of heat treatment.
3. Freezing: Limited information; cells are not viable, but there is no effect on IgA content. Fat content is altered by freezing and thawing.

Storage

1. Use sterile glass or hard food-grade plastic containers (to ensure minimal loss of immunologic properties and fat-soluble vitamins)[5,15,338] with an airtight lid (to maintain closed system).[5,15,338] Milk stored in plastic bags may lose immune components and/or become contaminated.[325] Use a new container for each expression. Place amount for one feeding/container.
2. Label with name, date, and time of collection, so that oldest milk is used first and colostrum is fed in the order in which it was pumped.[5]
3. Store in refrigerator for 24 hours (at 0° to 4° C [32° to 39.2° F]) or for longer periods (at –18° C [0° F]).

bacteria, and possible "hot spots" in the liquid.[10,353] The Human Milk Banking Association of North America recommends warming feedings to body temperature for preterm infants.[193] However, research shows a range of temperatures at which feedings are actually delivered, from a low of 21.8° C[115] to a high of 46.4° C.[244] Commercial warming devices are either waterless or heat milk with water (below the level of the container lid).

Fresh breast milk is preferable for feedings because it has the greatest amount of immunologic properties. If the mother visits the infant at feeding time, she may pump her breasts, and the breast milk can be immediately fed to the infant, if the infant cannot be put to the breast.

Maternal Care

A mother may be so concerned about the welfare of her infant that she spends most of her time at the hospital and receives inadequate rest, which is a common cause of milk production problems. The care plan includes encouraging, educating, and suggesting to the mother that she go home and rest, which may require someone to assist with the care of the newborn's siblings. The stress of having a sick infant and the time spent at the hospital may mean that the mother does not receive adequate nutrition.

It is necessary to add about 600 kcal to the nonpregnant diet and to replace elements, such as calcium, minerals, and fat-soluble vitamins, used in producing milk. The recommended dietary increases are even greater than those during pregnancy.[468] Adequate fluid intake (six to eight glasses of water, skim milk, or other noncaffeinated liquids) should be consumed every day. Certain components of breast milk (e.g., quantity, protein and calcium content) do not vary with the mother's diet, whereas others (e.g., fatty and amino acids, lysine, methionine, water-soluble vitamins) vary with maternal intake.

A mother's diet does not have much effect on the quality of the breast milk (unless malnutrition intervenes) but affects the mother's overall health. She should be reminded to eat a balanced diet. Vegetarian diets should be supplemented with about 4 mg/day of cyanocobalamin (vitamin B12) to prevent neurologic impairment in the breastfed infant.[68,245]

Anticipatory Guidance and Realistic Expectations

Anticipatory guidance is essential for mothers who are breastfeeding preterm infants. Mothers must be informed in the beginning that their milk supply may dwindle, even though they closely adhere to the pumping schedule. This is normal, because most pumps do not stimulate the breast as efficiently and physiologically as the suckling infant. Use of breast pumps that mimic the sucking pattern of the human infant result in greater amounts of pumped milk and are more efficient, comfortable, and convenient.[293,347,358] **When the pumping regimen begins, explaining and drawing the mother a picture (Fig. 18.12) of what is commonly experienced helps alleviate guilt caused by a dwindling milk supply. A rather sparse supply of milk does not mean she cannot nurse the infant, because the milk supply builds in response to the infant's nutritive suckle. The parent should be taught that**

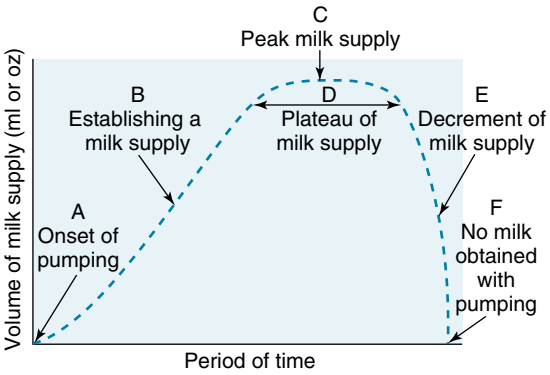

FIGURE 18.12 Establishing and maintaining milk supply by pumping. **A**, Pumping begins. **B**, Milk supply is established and increases. **C**, Peak or maximum volume of milk is established and plateaus. **D**, Gradually, supply begins to dwindle and may totally cease. **E** and **F**, The volume of milk and the period for decline in supply to begin and end in no milk production is an individual process. Some women begin and end this cycle in days or weeks; others are able to pump for months. Even if the supply dwindles to no milk, nutritive *suckling* of the infant with a Lact-Aid Nursing Trainer in place (see Fig. 18.10) will reestablish the supply.

there is no correlation between the amount of breast milk expressed and the amount of milk a mother actually lets down when the infant is at the breast.

Breastfeeding problems may be particularly detrimental to the mother's perception of breastfeeding success. **Disappointment with the breastfeeding experience may result from unrealistic expectations about breastfeeding the preterm infant. Establishing realistic parental expectations for the first time the infant breastfeeds decreases disappointment from unattainable goals.** Breastfeeding, like parenting, is not instinctual but, rather, is a learned behavior for both the mother and the infant. No one, including the health care provider, should expect immediate latch-on and vigorous sucking. **The first several attempts at breastfeeding may consist only of direct skin contact, nuzzling, and licking behaviors by the infant and cuddling and positioning by the mother.[412] Any actual sucking is an "extra" reward but should not be anticipated.**

Facilitating Breastfeeding Success

Emotional support during breastfeeding of a normal or sick infant facilitates a successful experience for both the mother and the infant.[325] Mothers are more successful with breastfeeding when they have a positive attitude toward breastfeeding, have breastfeeding goals that change during the NICU stay,[187] are confident in their ability, and have support from significant others (both professionals and laypeople).[325,410] Breastfeeding support programs in the NICU result in improved breastfeeding rates at discharge. Use of peer counselors and lactation consultants has been shown to positively influence the provision of breast milk to infants in the NICU.[297,325]

The incidence and duration of breastfeeding preterm or sick newborns vary among NICUs and among countries. There is an inverse relationship between gestational age and duration of breastfeeding, with most mothers (more than 50%) abandoning breastfeeding before their infants are discharged from the hospital.[226,287] In a German cohort study, the average duration of breast milk feedings in VLBW infants was one-third of that of a matched group of term infants.[226] A recent population-based French study in a socioeconomically deprived area found an increase in breastfeeding initiation rates among preterm infants from 52.9% to 61%, especially among the very preterm infants whose rates rose at 2.2% per year.[74]

In the United States, older studies found that between 30% and 54% of premature infants were exclusively receiving human milk at discharge,[99,183] but at 4 weeks only 51% were still receiving human milk,[183] and even fewer (10%) were exclusively feeding at the breast.[99] The Breast Milk Early Saves Trouble (BEST) program (initiated to improve use of breast milk in the first week of life in preterm infants <2000 g) resulted in 50% (vs. 33%) of preterm infants receiving EBM, 82% (vs. 74%) receiving some breast milk, and 33% (vs. 2%) receiving banked breast milk; trends of more mothers breastfeeding and more discharged home breastfeeding also occurred.[306] Using quality improvement methods and a 10-step process for promoting and protecting breastfeeding in vulnerable infants,[410] over a 3-year period there was a 3.1-fold increase in the odds of VLBW infants receiving mother's own milk at discharge.[134]

Establishing an adequate milk supply is a key factor in successful transition from primarily bottle feeding at discharge (e.g., 60% of the infants were discharged when direct breastfeeding was less than 50% of the time) to

primarily breastfeeding at home.[471] The most common reason cited by mothers for discontinuation of breastfeeding (both in the hospital and after discharge) is inadequate milk supply (or "not getting enough").[57,215,287,471] Early initiation and establishment of adequate feeding at the breast before discharge encourages both mothers and professionals that exclusive breastfeeding is successful. **However, the early postdischarge period may be significantly stressful for mothers, because the breastfeeding pattern of a preterm infant may predispose to underconsumption (i.e., inability to compensate for inadequate intake in one feeding by increasing the number or intake of subsequent feedings), result in behaviors indicative of inadequate intake, and require nutritional supplementation.[215,296]**

Education and training about the many facets of breastfeeding are essential for medical and nursing staff.* Education about human milk use in the NICU has been shown to change NICU nursing staff's knowledge and attitudes.[30,151,248] Staff attitudes and behaviors are important to breastfeeding families and affect the breastfeeding experience,[35,341] as well as increasing human milk feeding rates.[151,248,302] A multidimensional approach to such education includes providing the staff with manuals, guides, and other educational materials, as well as scheduling routine classes, in-service training, and continuing education workshops. Moreover, professionals with clinical expertise should be identified; these resource personnel can increase the staff's competency in counseling and assisting breastfeeding families. A multidisciplinary quality improvement approach of parent and professional education, a resource team of nurses, and lactation consultation time focused on the VLBW infant resulted in a change of breast milk availability at discharge from 36% to 80%.[35]

Evidence-based protocols addressing breastfeeding can outline a consistent approach for staff and provide resource material that addresses successful strategies for handling common problems. Protocols can also reduce the amount of incorrect information that is disseminated.[295] A number of protocols, including a model hospital policy[341] for managing breastfeeding issues, have been developed by the ABM and are available from their website (www.bfmed.org).

Providing a breastfeeding program for preterm infants that is grounded in evidence-based practices demonstrates strong success.[296,297] The Rush Mother's Milk Club is an evidence-based NICU lactation program in which 98% of mothers provide milk for their infants, even though 50% of these mothers initially intended to breastfeed.[297] Seventy-three percent of mothers of VLBW infants initiated breastfeeding, and breastfeeding outcomes of low-income black mothers were 63%.[297] This program provides assistance to low-income mothers who are a group known to have low breastfeeding rates. Among these mothers, the average amount of human milk provided to VLBW infants exceeded 60 mL/kg/day, and total human milk intake was 71% of total enteral feeding volume.[297] Support groups with mothers who have had similar experiences are helpful in supplementing support obtained from significant others and professionals. Table 18.8 shows evidence-based barriers and facilitators of human milk feedings at and after discharge for VLBW infants.

A study of lactation counseling for mothers of VLBW preterm infants showed that more mothers decided to pump breast milk, mainly because of the health benefits for their infant.[405] In mothers who intended to formula feed, there was an 85% milk expression rate; in mothers intending to breastfeed, the rate was 100%. Black and Hispanic mothers pumped at 95% and 93% rates, respectively. All mothers believed that pumping was worth the effort and appreciated the help they received; none felt more stress or anxiety.

Breast milk is the best milk, especially for a sick or premature infant. By understanding normal lactation, the health care provider can support the breastfeeding dyad when breastfeeding is delayed or disrupted.

TABLE 18.8 BARRIERS AND FACILITATORS OF HUMAN MILK FEEDINGS FOR (VLBW) PREMATURE INFANTS AT AND AFTER DISCHARGE FROM NICU: RESEARCH BASIS

BARRIERS	FACILITATORS
Social and Neighborhood Structural Factors: • Black race[366,454] (with limited role models and exposure to breastfeeding)[128] • Perception of breastfeeding support by black mothers from their mothers (i.e., infant's maternal grandmother)[128] • WIC eligibility[128,366] • Previous experience with formula feeding[128] • Presence of additional children in household[128] • Longer LOS[366] • Living in a neighborhood with lower education levels[56,*] and poverty[403] • Travel/distance to NICU[403] • Return to work/school[403,405]	**Social and Neighborhood Structural Factors:** • Older maternal age[128] • Hispanic/Caucasian/Asian ethnicity[128,366] • Married[128] • Higher level of maternal education[182] • Near time of discharge: maternal goal to provide any human milk[128,187] • Female infant[128] • Lack of WIC eligibility[128,366] • Shorter LOS[366] • Living in a highly educated neighborhood[56,*] • Family support[24,403]

Maternal Factors:
Initiating milk expression:
• Pregnancy complications[196,224,296,297,403]
• Anxiety regarding infant's health[403]
• Lack of privacy[403]
• Breast pump dependency: lack of infant nutritive sucking stimuli to breast; dislike and inconvenience[296]
After NICU discharge:
• Difficulty with time management[403]
• Low milk supply[187,296,405]
• Inability to pump as frequently as needed[405]
• Perception that human milk has "done its job" in preventing NICU complications[187]
• Breast pump dependency: dislike and inconvenience[296]
	Maternal Factors:
	• Obstetric factors[466]:
	  • Primiparous
	  • Received ANS
	  • Vaginal, singleton birth
	• Positive attitudes toward pumping[403]
	• Anticipation of breastfeeding[403]
	• Establishing full human milk volume with pumping by 14 days postpartum[297,299]: Three times more likely to provide human milk at discharge[188]

Breastfeeding Programmatic Factors:
• Inconsistent/lack of information about the science of human milk, lactation, and breastfeeding
• Lack of peer counselors who have provided human milk for their VLBW infants in and after the NICU
• Delayed breast pump use,[196,329] long intervals between pumping,[299] fewer pumping episodes (<6 times/day)[196]
• Prolonged hand expression, lack of access to breast pump[257]
• Using manual or small electric breast pumps after NICU discharge[403]
• Lack of evidence-based decisions about the use of donor human milk.[298] Fewer black mothers providing any human milk at discharge when donor milk program introduced[214]
• Lack of developmentally based transitioning to feeding at the breast.
  • Failure to encourage and facilitate early skin-to-skin contact at/shortly after birth
  • Failure to provide taste and smell of mother's own breast milk by oral care with colostrum (see Box 18.3)
• Determining readiness for initiation of oral feedings based on gestational age, postconceptual age, and/or birth weight rather than individual assessment and research evidence in Table 18.5
• Initiating oral enteral feeding by bottle feeding, even if maternal goal is breastfeeding[45]
	Breastfeeding Programmatic Factors:
	• Consistent, information about the science of human milk, lactation, and breastfeeding[24,297]
	• Timely information about the health benefits for the infant so that an informed decision can be made[187,296,303,405]
	• Supportive NICU environment with multidisciplinary lactation teams and rounds[24,35]
	• NICU staff education that increases knowledge of evidence-based practices and influences staff attitudes[35,248]
	• Use of breastfeeding peer counselors[295,374–376]
	• Early (within first hour after birth) breast pump use[329]
	• Use of more physiologic breast pumps[35,292,293,347,358] with pumping intervals of every 2–4 hr (8–12 pumping episodes/day)
	• Use of evidence-based milk expression protocols[222,466]
	• Protection, storage, and safe handling of expressed milk[224,296]; use of donor human milk[466]
	• Use of developmentally based transitioning to feeding at the breast[224]:
	  • Encourage and facilitate skin-to-skin contact with mother at/shortly after birth, if possible[242] (see Table 5.1)
	  • Providing taste and smell of mother's own breast milk by oral care with colostrum (see Box 18.3)
	• Determining readiness to initiate oral feedings by individual assessment based on evidence from research in Table 18.5
	• First enteral feeding is mother's own colostrum/directly suckled from breast, if possible[63,466]

19 SKIN AND SKIN CARE

CAROLYN LUND AND DAVID J. DURAND

The skin is a large organ in premature and term infants, comprising at least 13% of body weight in contrast to 3% of the body weight in adults.[77] Skin functions include thermoregulation, barrier against toxins and infections, water and electrolyte excretion, fat storage and insulation, and tactile sensation.

Like many other organs, the skin of a premature infant is immature. The combination of immaturity with the need for intensive care monitoring and procedures places **premature infants at risk for skin trauma and loss of skin integrity. Skin trauma and skin immaturity have serious consequences for infants in the neonatal intensive care unit (NICU), including problems in thermoregulation, fluid and electrolyte balance, diversion of calories for tissue repair, discomfort, potential toxicity from absorbed substances, and increased risk for infection.**

This chapter reviews the physiology of term and premature infants' skin, the differences in structure and function related to skin immaturity, and prevention and treatment strategies to promote optimal skin integrity for infants in the NICU.

PHYSIOLOGY

There are three layers to the skin: the epidermis, the dermis, and the subcutaneous layer (Fig. 19.1). The *epidermis* is comprised of the stratum corneum, a nonliving layer, and the basal layer. The *stratum corneum* is formed of lipids and protein in "brick and mortar" configuration. **The basal layer of the epidermis replaces the stratum corneum with cells called *keratinocytes.*** Approximately every 26 days, keratinocytes migrate from the basal layer to the exfoliated layers of the stratum corneum. In addition to keratinocytes, *melanocytes* are also found in the basal layer.

The *dermis,* a woven layer of collagen and elastin fibers, is 2 to 4 mm thick at birth. It contains nerves, blood vessels, and hair follicles. **Sensations of heat, touch, pressure, and pain originate in the dermal layer. Sebaceous glands and sweat glands are located in the dermis and in the subcutaneous layer of the skin.** Sweat glands become mature in term infants during the first week of life, whereas maturation in premature infants occurs between 21 and 33 days and perhaps even longer in extremely premature infants.

The *subcutaneous layer* is composed of fatty connective tissue, with fat deposition occurring primarily during the last trimester of pregnancy. This layer provides heat insulation and functions as a calorie reservoir.

The skin of a normal term infant is covered with *vernix caseosa,* a "cheesy" substance composed of water (80%), lipids and proteins,[127] sebum from sebaceous glands, broken-off lanugo, and desquamated cells from the amnion. **Vernix production begins at the end of the second trimester, accumulates on fetal skin in a cephalocaudal manner,**[65] and protects the fetus against maceration from the amniotic fluid and chafing caused by crowding in utero. Vernix detaches from fetal skin as the levels of pulmonary surfactant rise, resulting in a progressive increase in the turbidity of the amniotic fluid.[65,100] **Leaving residual vernix intact may be beneficial after delivery, because the presence of vernix produces earlier acidification of the skin, facilitates colonization by normal bacterial flora, and serves as a natural moisturizer for the skin.**[126,127]

BLUE type highlights content that is particularly applicable to clinical settings.

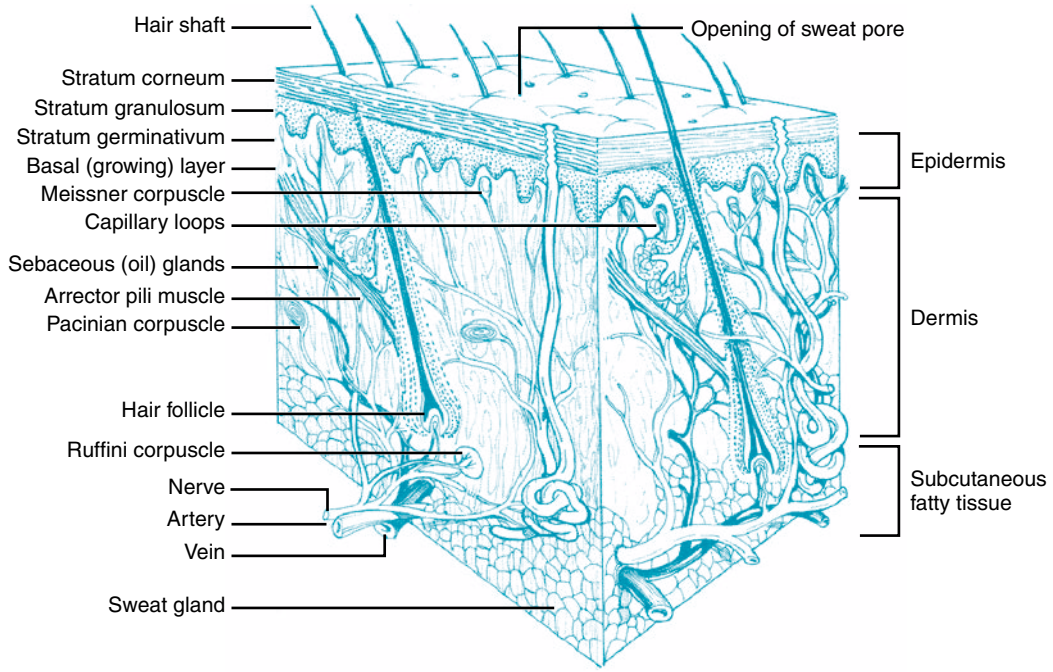

FIGURE 19.1 Cross section of skin layers and anatomic structures. (From Skillman NJ. *Principles of Infant Skin Care.* Skillman, NJ: Johnson & Johnson; 1994.)

The skin of premature infants is thinner than that of term infants and may appear transparent or even gelatinous in extremely immature infants. There is usually a ruddy, red appearance caused by the underdeveloped stratum corneum, making **skin color a poor tool for assessing the oxygenation status of very immature infants.** There are fewer wrinkles on skin surfaces than in term infants, and the skin is covered by lanugo to varying degrees, depending on maturity; these fine hairs cover the upper back, arms, and forehead. The amount of *vernix caseosa* depends on the gestational age at birth. **The subcutaneous layer in premature infants is often edematous because of an excess of cutaneous water and sodium (see Chapter 14).**

ETIOLOGY

Term Newborn Skin Variations

Although the basic skin structures are the same in all term newborns without dermatologic disease, there may be **cutaneous variations seen on physical examination.** These variations (Table 19.1) are not considered pathologic, but it is useful for clinicians to know them, because many parents ask the significance of physical variations as they examine their newborn.

Physiologic and Anatomic Differences in Premature Skin

There are developmental differences in skin physiology and anatomy between skin of full-term and premature infants compared with skin of older children and adults. This section discusses these differences and identifies the implications for care.

UNDERDEVELOPMENT OF THE STRATUM CORNEUM

The *stratum corneum*, the nonliving layer of the epidermis that is responsible for controlling evaporative heat loss and transepidermal water loss (TEWL), contains 10 to 20 layers in adults and term infants. Term infants have been shown to have lower transepidermal water loss than adults,

TABLE 19.1 NORMAL VARIATIONS OF TERM NEWBORN SKIN

VARIATION	DESCRIPTION
Linea nigra	Line of increased pigmentation from umbilicus to genitalia
Mongolian spots	Irregular, blue-gray, bruise-like spots Usually seen over sacrum and buttocks, may extend over back and shoulders Caused by pigmented cells in dermis Most common in infants with darker pigmentation
Lanugo	Fine, downy hair over back, shoulders, and face Shed at 32–36 weeks' gestation
Milia	White, pinhead-size bumps over chin, cheeks, nose, and forehead Tiny epidermal cysts If on palate, called *Epstein pearls*
Miliaria	Caused by retention of sweat from edema in stratum corneum that blocks sweat glands Most common is rubra (prickly pear), but there are also clear versions
Harlequin sign	Color of half of body turns deep red, whereas the other half is pale Caused by immature autoregulation of blood flow
Vernix caseosa	Gray-white, cheesy substance that protects fetal skin in utero Gradually diminishes near term
Cutis marmorata	Mottling caused by vasomotor immaturity
Erythema toxicum neonatorum	Small, firm white or yellow pustules with erythematous margin Most often seen on trunk, arms, and perineal area Benign condition seen in 30%–70% of newborns
Acne neonatorum	Acne-like rash seen in newborns at several weeks of age Caused by stimulation of sebaceous glands by maternal hormones More common in males Instruct caregivers not to use creams, lotions, or ointments because they can worsen the rash
Transient neonatal pustular melanosis	Resembles miliaria but present at birth Most frequently found on face, palms of hands, soles of feet Not infectious or contagious
Café-au-lait spots	Irregularly shaped oval lesions If large size (>4 × >6 cm), or if >6 in number, associated with neurofibromatosis

with the lowest levels seen on the first day of life.[136] Despite reports of normal barrier function at birth, other studies indicate that infant **skin is prone to higher percutaneous absorption and prone to irritant and contact dermatitis,** which has prompted others to maintain that barrier function is not fully developed in the term neonate and young infant.[63,66] **The infant stratum corneum is 30% thinner than adult,** with the overall epidermis 20% to 30% smaller. ***Keratinocyte*** **cells are small, with a higher cell turnover rate that may explain some observations of faster wound healing in infant skin.**[119]

Premature infants have fewer layers of *stratum corneum* depending on their gestational age; at less than 30 weeks' gestation, it may contain only two or three layers (Fig. 19.2), and extremely premature infants of less than 24 weeks' gestation are just beginning to develop the stratum corneum.[62,66] **Another function of the stratum corneum—protection against toxins and infectious agents such as bacteria and viruses—is minimal in premature infants, leaving them vulnerable to percutaneously transmitted infections and toxicity from topically applied substances.**

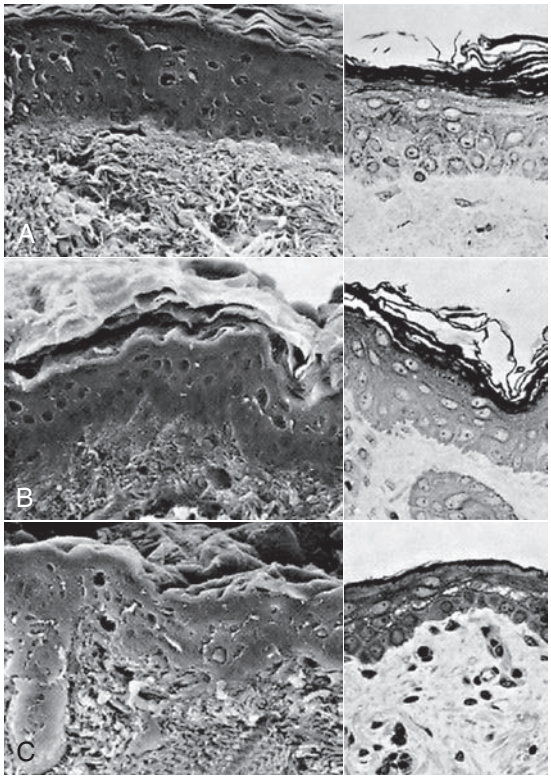

FIGURE 19.2 Photomicrograph of the stratum corneum in an adult **(A)**, a term newborn **(B)**, and a premature infant of 28 weeks' gestation **(C)**. Note fewer layers of stratum corneum in the premature infant. (From Holbrook KA. A histological comparison of infant and adult skin. In: Maibach HI, Boisits EK, eds. *Neonatal Skin: Structure and Function*. New York, NY: Marcel Dekker; 1982.)

The transition from the aquatic, intrauterine environment to the atmospheric, external environment has been thought to result in accelerated maturation of the stratum corneum and more mature function after the first 10 to 14 days of life.[49,63] However, other authors cite **a slower process in premature infants less than 27 weeks' gestation, with rates of TEWL nearly double adult levels even at 28 days of life.[117] Premature infants of 23 to 25 weeks' gestation have losses 10 times higher than term infants initially, and they continue to have elevated heat and water loss resulting from immature barrier function for a longer period.[2]** The maturation process can take as long as 8 weeks in an infant of 23 weeks' gestation.[73]

DERMAL INSTABILITY

The dermis is made of collagen and elastin fibers in a gel matrix, providing mechanical strength, protection, and elasticity to the skin. **The dermis of the term newborn is thinner than the adult dermis and has a higher water content.[67,85]**

Collagen deposition in the dermis increases with advancing gestational age, preventing fluid from accumulating in this layer. **Premature infants have a tendency to become edematous, because they have less collagen and fewer elastin fibers in the dermis.**

Both term and premature infants may be prone to necrotic injury from excessive edema because of alteration in blood flow and perfusion to the epidermis. Edematous infants need protection from pressure and ischemic injury, including routine turning and the use of surfaces to minimize pressure points such as gelled mattresses or pads.[10]

DIMINISHED COHESION BETWEEN EPIDERMIS AND DERMIS

Numerous fibrils connect the epidermis to the dermis at the *dermo-epidermal junction*. These fibrils are more widely spaced and fewer in number in the premature infant[67] (Fig. 19.3) **but become stronger with advancing gestational and postnatal age.** Genetically abnormal fibrils at this junction are found in certain types of the genetic disorder *epidermolysis bullosa,* a blistering skin condition that occurs with even minimal trauma. **Premature infants also are prone to blistering from injury, although this decreases as they mature. Diminished cohesion also places premature infants at risk for injury from adhesive removal. Particularly if extremely aggressive adhesives are used, there may be a stronger bond of the adhesive to the epidermis than of the epidermis to the dermis, and epidermal stripping may result during adhesive removal.[88]**

SKIN pH

The ability of the skin surface to form and maintain an acid surface is a function of various chemical and biologic processes. An acid skin surface with a pH less than 5 has been documented extensively in adults and children.[17] **This *acid mantle* contributes to the stratum corneum's innate immune function by inhibiting the growth of pathogenic microorganisms.[128]**

Term newborns are born with a relatively alkaline skin surface, measuring a mean pH

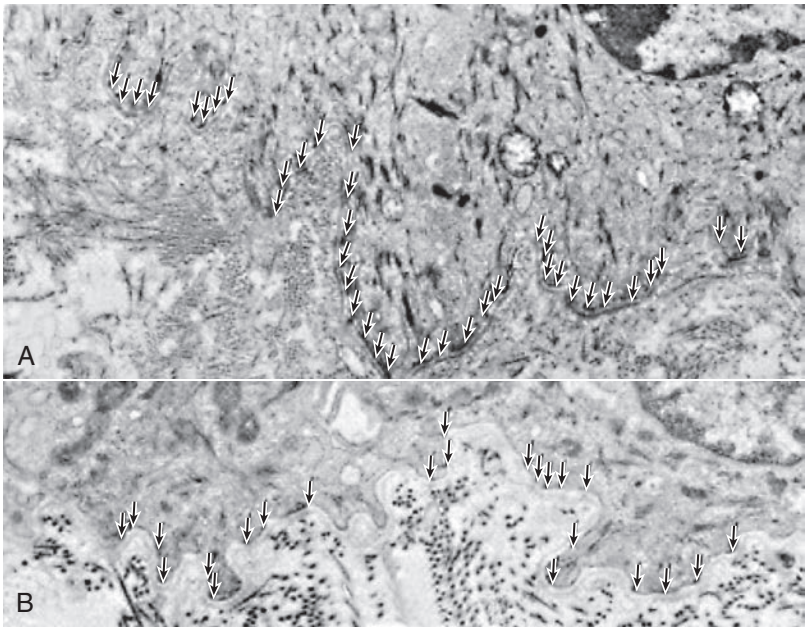

FIGURE 19.3 **A** and **B**, *Arrows* indicate fibrils called *hemidesmosomes,* which anchor the epidermis to the dermis. **B**, They are fewer in number and more widely spaced in the premature infant. (From Holbrook KA. A histological comparison of infant and adult skin. In: Maibach HI, Boisits EK, eds. *Neonatal Skin: Structure and Function.* New York, NY: Marcel Dekker; 1982.)

of 6.34. Within 4 days the pH declines to a mean of 4.95.[17] Skin pH measurements have been reported in **premature infants of varying gestational ages, and the pH was above 6 on the first day, decreasing to 5.5 during the first week, and gradually declining to 5 during the first month.**[51] **Bathing and other skin care practices alter skin pH; it may take an hour or longer to regenerate the acid mantle after bathing with an alkaline soap.** Skin that is occluded by wearing diapers has been shown to have a pH of 6, which is known to be a risk factor in the development of diaper dermatitis.[130] This may occur because an alkaline skin surface may reduce stratum corneum integrity and enhance susceptibility to mechanical damage.[130]

PREVENTION

During daily skin care practices such as bathing, emollient use, antimicrobial skin disinfection, and adhesive removal, the skin of newborns is at risk for trauma or disruption of normal barrier function. This is particularly true of newborns in the NICU, who may have been born prematurely or may be critically ill or require surgery.

This section reviews basic skin care practices in terms of impact on skin integrity, preventing potential toxicity, and reducing exposure to potentially sensitizing chemicals. **Recommendations for preventing trauma, protecting immature barrier function, and promoting skin integrity supported by scientific evidence are presented. These recommendations also are integrated into an evidence-based skin care guideline for health professionals.**[10]

Bathing

Bathing the newborn provides overall hygiene, aesthetics, and protection of health care workers by removing blood and body fluids. However, **bathing during the immediate post-birth period can result in hypothermia, increased oxygen consumption, and respiratory distress.** There remains a debate about when the first bath should be given, and even whether to bathe the newborn at all.[34] The Neonatal Skin Care Evidence-Based Clinical Practice Guideline recommends **giving the**

first bath when thermal and cardiorespiratory stability has been achieved, between 6 and 24 hours of age.[10] The World Health Organization (WHO) recommends delaying the bath for 24 hours, or if this is not possible due to cultural reasons, waiting at least 6 hours in an effort to prevent hypothermia especially in developing countries.[135] However, infants born to a mother who is HIV positive should be bathed as soon as possible after delivery once their temperatures have stabilized.[7]

The first bath may be given by sponge bathing, sitting in a small basin, or an immersion bath in a larger tub. Immersion bathing places the infant's entire body, except the head and neck, into warm water (37.8° to 38.8° C) deep enough to cover the shoulders. Studies including over 1000 full term newborns report that tub or immersion bathing, compared to sponge bathing, maintains temperature better, causes less crying and distress for the infant, and does not result in increased infection, even with the umbilical cord in place.[25,33] A study of 100 late preterm infants (35 to 36⅘ weeks gestation) randomized to immersion tub bathing or sponge bathing after 24 hours of life reported higher temperatures and less variability in body temperature when immersion bathed.[86]

The term "swaddled bath" describes using a cloth wrapped around the baby while lowering them into the tub to provide comfort. A randomized controlled study of providing this support for full term newborns during their first bath found swaddled bathing was more effective in maintaining temperature and other physiologic parameters such as heart rate and oxygen saturation.[26] An additional benefit is that this technique reduces parental stress during bathing.[50]

The Neonatal Skin Care Guideline recommends using warm tap water with or without a mild cleansing bar or liquid cleanser that has a neutral or slightly acidic pH to assist in the removal of blood and meconium, as water alone may not easily remove some lipid-soluble substances such as meconium. For premature infants <32 weeks, warm water only during the first week of life is the recommendation.[10]

Leaving residual vernix caseosa on the skin is important, as vernix facilitates skin adaptation including skin hydration and the formation of the acid mantle of the skin surface.[127] WHO guidelines for newborn care recommends leaving vernix intact for at least 6 hours.[126,135]

Once the acid mantle is established, bathing can alter the skin pH for a period of time, even with water alone, in older infants.[57] Bathing two to three times per week with cleansing products compared to water alone has been shown to have little or no difference on skin pH, TEWL, and stratum corneum hydration (SCH) in the neonatal period in full-term healthy infants.[45,55,82] Similar studies involving measuring skin parameters have not been performed in hospitalized neonates or in premature infants. The recommendation is to select cleansers that have neutral or mildly acidic pH (5.5 to 7.0) and to bathe the infant no more than every other day.[10]

The effects of bathing on skin parameters in small premature infants have not been studied to date. In an effort to reduce alterations in skin pH, dryness, and irritation in premature infants less than 32 weeks, cleanse with warm water baths during the first week using soft cotton cloths, cotton balls, or the caregiver's hands.[10] Skin colonization with bacteria does not increase with bathing as infrequently as every 4 days.[109] Less frequent bathing may offer other advantages for premature infants, who have demonstrated physiologic and behavioral disruptions during sponge baths.[106] Immersion bathing, even of stable infants on ventilators or nasal continuous positive airway pressure (CPAP), may be soothing and less stressful.[4]

Emollients

The skin surface of term newborns is drier than that of adults but becomes gradually better hydrated as the eccrine sweat glands mature during the first year of life.[113] Maintaining the hydration of the ***stratum corneum*** is necessary for an intact skin surface and normal barrier function. Skin that is dry, scaly, or cracking not only is uncomfortable but can also be a portal of entry for microorganisms. Products used to counteract dryness are called moisturizers, emollients, or lubricants. Common emollients include mineral oil, petrolatum, and lanolin and its derivatives. Emollients are sometimes divided into oil-in-water or water-in-oil emulsions. Emollient use to prevent dermatitis and improve skin integrity has been studied in several randomized, controlled trials in premature infants.

In one report, premature infants of 29 to 36 weeks' gestation were treated with Eucerin cream daily and had less dermatitis as measured by a visual grading scale but no differences in direct measurements of TEWL with an evaporimeter.[80] In a later study, **premature infants of both lower gestational and younger postnatal age were treated with Aquaphor ointment, a water-miscible oil-in-water preparation that contains neither dyes nor perfumes.** In this study there was improvement in both TEWL and visual scale dermatitis. **No increases in skin surface temperatures or thermal burns were seen, even when the emollient was applied to infants under radiant heaters or phototherapy lights.** In addition, **cutaneous cultures revealed no increase in bacterial or fungal colonization on skin treated with emollients.** It was noted that a smaller number of treated infants had positive blood or cerebrospinal fluid culture results compared with control subjects, although the study was not large enough to prove this effect.[102]

A large, randomized controlled trial of 1191 infants with birth weights of 501 to 1000 g was conducted to determine whether **twice-daily application of Aquaphor ointment would reduce combined outcome measures of mortality and sepsis. Although skin integrity appeared improved with routine emollient use, no effect was seen in the outcomes of sepsis plus mortality.** Of note, an **increase in coagulase-negative *Staphylococcus epidermidis* bloodstream infections was seen in infants with birth weights below 750 g, although the mechanism and relationship to emollient use are not clearly understood.**[47] **Several other studies have not reported higher infection rates when comparing emollient therapy with no treatment**[16,75] **and report benefits in fluid and electrolyte balance, as well as less dermatitis.**

A *Cochrane* review evaluated randomized controlled trials of emollient use in the NICU and concluded that the prophylactic application of topical ointment increases the risk of coagulase-negative *Staphylococcus* infection and other nosocomial infections. **The routine use of emollients in preterm infants is not recommended.**[35]

The benefits of emollient use in premature infants must be carefully weighed against the risk of infection. In general, emollients can be safely used in this population to treat skin with excessive drying, skin cracking, and fissures. They may also be beneficial in reducing TEWL and evaporative heat loss, although methods such as using a high-humidity environment are also available for this purpose. **Small tubes or jars for single patient use are recommended to prevent contamination with microorganisms.**

There is little consensus to date about the routine use of emollients for full-term newborns.[71] One study reports improved skin parameters in healthy full term infants when the skin care regime included a "baby cream" emollient after bathing and did not adversely affect bacterial skin colonization.[55] Some studies report a **decreased risk of developing atopic dermatitis in infants with a strong family history of this disorder with daily use of emollients in infancy**, so the routine use of emollients may be indicated in this population.[68]

Skin Disinfectants

Use of skin disinfectants prior to invasive procedures such as inserting intravenous lines, venipuncture, arterial puncture, umbilical catheter placement, and chest tube placement is common practice in neonatal nurseries. **Concerns with disinfection practices include the effects of absorption of disinfectants and skin injury resulting from topical skin preparation with these agents, which must be weighed against their effectiveness in preventing infection.**

Disinfectants that are used in newborns include 70% isopropyl alcohol (IA), 10% povidone-iodine (PI), and chlorhexidine gluconate (CHG), in varying concentrations as both an aqueous solution and one combined with 70% isopropyl alcohol (CHG/IA). It is widely accepted that **CHG-containing formulations are the most effective for skin disinfection in children and adults for central venous catheter insertion and dressing changes, and their use is recommended as best practice in several guidelines.**[30,95] However, there are **no studies in neonates that have confirmed the superior efficacy of CHG preparations over other disinfectants, such as PI, in the prevention of bloodstream infection.**[107,115] Therefore, **Centers for Disease Control and Prevention (CDC) guidelines have maintained that there is insufficient evidence to make a recommendation about the safety or efficacy of CHG products in infants younger than 2 months of age.**[29]

Use of 0.5% CHG in isopropyl alcohol reduces peripheral IV catheter colonization in premature and term newborns compared with use of povidone-iodine.[53] A randomized controlled trial (RCT) of 344 infants admitted to the NICU and special care nursery (SCN) settings showed significantly fewer blood-culture contaminants in infants having skin disinfection with 1% aqueous CHG compared with those using 10% PI.[103]

A sequential study reported that the rate of positive blood cultures (the number of true infections) or contaminated cultures during the time when 10% PI was used in this NICU was not statistically different from a subsequent period when 0.5% CHG/IA was used.[83] A pilot trial of 47 infants who weighed more than 1500 g and were older than 7 days of age evaluated cutaneous tolerance of 2% CHG/IA compared with 10% PI for peripherally inserted central venous catheter (PICC) placement. There were no differences in the number of bloodstream infections or sepsis evaluations between the two groups, but this pilot study was not powered to look at bloodstream infection rates.[54] An RCT of 304 preterm infants compared 2% CHG/IA to 10% PI for insertion of 815 central venous catheters and reported no difference between the proportion of catheter-related bloodstream infections between the two disinfectants, although more infants in the PI group had thyroid dysfunction. The authors acknowledged that the study was not adequately powered to detect differences in actual numbers of catheter-related bloodstream infections and that a larger study is needed.[76]

TOXICITY FROM SKIN DISINFECTANTS

If absorbed through the skin, PI has been shown to alter thyroid function in premature newborns. A systematic review of 15 articles reported evidence of thyroid dysfunction in premature infants exposed to iodine-containing disinfectants, with incidence ranging from 12 to 33 cases per 100 infants. The review also found no long-term neurodevelopmental studies that cited harm from exposure to iodine-containing solutions, and although the researchers recommended restricting iodine-containing solutions in premature infants, more research is needed.[3]

Systemic toxicity from percutaneous absorption of CHG in neonates has been raised as a concern. A small study of CHG antisepsis for PICC placement and subsequent dressing changes in premature infants who weighed more than 1500 g found measurable concentrations of CHG, ranging from 13 to 100 mcg/mL, in 7 of the 10 infants who had levels drawn. However, there were no reported systemic side effects. **The role of IA in combination with CHG may be a possible contributing factor to cutaneous absorption of CHG.**[54] Another study involving 20 premature infants with a median gestational age of 28 weeks had an extremity disinfected with 2% aqueous CHG prior to insertion of a PICC. Ten infants had detectable serum CHG levels ranging from 1.6 to 206 mcg/mL, with the highest levels occurring 2 to 3 days after initial exposure.[32]

Past reports of neurotoxicity from exposure to hexachlorophene bathing[9,28] have **prompted research on the potential neurotoxicity from systemic absorption of CHG.** An in vitro model of neurite cells was exposed to CHG levels comparable to the highest levels reported in premature infants. CHG inhibited L1-mediated neurite growth, and researchers concluded that it is important to determine whether the blood–brain barrier is permeable to CHG in premature infants.[97]

There is interest in using CHG to decrease infection in adult and pediatric ICU patients and patients with central venous catheters with daily wiping of skin surfaces with CHG.[97] A study was undertaken in a NICU population using 2% CHG-impregnated wipes in a quasi-experimental design, comparing the treated infants to a historical cohort.The algorithm for wiping the skin with CHG determined the frequency based on postnatal age and weight. A decrease in central line–associated bloodstream infections was reported, but infants weighing less than 1000 g and younger than 28 days were excluded from CHG bathing. Serum CHG levels were not obtained.[108]

Numerous case reports document chemical burns in premature infants from disinfectants containing CHG; these include various concentrations of CHG, both aqueous and alcohol preparations.* There have also been reports of chemical burns from IA and PI solutions in extremely-low-birthweight (ELBW) infants.[114] Fig. 19.4 shows skin injury resulting from skin disinfectant.

The United Kingdom Medicines and Healthcare Products Regulatory Agency published a review of 44 case reports of chemical burns after the

*References 23, 79, 81, 93, 101, 110.

FIGURE 19.4 Skin injury resulting from skin disinfectant.

application of aqueous or alcohol-based CHG solutions. **Most burns occurred in premature infants younger than 26 weeks of gestation or those who weighed less than 1000 g with long-term sequelae in some infants, to include scarring, discoloration, and keloid formation.**[19] Because of these concerns, **safety labeling in the United States and Europe continues to state the potential for chemical burns from CHG solutions used for skin disinfection in premature infants.**[105,124]

Several studies have been undertaken to determine how CHG affects skin integrity. A prospective study of 40 infants with a mean gestational age of 32 weeks (range of 23 to 39 weeks) found that the use of 2% CHG/IA for PICC insertion and weekly dressing changes compromised skin-barrier function, which was measured by elevated TEWL, an increase in erythema, and dryness.[125] A pilot trial comparing **2% CHG/IA in 47 premature infants weighing more than 1500 g and older than 7 days of age found no increase in skin redness or breakdown when CHG was used for PICC insertion and weekly dressing changes and only one incidence of erythema in a newborn treated with PI.**[54]

The selection of appropriate disinfectants in neonates remains a dilemma, particularly for extremely premature infants during the first weeks of life. CHG products in the United States are limited to a 2% aqueous surgical scrub solution available only in 4 ounce bottles, and a 2% and 3.15% chlorhexidine solution in 70% isopropyl alcohol available in single-use packaging. **The U.S. Food and Drug Administration states that chlorhexidine-containing disinfectants should be used with care in premature infants or infants less than 2 months of age, as these may cause skin irritation and chemical burns.**[124] **PI continues to be used in many nurseries to avoid the above complications, although the issues of thyroid toxicity remain a concern.**

Although removal of disinfectants with sterile water or saline after a completed procedure is advocated,[10] **the manufacturer of the 2% CHG/IA product advises that removal not be attempted, as the residual effect of the disinfectant on the skin may be beneficial.** However, it is not known whether this feature may contribute to skin irritancy and absorption of CHG in newborns and premature infants.

CHG should not be used as preoperative skin disinfection on the face or head because misuse has been reported to result in injury if it remains in contact with either the eye or ear during surgical procedures. However, **careful use before scalp intravenous or central-line insertion is acceptable, providing that splashing or using excessive amounts of chlorhexidine is avoided.** In addition, there is no clinical data to discourage the use of chlorhexidine gluconate products prior to lumbar puncture or epidural catheter placement, as this is considered skin antisepsis.[98]

UMBILICAL CORD CARE

The use of antibiotic ointments and skin antiseptics to the umbilical cord can prolong the time to cord separation and has no beneficial effect on the frequency of infection.[138] Although the umbilicus is a possible route for infection by invasive pathogenic microorganisms until healed, **the evidence suggests that dry cord care, defined as keeping the cord clean and leaving it exposed to air or loosely covered by a clean cloth, is effective for infants born in high-resource countries.**[120]

For newborns born in health facilities, dry cord care is recommended as evidence-based practice. A cluster RCT in France, involving over 8000 near-term and term newborns found dry cord care was not inferior to antiseptic cord care in preventing omphalitis.[60] A group of 150 consecutively born, healthy, late-preterm and term infants born in a hospital setting in Taiwan (high humidity, subtropical country) were randomized to alcohol or dry cord care. **Cord separation time was significantly**

decreased for those infants having dry cord care compared with those cleansed with 95% isopropyl alcohol, and the incidence of cord infection was not increased.[69] A meta-analysis showed the use of topical isopropyl alcohol was not superior to dry cord care in reducing the incidence of omphalitits.[70]

Recommendations for umbilical cord care include washing hands before handling the cord, and, if the cord becomes soiled with urine or stool, cleansing with water, drying with absorbent gauze, and keeping the diaper folded down and away from the umbilical stump to prevent contamination.[10] The development of omphalitis is not necessarily related to cord disinfection, because it also occurs in infants who have received topical disinfectants. **Vigilant attention to the signs and symptoms of omphalitis is necessary by health professionals. Parents need guidance about how to manage the umbilical cord and when to consult their health care provider.[46]**

Medical Adhesives

Hospitalized newborns often require medical adhesives to secure life support and monitoring equipment such as endotracheal tubes, intravenous devices, oxygen saturation sensors, and electrodes. Categories of medical adhesives include acrylates, hydrocolloids, hydrogels, and silicone-based adhesives.[88]

Acrylate-based adhesives include products such as paper, plastic, and soft cloth tape. Adherence of these tapes increases over time, and they may leave a residue on the skin after removal.[96] **These acrylate adhesive tapes adhere well to both skin and medical devices and are often selected for use in intensive care settings.** Acrylate adhesives are also found on polyurethane films, such as transparent adhesive dressings. These allow visualization of catheter insertions sites and are permeable to water vapor, oxygen, and carbon dioxide, allowing the skin to breathe.[41]

Hydrocolloid adhesives are used to protect peristomal skin for ostomy patients and are also a wound dressing. Because **hydrocolloids absorb moisture and mold well to skin surfaces, they are used as a platform between skin and acrylate tapes and transparent dressings.[20,104]** In some cases hydrocolloids are integrated into products such as endotracheal tube securement devices. Hydrocolloids cause skin trauma that is equal to acrylate tape when removed at 24 hours.[89] Decreased skin-barrier function and erythema under hydrocolloid adhesives has also been found.[137] A comparison of transparent dressing placed directly on the skin versus a transparent dressing place over a hydrocolloid base found no statistically significant quantitative difference.[20] However nurses participating in the study preferred transparent dressings placed over a hydrocolloid base as a more effective adhesive and a belief that it was gentle for the skin.

Hydrogel adhesives are found in some products such as EKG electrodes, temperature probe covers, and in dressings for wounds where they may have a cooling or analgesic effect on damaged skin. Hydrogel adhesives have been shown to reduce the trauma associated with electrode removal.[41,89] However, adherence is not adequate to secure critical lines and tubes, nor do they adhere well in humidified incubators.

Silicone-based adhesive products adhere well to skin with minimal discomfort when removed. These adhesives hold promise for developing products that adhere and cause minimal skin trauma such as erythema, skin stripping, and keratin loss, compared with acrylate-based paper tapes when removed from the skin of pediatric patients.[61] However, silicone adhesives do not adhere well to plastic devices, such as nasogastric tubes and cannulas, which limits their use. **Dressings with silicone adhesive borders can be lifted up and replaced for wound assessment.** Silicone tapes can be used to secure brain-monitoring electrodes because they adhere well to hair and can be removed with minimal discomfort.

Newborns are at high risk for medical adhesive related skin injury (MARSI), a term first used in a consensus paper involving a number of different health providers.[96] **Types of MARSI include skin stripping, skin tears, and contact and allergic dermatitis.** In an evidence-based practice project for the Neonatal Skin Care Guideline that included skin assessments for 2820 premature and full-term newborns, **adhesives were the primary cause of skin breakdown.[90] Functional changes in premature skin, including altered skin barrier function (measured as increases in TEWL), are seen after one application/removal of adhesive tape in premature infants,[63,89]** compared to similar results

after 10 consecutive applications and removals in adults.[84]

Topical skin protectants, wiped on prior to attaching adhesives, protect the skin from adhesives as well as fecal and ostomy output and urine. Silicone-based skin barrier films do not sting when applied, rapidly evaporate, do not leave a residue, reduce TEWL, and provide skin protection.[22] Additional research on skin protectants is warranted in a larger ELBW population.

Removal of medical adhesives can result in skin stripping and pain. A technique involving slowly pulling adhesives at a very low angle parallel to the skin surface while holding the surrounding skin in place may reduce epidermal stripping.[91,96] **Adhesive removers aid in the removal of medical adhesives. Three categories of adhesive removers: include alcohol–organic-based solvents, oil-based solvents, and silicone-based removers.**[36] **Removers containing solvents such as hydrocarbon derivatives, petrolatum distillates, or isopropyl alcohol carry the potential of systemic and topical toxicities.** A case report of a premature infant developing a severe dermatologic reaction (i.e., blistering and hemorrhage) to an adhesive remover led to concerns about safety with these products in the NICU population.[72] **Oil-based solvents based on paraffin or citrus oil extracts release the bond between skin and adhesive. However, they leave a residue that prevents adherence during reapplication of adhesives to the site where they were previously applied.**

Silicone-based removers effectively assist in removal of adhesives. These evaporate readily after application without drying of the skin and are less likely to leave a residue. Silicone-based removers are available in spray, liquid, lotion, or wipe formulations.[36] The safety and effectiveness of silicone-based removers in the neonatal population has been described, including infants with epidermolysis bullosa.[37,43]

DATA COLLECTION

History

The gestational age and postnatal age of neonates in the NICU are both important considerations for determining appropriate skin care practices. Premature infants of lower gestational ages have underdeveloped skin layers and function. With advancing postnatal age and maturation there is improved skin integrity and skin barrier function.

Reviewing the maternal history for any dermatologic diseases is also important. **Many of the most severe skin diseases, such as forms of *congenital ichthyosis* or *epidermolysis bullosa,* are inherited disorders.** A positive family history alerts the clinician to the potential for developing these rare disorders.

Signs and Symptoms

A thorough daily examination of all skin surfaces reveals the state of skin integrity for neonates in the NICU. Early signs such as skin abrasions or small excoriations may call for either diagnostic or treatment procedures. **A scoring tool such as the *Neonatal Skin Condition Score* (NSCS)** (Box 19.1), used in the Association of Women's Health, Obstetric, and Neonatal Nurses (AWHONN)/National Association of Neonatal Nurses (NANN) research-based practice project,[90] **has been extensively used in both premature and full-term infants, with validity and reliability established.**[92] **This scoring system can be integrated into skin care protocols to identify neonates with excessive dryness, erythema, or skin breakdown.**[10] Risk factors for skin injury in individual patients are listed in Box 19.2. **In the first week of life in ELBW infants (<30 weeks, <1000 g), there may be problems with thermoregulation (see Chapter 6) and dehydration (see Chapter 14) because of the large evaporative heat losses and transepidermal water losses through the immature stratum corneum.**

The Braden Q and Starkid Scales assess risk for pressure sores.[39] However, in these studies the number of neonates is unknown, so the applicability of these tools to a NICU population is undetermined. The Braden QD was developed to predict hospital-acquired pressure injuries (HAPI) in pediatric patients, including those caused by both immobility and medical devices.[40] The Braden QD evaluates for intensity and duration of pressure based on the patient's mobility and sensory perception. However, there is no scoring for prematurity or gestational age, both important aspects of skin tolerance in NICU patients, so how helpful it is to use the Braden QD in NICU patients is questionable. It is also important to recognize that risk assessment is

BOX 19.1 THE NEONATAL SKIN CONDITION SCORE

Dryness
1 = Normal, no sign of dry skin
2 = Dry skin, visible scaling
3 = Very dry skin, cracking/fissures

Erythema
1 = No evidence of erythema
2 = Visible erythema <50% body surface
3 = Visible erythema >50% body surface

Breakdown
1 = None evident
2 = Small localized areas
3 = Extensive

Note: Perfect score = 3; worst score = 9.

BOX 19.2 RISK FACTORS FOR SKIN INJURY

- Gestational age <32 weeks
- Edema
- Use of paralytic agents and vasopressors
- Multiple tubes and lines
- Numerous monitors
- Surgical wounds
- Ostomies
- Technologies that limit movement: high ventilation, extracorporeal membrane oxygenator
- Respiratory device interfaces, such as nasal continuous positive airway pressure

not the same as skin assessment, and careful observation and documentation of the skin condition is an essential component of skin care in NICU patients.

Laboratory Data

With the many skin excoriations in both small and large neonates that result from traumatic events such as adhesive removal or pressure necrosis, there is the potential for infection through this portal of entry in the skin. In VLBW infants it may be useful to obtain a skin culture, Gram stain, or potassium hydroxide preparation[14] for early detection of microorganisms that can lead to systemic illness in these immunocompromised patients. **A skin surface culture is helpful if the skin breakdown cannot be traced to a traumatic injury, because the origin of the breakdown often is linked to infection, especially with fungal infections**[112] or *staphylococcal scalded skin syndrome.* **A more comprehensive workup for infection may be indicated if there is evidence of clinical deterioration in infants with extensive skin breakdown (see Chapter 22).** If the culture is positive for a candidiasis species, antifungal ointment and systemic treatment with fluconazole or amphotericin may prevent devastating disseminated disease.[18,74] Although fungal causes are sometimes suspected, other microorganisms such as *Staphylococcus aureus* species, *E. coli,* and other gram-negative bacteria have been cultured in extremely premature infants. The knowledge of their skin colonization may be very useful in guiding systemic treatment should their clinical condition worsen, suggesting systemic disease including sepsis.

TREATMENT

Skin Injuries

Although little clinical research is available to guide selection of topical agents and products to treat skin injuries in neonates, there are several principles to help inform practitioners. **These include the concept of moist wound healing, gentle cleansing, and understanding the proper application of appropriate dressings.**[38]

Ointments are sometimes used on skin injuries because of their antibacterial or antifungal properties. Petrolatum-based emollients and ointments are used to cover wounds and provide a semi-occlusive layer that facilitates the migration of epithelial cells across the surface and may actually become part of the stratum corneum layer during the healing process. Antibacterial ointments such as Polysporin, Bacitracin, or Bactroban are useful to treat gram-positive colonized surfaces but can actually promote the growth of gram-negative organisms.[118] Many dermatologists recommend against the use of Neosporin because of the potential for developing later sensitization to

this ointment, although sensitization to Bacitracin is also being reported with increasing frequency.[94] **If fungal infection is suspected, nystatin ointment is used and can also be applied to surrounding intact skin to prevent extension of the infection.** In general, ointments are preferable to creams in this application because of better adherence and healing properties.

Gentle cleansing of the skin injury or wound removes debris and exudate, thus promoting a clean wound bed. The presence of debris, exudate, or necrotic tissue impedes wound healing, while their removal reduces the level of bacterial contamination.[38] **Wound cleansing is best accomplished by gentle irrigation with normal saline, either diluted or undiluted, using a 20 to 60 mL syringe and a blunt intravenous catheter.**[10] **The use of antiseptic solutions and cleansers are to be avoided, as these can cause further injury to delicate healing tissue and may delay healing.**[111,134]

Dressings for wound care and for skin injury should be occlusive and nonadherent to promote moist healing and facilitate the migration of epithelial cells. These include silicone dressings, hydrocolloid dressings, hydrogel dressings, transparent dressings, and dressings made of foam or other composite materials. In addition, some dressings may be impregnated with silver ions that may bestow potential benefit due to their anti-infective properties.[52] Although use of silver-containing creams and dressings were initially avoided because of concerns about toxicity, **recent research demonstrates safe uses of silver-containing agents in neonates.**[12,121]

Medical grade honey, both as an ointment or in a dressing, has also been used in neonatal skin injuries. Benefits of medical grade honey include that it (1) facilitates debridement,[6] (2) has anti-infective properties, and (3) facilitates the moist healing cascade.[5] Several case studies report positive results using medical grade honey in premature infants.[21,48,99]

Surgical wounds that open or dehisce are infrequent but require expert wound management. Nutrition is often a part of the process in promoting wound healing, as is the prevention of infection.[56] Often the surgeon or a wound/ostomy specialist designs an appropriate wound management program for individual situations.

FIGURE 19.5 IV extravasation injury with swelling, discoloration, and leaking of fluid.

Intravenous Extravasations

The extravasation of intravenous fluids and medications can result in skin injury and in some cases deep-tissue injury to muscle and nerves (Fig. 19.5). Newborns are more susceptible to extravasation injuries because of their immature skin, lack of subcutaneous tissue, and the small size of their blood vessels.[8] Extravasation injuries are iatrogenic complications that can lead to pain, prolonged hospitalization, and increased morbidity, such as infection. Extravasation injuries can also result in increased hospital costs and the potential for legal action.

Prevention includes meticulous monitoring of intravenous sites, low threshold for removing IV catheters when suspicious, and immediate interventions that reduce the extent of tissue injury. Some of the risk factors for tissue injury from intravenous extravasations in NICU patients are listed in Box 19.3.

Hourly assessment of the IV insertion site is recommended with more frequent assessments during administration of certain medications. Although an infusion pump can indicate increasing pressure, these are not sensitive enough to detect infiltration of fluid into the tissue and should not be relied on as an infiltration detection device.[8,123] Quality-improvement efforts involving standardizing assessment strategies are beneficial, such as "Touch, Look, Compare" and "Assess, Compare, Touch."[123,133] In one NICU standardizing IV site assessment, along with review

BOX 19.3 RISKS FOR TISSUE INJURY FROM IV EXTRAVASATION

- Length of exposure to extravasation fluid, medication
- Nature of extravasation fluid(s), medication(s):
  - Hypertonic solutions containing high concentrations of calcium, potassium, glucose or amino acids, such as total parenteral nutrition, glucose concentrations of >10%
  - Medications with vesicant properties such vancomycin, nafcillin, calcium chloride/gluconate, acyclovir, phenobarbital, potassium, phenytoin, digoxin, dopamine, dobutamine, epinephrine, etc.
- Mechanical compression caused by electronic infusion pumps

of factors such as catheter type, securement method, and daily review of catheter necessity, resulted in a reduction in infiltrations rates over a 6-month period.[131] **"When in Doubt, Pull the Catheter Out" using an evidence-based protocol to prevent infiltration, which includes standardized IV assessments, staging of infiltration, and an algorithm for evaluation and treatment which contains wound care recommendations has been published.**[44]

Prevention of more extensive tissue injury after infiltration is an important consideration. The insertion site should be clearly visible with appropriate documentation *every* hour. Medical adhesive tape should be carefully placed on the extremity to avoid obstruction of venous return. Tape placed loosely over a bony prominence, such as the knee or elbow, allows extravasated fluids and medications to disperse over a larger surface area and thus reduce the risk of injury, compared with extravasation that is limited to a small surface area. In some NICUs, taping strategies are used that do not involve securing the limb to an IV board, which avoids this problem. Avoiding extremities with poor perfusion in favor of better-perfused scalp veins (except, of course, those on the forehead) may also be prudent. **Using central venous lines such as peripherally inserted central catheters to infuse highly irritating solutions and medications is also recommended.**

Risk factors for extravasation include the type of fluid that is being infused, its chemical properties, osmolality, and pH.[59] Normal serum osmolality is 280 to 295 mOsm/kg, and solutions that exceed this are considered hypertonic. Solutions that are infusing through a peripheral vein in a neonate should stay within this range.[44] Glucose concentrations higher than 12.5% are at risk for extravasation injury.[132] Some medications can be both hyperosmolar and irritating due to pH extremes. **Vesicants are very irritating medications and solutions and should be either avoided or carefully watched during infusion. Posting a chart listing vesicant solutions and medications is helpful for caregivers who prescribe and administer neonatal medications, as well as identifying neonates who would benefit from central venous access.**[59]

Once an IV extravasation occurs, immediate measures to reduce injury are instituted.[44] **The device should be carefully removed, and the extremity elevated (if it is an arm or leg). Treatment with heat or moisture is not recommended because the compromised tissue could be further injured by a burn or the effects of maceration. Making multiple puncture holes over the area of greatest swelling and squeezing to allow the fluid to leak out of the tissue releases the infiltrated fluid and can potentially prevent skin injury.**[31,116] **Saline washout has also been described,**[78] **although no randomized trial has been published to compare efficacy.**[58]

Hyaluronidase is an enzyme that facilitates diffusion of the extravasated fluids by temporarily dissolving the normal interstitial barriers decreasing tissue damage and injury following extravasation.[15,44] **A dose of 15 to 20 units is administered in five subcutaneous injections around the periphery of the extravasation**[44] and may be repeated (Figs. 19.6 and 19.7). Keeping the site moist for several hours using a hydrogel product or moist compresses may also be beneficial.

If tissue damage results despite the immediate care measures, the use of topical wound care treatments are necessary. In the most severe cases of deep-tissue necrosis after extravasation injury, a surgical or plastic surgery consultation may be necessary.

Diaper Dermatitis

A common skin disruption that occurs in neonates and infants is *diaper dermatitis* (diaper rash). This term encompasses a range of processes that affect the perineum, groin, thighs, buttocks, and anal area of infants who are incontinent and wear some covering to collect urine and feces. **Diaper dermatitis**

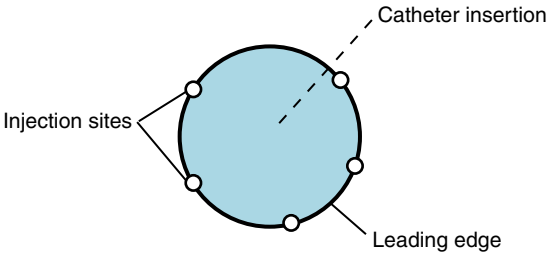

FIGURE 19.6 Technique for administration of hyaluronidase and/or phentolamine. A total volume of 1 mL is administered at five sites subcutaneously (0.2 mL each) around the periphery of the intravenous extravasation.

FIGURE 19.7 Hyaluronidase (Vitrase) being administered to extravasation in hand using 27-gauge needle.

can be caused by many different mechanisms, but the condition of the skin has a direct role in the progression of skin injury. Review articles provide an excellent background for current evidence-based care in the prevention of and treatment for diaper dermatitis.[1,64]

The pathogenesis of diaper dermatitis is partly related to the degree of wetness of the skin. **Skin that is moist and macerated becomes more permeable and susceptible to injury because wetness increases friction. In addition, moisture-laden skin is more likely to contain microorganisms than dry skin.**

Another component in the process of skin injury from diaper dermatitis is the effect of an alkaline pH. **Normal skin pH is acidic—ranging between 4.0 and 5.5—but can become alkaline when it is diapered.[130] The increased pH of the skin increases its vulnerability to injury and penetration by microorganisms and stimulates fecal enzyme activity.** Specifically, both protease and lipase in stool can injure the skin, which is made up of protein and fat components. These enzymes can quickly cause significant injury to the epidermis and are responsible for the contact irritant diaper dermatitis that is commonly seen.

Strategies for preventing diaper dermatitis include maintaining a skin surface that is dry and has a normal (acidic) skin pH. Frequent diaper changes are recommended, especially in the newborn period. Insufficient evidence exists to support any specific type of diaper for preventing diaper dermatitis.[13] **However, superabsorbent gelled diapers with breathable covers have been shown to keep skin surfaces dryer by "wicking" the moisture away from the skin and separating urine from feces.[27,42] Use of powders is discouraged because of the risk of inhalation of particles into the respiratory tract.**

After skin injury from diaper dermatitis has occurred, protecting injured skin to prevent reinjury is the primary goal of treatment. Topical treatment for diaper dermatitis involves ointments and creams containing a variety of ingredients. Most contain zinc oxide and petrolatum and are generally similar in composition.[64,129] **Generous application of protective skin barriers that contain zinc oxide can prevent further injury while allowing skin to heal. Once skin excoriations occur, keeping skin open to air may not be effective, because the already impaired tissue may be reinjured with fecal contact, and dryness is counterproductive to healing. It is not necessary or desirable to completely remove skin barrier products with diaper changes, because this may disrupt healing tissue. Instead, remove as much waste material as possible and reapply the barrier generously to the affected areas with each diaper change.** Another class of barrier products are *semipermeable barrier films,* **designed to repel moisture and protect the skin from irritants.[64,129]** Although these products are FDA approved for use in infants older than 30 days of age, they can be used "off label" and have been beneficial for neonatal ostomy care.[122]

If *Candida albicans* is involved in the diaper dermatitis, it is necessary to use an antifungal ointment or cream (Fig. 19.8). Antifungal preparations include Mycostatin, miconazole, clotrimazole, and ketoconazole in ointment or cream forms; ointments are preferable to coat the skin and repel moisture. If the dermatitis is

both fungal and a contact irritant dermatitis, it may be necessary to layer the ointment with the antifungal preparation: (1) Mycostatin powder is used, (2) followed by an application of alcohol-free skin protectant to seal the powder onto the skin surface, and (3) a generous application of a skin barrier cream is then done, such as zinc oxide or pectin paste.

Occasionally infants may experience extremely severe diaper dermatitis from intestinal malabsorption syndromes or if there is constant dribbling of stool (i.e., decreased or lack of rectal innervation [myelomeningocele, bladder exstrophy, or following a "pull-through" procedure for Hirschsprung disease]). With malabsorption, stool not only is more frequent but also may have a high pH because of rapid transit through the small intestine resulting in significant amounts of undigested carbohydrates and stool enzymes. Severe diaper dermatitis in this case can be a symptom of a more severe nutritional deficiency, or even dehydration, and needs thorough medical evaluation.

While optimal nutritional therapy is being addressed with special diets or parenteral nutrition, skin protection from injury should be initiated. Products that contain pectin without alcohol (such as Ilex, a nonalcohol pectin paste) may provide a sturdier barrier for these infants than zinc oxide preparations. The skin should be thoroughly cleansed before a very thick application of the pectin paste. Then it is necessary to apply a greasy ointment because the pectin-based paste may adhere to the diaper. When the infant has a stool, it is not necessary to completely remove the barrier paste; the stool can be wiped away as much as possible before the thick paste barrier is reapplied. The skin will heal under this protective covering as long as it is protected from reinjury.[87] If fungal infection is a component of the dermatitis, antifungal therapy must be instituted in addition to the protective barriers. In this case, Mycostatin powder attached with alcohol-free skin protectant is the first layer; then the barrier cream is applied as described previously.

FIGURE 19.8 Diaper dermatitis caused by a *Candida albicans* infection. Red pustular satellite lesions extend into the periphery.

COMPLICATIONS

Improper handling of newborn skin (and injudicious use of products) can cause damage, prevent healing, and interfere with normal maturation processes. Other compromised skin integrity can lead to infection, pain and discomfort, and diversion of calories for tissue repair. Other dangers include toxicity from topically applied substances that are readily absorbed by small infants with a large surface area to body weight ratio and immature renal and hepatic function that cannot detoxify chemicals readily.

Injury from infiltrated IV solutions can cause skin injury and occasionally deep tissue necrosis with both muscle and nerve damage (Fig. 19.9). Factors that increase the risk of injury from IV extravasations include length of time between extravasation and treatment; hypertonic solutions, such as those with high calcium, potassium, amino acid, or glucose solutions; medications such as nafcillin that are irritating to veins; and the use of mechanical pumps for infusions. There

FIGURE 19.9 IV extravasation injury that requires plastic surgery.

may be an added risk for injury in patients with **poor perfusion to extremities and in limbs that have been secured with restricting adhesives that obstruct venous return.**

If the **epidermis has been injured, it can easily become a portal of entry for infection.** Thus a contact irritant diaper dermatitis can progress to a fungal or staphylococcal infection. *Staphylococcus aureus* can **cause pustule formation at hair follicles and is a rare complication of diaper dermatitis.** The mechanism for fungal diaper dermatitis is still debated. Some researchers believe that *Candida albicans* infection is a secondary invasion to skin that has been previously injured, whereas others see this organism as a primary cause of skin disruption.

***Candida albicans* diaper dermatitis causes an intense inflammation that is bright red and sharply demarginated** in the inguinal folds, buttocks, thighs, abdomen, and genitalia, often with satellite lesions that extend the rash over the trunk (Fig. 19.8). ***Candida albicans* can be harbored in the gastrointestinal tract, necessitating oral therapy if lesions are found in the mouth.**

PARENT TEACHING

It is the responsibility of professionals to teach parents informally during caregiving about procedures such as bathing, cord care, and diaper changes and to prepare written materials about appropriate skin care practices for their infant after discharge from the NICU (see Box 19.4). **Parents will need education about the normal mechanisms of cord healing,** including the range of appearance in umbilical cords, because some cords can appear very moist and soggy. **The cord can be cleansed with water if it becomes soiled with urine or stool.**[10] **Inform parents that minimal use of skin care products is optimal and may reduce the incidence of contact sensitization to chemicals.**[24] It is also extremely useful to **educate parents about the mechanisms that are involved in diaper dermatitis so that prevention is stressed** and appropriate interventions are selected depending on the underlying cause. A parent education handout in PDF form, based on the AWHONN *Evidence-Based Neonatal Skin Care Guideline* (Newborn Skin Parent Brochure 2014),[11] is now available online at www.health4mom.org/zones/newborn-skin-care-basics.

BOX 19.4 PARENT/CAREGIVER TEACHING
APPROPRIATE SKIN CARE PRACTICES

- Baby needs to be bathed only two or three times per week: sponge bath with water between tub bathings.
- Use on the skin only products that have as few additives and as little fragrance as possible; minimal skin care products reduce the incidence of contact sensitization of the skin by added chemicals.
- Do not use powder because of inhalation into baby's lungs.
- Prevent diaper rash by frequently changing wet and soiled diapers, cleansing diaper area, and using diapers that "wick" moisture away from the skin. If baby's skin becomes red and irritated with one brand of disposable diaper, try another brand.
- Treat diaper rash by using protective skin barriers (e.g., zinc oxide) with each diaper change to prevent further injury and allow skin to heal. Clean waste from skin barrier but do not clean off the skin barrier because this may disrupt skin healing.
- Diaper rash caused by a yeast infection requires antifungal medication.
- Umbilical cord dries and falls off within 7 to 10 days. Turn diaper back away from the cord until it falls off; as the cord separates, a small amount of blood stain may be on the diaper. Keep cord area clean, and rinse with water if it becomes soiled with urine or stool. Call the health care provider immediately if the cord develops an area of red, warm-to-touch skin at the base, a foul odor, or drainage from the base of the cord.

Developmental differences in the anatomy and physiology of neonatal skin affect skin integrity for term and premature infants in the NICU. Prevention is the primary focus of care, and decisions about the best way to provide basic skin care and hygiene based on current research are essential for care providers, both professionals and parents.

20 NEWBORN HEMATOLOGY

CHRISTOPHER MCKINNEY, BETH BOULDEN WARREN, AND SUSAN HARVEY

RED BLOOD CELLS

Physiology

Red blood cells (RBCs) are primarily responsible for the transportation and delivery of oxygen to tissues in the body. Red blood corpuscles are simple cells composed of a membrane encasing hemoglobin with an energy system to fuel the cells and an enzyme system to maintain an adequate redox environment to protect against oxidative damage. **Hemoglobin is the protein in RBCs that carries oxygen, binding and releasing it based on concentration differences.** Ex utero, RBCs absorb oxygen by diffusion in the lungs, where the oxygen tension of the alveolar air is higher than that of the capillary blood, and release it from the systemic capillaries, where the oxygen tension is higher than that of surrounding tissues. In utero, oxygen diffuses to the fetus from the placental venous circulation.

Fetal red blood cells contain a unique hemoglobin (fetal hemoglobin, *hemoglobin F*) in which the two beta chains of adult hemoglobin *(hemoglobin A_1)* are replaced by two gamma chains. *Fetal hemoglobin* has a higher affinity for oxygen than does adult hemoglobin, allowing fetal RBCs to compete successfully for available oxygen. Normal fetal RBCs have an increased mean corpuscular hemoglobin (MCH), mean corpuscular volume (MCV), hemoglobin, and hematocrit compared with adult RBCs. After birth, with the transition to air breathing and a higher blood oxygen tension, the hypoxic stimulus driving fetal red cell production in the bone marrow ceases. **The plasma concentration of *erythropoietin,* a hormone that stimulates bone marrow production of RBCs, falls.** The number of circulating *reticulocytes,* which are young RBCs in the circulation, decreases. Subsequently, the hemoglobin and hematocrit diminish until they reach a new equilibrium. **Postnatal changes in RBC production include an increase in the ratio of hemoglobin A to hemoglobin F and an increase in levels of the red cell enzyme *2,3-diphosphoglycerate* (2,3-DPG). 2,3-DPG promotes the release of oxygen to tissues by decreasing the affinity of hemoglobin to oxygen.** Oxygen delivery in the neonate is enhanced by increases in the concentrations of hemoglobin A and RBC concentration of 2,3-DPG.

The production of hematopoietic cells first appears within the yolk sac in the 14-day embryo and disappears by the eleventh week of gestation.[60] *Hematopoiesis* in other tissues results from colonization by stem cells derived from the yolk sac.[15] By the fifth to sixth week, embryonic erythropoietic activity is present in the liver and is the primary source of RBC production by 8 to 9 weeks.[174]

Between the eighth and twelfth weeks, the spleen and lymph nodes are involved in erythropoiesis.[38] Other tissues and organs involved in erythropoiesis include the kidney, thymus, and connective tissue. **Erythropoiesis shifts to the bone marrow at 10 to 11 weeks.** This activity increases rapidly until the 24th week, when bone marrow erythropoiesis replaces liver erythropoiesis. **There is no evidence of erythropoietin production before the**

BLUE type highlights content that is particularly applicable to clinical settings.

tenth week.[196] After the 10th week of gestation, erythropoietin production rises and appears to stimulate RBC production in the bone marrow during the third trimester.[55] Initially, erythropoietin is produced in the fetal liver, and by the last trimester, production relocates to the kidneys. The level of erythropoietin gradually rises to significant levels after the 34th week of gestation.[38] Elevated erythropoietin levels occur when the fetus is hypoxic.

In more than 90% of healthy term infants, the hematocrit range is 48% to 60%, and the hemoglobin range is 16 to 20 g/dL.[74] Changes in erythropoiesis around the time of birth are shown in Table 20.1.[38] Normally after a term birth, hemoglobin concentrations fall from a mean of 17 g/dL to approximately 11 g/dL by 2 to 3 months of age. This nadir in RBC values is called ***physiologic anemia of the newborn*** and is a normal process in the adaptation to extrauterine life.

Several factors influence the interpretation of hematocrit values in the newborn, including age of the infant (both in hours and days), site of blood collection, and method of analysis. Hematocrit changes significantly during the first 24 hours of life; it peaks at 2 hours of age and then progressively drops, with decreases at 6 and 24 hours of age.[164] The method used to determine hematocrit can significantly affect the value. ***Capillary hematocrit*** measurements are highly subject to variations in blood flow; hematocrit results generally are highest in capillary samples, intermediate in venous samples, and lowest in arterial samples.[86,121,180] Prewarming the site minimizes the artifactual increase in the hematocrit. In both term and preterm infants, there can be as much as a 20% difference between the hematocrit obtained from a capillary puncture (commonly termed ***heel stick***) and the hematocrit drawn from a central vein.

Interpretation of blood count parameters requires an understanding of the source of the reference values. Normal ranges are generally derived from large populations of healthy subjects for whom major confounding medical conditions, including personal and familial disorders, can be excluded. The newborn infant, particularly the preterm baby, is at risk for many complicating conditions, such as infection, hypoxia, and inflammation, and it is difficult to determine if a preterm infant is healthy at birth. In settings such as this, reference ranges are often used. Reference ranges determine values of a parameter of interest in a population that has no known confounding illness. Reference ranges for most blood tests in term and preterm infants are derived from relatively small sample sizes. From the Intermountain Healthcare System, a large primary care–based health network, reference ranges of various blood indices from a very large population of infants (>20,000 infants) have been derived.[66] For otherwise healthy extremely preterm infants (<28 weeks), the lower 5% of hemoglobin was slightly less than 10 g/dL, and the hematocrit was slightly less than 30%. In comparison, the lower limits for infants 32 weeks of gestation and greater were 13 g/dL and 40% (Fig. 20.1).[74]

TABLE 20.1 CHANGES IN ERYTHROPOIESIS AROUND THE TIME OF TERM BIRTH

	IN UTERO	POSTDELIVERY
Oxygen saturation (%)	45*	95
Erythropoietin levels	High	Undetectable
Red cell production	Rapid	<10% (by day 7)
Reticulocyte count (%)	3–7	0–1 (by day 7)
Hemoglobin (g/dL)	16.8	18.4
Hematocrit (%)	53	58
MCV (fL)	107	98 (by day 7)
MCHC (g/dL) [5,8]	31.7	33 (by day 7)

*Mean values represented.
MCHC, Mean corpuscular hemoglobin concentration; *MCV,* mean corpuscular volume.

Pathophysiology of Anemia

Anemia is defined as a decrease in RBC mass usually reflected by a hemoglobin concentration or hematocrit less than the 2.5th percentile for age, gender, and ethnicity. Anemia results in an impairment in tissue oxygen delivery resulting in hypoxia and acidosis. For a normal full-term infant in the first week of life, hemoglobin values less than 13 g/dL signify anemia.

Determination of the cause of anemia is important to direct treatment. Anemia in the newborn results from one or more of the following basic mechanisms:

- Blood loss (acute or chronic)
- Decreased RBC production
- Decreased RBC survival (hemolysis)

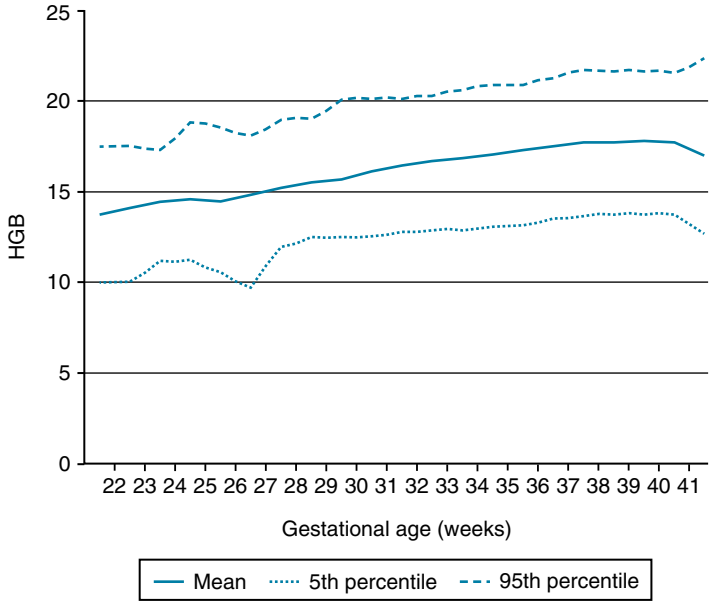

FIGURE 20.1 Reference ranges (5th percentile, mean, and 95th percentile) are shown for blood hemoglobin concentrations obtained during the first 6 hours after birth among patients 22 to 42 weeks' gestational age. Values were excluded if the diagnosis included abruption, placenta previa, or known fetal anemia, or if a blood transfusion was given before the first hemoglobin was measured. (From Joplin J, Henry E, Wiedmeier SE, Christensen RD. Reference ranges for hematocrit and blood hemoglobin concentration during the neonatal period. *Pediatrics.* 2009;123:e333.)

BLOOD LOSS

Acute and chronic blood losses are the most common causes of anemia in the neonate. Blood loss can occur in utero, perinatally, or postnatally. **The total blood volume of the fetus is approximately 90 mL/kg. Large blood loss can cause profound asphyxia and death; determination of a profound drop in hemoglobin and hematocrit may lag by hours as blood volume equilibrates. Anemia caused by chronic blood loss is better tolerated because the neonate is able to compensate for the gradual loss in RBC mass by increasing production of 2,3-DPG.** There is a large differential for blood loss in the neonate (Box 20.1).

Fetomaternal transfusion is a common cause of occult blood loss in the fetus. **Some degree of fetomaternal blood mixing occurs in almost 50% of all pregnancies.**[31] **Massive fetomaternal hemorrhage defined as greater than 30 mL occurs in only 3 of 1000 pregnancies.**[156] The *Kleihauer-Betke* acid elution test is used to confirm the presence of fetal blood cells in the maternal circulation.[198] This test depends on the increased acid resistance of fetal hemoglobin. Fetal cells retain red staining of hemoglobin after acid exposure, whereas adult cells (also called *ghost cells*) are very pale because hemoglobin has been eluted. **The volume of fetal blood in the maternal circulation is estimated by counting fetal RBCs on the maternal blood smear under light microscopy. Ten fetal cells per 30 fields viewed under high power are equal to 1 mL of fetal blood.**

***Twin-to-twin transfusion* is another cause of occult blood loss and is seen in 15% to 30% of all monochorionic twins with abnormalities of placental blood vessels.**[49,179] The anemic twin is on the arterial side of the placental vascular malformation. The clinical significance of twin-to-twin transfusion depends on the duration of blood transfer. **With chronic transfusion, a 20% weight discordance similar to that observed with placental insufficiency can be found; the recipient twin (i.e. the plethoric or polycythemic one) usually suffers greater morbidity.**[129,179]

Intracranial bleeding associated with prematurity, later birth order of a multiple-gestation delivery, rapid or breech delivery, or massive cephalohematoma can cause anemia. Other forms of neonatal

BOX 20.1 CAUSES OF BLOOD LOSS IN THE NEONATE

1. Hemorrhage before birth
   a. Fetomaternal
      Traumatic amniocentesis or periumbilical blood sampling
      Spontaneous
      Chronic gastrointestinal bleeding
      Blunt trauma to the maternal abdomen
      Post–external version
   b. Twin-to-twin
   c. External
      Abruptio placentae
      Placenta previa
2. Hemorrhage during birth
   a. Placental malformation
      Chorangioma
      Chorangiocarcinoma
   b. Hematoma of the cord or placenta
   c. Rupture of a normal umbilical cord
      Precipitous delivery
      Entanglement
   d. Rupture of an abnormal umbilical cord
      Varices
      Aneurysm
   e. Rupture of anomalous vessels
      Aberrant vessel
      Velamentous insertion of the cord
      Communicating vessels in the multilobular placenta
   f. Incision of placenta during cesarean delivery
3. Internal fetal or neonatal hemorrhage
   a. Intracranial
   b. Giant cephalohematoma, caput succedaneum
   c. Pulmonary
   d. Retroperitoneum
   e. Subcapsular liver or spleen
   f. Renal or adrenal
4. External neonatal hemorrhage
   a. Delayed clamping of the umbilical cord
   b. Gastrointestinal
   c. Iatrogenic from blood sampling

Modified from Luchtman-Jones L, Schwartz A, Wilson D. Hematologic problems in the fetus and neonate. In: Fanaroff A, ed. *Neonatal-Perinatal Medicine: Diseases of the Fetus and Infant.* Vol 2. St Louis, MO: Mosby; 1997.

hemorrhage predisposing to anemia include umbilical, retroperitoneal, adrenal, renal, and gastrointestinal (GI) bleeding, as well as ruptured liver or spleen.

Swallowed maternal blood **may be confused with GI bleeding. The Apt test is used to distinguish swallowed maternal blood from neonatal blood and is based on alkali resistance of fetal hemoglobin.**[9] A 1% solution of sodium hydroxide is added to 5 mL of diluted blood. Fetal hemoglobin remains pink, but adult hemoglobin becomes yellow.

Iatrogenic blood loss **results from blood sampling with inadequate replacement.** Premature infants can have a blood volume that is as little as 50 mL, so even a small amount of phlebotomized blood may result in anemia. **Strategies for preventing iatrogenic blood loss include sampling of umbilical cord blood for initial laboratory evaluation, using pediatric microcontainers and specialized equipment that can perform assays using smaller blood volumes, and avoiding excessive testing.**[72]

DECREASED RED BLOOD CELL PRODUCTION

Anemia caused by decreased production of RBCs tends to develop slowly, allowing time for physiologic compensation. Affected infants may have few signs of anemia other than pallor. The reticulocyte count will be low and inappropriate for the degree of anemia.

Worldwide, iron deficiency is the leading cause of anemia in infancy and childhood. Iron-deficiency anemia can occur at any time when growth exceeds the ability of the stores and dietary intake to supply sufficient iron for erythropoiesis. **Newborn iron stores are proportional to gestational age and weight at time of delivery. More than 80% of newborn iron stores are transferred from the mother to the fetus in the last trimester.**[101] **Typically term infants are born with iron stores sufficient to support new RBC production until they double their birth weight.**[126] Infants who are exclusively fed breast milk or iron-enriched formula and cereal are less likely to develop iron-deficiency anemia. At birth, delayed cord clamping reduces the incidence of anemia at 8 to 12 months of age.[76] **Premature infants have iron stores adequate for less than 3 months postnatally because of low birth weight, faster rate of growth, and iatrogenic blood losses. Iron supplementation is necessary**

TABLE 20.2 RECOMMENDED IRON SUPPLEMENTATION FOR THE NEONATE

GROUP	DOSE (mg/kg/DAY)	INITIATION, DURATION
Full term	1	4 mo to 3 yr
Preterm, low birth weight	2	2 mo to 1 yr, then
	1	1–3 yr
Very low birth weight	4	2 mo to 1 yr, then
	1	1–3 yr

mo, Month; *yr*, year.

early in preterm infants to prevent anemia (Table 20.2).

Iron deficiency causes a hypochromic, microcytic anemia. The peripheral smear shows small, pale RBCs with a large variety of shapes and sizes, resulting in an increased relative distribution of width (RDW). The platelet count is increased and may be greater than 1,000,000/μL. **Mild forms of iron deficiency may be confused with other causes of anemia, including infection and thalassemia. A therapeutic trial of iron can be used to diagnose iron deficiency. Although the American Academy of Pediatrics recommends 2 to 4 mg/kg/day of elemental iron for preterm infants and 4 to 6 mg/kg/day for preterm infants receiving concomitant erythropoietin, higher doses for prevention of iron deficiency may be associated with improved outcomes.**[79]

Iron deficiency with or without accompanying anemia has been associated with cognitive and behavioral deficits.[100] One longitudinal study followed patients diagnosed with iron deficiency in early infancy for 10 years and found higher rates of psychomotor impairment and specific cognitive deficits, including spatial memory, selective recall, and attention.[88] More recent studies of iron-deficiency anemia in infancy also found lower gross motor development and locomotion at 9 months of age[154] and an increase in adolescent behavioral problems.[45] Possible biologic mechanisms for this effect of iron deficiency include impairment of iron-dependent cytochromes, decreased myelination, and alterations in neurotransmitter systems, which have been demonstrated in iron-restricted animal models.

Anemia of prematurity is common in infants born at less than 35 weeks of gestation. This appears as a normocytic, normochromic anemia between 2 and 6 weeks characterized by a low reticulocyte count and an inadequate response to erythropoietin.[160] **If hemoglobin levels drop below 10 g/dL, the infant may display decreased activity, poor growth, tachypnea, and tachycardia.** Randomized placebo-controlled trials demonstrate that preterm infants can respond to erythropoietin with decreased amount of blood transfused if they are also supplemented with iron.[107] However, the decrease in volume of transfused blood does not result in a decrease in donor exposures.[123] **Delayed umbilical cord clamping/milking can reduce both the number and exposure to transfusions among premature infants and the incidence of late anemia in infancy among term infants.**[56,76,102,137,163]Another recent RCT found that milking the umbilical cord in preterm infants resulted in a significantly higher initial hemoglobin and hematocrit with a reduction in the need for transfusions but a higher need for phototherapy.[85]

***Hypothyroidism*, deficiency of transcobalamin II, and inborn errors of cobalamin utilization cause macrocytic anemia** because of decreased and ineffective bone marrow production. **Metabolic causes of anemia are important to diagnose and treat because deficiencies can cause permanent neurologic and cognitive deficits.**

***Diamond-Blackfan anemia* is an inherited pure red cell aplasia** that may be caused by a mutation in one of numerous ribosomal protein genes.[50] This normocytic or macrocytic anemia manifests at birth in 10% and by one month in 25% of affected infants. **Signs and symptoms include pallor, anemia, and reticulocytopenia.** In red cell aplasia, the platelet count may be moderately elevated and the leukocyte count may be slightly decreased. Bone marrow examination is normocellular with a paucity of erythroid precursors. **Thirty percent of affected infants demonstrate congenital anomalies, primarily of the head, face, eyes, and thumb.** The syndrome can have autosomal dominant or autosomal recessive inheritance. As infants grow older, characteristics of fetal erythropoiesis persist, including elevations in fetal hemoglobin, *i* antigen, and red cell adenosine deaminase, as well as fetal patterns of red cell enzymes. **Seventy percent of affected infants respond to corticosteroid therapy.** Because of the toxicity of chronic corticosteroid exposure (e.g., growth impairment, decreased bone density, cataract

formation), a trial of this therapy is usually deferred until the patient is 1 year of age, and until then the infant is chronically transfused with packed red blood cells (PRBCs). Infants who do not respond to steroids require long-term RBC transfusion therapy and are at risk for subsequent iron overload.[50]

Fanconi's anemia **is a congenital syndrome of progressive bone marrow failure with autosomal recessive inheritance** that is caused by increased chromosomal breakage and a defect in the ability to repair damaged DNA.[87] At birth, infants with this type of anemia may be recognized by one or more of the associated congenital defects, which include microcephaly, short stature, absent or abnormal thumb, and other abnormalities of the integumentary, musculoskeletal, or urogenital systems. Thrombocytopenia and an elevated MCV usually are the first hematologic abnormalities, but they are seldom recognized in the neonatal period. Chromosomal breakage analyses and specific molecular diagnosis have been used for prenatal diagnosis. **Diamond-Blackfan and Fanconi's anemias have been successfully treated with bone marrow transplantation.**

B19 parvovirus **preferentially infects erythroid precursors in the bone marrow and exerts an inhibitory effect on the production of RBCs.**[125,187] Infection with B19 parvovirus during pregnancy can cause hydrops *fetalis*, the clinical syndrome caused by severe intrauterine anemia of any cause and consisting of congestive heart failure, massive skin edema, and possible intrauterine demise, especially during the first two trimesters.[125,187] Early detection of parvovirus infection in pregnant women and serial examinations with ultrasonography are important to diagnose and monitor the condition. Affected fetuses have been supported successfully with intrauterine transfusions of RBCs. Postnatal infection with parvovirus does not cause anemia in most infants unless they have preexisting shortened RBC survival. Infants with congenital or acquired immunodeficiency may become anemic because of an inability to clear parvovirus.

SHORTENED RED BLOOD CELL SURVIVAL

Adult RBCs circulate for an average of 120 days. Normal neonatal RBCs have a circulating half-life reduction of 20% to 25% compared with the RBCs of older children or adults. Survival of RBCs of premature infants is reduced by approximately 50%. Senescent RBCs are removed from the circulation by the reticuloendothelial system. Bilirubin is produced by degradation of the heme moiety of hemoglobin, and RBC iron is recycled. Many conditions accelerate the removal of RBCs from the circulation.

Hemolysis **is a term for RBC destruction that is premature in terms of the expected life span of the RBCs relative to postconceptual age.** *Hyperbilirubinemia* is evident in most cases of hemolysis. Compensatory reticulocytosis is usually present. However, in the presence of chronic illness, nutritional deficiency, or congenital infection, the reticulocyte count may be lower than expected for the degree of anemia. **In the most severe cases of intrauterine hemolysis, the outcome is *hydrops fetalis* (Box 20.2).**

Isoimmune hemolytic anemia occurs when fetal cells, bearing antigens of paternal origin that are not shared by the mother, **enter the maternal circulation and stimulate production of immunoglobulin G (IgG) antibodies.** The IgG antibodies are transferred across the placenta, coat fetal RBCs, and mediate their removal from the circulation through the reticuloendothelial system.

The major fetal RBC antigens responsible for isoimmune hemolytic anemia include the Rh (also called D) antigen in an Rh-negative mother and the blood group A and B antigens in a group O mother. *Kell, Duffy,* and *Kidd antigens* can also cause isoimmune hemolytic anemia. Sources of maternal sensitization to fetal RBC antigens include chorionic villus sampling, amniocentesis, abortion, rupture of an ectopic pregnancy, maternal blood transfusion, and fetomaternal transfusion. **To prevent sensitization, anti-Rh antibodies derived from plasma of previously sensitized donors are given to Rh-negative mothers at 28 weeks of gestation, at delivery, and at the time of any of the previously mentioned events.** These antibodies coat any fetal RBCs present in the maternal circulation and prevent them from initiating the maternal immune response. Thus they provide a form of passive immunization. **With widespread use of Rh immunoglobulin (Ig) in Rh-negative mothers, the rate of Rh isoimmunization has dropped by over 90% to about 3 per 1000 pregnancies.**[4,99] The rate of Rh hemolytic disease in the United States is 1 case per 1000 live births.[24] The persistence of Rh isoimmunization may be attributed to failures

BOX 20.2 CAUSES OF SHORTENED RED CELL SURVIVAL IN THE NEONATE

1. Isoimmune-mediated hemolysis
   a. Rh incompatibility
   b. ABO incompatibility
   c. Minor blood cell antigen incompatibility
2. Infection
   a. Bacterial sepsis
   b. *Campylobacter jejuni*
   c. *Clostridium welchii*
   d. Rubella
   e. Cytomegalovirus
   f. Epstein-Barr virus
   g. Disseminated herpes
   h. Malaria
   i. Toxoplasmosis
   j. Syphilis
3. Microangiopathic and macroangiopathic
   a. Cavernous hemangioma (Kasabach-Merritt)
   b. Renal vein thrombosis
   c. Disseminated intravascular coagulation
   d. Severe coarctation of the aorta
   e. Renal artery stenosis
4. Vitamin E deficiency
5. Congenital red cell membrane disorders
   a. Hereditary spherocytosis
   b. Hereditary elliptocytosis
      i. Hereditary poikilocytosis
      ii. Hereditary pyropoikilocytosis
      iii. Hereditary stomatocytosis
   c. Infantile pyknocytosis
6. Congenital red cell enzyme disorders
   a. Glucose-6-phosphate dehydrogenase deficiency
   b. Pyruvate kinase deficiency
7. Congenital hemoglobinopathies
   a. Alpha and gamma chain defects including thalassemias; structural abnormalities; unstable hemoglobin
8. Metabolic disorders
   a. Galactosemia
   b. Organic aciduria; orotic aciduria
   c. Prolonged or recurrent acidosis
9. Liver disease

in administering Rh Ig to all women at risk and incorrect dosing. Women who receive no prenatal care and women who develop silent antenatal sensitization compose two populations that are difficult to reach with prevention strategies.[4]

***ABO hemolytic anemia* is more common than Rh hemolytic disease but less severe. Unlike Rh disease, hemolysis secondary to ABO incompatibility can occur during the first pregnancy** because A and B antigens are ubiquitous in foods and bacteria, causing sensitization. Most isoimmune hemolytic diseases that are not related to ABO or Rh incompatibility are caused by sensitization to minor blood group antigens Kell, Duffy, Lewis, Kidd, M, or S. Mothers should be screened at 34 weeks for antibodies to these minor blood group antigens.

***Congenital bacterial* and *viral infections* may cause hemolytic anemia and bone marrow suppression with reticulocytopenia.** Microspherocytes may be very prominent.

***Microangiopathies* and *macroangiopathies* are characterized by red cell fragmentation, shortened red cell survival, and thrombocytopenia.** Coagulation proteins are also consumed in cavernous hemangiomas and disseminated intravascular coagulation (DIC).

***Vitamin E* is a fat-soluble vitamin that functions as an antioxidant. Deficiency of vitamin E manifests with hemolytic anemia, reticulocytosis, thrombocytosis, and edema of the lower extremities.**[21] Diets high in polyunsaturated fatty acids and iron increase requirements for vitamin E. With current supplementation of infant formulas and parenteral nutrition with vitamin E, prevention of vitamin E deficiency using a water-soluble form of tocopherol is not currently necessary.

Intrinsic red cell defects are a rare but important cause of shortened red cell survival in the neonate. Because even normal neonates have shortened red cell survival and hyperbilirubinemia, the presentation of these syndromes with anemia and hyperbilirubinemia in the neonate often is more severe than in older affected family members. Splenomegaly develops later in infancy or early childhood. A preliminary diagnosis of constitutional red cell defect is made by family history and careful inspection of the peripheral smear. Abnormally shaped RBCs, including spherocytes, elliptocytes,

pyknocytes, "bite cells," target cells, and other bizarre morphologic structures, are often characteristic of the specific red cell defect.

Constitutional defects in red cell membranes cause lifelong hemolytic anemia. ***Hereditary spherocytosis* is the most common red cell membrane defect and is usually inherited as an autosomal dominant trait** primarily affecting infants of Northern European descent. This is a common cause of exaggerated jaundice in the neonate. ***Pyropoikilocytosis,* an infantile form of the mild membrane defect *hereditary elliptocytosis,*** is characterized by striking red cell pyknocytes and fragments on peripheral smear with evidence of mild hemolysis. Typical elliptocytes may not become apparent until a few months of life. **Patients usually do not have long-term issues outside of the neonatal period.**

Glucose-6-phosphate dehydrogenase (G6PD) is the first rate-limiting enzyme in the pentose phosphate pathway. This enzyme is important in the production of nicotinamide adenine dinucleotide phosphate (NADPH), which is responsible for maintaining an adequate supply of reduced glutathione and preventing oxidative damage to the RBC from reactive oxygen species. **G6PD deficiency is the most common inherited disorder of red blood cells and is transmitted as an X-linked recessive trait; therefore affected infants are overwhelmingly male.** Females may also be affected through excessive lyonization of the unaffected X chromosome or coinheritance of biallelic mutations. There are many isoforms of abnormal G6PD enzymes. The Mediterranean type produces severe hemolysis, whereas the form found in African Americans is usually mild.[4,90] **Infants are asymptomatic until challenged with oxidant stresses from infections or drugs but may present with prolonged neonatal hyperbilirubinemia.** Agents associated with hemolysis in G6PD-deficient infants are shown in Box 20.3. ***Pyruvate kinase deficiency* is the second most common RBC enzyme defect.** Pyruvate kinase is a glycolytic enzyme involved in the production of ATP that is used as an energy source by RBCs for ATP-dependent cation pumps. Deficiency of this enzyme results in a chronic hemolytic anemia with varying degrees of severity. Some patients may develop splenomegaly or gallstones, or they may require chronic blood transfusions. Pyruvate kinase deficiency may be inherited in either an autosomal dominant or autosomal recessive fashion and thus may be seen in female or male infants.

***Hemoglobinopathies* are inherited disorders resulting from gene mutations that affect the quantity or quality of globin chains.** Thalassemias are quantitative disorders resulting in decreased or absent production of specific globin chains. Thalassemias are categorized according to the affected globin chain (e.g., alpha, beta, or gamma) and the severity of the clinical phenotype (thalassemia trait, thalassemia intermedia, or thalassemia major). **Hemoglobinopathies presenting at birth affect either the alpha or gamma chain of hemoglobin.**[41] Hemoglobin beta chains are not the predominant globin chain until 3 months of postnatal age; therefore defects of beta chains, such as *sickle cell anemia* and *beta-thalassemia,* do not present in the neonate. Because there are four genes controlling alpha globin synthesis (two on each allele of chromosome 16), clinical presentations may range from asymptomatic (one alpha hemoglobin gene deletion) to abnormalities incompatible with life (absence of production from all four alpha globin genes), resulting in hydrops fetalis.[175] Most infants with moderate to severe anemia related to alpha-thalassemia have a three-gene deletion, termed *hemoglobin H disease.* Alpha globin is an essential component of both hemoglobin F and hemoglobin A. Alpha thalassemia may be detected on universal newborn screening by the presence of hemoglobin Barts, which is composed of a tetramer of gamma chains. Hemoglobin Barts is replaced later by the compensatory hemoglobin, hemoglobin H, which is a beta-chain tetramer. In Western populations, there has been a dramatic decline in the incidence of new births with severe thalassemia syndromes because of the widespread use of molecular diagnostic techniques by couples at risk.

***Methemoglobin* contains an oxidized form of heme iron, Fe^{3+}, which renders it incapable of reversible binding to oxygen.** Constitutional methemoglobinemia presenting in the neonatal period is caused either by deficiency of the red cell enzyme *methemoglobin reductase* or by an *M hemoglobinopathy* of the gamma chain of hemoglobin. **Infants with either of these disorders present with cyanosis of the skin and mucous membranes** but are otherwise usually asymptomatic. ***Acquired methemoglobinemia* can be life-threatening because of severe hypoxemia.** Normal newborn infants are at

BOX 20.3 SOME AGENTS REPORTED TO PRODUCE HEMOLYSIS IN PATIENTS WITH G6PD DEFICIENCY

Drugs and Chemicals Clearly Shown to Cause Clinically Significant Hemolytic Anemia in G6PD Deficiency

Acetanilide
Methylene blue
Nalidixic acid (NegGram)
Naphthalene
Niridazole (Ambilhar)
Phenylhydrazine
Primaquine
Pamaquine
Pentaquine
Sulfanilamide
Sulfacetamide
Sulfapyridine
Sulfamethoxazole (Gantanol)
Thiazolsulfone
Toluidine blue
Trinitrotoluene

Drugs Probably Safe in Normal Therapeutic Doses for G6PD-Deficient Individuals (without Nonspherocytic Hemolytic Anemia)

Acetaminophen (Paracetamol, Tylenol, Traralgon, Hydroxyacetanilide)
Acetophenetidine (Phenacetin)
Acetylsalicylic acid (aspirin)
Aminopyrine (Pyramidon, Amidopyrine)
Antazoline (Antistine)
Antipyrine
Ascorbic acid (vitamin C)
Benzhexol (Artane)
Chloramphenicol
Chlorguanidine (Proguanil, Paludrine)
Chloroquine
Colchicine
Diphenhydramine (Benadryl)
L-dopa
Menadione sodium bisulfite (Hykinone)
Menaphthone
p-Aminobenzoic acid
Phenylbutazone
Phenytoin
Probenecid (Benemid)
Procaine amide hydrochloride (Pronestyl)
Pyrimethamine (Daraprim)
Quinidine
Quinine
Streptomycin
Sulfacytine
Sulfadiazine
Sulfaguanidine
Sulfamerazine
Sulfamethoxypyridazine (Kynex)
Sulfisoxazole (Gantrisin)
Trimethoprim
Tripelennamine (Pyribenzamine)
Vitamin K

G6PD, Glucose-6-phosphate dehydrogenase.

risk for developing toxic/acquired methemoglobinemia from environmental toxins and pharmacologic agents because neonatal RBCs contain lower levels of the enzyme *NADH-methemoglobin reductase.* In addition to the ingestion of nitrates, lidocaine and its derivatives, aniline dyes, and dapsone are the most common drugs precipitating methemoglobinemia.

Data Collection

HISTORY

A careful history should solicit a maternal history of illness and dietary intake during pregnancy, delivery type, hemorrhage, transfusion or iron therapy, and any abnormal occurrences during birth. A family history should include specific questioning about anemia, iron or transfusion therapy, pallor, jaundice, splenomegaly, splenectomy, gallstones, cholecystectomy, or congenital malformations in the parents, grandparents, siblings, aunts, uncles, and cousins of the infant.

SIGNS AND SYMPTOMS

In performing a physical examination of a newborn with anemia, attention should be paid to the infant's cardiovascular function, general vigor, and signs of pallor, jaundice, skin lesions, hepatosplenomegaly, lymphadenopathy, and congenital malformation (Box 20.4).

BOX 20.4 CRITICAL FINDINGS
SIGNS AND SYMPTOMS OF ANEMIA IN THE NEONATE

1. Acute anemia (with hemorrhage, anemia may not be present initially; hemodilution develops over 3 to 4 hours)
   a. Hypovolemia, hypotension
   b. Hypoxemia, tachypnea
   c. Tachycardia
2. Chronic anemia (may be well compensated)
   a. Pallor, metabolic acidosis, poor growth
   b. High-output congestive heart failure
   c. Persistent or increased oxygen requirement
   d. Iron deficiency with hypochromia, microcytosis

LABORATORY DATA

The diagnosis of anemia is based on the hemoglobin and hematocrit in comparison with normal values established for postconceptional and postnatal age. Initial laboratory evaluation of anemia should include a complete blood count (CBC) with careful attention to the RBC indices, reticulocyte count, and a review of the peripheral blood smear. Additional laboratory testing depends on the characterization of the anemia (Table 20.3). **The mean cell hemoglobin concentration (MCHC) is usually greater than 36 g/dL, and the MCHC/mean cell volume ratio may be elevated greater than 0.36 in patients with hereditary spherocytosis.**[29] If the peripheral smear suggests a constitutional RBC abnormality by severe anisocytosis, poikilocytosis, spherocytes, blister cells, bite cells, or elevated RDW, an ACD tube (yellow) for assay of G6PD, pyruvate kinase, and other red cell enzymes and an EDTA tube (lavender) for assay of red cell membrane proteins and hemoglobin electrophoresis should be obtained before transfusing the baby. **A clinical decision tree in the evaluation of anemia is shown in** Fig. 20.2.

TABLE 20.3 CHARACTERIZATION OF ANEMIA

CHARACTERIZATION	TEST
Blood loss	Kleihauer-Betke on maternal sample
	Apt test on gastric blood from infant as indicated
Bone marrow production	Reticulocyte count
	Platelet and white blood cell count
	Erythropoietin level
	T_3, T_4, TSH
	Bone marrow aspirate and biopsy
	Fetal hemoglobin iAg, MCV
Iron deficiency	Ferritin, iron, and iron-binding capacity
Antibody mediated	Maternal and infant blood type
	Direct and indirect Coombs' tests
Hemolysis	Bilirubin
	Coagulation tests (if sepsis or liver disease is suspected)
	Osmotic fragility, specific determinations of red cell membrane proteins, enzymes, hemoglobin, and ceruloplasmin as indicated
Infection	Culture and serologies as appropriate
Microangiopathy, macroangiopathy	DIC screen
Vitamin E deficiency	Vitamin E level
Metabolic disorder	pH, lactate, pyruvate
	Galactosemia screen

DIC, Disseminated intravascular coagulation; *MCV,* mean corpuscular volume; *TSH,* thyroid-stimulating hormone.

Treatment of Anemia

If acute blood loss is suspected and the infant is pale and limp at birth, blood pressure should be monitored, perfusion should be assessed, a bolus of intravenous (IV) fluids started at 20 mL/kg, and oxygen administered. A catheter should be inserted into the umbilical artery to measure blood gases. Blood should be obtained for CBC, reticulocyte count, Coombs' test, blood type, fractionated bilirubin, and serum screen for blood group antibodies. Because infants less than 4 months of age rarely produce antibodies against blood group antigens, maternal serum can be used in the antibody screen.

Once the infant's condition stabilizes, a decision can be made about transfusion based on clinical status. If the infant is anemic with signs of hypoxemia or has underlying pulmonary or cardiac disease, transfusion of 10 mL/kg of RBCs

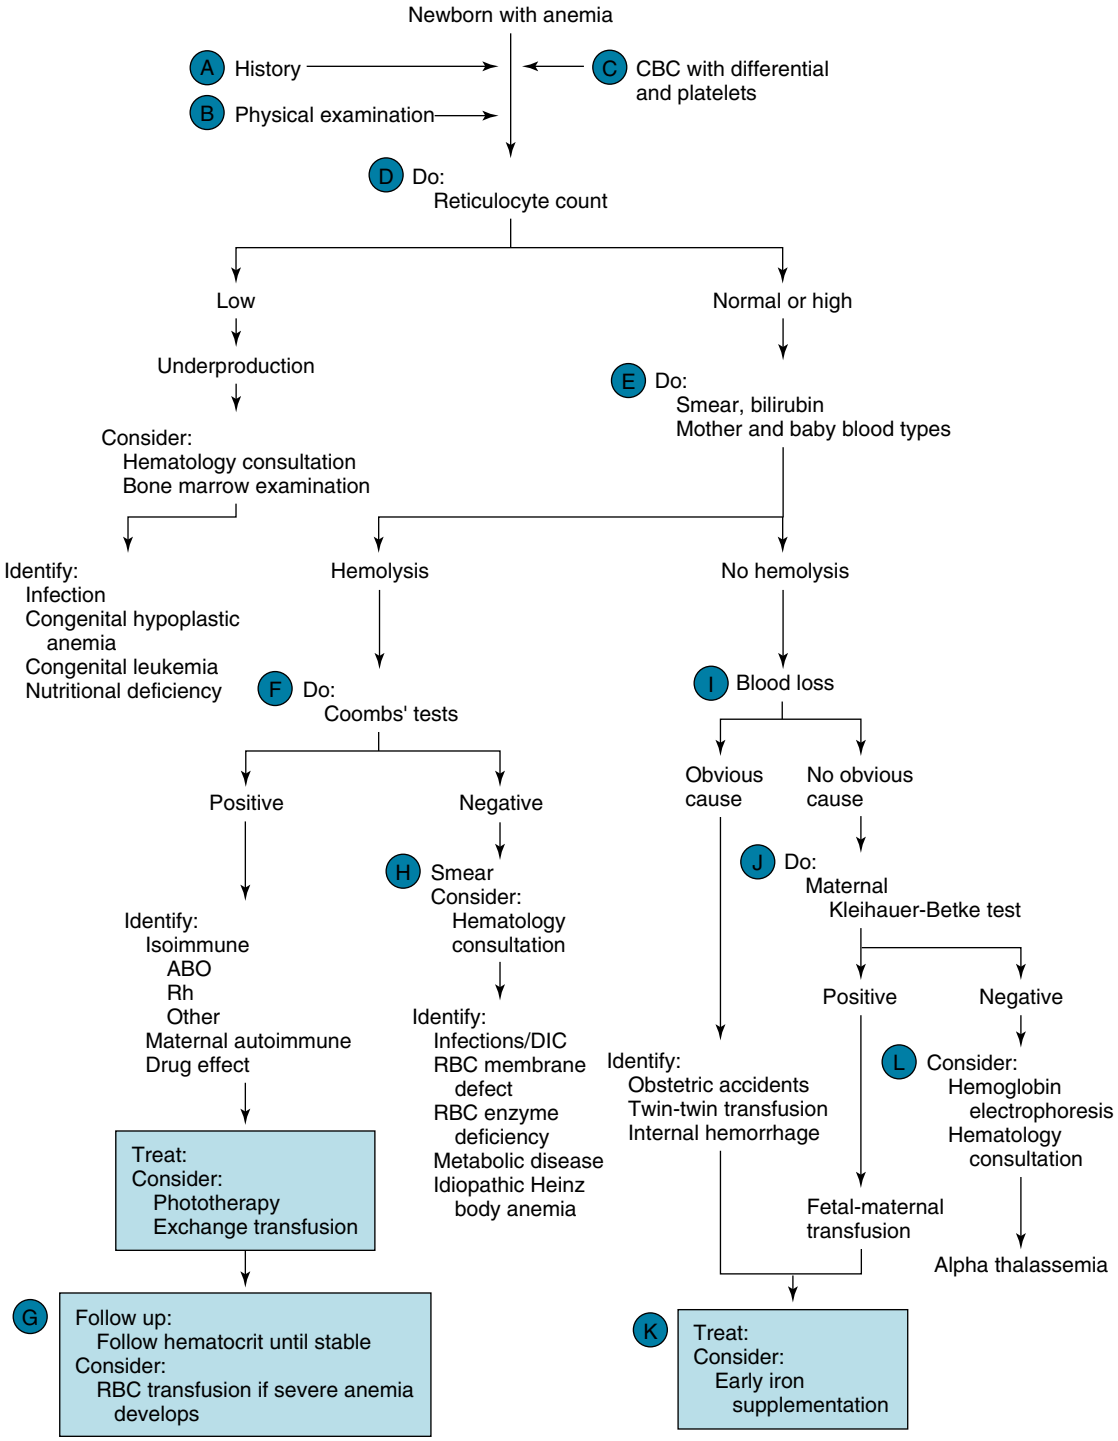

FIGURE 20.2 Clinical decision tree in the evaluation of anemia. *CBC,* Complete blood count; *DIC,* disseminated intravascular coagulation; *RBC,* red blood cell. (From Lane PA, Nuss R. Anemia in the newborn. In Berman S, ed: *Pediatric Decision Making.* 3rd ed. St Louis, MO: Mosby; 1996.)

Continued

A. In the history, document any prenatal infections or drug use. Also note any history of maternal vaginal bleeding, placenta previa, abruptio placentae, or umbilical cord rupture, constriction or velamentous insertion, as well as cesarean, breech, or traumatic delivery. Obtain a family history of neonatal jaundice, anemia, splenomegaly, and unexplained gallstones.
B. In the physical examination, note tachypnea, tachycardia, peripheral vasoconstriction (acute blood loss), and hepatosplenomegaly (chronic anemia, intrauterine infection, congenital malignancy). Jaundice appearing before 24 hours of age suggests significant hemolysis.
C. A hematocrit less than 45% during the first 3 days of life is abnormal and requires explanation. The mean corpuscular volume (MCV) at birth is normally above 95. An MCV below 95 suggests alpha-thalassemia or chronic intrauterine blood loss (as with fetal maternal transfusion). Rarely, a low MCV may be seen with hemolytic disease caused by hereditary elliptocytosis or pyropoikilocytosis. The presence of neutropenia or thrombocytopenia suggests the possibility of infection. Except in an emergency, no anemic newborn should receive a blood transfusion before adequate diagnostic studies.
D. Normal reticulocyte values are 3% to 7% during the first day of life and 1% to 3% during the second and third days. A low reticulocyte count in the presence of significant anemia suggests bone marrow failure.
E. An indirect hyperbilirubinemia, abnormal peripheral blood smear, or ABO or Rh incompatibility between the mother and infant suggests hemolysis.
F. Perform direct and indirect Coombs' tests. ABO isoimmunization is usually associated with a negative direct and a positive indirect Coombs' test.
G. Infants with immune hemolysis have varying degrees of hemolysis, which may continue for 3 months. Severe, life-threatening anemia may develop in infants with Rh sensitization; such infants require close follow-up with serial hematocrit measurements until the hemolysis resolves.
H. Examine the peripheral blood smear. Spherocytes suggest ABO isoimmunization, hereditary spherocytosis, or infection (e.g., cytomegalovirus). Red cell fragmentation suggests intravascular hemolysis (infection, disseminated intravascular coagulation [DIC]). Consider infection or DIC in any ill newborn with hemolysis, particularly if thrombocytopenia is also present.
I. Review the obstetric history and examine the placenta for clues to the cause of fetal blood loss.
J. Perform a Kleihauer-Betke test to detect fetal red cells in the maternal circulation. False-negative results occur when an ABO incompatibility results in the rapid clearance of the infant's red cells from the maternal circulation.
K. Newborns with significant prenatal or perinatal blood loss are at risk for iron deficiency during the first 6 months of life.
L. Anemic infants without evidence of hemolysis or blood loss whose mothers have a negative Kleihauer-Betke test may have alpha-thalassemia, especially if the MCV is below 95. Ethnic groups affected most often include South and Southeast Asians, Mediterraneans, and Africans. The diagnosis of alpha-thalassemia may be confirmed with a hemoglobin electrophoresis that shows hemoglobin Barts.

over 2 to 3 hours will serve to increase oxygen-carrying capacity (see discussion on diagnosis of congenital red cell defects in the Laboratory Data section earlier in this chapter). **Normally, larger quantities of blood should not be given in one transfusion.** Most blood banks at institutions with neonatal intensive care units have protocols for neonatal blood transfusion and will give leukodepleted, either type-specific or O-negative non-crossmatched RBCs if the antibody screen is negative. **Blood used for transfusion should be less than 7 days old and negative or reduced for cytomegalovirus (CMV).** Irradiation of RBCs and other blood cell products to prevent graft-versus-host disease is recommended for intrauterine transfusions or neonatal exchange transfusion and for infants with congenital or acquired immune deficiency. **For infants with continuing hemorrhage requiring massive transfusion exceeding one blood volume, transfusions of fresh frozen plasma (FFP) are necessary to replace clotting factors and prevent the consumptive coagulopathy that results from massive transfusion of stored blood. Platelet transfusions may also be needed.**

An order from a physician or nurse practitioner is necessary for any blood transfusion. Parental consent should be obtained by the physician before transfusion. **In the neonatal intensive care nursery, a policy of "double-checking" blood is essential to ensure that the proper blood is being administered to the infant. Blood should be warmed and administered through a blood filter of 40 μm or finer. Fresh blood can be administered through a 25-gauge needle without significant hemolysis.**

Directed donor programs may be used in hospitals for nonemergent blood transfusions, especially

in small preterm infants. In most cases, **biologic parents are able to serve as directed donors for their neonates.** Preparation of directed donations is more costly than standard blood units and requires the same time for testing; however, **there are no scientific data that suggest directed donor programs increase blood safety**. Some immunologic incompatibilities may exist between maternal and paternal donors; therefore the **following guidelines should be considered for parental donors:**[128]

- Mothers should not provide blood components containing plasma. If maternal RBCs are transfused, they should be washed.
- Fathers are not recommended as blood cell (red, white, or platelet) donors for their newborns unless maternal serum is shown to lack cytotoxic antibodies.
- All parental blood components should be irradiated before transfusion to the infant to prevent transfusion-associated graft-versus-host disease.

A recent study compared parental-directed versus non–parental-directed blood donation in a pediatric tertiary center in the United States. Both first-time parental and community donors were found to have a higher rate of infectious disease risk when compared with repeat blood donors. The highest rates of positive infectious disease testing occurred among the first-time parental donors. These researchers **recommend use of repeat donors and first-time nonparental donors and discourage first-time parental donation.**[70]

The equipment necessary for blood transfusion includes a filter, extension tubing, and a pump. Except in extreme emergencies, blood should be administered through a peripheral catheter rather than through an umbilical artery catheter (UAC). It is essential to confirm that the unit of blood infused matches the typed blood bank form and assigned number, patient name, and patient hospital number. The expiration date and time must be respected. IV tubing used for blood transfusion should be flushed with 0.45% normal saline solution before use.

Blood bags should not be used for more than 4 hours after opening. Vital signs are obtained and recorded every 15 minutes during blood transfusion. Careful observations should be made for reactions, including increased temperature, diaphoresis, irregular respiration, bradycardia, restlessness, and pallor. Transfusions should be stopped promptly if any of these signs are present. All materials used for blood transfusion should be disposed of properly.

Infants who are anemic as a result of acute or chronic external blood loss who do not require transfusion therapy should be treated with iron replacement 6 mg/kg/day until the blood count is normal and then for 2 additional months to replace stores.

Infants who are born with *isoimmune hemolytic anemia* are often treated with exchange transfusion. In this procedure, catheters placed in central and peripheral veins (or a central vein and artery) are used to remove the infant's blood in small aliquots and replace it with packed RBCs usually reconstituted with FFP. General guidelines for aliquot volumes are as follows:

- 3 kg : 20 mL per aliquot
- 2 kg : 15 mL per aliquot
- 1 kg : 5 mL per aliquot

Infants who are treated for isoimmune hemolytic anemia with intrauterine transfusions may be born with normal or near-normal hematocrit and bilirubin levels. **Exchange transfusion is often used early after delivery to remove antibodies and decrease postnatal hemolysis.** Hyperbilirubinemia can be managed subsequently using phototherapy (see Chapter 21).

Data regarding the use of intravenous immunoglobulin (IVIG) for treatment of hemolytic disease of the newborn are conflicting. Although a recent systematic review demonstrated a decrease in the need for exchange transfusions in patients treated with IVIG, several high-quality prospective, randomized clinical trials have not shown a benefit.[155,167,198,199] Additionally, there is **some evidence that high-dose IVIG administration may be associated with increased rates of necrotizing enterocolitis.**[54,189] Therefore, there is no consensus for the routine use of IVIG in severe hemolytic disease of the newborn at this time.

Prevention of Anemia

Many forms of neonatal anemia are preventable. Improved fetal monitoring and obstetric care may prevent anemia caused by blood loss during delivery.

Administering RhIg to unsensitized Rh-negative mothers within 72 hours of delivery of an Rh-positive infant prevents most cases of hydrops fetalis in subsequent pregnancies. For previously sensitized Rh-negative mothers

carrying Rh-positive fetuses, amniocentesis performed between 20 and 22 weeks of gestation may allow for intrauterine transfusion of Rh-negative RBCs and possible early delivery of a nonhydropic infant. **Prenatal diagnosis of severe thalassemia syndromes and sickle cell anemia is possible.** Intrauterine transfusions are also indicated for infants with alpha-thalassemia major.

Hemolysis may be prevented in infants with significant G6PD deficiency by avoiding administration of drugs known to present an oxidative stress to the RBCs. Supportive care consisting of phototherapy and IV hydration may be required in the setting of hyperbilirubinemia.

Low-birth-weight (LBW) premature infants are at high risk for late-onset anemia because of low endogenous production of erythropoietin, exacerbated by phlebotomy losses for laboratory surveillance. Inadequate nutrition and other factors also may play a significant role. Strategies for minimizing blood donor exposure related to anemia of prematurity include delayed umbilical cord clamping, using placental blood for initial laboratory studies, decreasing the number of blood draws, using the absolute minimum quantity of blood possible for testing, and using satellite packs (aliquots of a larger unit from a single donor) for transfusion.

LBW premature infants often undergo transfusion because they are critically ill and have the highest blood sampling loss in relation to their weight. In an attempt to reduce the number of transfusions and donor exposure, most centers have implemented more restrictive transfusion guidelines, with very encouraging results. **Recombinant human erythropoietin (r-HuEPO) has been successfully used to decrease the severity of anemia and lessen the use of blood transfusion in small premature infants.** The clinical benefits of erythropoietin administration may be trivial because it has not been shown to decrease the total number of donor exposures when using a conservative transfusion protocol employing satellite packs.[2,123] **In addition, there is also evidence suggesting an association between r-HuEPO and retinopathy of prematurity (ROP).**[75,97,188] **More recent studies show that anemia in the first week of life in preterm infants less than 28 weeks' gestational age is a significant risk factor for severe ROP,**[89] **but erythropoietin promotor variant is not associated with severe ROP with or without r-HuEPO administration,**[39] **and early r-HuEPO administration is not associated with increased risk for ROP.**[26] The benefits of therapy other than decreased exposure to blood transfusion are also unknown at present. Potential improvements in organ maturation or infant growth because of higher sustained levels of hemoglobin and improved neural development are speculative at present.

Treatment with EPO is most frequently considered in infants of birth weight 800 to 1300 g. Infants with a birth weight less than 800 g may receive so many transfusions early in their hospital course that treating with r-HuEPO may confer no substantial additional benefit. Infants with a birth weight of more than 1300 g rarely require blood transfusion.

If the decision is made to treat with r-HuEPO, therapy can begin when infants are stable and able to tolerate iron supplementation, usually when tolerating approximately 60% of caloric requirements by enteral feedings. The recommended dose of r-HuEPO is 400 U/kg given IV or subcutaneously three times weekly. Oral iron supplementation should be initiated at the time of therapy. A baseline hematocrit measurement and reticulocyte count should be obtained and followed weekly. **Dosing should be adjusted to maintain a reticulocyte count above 6%.** Once treatment is discontinued, hematocrit levels should be monitored every other week until stable.[122]

The *treatment of methemoglobinemia* is methylene blue, 1 to 2 mg/kg given intravenously over 5 to 10 minutes or orally; this therapy is ineffective in infants with deficient NADPH or G6PD, as well as M-hemoglobinopathies. **Treatment of methemoglobinemia in G6PD-deficient infants consists of ascorbic acid, 200 to 500 mg/kg/day.**[71,149]

POLYCYTHEMIA AND HYPERVISCOSITY

Physiology

Neonatal polycythemia **in a term infant is defined by a peripheral venous hemoglobin and hematocrit more than 2 standard deviations (SDs) above the mean; this translates to a hemoglobin greater than 22 g/dL and a hematocrit greater than 65%.**[63] Viscosity is related to but not identical to hematocrit. **The viscosity of blood increases**

linearly with hematocrit up to a hematocrit of 60% and then increases exponentially, but inconsistently thereafter.[91] Although viscosity may be measured directly, required instrumentation is not widely available in clinical laboratories, and hematocrit is often used as a surrogate for viscosity. Blood sampling at 12 hours postnatal age seems ideal to determine hematocrit and viscosity for diagnosis of polycythemic hyperviscosity.[164] Capillary hematocrit can be used as a screening test, but a central venous sample should be analyzed to confirm an abnormally high capillary hematocrit because these values may differ by as much as 20%.[86]

Pathophysiology

The pathophysiology of polycythemia can be attributed to either hyperviscosity or increased RBC mass. ***Hyperviscosity*** is a syndrome of circulatory impairment resulting from increased resistance to blood flow. Complications of polycythemia and hyperviscosity include respiratory distress, congestive heart failure, neurologic signs, and sequelae, such as significant motor and mental retardation and cerebral palsy. Thromboemboli, arterial ischemic stroke, necrotizing enterocolitis, and acute tubular necrosis are additional complications. Complications related to increased RBC mass include hypoglycemia and hyperbilirubinemia.

Polycythemia can result from a large number of perinatal complications, as shown in Box 20.5. Polycythemia and hyperviscosity result from chronic hypoxia, such as that associated with intrauterine growth restriction. However, the cause of polycythemia and hyperviscosity in otherwise normally developed term infants may be unknown. Although delayed cord clamping and umbilical cord milking have been cited as the most frequent causes of polycythemia in term infants, randomized clinical trials in term and near-term infants refute this assertion.[5,106,177] Infants in these trials demonstrated higher hemoglobin and increased ferritin levels with less anemia than infants undergoing early cord clamping, without cord milking. There was also no difference in the incidence of polycythemia or jaundice.[5,106,177]

In up to one-third of ***monochorionic twins***, there is a significant transfusion of blood from one twin into the other, defined as a discrepancy in the infants' blood counts of greater than 5 g/dL of hemoglobin. The recipient twin is usually larger and prone to cardiorespiratory symptoms, hyperviscosity, and hyperbilirubinemia, whereas the donor twin is smaller, anemic, and at risk for congestive heart failure.[173,179] Blood viscosity correlates better with symptoms than does hematocrit.[129] In addition, clinical signs and symptoms may be related to an underlying condition instead of polycythemia per se.

BOX 20.5 CAUSES OF NEONATAL POLYCYTHEMIA

1. Placental transfusion
   a. Excessive transfusion with umbilical cord milking
   b. Twin-to-twin transfusion
2. Intrauterine hypoxia/placental vascular insufficiency
   a. Intrauterine growth restriction syndrome
   b. Maternal diabetes
   c. Maternal smoking
   d. Maternal hypertension syndromes
   e. Maternal cyanotic heart disease
3. Fetal factors
   a. Trisomy 13, 18, 21
   b. Hyperthyroidism
   c. Neonatal thyrotoxicosis
   d. Congenital adrenal hyperplasia
   e. Beckwith-Wiedemann syndrome
4. High altitude
5. Idiopathic

Data Collection

HISTORY

In addition to a complete history of the pregnancy and delivery, questions should be directed to pertinent maternal medical conditions, including insulin-dependent diabetes mellitus, hypertension, and heart disease. Additional maternal risk factors include cigarette smoking and living at high altitude. Fetal risk factors include documented intrauterine growth restriction and umbilical cord milking.

SIGNS AND SYMPTOMS

Newborn infants with hematocrit values greater than 65% to 70% may manifest symptoms because of increased viscosity.[157] Physical

examination may be normal except for plethora and, occasionally, cyanosis. Neurologic findings may include lethargy, irritability, hypotonia, tremor, seizures, and poor suck. Tachypnea, tachycardia, and respiratory distress may be present. Poor GI function is common with abdominal distention, decreased bowel sounds, and poor feeding.

LABORATORY DATA

The diagnosis of polycythemia is based on hemoglobin and hematocrit in comparison with 2 SD normal values for postconceptual and postnatal age. The diagnosis of hyperviscosity may be based on direct viscosity measurement, but usually is assigned based on polycythemia in the presence of consistent clinical signs and symptoms. Affected infants often have thrombocytopenia, hyperbilirubinemia, and hypoglycemia. Tests to rule out hyperthyroidism and adrenal hyperplasia should be performed when indicated. Chromosome analysis should be considered for babies with dysmorphic features.

Treatment

Therapy for polycythemia should be based on the presence of clinical signs and symptoms consistent with hyperviscosity and not laboratory values alone. Traditionally, treatment of polycythemia aims to decrease blood viscosity through phlebotomy or partial exchange transfusion with replacement of removed RBC volume with volume expanders. Supportive care measures should also include IV fluids to treat hypoglycemia and phototherapy to treat hyperbilirubinemia. Although partial exchange transfusion may increase short-term cerebral blood flow,[51] the long-term benefits (follow-up at >2 years) appear to be negligible, with no difference in neurodevelopmental outcomes in patients who were managed conservatively with observation and fluids.[113,109]

Neurologic sequelae in babies with hyperviscosity appear to be related to prenatal risk factors for fetal asphyxia as much as or more so than hematocrit at birth.[150] Additionally, there may be a relationship between partial exchange transfusion and increased GI morbidity related to necrotizing enterocolitis.[127] In general, all peripheral hematocrits greater than 65% need to be checked and confirmed in a central venous sample. Asymptomatic infants with a hematocrit 60% to 70% may be managed conservatively with adequate hydration and glucose monitoring. Some centers recommend that partial exchange transfusion in asymptomatic patients be limited to patients with repeated venous hematocrit measurements greater than 70%.[12,158] For symptomatic patients, conservative treatment aimed at plasma expansion using early feeding or IV fluids may be attempted. However, partial exchange transfusion should be strongly considered in patients with significant cardiopulmonary or neurologic symptoms and those with a central venous hematocrit greater than 70%.

FFP has not shown greater efficacy than saline in an initial correction in hematocrit or viscosity or in improvement in outcome. In a randomized controlled trial, partial exchange transfusion using crystalloid solution (lactated Ringer's solution) was as effective as partial exchange transfusion using a colloid (plasma) in decreasing the hematocrit of polycythemic neonates.[147] Crystalloid solutions are preferable to colloids because they are less expensive and are free from the risk for transmitted infection. Exchange transfusion often requires placement of an umbilical venous catheter (UVC). Risks of umbilical catheterization in polycythemic infants include portal vein thrombosis, phlebitis of the portal vein, and decreased plasma volume (with phlebotomy alone). In addition, infants with polycythemia and hyperviscosity are at increased risk of spontaneous large vessel thrombosis, especially renal vein thrombosis and stroke.

COAGULATION

Physiology

When a blood vessel is torn, blood clots form at the site of vessel injury through a series of carefully controlled cellular and enzymatic reactions. First, *platelets,* which are small, platelike blood cells without nuclei, adhere to the damaged vessel wall by binding to *von Willebrand Factor (VWF)* from Weibel-Palade bodies of the endothelial cells and binding to collagen in the subendothelial matrix. *Glycoprotein (GP)1bα* in nonactivated platelets binds VWF transiently, causing platelet rolling. As contact time between platelets and the subendothelium

increases, platelets adhere to collagen through *GPIa/IIa* (or α2β1) and *GPVI* receptors. As platelets become activated by collagen binding, *GP1bα* joins *GP1bβ*, *GPIX*, and *GPV* (*GP1b-IX-V*) to bind VWF more tightly.[16] The platelets release *adenosine diphosphate (ADP),* which recruits more platelets to the activation process. Activated platelets express a receptor for the blood protein fibrinogen, *GPIIb/IIIa,* which binds to adjoining platelets, leading to platelet aggregation.[96]

Fibrinogen is a contractile protein that pulls platelets together, forming a tightly woven net over the vessel tear. *VWF, fibronectin, and thrombospondin* similarly link activated platelets through the *GPIIb/IIIa receptor.* This is known as a *platelet plug* and is responsible for the initial cessation of bleeding, especially in mucous membranes of the nose, mouth, throat, and GI and genitourinary tracts. At the same time, *thromboxanes* produced by the platelet prostaglandin pathway stimulate platelet aggregation, vasoconstriction, and decreased local blood flow.

Fig. 20.3 **shows the sequential reactions in activation of coagulation known as the *clotting cascade,* which leads to activation of *thrombin,* an important coagulation regulator, and *fibrin,* which stabilizes clot formation.**[96] Procoagulant factors II, VII, IX, and X and regulatory proteins protein C and protein S are all produced in the liver and require vitamin K to become functional. Vitamin K catalyzes the transfer of carboxyl groups to the gamma carbons of glutamic acid residues in vitamin K–dependent proteins; only after carboxylation can these unique proteins bind to phospholipid surfaces via calcium.[59]

The coagulation proteins in blood are inert proenzymes called *zymogens* until they are activated. The primary activation process involves exposure of a potent membrane protein for clotting activation called *tissue factor,* for which the tissue factor pathway of coagulation activation is named (see Fig. 20.3, *panel 2*). Tissue factor is normally hidden in the subendothelium and becomes exposed by vascular injury, or it is presented on the intact surface of monocytes and endothelial cells through the inflammatory process. Small amounts of circulating *activated factor VII (FVIIa)* in the plasma bind to exposed tissue factor and form a complex that results in the sequential activation first of factor X to factor Xa and then of factor II (also called *prothrombin*) to factor IIa (also called *thrombin*). These biochemical reactions are similar in that they take place preferentially on procoagulant phospholipid surfaces of activated endothelial cells and platelets at the site of injury, involve calcium-dependent binding to the phospholipid surface, and can be accelerated by cofactors *(activated factors VIII [FVIIIa] and V [FVa]).*

The contact activation pathway is an alternative route to factor X activation. In this pathway, factor XII is activated by contact with negatively charged subendothelial collagen or by acidosis, cold, or heat injury. Activated factor XII subsequently activates factors XI and IX. *Prekallikrein* and high-molecular-weight *kininogen* serve as cofactors for activation. Contact activation initiates clot lysis and also many inflammatory pathways, including the complement system, which is important for host defense. There is cross-activation between the tissue factor and contact pathways, and they do not function completely independently.

***Thrombin* is the terminal coagulation enzyme and functions as an important regulator of coagulation.** It is a potent platelet activator, and it provides positive feedback activation of factors VIII and V. Thrombin cleaves fibrinogen to form a sticky fibrin strand. Factor XIII is activated by thrombin and cross-links the fibrin strand, greatly increasing its strength and stability. Fibrin then contracts and forms a tight dense clot. A fibrin clot holds apposed surfaces together for about 1 week as thrombin and other growth factors stimulate fibroblasts to grow. Ultimately, scar tissue bridges the original injury.

Thrombin also inhibits coagulation; when complexed to the cell receptor, *thrombomodulin,* it initiates the inactivation of factors VIIIa and Va through activation of protein C (APC). The endothelial protein C receptor (EPCR) enhances the activation of protein C and complements the important protein C system.[36]

Blood clots are dissolved by enzymes in the *fibrinolytic system,* and components of the fibrinolytic system are activated by tissue damage and procoagulant proteins. The blood zymogen plasminogen is activated by tissue plasminogen activator (tPA) or urokinase-type plasminogen activator (uPA), which is released from vascular endothelial cells or renal epithelial cells, respectively. Thrombin also activates a protein called the *thrombin activatable fibrinolytic inhibitor (TAFI),* which removes lysine residues from fibrin resulting in inhibited binding of plasminogen and tPA to fibrin, decreasing fibrinolysis. The activated enzyme plasmin cleaves the fibrin clot into fragments of various sizes, called *fibrin split*

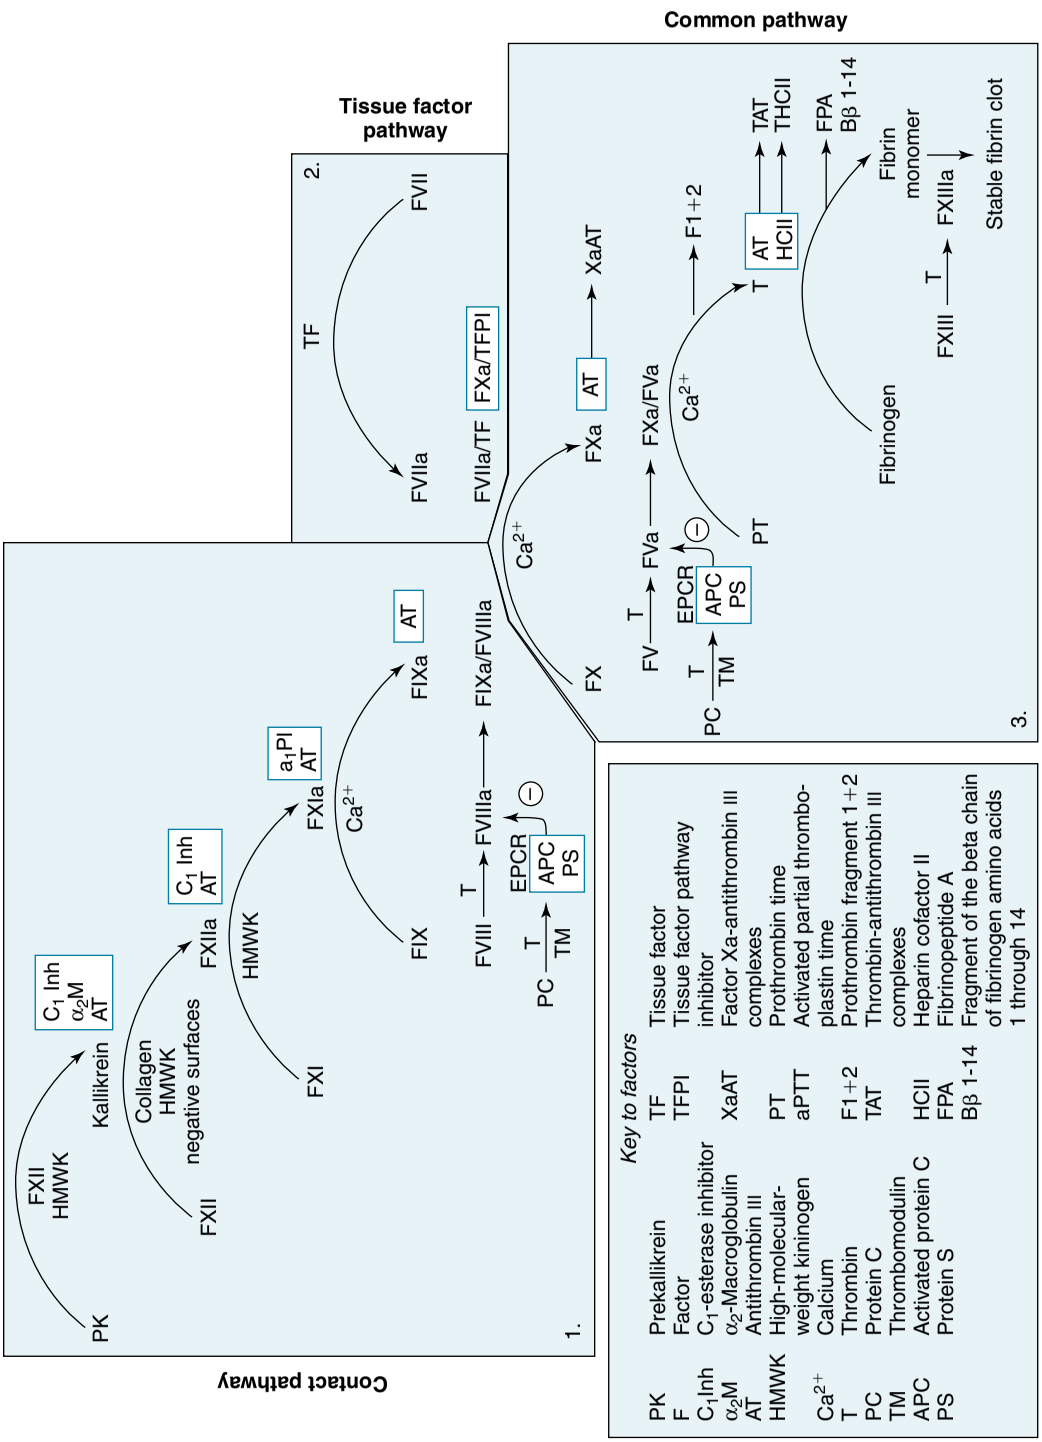

FIGURE 20.3 The clotting cascade. The aPTT screening test and coagulation test factors are included in *panels 1 and 3*. The PT test factors are shown in *panels 2 and 3*. Proteins encased in *boxes* inhibit the procoagulant reactions. *EPCR*, Endothelial protein C receptor.

products (FSPs). Split products that contain factor XIII–mediated cross-linked fibrin are called *D-dimer* fragments.

Several proteins are responsible for regulating the coagulation process and ensuring that these powerful enzymes are not activated in the systemic circulation, causing uncontrolled blood clotting. The most important of these regulatory proteins are antithrombin (AT), protein C, and the protein C cofactor, protein S. Heparin cofactor II, alpha$_2$-macroglobulin, and alpha$_1$-antitrypsin also function as coagulation regulatory proteins. Plasminogen activator inhibitor (PAI) and fibrin binding of plasminogen regulate the activation of fibrinolysis.

NORMAL VALUES

In general, healthy term and preterm infants have platelet counts within the normal adult range. A study of cord blood from more than 34,000 deliveries between 22 and 42 weeks of gestation determined **mean platelet counts ranging from 200,000 to 250,000/μL that increased slightly with gestational age.** The lowest fifth percentile was slightly above or below 100,000/μL in otherwise well infants less than 33 weeks of gestation[28](Fig. 20.4). **In addition, platelet counts increased rapidly after birth, and the fifth percentile was 150,000/μL by 7 days regardless of gestational age.**[28] Certain tests of specific platelet function, including platelet aggregation to physiologic agonists and flow cytometry evaluation of platelet activation, suggest **platelet hyporeactivity at birth and for the first 10 to 14 days of life, with more pronounced effects in premature infants less than 30 weeks' gestational age.**[168] Studies on the duration of platelet hyporeactivity have had mixed results, with some studies reporting normalization to adult levels within a few weeks[166,170] and others reporting a longer period of hyporeactivity.[67,170] Classical aggregometry is difficult to perform in the neonatal period because of a large required blood volume.[170] The platelet function analyzer (PFA-100) is a whole blood test that estimates platelet function by occlusion of a membrane coated with either collagen and epinephrine or collagen and ADP. In contrast with the suggestion of hyporeactivity in aggregation and flow cytometry studies, neonatal platelets have shorter

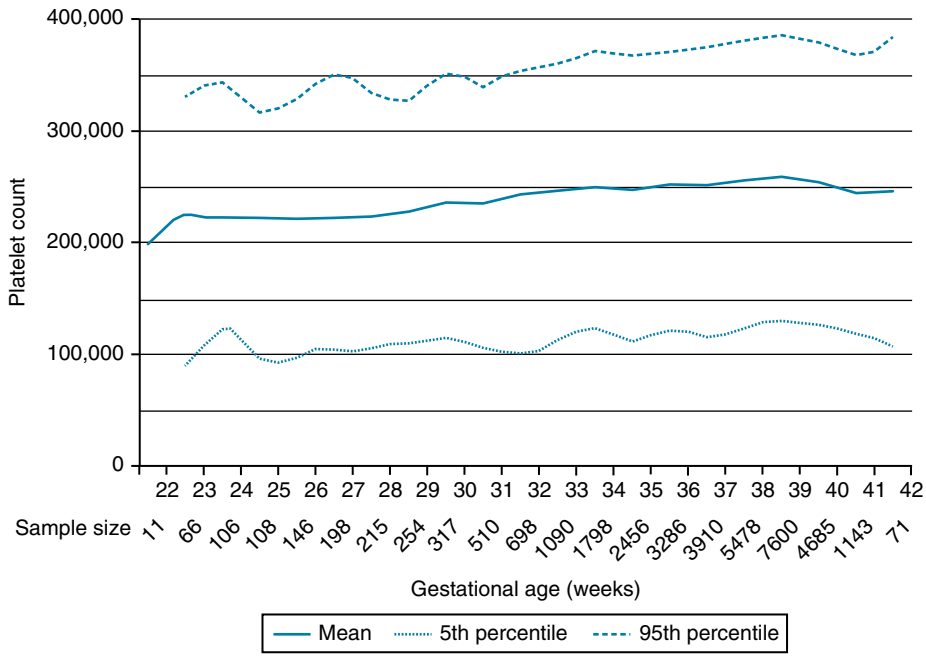

FIGURE 20.4 Reference ranges for platelet counts on the day of birth according to gestational age 22 to 42 weeks. Values were excluded from infants diagnosed with bacterial or fungal sepsis, necrotizing enterocolitis (NEC), or extracorporeal membrane oxygenation (ECMO). (From Christensen RD, Henry E, Del Vecchio A. Thrombocytosis and thrombocytopenia in the NICU. *J Matern Fetal Neonatal Med.* 2012;25:15.)

closure times in the PFA-100 than adult platelets do.[168] Of note, the PFA-100 is primarily used for severe platelet dysfunction such as Glanzmann's thrombasthenia or severe von Willebrand disease and is not sensitive to milder platelet function defects.[19] In addition, the PFA-100 can be falsely abnormal if hematocrit or platelet count is too low. Overall, **newborn platelet hyporeactivity is felt to be balanced by enhancement of other aspects of the coagulation system, and it likely does not increase bleeding risk.**[168]

The *coagulation system* of the newborn infant is unique in that blood clotting proteins mature at different rates (Table 20.4).[65] Mean levels of factors V and VIII and fibrinogen (factor I) are within the normal adult range by 20 weeks of fetal development. Very low levels of these clotting proteins are never normal. The level of the VWF is elevated above adult normal values at birth, and the neonatal VWF *multimers* (assembled VWF protein subunits) include ultralarge forms, which makes the protein more adherent to platelets and vessel walls. **Fetal fibrinogen differs from the adult molecule in its increased content of sialic acid. This prolongs the thrombin time (TT) of the neonate,**[57] **but it is likely that this balances with other changes so there is no net change in bleeding risk.**[112,53] Vitamin K–dependent factors II, VII, IX, and X and protein C and protein S develop very slowly.[6,11] Factor IX does not reach its full adult potential until after 6 months of age; protein C may not reach adult levels until puberty. It is very difficult to determine if these proteins are genetically deficient during the neonatal period.

The clotting system is evaluated using a hemostasis screen, which includes testing for the activated partial thromboplastin time (aPTT), prothrombin time (PT), thrombin time (TT), fibrinogen activity, and platelet count. A test of platelet function, such as the PFA-100, can be included but is not standard. **The PT and aPTT are often prolonged in neonates compared with older children and adults**[7,8,112] **and more prolonged in preterm neonates than in term neonates.**[117,142,143] The TT is slightly prolonged because of fetal fibrinogen until 3 weeks of age. The fibrinogen mean is within the normal adult range at birth in stable term and preterm infants. **Normal ranges can vary with testing reagents, so all values should be interpreted using an age- and laboratory-specific reference range.**[68]

Global coagulation assays that measure thrombin generation over time or clot strength through thromboelastography have been studied to attempt to determine the clinical influences of differences in the neonatal coagulation system. Neonatal plasma generates less thrombin than adult plasma, but thrombin activity is generated after a shorter lag time than that determined in adult plasma.[34,35,171] Similarly, in thromboelastography, the maximum clot formation is lower in neonates than in adults, but the times to clot initiation and clot formation are shorter in neonates than in adults.[169]

The clinical significance of these differences between the neonatal coagulation system and older children and adults is unclear;[142] **treatment of abnormal laboratory values in the absence of clinical bleeding is not recommended.**[27]

BLEEDING

Pathophysiology

THROMBOCYTOPENIA

***Thrombocytopenia* is a general term that denotes a decreased number of platelets in the infant's blood. Thrombocytopenia is the most common coagulation disorder in the neonate.** Determining whether the infant appears well or ill will influence the diagnostic approach, as the causes of thrombocytopenia in an otherwise well infant differ from those in an acutely ill neonate (Box 20.6).

A well-appearing infant is likely to suffer from *neonatal alloimmune thrombocytopenia* (NAIT), in which the platelets are coated by circulating antibody and rapidly cleared from the circulation by the spleen and liver. Alloimmune thrombocytopenia develops when the mother is negative for a platelet antigen, usually PLA-1, for which the father is positive. **Fifty percent of recognized cases of NAIT occur in a mother's first infant.** Subsequent infants can be more severely involved. **Presentations of NAIT range from asymptomatic infants in whom a low platelet count is detected coincidentally on a blood count to fatal cases of intracranial hemorrhage with onset in utero.** Infants of mothers with ***idiopathic thrombocytopenic purpura (ITP)* may have a low platelet count because the maternal antibody crosses the placenta to the infant, but they do not usually develop life-threatening hemorrhage.**[20]

BOX 20.6 CAUSES OF THROMBOCYTOPENIA IN THE NEWBORN INFANT

1. Well infant
   a. Immune
      Neonatal alloimmune thrombocytopenia (NAIT)
      Maternal idiopathic thrombocytopenia purpura
   b. Constitutional
      Thrombocytopenia–absent radius syndrome
      Amegakaryocytic thrombocytopenia
      Wiskott-Aldrich syndrome
      Fanconi's anemia
      Bernard-Soulier syndrome
      Autosomal dominant thrombocytopenia
2. Sick infant
   a. Respiratory distress syndrome
   b. Bacterial sepsis
   c. Viral infection
   d. Necrotizing enterocolitis
   e. Hyperviscosity
   f. Disseminated intravascular coagulation
3. Infant appearing either well or sick
   a. Kasabach-Merritt (giant hemangioma) syndrome
   b. Trisomy 13, 18, 21
   c. Leukemia
   d. Thrombosis

NAIT, Neonatal alloimmune thrombocytopenia.

Constitutional thrombocytopenia is rare. Affected infants often manifest congenital skeletal malformations of the hands and arms. ***Thrombocytopenia–absent radius (TAR) syndrome*** is a rare but well-characterized platelet syndrome. A bone marrow examination is important to evaluate the megakaryocyte pool. In ***Bernard-Soulier syndrome,*** the platelet number is moderately decreased and giant platelets are seen on the peripheral smear. Infants with ***trisomy 21 (Down syndrome),*** trisomy 18, or trisomy 13 can manifest abnormal platelet counts without apparent illness. The bone marrow of infants with Down syndrome is highly reactive.

Infants with ***large-cavernous hemangiomas*** and ***arteriovenous malformations*** can also trap platelets and consume fibrinogen. Clues to these syndromes include skin hemangiomas; bruits over the liver, spleen, or brain; and high-output congestive heart failure with a structurally normal heart. ***Kaposiform hemangioendothelioma (KHE)*** is a specific vascular tumor associated with a severe, often life-threatening coagulopathy with platelet and fibrinogen trapping resulting in severe thrombocytopenia and hypofibrinogenemia, which is known as the *Kasabach-Merritt phenomenon (KMP)*. KHE presents with affected infants showing a very low platelet number and fibrinogen with elevated D-dimer. Bleeding, including intracranial hemorrhage, can be life-threatening.[1]

Sick infants usually manifest moderate thrombocytopenia. Bacterial and viral infections are the most common cause of thrombocytopenia in the newborn infant and must be excluded in any thrombocytopenic neonate. The infant of a mother with chorioamnionitis often demonstrates thrombocytopenia in the cord blood. Thrombocytopenia develops in most infants with respiratory distress severe enough to require mechanical ventilation. The lowest platelet counts are usually found on about day 3 of life, and normal counts recover by day 10 if the infant's course is not complicated by infection or thrombosis.[141] Infants less than 32 weeks' gestational age with respiratory distress syndrome and severe thrombocytopenia are at increased risk for intracranial hemorrhage.

VITAMIN K DEFICIENCY

The most important bleeding syndrome in the otherwise stable neonate is vitamin K deficiency bleeding (VKDB), previously called ***hemorrhagic disease of the newborn.***[162,172] There is at least a tenfold gradient in vitamin K concentration between the maternal and fetal plasma, with inefficient transmission across the placenta.[162,172] It is not known why fetal levels of vitamin K are maintained at low levels physiologically, but it has been speculated that because high levels of vitamin K are mutagenic in vitro, low levels of vitamin K may be protective during the rapid cellular proliferation and differentiation in utero. Marginal fetal vitamin K levels are further compromised by maternal use of anticonvulsants or warfarin. Approximately 3% of cord blood samples from normal term pregnancies show biochemical evidence of noncarboxylated clotting proteins related to vitamin K deficiency.[161] ***Early VKDB*** presents within the first 24 hours of life with skin bruising, massive cephalohematoma, GI bleeding, or intracranial hemorrhage. ***Classic VKDB*** presents between 1 and 7 days

of life; *late VKDB* occurs between 2 weeks and 6 months of life (predominantly by 2 months of age).[172] The recommendation of the American Academy of Pediatrics and the European Society for Paediatric Gastroenterology, Hepatology and Nutrition is to **give every neonate 1 mg of vitamin K by intramuscular (IM) injection**[2,108]**; this is adequate to prevent bleeding in most infants (see** Table 5.3**).** Vitamin K prophylaxis can be achieved with use of an oral vitamin K preparation; however, it may be less effective than IM preparations at preventing late VKDB,[3,108,157,184] particularly because of difficulty adhering to multiple doses over the first 6 weeks of life.[172] Several different oral dosing regimens have been described,[69,108,136,184] including one discussed in Chapter 5. One study published in 1992 raised concerns that IM vitamin K could increase the risk of childhood leukemia; however, this study has been refuted.*

Vitamin K concentrations are physiologically very low in human breast milk; cow's milk and infant formulas contain significantly more vitamin K (≤15 and ≥60 μg/L, respectively),[108,162,153] **although the bioavailability of vitamin K is enhanced in infants receiving only breast milk.**[162] **Infants who are fed breast milk are at increased risk of vitamin K deficiency.**[172] **In addition, infants with fat malabsorption caused by cystic fibrosis, alpha$_1$-antitrypsin deficiency, or biliary atresia and infants treated with prolonged courses of antibiotics are at increased risk of late vitamin K deficiency. All infants with late-onset vitamin K deficiency should be evaluated for a fat malabsorption syndrome.**[162]

HEMOPHILIA AND OTHER CONGENITAL BLEEDING DISORDERS

The *hemophilias* are a group of lifelong bleeding disorders caused by genetic deficiencies of coagulation proteins. The most common congenital bleeding disorders are factor VIII deficiency (hemophilia A), with an incidence of 1:5,000 live births,[115] and factor IX deficiency (hemophilia B), with an incidence of 1:20,000 live births.[116] Both factors VIII and IX are encoded on the X chromosome; thus deficiency states are manifested primarily in males, with carriers manifesting no symptoms or mild symptoms.[144] Hemophilia can be severe (factor level <1% of normal), moderate (factor level 2% to 5%), or mild (factor level 6% to 40%).[144]

Most infants with even severe hemophilia appear to tolerate labor and a routine vaginal delivery with no undue problems. However, **newborns with hemophilia are 44 times more likely than the general population to experience intracranial hemorrhage at birth, with a higher incidence after vaginal-assisted births and a lower incidence with Caesarian delivery.**[40] **Current recommendations call for vaginal delivery in the absence of complications; however, cesarean delivery should be elected to avoid prolonged or difficult labor. Use of vacuum extraction or forceps to assist delivery should be avoided.**[105]

Approximately 50% of male infants with severe hemophilia will hemorrhage from a circumcision.[83] The absence of procedure-related bleeding in the neonatal period does not exclude hemophilia because hemostasis can be supported by physiologically increased platelet function around birth.

Deficiencies of other coagulation factors, including fibrinogen, or factors XI (hemophilia C), II, V, VII, X, or XIII, are inherited as autosomal traits with severe bleeding manifested with homozygous or compound heterozygous deficiency.[144] Heterozygous deficiencies are less likely to present during infancy. Prolonged bleeding from the umbilical cord stump is suggestive of factor XIII deficiency. ***Von Willebrand disease* is the most common inherited bleeding disorder;** however, only those with the most severe type of VWD (type 3) present in infancy and young childhood.[152,165]

LIVER FAILURE

The coagulopathy of liver failure is complex and includes thrombocytopenia, platelet dysfunction, decreased synthesis of coagulation proteins in the liver, and enhanced fibrinolysis. Severe liver disease is characterized by a markedly abnormal PT in excess of aPTT prolongation, along with other signs of liver dysfunction, such as hepatomegaly, jaundice, and elevated liver enzymes. **Liver failure in the neonatal period can result from viral hepatitis or rare metabolic disorders such as infantile hemochromatosis.**[14] **Infants with liver dysfunction manifest bleeding into the skin, GI tract, retroperitoneum, and cranium. Invasive procedures, such as liver biopsy, can provoke severe bleeding but have been shown to be generally safe with the precaution**

*References 3, 22, 46, 130, 131, 146, 148, 181.

of transfusing FFP if the international normalized ratio (INR) is greater than or equal to 1.5 before the procedure, or transfusing platelets if the platelet count is less than 50,000/μL.[23]

CONGENITAL PLATELET DYSFUNCTION

Genetic platelet function defects causing severe bleeding in the neonatal period are rare. ***Glanzmann's thrombasthenia*** is an autosomal recessive disorder resulting from a severe deficiency or dysfunction in the platelet fibrinogen receptor GPIIb/IIIa. Severe neonatal bleeding, including intracranial hemorrhage, can occur. Platelet number is normal in this syndrome. Absent receptors can be determined by flow cytometry, and genetic mutations have been determined, but all cases can be diagnosed by severe abnormalities on platelet aggregation studies or PFA-100 in the context of normal hematocrit and platelet count.[73] ***Bernard-Soulier*** is an autosomal recessive disorder from a defect in the platelet GPIb/IX/V receptor for VWF that also results in macrothrombocytopenia.[118]

Platelet storage pool disorders can be suspected from abnormal granule staining on the peripheral smear. ***Hermansky-Pudlak syndrome*** is a recessively inherited syndrome characterized by the absence of platelet-dense granules, often with oculocutaneous albinism.[73,118] ***Chédiak-Higashi disease*** is an autosomal recessive disease characterized by large, dysfunctional platelet granules and granulocytic cytoplasmic granules, with associated immunodeficiency.[73] ***Wiskott-Aldrich syndrome*** is an X-linked disease associated with small dysfunctional platelets, severe eczema, and immunodeficiency.[118] In *gray platelet syndrome,* the alpha granules are absent, the platelets have a pale appearance on the peripheral smear, and the bleeding phenotype is typically mild.[73] Acquired platelet dysfunction can cause bleeding in the first several days of life in an infant after maternal use of aspirin or other drugs affecting platelet function shortly before delivery.[172]

Diagnosis and Management

HISTORY

A history of maternal bleeding, medical and obstetric diagnoses, and medications should be elicited for every infant at birth. A careful family history for bleeding disorders in the parents, grandparents, siblings, aunts, uncles, and cousins should be taken as part of every admission evaluation. Specific questions must be asked about excessive bleeding with surgeries (including dental procedures), menses, childbirth, traumas, and spontaneous bleeding events. Efforts should be made to obtain confirmatory medical records for any positive response. Procedures, including circumcision, should not be performed until the possibility of a bleeding disorder in the infant is excluded. The administration of vitamin K to the infant should be confirmed by review of the chart.

SIGNS AND SYMPTOMS

Thrombocytopenia usually manifests with small, flat hemorrhages into the skin called ***petechiae*** that do not blanch with pressure. Petechiae may be concentrated in skin creases of the neck and axilla and around the site of a tourniquet or may be scattered over the entire body. More severe thrombocytopenia results in large ***ecchymoses,*** which are flat bruises. Infants with severe thrombocytopenia may hemorrhage into the central nervous system or GI tract.

Bleeding with coagulation disorders can manifest as palpable ***hematomas*** of the skin and scalp. Large cephalohematomas are common and can result in a decreased hematocrit. Intracranial, retroperitoneal, intraperitoneal, GI, and genitourinary bleeding may occur. Bleeding with surgeries or procedures may be immediate or delayed. Three-fourths of infants affected with severe hemophilia are diagnosed in the first month of life.

Hemangiomas are dark red raised lesions that blanch with pressure. KHE tumors are usually solitary indurated tumors with a pebbly rough surface and indistinct margins. The lesions may be associated with hypertrichosis or increased sweating. ***Arteriovenous malformations*** may not have skin manifestations but may have overlying swelling and warmth, and an overlying bruit may be heard.

LABORATORY DATA

Any infant with bleeding signs should be evaluated with a hemostasis screen and a platelet count. The CBC should be reviewed with attention to all cell lines. The peripheral smear should be carefully inspected for evidence of giant platelets or platelet clumping in the feathered edge of

the smear. **The results of the hemostasis screen in the healthy infant and during many states of illness are shown in** Table 20.5. **PT and/or PTT will be prolonged if any factor level is below the threshold of the test (typically around 30%).** Low factor levels caused by vitamin K deficiency can be confirmed with PIVKA (protein induced by vitamin K absence or antagonism, also called *des-gamma-carboxy-prothrombin*) testing, which examines the amount of prothrombin that has not been carboxylated with vitamin K.[62] **The possibility of hemophilia should be excluded by specific assay of factor VIII and factor IX. Severe *von Willebrand disease* can present with excessive bleeding in the neonatal period and is diagnosed by VWF activity that is less than 10% (IU/dL). In addition, fibrinogen and factors XIII, alpha2-antiplasmin, and plasminogen activator inhibitor-1 (PAI-1) should be assayed in a term infant with unexplained significant hemorrhage,** such as intracranial hemorrhage. If Glanzmann's or a similar congenital platelet dysfunction is suspected, **platelet function should be assessed with a screening test** (e.g., the PFA-100), platelet aggregation studies, or platelet receptor flow cytometry studies. **Heparin-induced thrombocytopenia (HIT) is rare in pediatrics[119] but should be considered in patients with a drop in platelet count greater than or equal to 50% to below 150,000/μL without an alternative cause, typically after 5 days of heparin administration.**[145]

Treatment

THROMBOCYTOPENIA

Therapy for thrombocytopenia depends on the overall health and stability of the neonate, as well as the cause of the thrombocytopenia. In immune thrombocytopenia, antibodies that are affecting neonatal platelets also may cause rapid destruction of transfused platelets. Platelet antibodies in infants with NAIT do not react against maternal platelets, and **washed maternal platelets are an effective therapy for affected infants with severe bleeding.**[168]

Thrombocytopenia in this disorder, as well as maternal autoimmune thrombocytopenia, responds well to IVIG. **Infants with alloimmune thrombocytopenia are likely to receive incompatible platelets from a random donor, and platelet transfusions, when needed, must be from a donor who shares the maternal antigen profile** if time and availability permit.

If HIT is suspected, heparin should be stopped promptly, a blood sample sent for HIT testing, and alternative anticoagulation (e.g., with *argatroban* or *bivalirudin*) should be substituted, until test results are obtained. Although there have been no prospective randomized clinical trials, infants with KHE and KMP have been treated with steroids and vincristine, either agent along with an antifibrinolytic agent (epsilon-aminocaproic acid or tranexamic acid), a platelet inhibitor (aspirin, ticlopidine, or clopidogrel), or

interferon-α.[47] There is currently an ongoing clinical trial using sirolimus for vascular malformations that include KHE.

The primary support for most other thrombocytopenic infants is replacement transfusions of platelets, which are derived from CMV-reduced donor units. A stable, otherwise healthy infant can tolerate a platelet count as low as 20,000/μL without undue risk of serious bleeding. A recent prospective, randomized multicenter clinical trial in **preterm infants less than 34 weeks' gestational age found that patients who were transfused at higher platelet thresholds of 50,000/μL had significantly increased rates of mortality and severe bleeding events compared with preterm infants who were transfused at a lower platelet threshold of 25,000/μL at 1 month postrandomization.**[32] This suggests that a more restrictive approach to platelet transfusions may result in more favorable outcomes.

VITAMIN K DEFICIENCY

Infants with vitamin K deficiency bleeding are treated with 1 to 5 mg of vitamin K by slow IV push or IM injection. FFP, 10 to 15 mL/kg, may be given to control active bleeding, and **the use of four-factor prothrombin concentrates,** which are vitamin K–dependent clotting factors purified from human plasma, **have also been used off-label to control active bleeding.**[141,197]

Neonates with severe liver disease can be treated for active bleeding or prepared for liver biopsy using transfusions of FFP and platelet concentrates. Parenteral administration of vitamin K should be confirmed; ongoing replacement may be necessary if there is fat malabsorption. There is no benefit to treating babies with liver disease and abnormal clotting tests but without clinical bleeding signs.[61] **Recombinant factor VIIa has been used to control bleeding in children with liver failure,**[17] although there may be an associated risk of thrombosis.[194] **Prothrombin complex concentrates have also been used off-label in liver failure** in a few cases. Although a meta-analysis did not yield sufficient evidence to allow a recommendation for use of prothrombin complex concentrates for bleeding in neonates,[197] **these concentrates may be dosed at much smaller volumes than FFP and may be clinically useful for situations in which close attention must be paid to volume status. Consultation with a regional hemophilia treatment center about use and availability of these specialized products is strongly recommended.**

HEMOPHILIA AND OTHER CONGENITAL BLEEDING DISORDERS

Treatment of congenital coagulation factor deficiencies is based on the deficient factor. The most specific product available should be used. **Factor VIII or IX should be replaced in a bleeding neonate (or for surgery) using intravenously administered recombinant or plasma-derived factor concentrates.** Although recombinant factor VIII products have previously been recommended because of a presumed decrease in risk of viral transmission, **treatment of severe factor VIII deficiency with plasma-derived factor VIII products decreases the risk of inhibitory allo-antibody formation to factor VIII,**[132] **a major complication that occurs in 30% of those with severe hemophilia A.** New treatments for hemophilia A and B are developing rapidly. **In 2018, the U.S. Food and Drug Administration (FDA) approved *emicizumab,* a subcutaneously administered bispecific antibody that mimics the activity of factor VIII, for prevention of bleeding in patients with hemophilia A of any age, with or without inhibitors.**[93,124] **Gene therapy and other nonfactor treatments are currently in clinical trials.**[10]

Factor VII may be replaced using recombinant factor VIIa in low doses of 15 to 25 mcg/kg every 6 to 12 hours. Viral-inactivated, human plasma–derived concentrates are available for VWF, fibrinogen, factor X, factor XIII, AT, and protein C. **Factor II (prothrombin) may be replaced using prothrombin complex concentrates; a hemophilia center pharmacist should be consulted for factor concentrations in specific brands and lots.**

If factor-specific concentrates are not available, factor XIII, factor VIII, and fibrinogen may be replaced with cryoprecipitate. Replacement of factor V, XI and other clotting proteins usually requires FFP. *Desmopressin (DDAVP),* a synthetic vasopressin that stimulates release of endothelial stores of factor VIII and VWF, **is generally not used in the neonate because of the possibility of seizures related to hyponatremia in this age group. Antifibrinolytic agents**

are effective for infants with fibrinolytic defects, such as severe deficiency of PAI-1, or to supplement other bleeding treatments. A hemophilia center should be involved in the diagnosis and management of all infants with congenital bleeding disorders.

CONGENITAL PLATELET DYSFUNCTION

In congenital platelet function disorders, bleeding can be treated with platelet transfusions and antifibrinolytics such as aminocaproic acid. Because of concern about the increased risk for development of platelet antibodies and platelet refractoriness, recombinant factor VIIa is also approved for the treatment of bleeding in Glanzmann's thrombasthenia.[134]

Prevention and Parent Teaching

Mothers should be instructed during pregnancy that vitamin K deficiency is routinely prevented with an IM injection of vitamin K to the neonate. Nursery personnel and primary care providers should be careful to document administration of vitamin K, especially for infants born at home. For babies whose parents refuse IM vitamin K, even after education, oral supplementation should be offered.

Bleeding in an infant with a bleeding disorder can be minimized by exerting care to prevent undue trauma. IM injections and other invasive procedures should be avoided if at all possible, although vitamin K may be safely administered to infants with severe hemophilia if a small-bore needle is used, care is taken not to Z-track the needle under the skin, and pressure is held at the site for at least 15 minutes using a pressure dressing. The infant should be handled in as gentle a manner as possible. Pressure for holding and placement of a tourniquet should be minimized. Extreme care should be taken with arterial puncture.

Replacement platelet or clotting factor infusions should be considered before any necessary invasive procedure. Parents should be educated about the nature of the bleeding disorder and its cause in their infant. They should know whether this is a time-limited complication of the neonatal course or a long-term concern. Infants with constitutional bleeding disorders have a lifelong risk of bleeding. The benefits and any risks of treatment must be conveyed to the infant's parents. Any other family member at risk of having a genetic bleeding disorder should be identified, screened, and counseled.

Education of families about hemophilia or constitutional platelet disorders begins as soon as the diagnosis is established. Parents should be instructed about routine infant care and the recognition of possible bleeding events, in coordination with hemophilia treatment center staff.

Thrombosis

PATHOPHYSIOLOGY

Thrombosis is an uncommon problem in pediatric patients, with increased incidence noted both in the neonatal period and after puberty.[138] The incidence of venous thromboembolism in the neonatal population has been increasing over time, and the incidence is higher in preterm infants than in term infants.[64,156] Physiologic correlates of the neonate's increased predisposition to thrombosis are shown in Boxes 20.7 and 20.8. The most common risk factor for venous thromboembolism is a central venous catheter (CVC)[64]. CVC-associated thrombosis should be suspected in an infant with a malfunctioning central line, an idiopathic falling platelet count, or unexplained swelling or discoloration. In addition, an infected clot should be suspected in an infant with diagnosed catheter-related thrombosis and alterations in temperature, respiratory stability, or cardiovascular stability.

Thrombi not associated with a CVC in the newborn period most commonly manifest as renal vein thrombosis (RVT), cerebral

BOX 20.7 PROTHROMBOTIC CHARACTERISTICS OF NEONATAL BLOOD

- Increased hematocrit values
- Increased concentration and size of von Willebrand factor multimers
- Increased concentration of circulating tissue factor in preterm infants
- Low concentrations of physiologic anticoagulants, antithrombin, protein C, protein S, and tissue factor pathway inhibitor
- Low concentration of the fibrinolytic protein plasminogen
- Small-caliber, reactive blood vessels

BOX 20.8 PATHOLOGIC CONDITIONS PREDISPOSING TO THROMBOSIS IN THE NEONATE

- Hypotension
- Hyperviscosity
- Severe genetic and acquired deficiencies of antithrombin, protein C, protein S, and plasminogen[113,121]
- Genetic mutations in factor V and prothrombin; elevations in homocysteine and lipoprotein(a)
- Mechanical obstruction by catheters
- Maternal diabetes mellitus

sinovenous thrombosis (CSVT), or perinatal stroke. Thrombosis in the stable term infant most often presents in the first few days of life and may be of fetal onset. RVT and CSVT may also be provoked by dehydration or other illness.

Testing for an underlying thrombophilia in a neonate is controversial[64] and should be considered on a case-by-case basis. In general, thrombophilia testing is unlikely to be beneficial in neonates with provoked thrombi and without a family history of thrombosis.

Perinatal stroke (before 28 days of age; see Chapter 26) is typically multifactorial, including prenatal blood circulation and placental changes at delivery. Thus, extension and recurrence rates are low, and treatment with aspirin or anticoagulants is often not indicated (see Chapter 26). Although thrombophilia testing after stroke is controversial,[33,77,120] a recent large case-control study suggests that thrombophilia risk is not increased in children with perinatal stroke.[33]

PURPURA FULMINANS

Purpura fulminans is a syndrome of skin necrosis from thrombosis in the postcapillary venules caused by severe deficiencies of protein C or protein S.[92,94,95] Most cases are caused by homozygous or compound heterozygous genetic defects, so urgent testing for protein C and protein S deficiency is needed. Protein C or protein S is usually below the laboratory limit of detection. Screening coagulation tests are often normal initially, but DIC quickly develops and can be controlled only by replacement of the missing protein. Purpura fulminans is uniformly fatal if untreated. Rarely, acquired deficiencies from maternal lupus anticoagulants can mimic these genetic syndromes. ***Purpura fulminans*** complicating bacterial sepsis or meningitis has a similar pathophysiology to genetic deficiency and is caused by acquired consumption of protein C and protein S at the endothelial cell surface. Purpura fulminans associated with infection usually manifests at a later age and is less fulminant than the genetic syndromes.[30]

THROMBOCYTOSIS

Thrombocytosis is typically defined as a platelet count greater than 450,000/μL, with extreme thrombocytosis defined as a platelet count greater than 1,000,000/μL.[81] Inflammation after infection is the most common cause of ***thrombocytosis*** in the neonatal period.[104,183] After interruption of platelet consumption by a thrombus, which occurs with successful implementation of anticoagulation, infants may often manifest thrombocytosis from increased bone marrow synthesis and release.[176] Down syndrome,[58,78] iron-deficiency anemia,[52] and maternal drugs and medications (e.g., methadone)[18] may also be associated with thrombocytosis. *Primary thrombocytosis* is a very rare syndrome that is seldom diagnosed in the neonatal period.[81]

HEPARIN-INDUCED THROMBOCYTOPENIA

Heparin-induced thrombocytopenia (HIT) has been described in neonates, especially infants with significant heparin exposure associated with cardiac surgery, cardiopulmonary bypass, or extracorporeal membrane oxygenation (ECMO).[145] HIT is caused by antibodies that develop against a complex of heparin with platelet factor IV on the platelet surface. When HIT is suspected, all heparin must be promptly removed, including solutions used to flush catheters. ***Parenteral direct thrombin inhibitors (DTIs)*** can be used as an alternative anticoagulant; ***argatroban*** and ***bivalirudin*** have been studied in the neonate.[192,193] Although bleeding, including intracranial hemorrhage, is a risk with these parenteral DTIs, it is unclear if they have a higher bleeding risk than heparin, as the drugs have not been directly compared.

Diagnosis and Management

HISTORY

For neonates in whom thrombosis has been discovered, family history is important in

determining if a workup for hypercoagulability should be initiated. A history of thrombosis, including deep vein thrombosis, pulmonary embolism, heart attack, or stroke in persons younger than 50 years of age in the parents, grandparents, siblings, aunts, uncles, and cousins of the infant, raises suspicion of genetic thrombophilia. Many family members affected with heterozygous deficiencies of AT, protein C, or protein S are asymptomatic. A history of fetal or neonatal death with thrombosis is helpful. Maternal obstetric complications have been linked to thrombophilia. A maternal history of severe or recurrent preeclampsia, severe intrauterine growth restriction, three first-trimester losses, or any fetal death beyond 10 weeks of gestation could indicate potential thrombophilia. Maternal abnormalities of fibrinogen are associated with placental abruption and early pregnancy loss . Maternal diabetes mellitus and placental transfer of antiphospholipid antibodies are causes of acquired neonatal thrombophilia.

Signs and Symptoms

THROMBOSIS

Signs and symptoms of thrombosis are dependent on the site of thrombosis. Signs of decreased organ perfusion and subsequent dysfunction indicate the possibility of a thrombosis. The classic presentation of ***renal vein thrombosis*** includes hematuria, proteinuria, thrombocytopenia, and hypertension.[114] Palpably enlarged kidneys may be noted on physical examination, and prenatal RVT should be considered in patients with unilateral or bilateral flank masses on initial examination.[82] ***Stroke*** usually presents with seizures during the first 24 hours of life or with early handedness preference. ***Aortic thromboses*** present with cool, pale extremities, decreased pulses and capillary refill, and upper extremity hypertension. Classic signs of arterial emboli include purple toes or fingers. Thrombosis can also present with an idiopathic decrease in platelet count.

Confirmation of thrombosis is made with ultrasound examination of the vasculature or with computed tomography or magnetic resonance imaging and angiography of the brain if there is concern for intracranial clot.

Purpura Fulminans. Purpura fulminans from congenital protein C or protein S deficiency is a dramatic syndrome that usually manifests within hours of birth. Infants develop patchy areas of skin thrombosis over the trunk and buttocks, usually in dependent areas. The lesions are palpable and initially dark red and quickly become dusky purple and then black; an eschar forms. The lesions are exquisitely painful. Most infants with severe protein C deficiency manifest a white light reflex of the eyes from in utero thrombosis of the primary vitreal veins with subsequent retinal detachment, hemorrhage, and blindness.[94] Imaging studies of the brain show evidence of CNS infarction in many infants. Renal vein thrombosis is not uncommon.

Thrombocytosis. Infants rarely manifest signs of thrombocytosis. Occasionally, platelet counts of greater than 2,000,000/μL are associated with cerebral ischemia and may manifest as poor feeding, irritability, lethargy, or a focal neurologic deficit.

LABORATORY EVALUATION

Before initiation of anticoagulation, a CBC including platelets and coagulation studies should be obtained. Because infants have physiologically prolonged baseline aPTT values, low and variable levels of AT, and accelerated drug clearance, anticoagulation with heparin products should be monitored using an anti-Xa activity level, if at all possible. If anti-Xa levels are subtherapeutic on high doses of unfractionated heparin, consider checking the AT level. In addition, infants who are refractory to the anticoagulant effects of unfractionated heparin often manifest an enhanced response to low-molecular-weight heparin. Screening for inherited thrombophilia should be guided by clinical presentation and family history.

Treatment. The optimal therapy for neonatal thrombosis has not been determined. In the absence of any significant contraindications, anticoagulation remains the standard of care for most neonatal thromboses to prevent clot extension, end-organ damage, development of pulmonary embolism, or post-thrombotic syndrome.[111] Anticoagulation must be weighed against the risk of bleeding for each individual case. The duration of anticoagulation is typically 3

months for venous clots and 7 days for arterial clots.[111] Long-term anticoagulation is necessary only in the small proportion of infants who have an ongoing trigger for thrombosis or who have experienced a thrombus recurrence.

Neonates are relatively heparin resistant compared with older children and adults and have baseline AT levels about 50% of the predicted value for adults.[8] Additionally, heparin has accelerated clearance and increased volume of distribution in the neonate, which can make it more difficult to achieve therapeutic anti-Xa levels.[102] Off-label use of AT concentrate has been increasing to help achieve therapeutic anticoagulation in heparin-resistant neonates.[42,151,185,186] Parenteral DTIs, including ***bivalirudin*** and ***argatroban***, do not require AT for therapeutic action. Several prospective studies, which included infants younger than 6 months of age, have been conducted using either *bivalirudin* or *argatroban*.[195,196] These studies found low rates of clinically significant bleeding complications with early clot resolution, although severe bleeding, including intracranial hemorrhage, is an important risk of any anticoagulant, especially in sick preterm infants.[195,196] Large prospective trials into the use of bivalirudin and argatroban in the neonatal population are needed. DTIs should only be used in consultation with hematology.

Thrombolytic, or fibrinolytic, therapy, involves localized or systemic infusion of an activator of the fibrinolytic system, typically tPA. Thrombolytic therapy is intended to rapidly restore blood flow. However, the risk of hemorrhage is greater with thrombolytic therapy, especially in preterm infants. Oozing around catheters is the most common bleeding complication of fibrinolytic therapy, but the most important complication is CNS bleeding, which occurs most often in infants with brain ischemia from a previous episode of asphyxia or hypotension. Thrombolytic therapy, if deemed acceptably safe, may be indicated for life- or limb-threatening aortic thrombosis and thromboses affecting shunts in infants with complex congenital heart disease.[182]

Thrombolytic therapy can also be considered for bilateral renal vein thrombosis,[13] although it should be recognized that many episodes of renal vein thrombosis have onset in utero, and clots may be too organized for effective thrombolysis. Kidney enlargement and certain imaging features can be used to estimate the age of the clot.

Dosing schemes for anticoagulation and fibrinolytic therapy are shown in Box 20.9.

PURPURA FULMINANS

Treatment of neonatal purpura fulminans caused by genetic thrombophilia is replacement of the deficient regulatory protein. Viral-inactivated, human

BOX 20.9 ANTITHROMBOTIC THERAPY IN THE NEONATE

Anticoagulant Therapy

Unfractionated Heparin

Term infants: 75 to 100 U/kg bolus per micromedex.

maintenance of 25-30 U/kg per micromedex; adjusted to maintain anti-Xa activity level of 0.3 to 0.7 U/mL

Preterm infants: 50 U/kg bolus

15 to 35 U/kg/hr maintenance; adjusted to maintain anti-Xa activity level of 0.3 to 0.7 U/mL

Low-Molecular-Weight Heparin (Enoxaparin)

1.5 mg/kg subcutaneously every 12 hours; adjusted to maintain anti-Xa activity level of 0.5 to 1 U/mL 4 hours after injection

Fibrinolytic Therapy

Tissue Plasminogen Activator (tPA)

0.1 to 0.5 mg/kg/hr for 4 to 12 hours (bleeding risk is greater at the higher doses) or 0.06 to 0.12 mg/kg/hr for 12 to 48 hours

Fibrinolytic therapy has been given to neonates both as higher-dose, shorter infusions and lower-dose, longer-term infusions. The higher-dose infusions may be more effective in thromboses that are acute, arterial, and smaller in volume (e.g., aortic or cardiac). Lower, longer infusions may be more efficacious in larger, older, or venous thromboses (e.g., subclavian or extensive vena cava).

Contraindications to tPA: Intracranial hemorrhage, surgery, or ischemia (poor Apgar scores) in previous 10 days; surgery within 7 days; invasive procedures within 72 hours; seizures within 48 hours; active bleeding

Concomitant with tPA, may give heparin 10 U/kg/hr (no bolus) or enoxaparin 0.5 mg/kg every 12 hours subcutaneously

Consider FFP 10 mL/kg every 24 hours to replace plasminogen.

Term infants show the highest dose requirements for unfractionated and low-molecular-weight heparin with increased volume of distribution and more rapid plasma elimination. Extremely preterm infants show the lowest dose requirements.

AT, Antithrombin; *FFP,* fresh frozen plasma; *tPA,* tissue plasminogen activator; *U,* units.

plasma–derived protein C concentrate is FDA approved for severe protein C deficiency. Protein S is currently available only in FFP. The hemophilia center staff members are the best resources for information on the availability and safety of existing replacement proteins. FFP may be administered while confirmatory laboratory assays are being performed, using 10 mL/kg every 8 to 12 hours. Prophylactic replacement with protein C concentrate is currently available for infants with severe genetic protein C deficiency, although some infants may be medically managed with anticoagulation alone after the neonatal period and up until puberty.

Infants with acquired deficiencies of protein C or S caused by autoantibodies may respond to IVIG or steroids in addition to plasma replacement. Infants with sepsis and purpura fulminans may require FFP or protein concentrate until antibiotics have successfully controlled their infection.

Parent Teaching

Parents of infants with severe genetic deficiencies of protein C or S require intensive education regarding the administration and monitoring of anticoagulation therapy, observation for early lesions of purpura fulminans or bleeding, and care and rehabilitation of early lesions. Parents of children without severe thrombophilia, but who will be discharged to home on anticoagulation, require similar teaching about the administration and monitoring of anticoagulation therapy and observation for bleeding complications.

DISSEMINATED INTRAVASCULAR COAGULATION

In DIC, the activation of blood-clotting proteins is initiated by tissue factor from bacterial products (endotoxin) or inflammation (cellular expression through protease activatable receptors) or through the contact system.[139] The activation of clotting proteins leads to a hypercoagulable state, and thromboses form, especially in the small vessels of the liver, spleen, brain, lungs, kidneys, and adrenal glands. The bone marrow and liver partially compensate by releasing platelets and clotting factors into circulation. However, the regulatory system of coagulation is immature in term and preterm neonates. The capacity to neutralize activated clotting proteins is quickly exhausted, and the resulting deficiency of platelets and clotting factors is called ***consumptive coagulopathy***. Thrombocytopenia in an ill infant is often part of the larger syndrome of DIC. DIC predisposes a preterm infant to intracranial hemorrhage.[178] Venous thrombosis of the germinal matrix occurs as the initial lesion, followed by post-thrombotic hemorrhage. Bleeding is also seen in the skin around indwelling catheters, endotracheal tubes, and chest tubes; into the lungs and other parenchyma; and in the urine and stool.

TREATMENT

Transfusion of platelets for infants with thrombosis or DIC may aggravate the platelet consumption unless specific therapy for the underlying condition is also administered. The primary treatment of DIC is reversal of the trigger (Box 20.10). Adequate ventilation, support of circulation and perfusion, treatment of sepsis, and general supportive care usually interrupt the DIC process within 48 hours. Routine infusion of FFP into infants with DIC without clinical bleeding does not improve infant outcomes, although infants with active bleeding require replacement of coagulation proteins and platelets to maintain minimal hemostatic levels.[61] Replacement of coagulation regulatory proteins in FFP or AT concentrate or inhibition of coagulation activation with low-dose heparin have been recommended in various guidelines and may be helpful in some situations.

BOX 20.10 THERAPY OF DISSEMINATED INTRAVASCULAR COAGULATION

1. Reverse the trigger: Treat the underlying disorder.
2. In bleeding infants, maintain hemostatic levels of fibrinogen (>100 mg/dL) and platelets (50,000/μL) using cryoprecipitate, FFP, and platelet concentrates (10 mL/kg). FFP is also indicated to treat bleeding infants with PT greater than 3 seconds above the upper limit of normal.
3. If necessary, replace regulatory proteins; antithrombin or protein C concentrate (50 to 150 U/kg).
4. Consider low-dose heparin therapy 10 U/kg/hr if survival of infused fibrinogen and platelets is less than 12 hours.

FFP, Fresh frozen plasma.

However, in a recent meta-analysis of 1340 adult patients, heparin was found to increase bleeding risk without improving mortality,[190] so coagulation inhibitors should be used with caution.

WHITE BLOOD CELLS

Physiology

White blood cell production in the fetus begins relatively late in human gestation (14 to 16 weeks) and appears to be limited to the bone marrow, in contrast with erythropoiesis, which is found earlier in the liver, spleen, and lymph nodes. The neutrophil reserve pool size is extremely small during the second trimester and increases slowly during gestation. At 18 to 20 weeks, the total fetal white cell count is approximately 4000 with 5% neutrophils.[133] This increases to 8.5%, or 350 absolute neutrophil count, by 26 to 30 weeks. Developmental levels of total granulocytes and neutrophils are shown in Fig. 20.5. Thus a baby born extremely premature has severely limited neutrophil capacity and is at increased risk for overwhelming bacterial infection.

White cell counts rise after normal delivery, with a peak at 12 hours, and gradually decline over the subsequent 48 hours, as shown in Fig. 20.6. Neutrophil counts must be evaluated with respect to postconceptual and postnatal age.

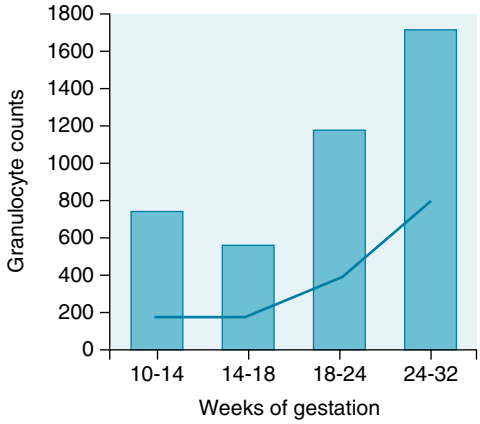

FIGURE 20.5 Mean and range of neutrophil counts at 10 to 14, 14 to 18, 18 to 24, and 24 to 32 weeks of gestation. (From Thomas DB, Yoffe JM. The cellular composition of foetal blood. *Br J Haematol.* 1962;8:290.)

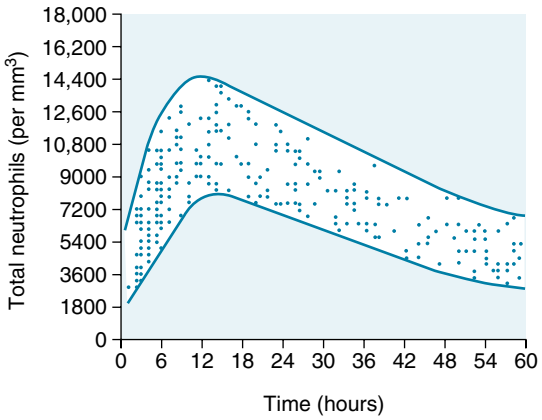

FIGURE 20.6 The total neutrophil count reference range in the first 60 hours of life. (From Monroe BL, Weinberg AG, Rosenfeld CR, et al. The neonatal blood count in health and disease. I. Reference values for neutrophilic cells. *J Pediatr.* 1979;95:89.)

Pathophysiology of Neutropenia

Neonatal neutropenia may be congenital or acquired and result from a decrease in production or survival of neutrophils. The two most common causes of neonatal neutropenia are infection and medication exposure.

Congenital causes of neutropenia include a variety of rare genetic conditions. Severe congenital neutropenia is characterized by myeloid hypoplasia in the bone marrow with an early arrest in maturation and has been linked to mutations in more than 20 genes (e.g. *ELANE, HAX1, GFI1, G6PC3, WAS*).[44] These are usually inherited in an autosomal recessive fashion and may present with isolated neutropenia complicated by severe recurrent bacterial and fungal infections or may be syndromic. Patients with ***Shwachman-Diamond syndrome*** typically present with failure to thrive and exhibit all or part of the classic triad of neutropenia (or other cytopenias), exocrine pancreatic insufficiency, and skeletal anomalies (metaphyseal dysplasia).[48] Patients with ***Chédiak-Higashi syndrome*** have oculocutaneous albinism, peripheral neuropathies, and characteristic large cytoplasmic inclusion granules on a peripheral blood smear. ***Reticular dysgenesis*** is a severe defect leading to absent production of all myeloid cells, including neutrophils, monocytes, macrophages, and lymphocytes. ***Myelokathexis*** is a disorder of intramedullary destruction and release of small numbers of neutrophils with abnormal morphology into

the peripheral circulation. In *dyskeratosis congenita,* an X-linked disorder consisting of nail dystrophy, hyperpigmented dystrophic skin, and leukoplakia, one-third of children develop neutropenia. In *cartilage-hair hypoplasia,* an autosomal recessive syndrome of short-limbed dysostosis, one-fourth of children develop neutropenia or lymphopenia. There are genetic forms of *familial neutropenia* that are more mild and less symptomatic. Most benign congenital neutropenia is not associated with infection and is not often detected in the neonatal period.

Increased destruction of neutrophils is mediated by antibodies, infection, or inflammation. *Congenital acquired neutropenia* can result from maternal lupus or drugs and is found in severe isoimmune hemolytic anemia. *Neonatal isoimmune neutropenia,* similar to NAIT, occurs in about 1 in 1000 live births and is often an incidental finding on CBC. **Most neutropenia developing in the neonatal period results from infection or other stresses, including respiratory distress syndrome and intracranial hemorrhage. Over one-half of infants born to mothers with preeclampsia may be neutropenic. The neutropenia is usually self-limited and may last more than 7 days. Neutropenia in the setting of very low birth weight infants with a history of maternal preeclampsia is associated with increased mortality.**[135] G-CSF can be successfully used to increase the absolute neutrophil count in these patients.[84] However, it is not clear whether cytokine treatment decreases the rates of culture-positive sepsis or mortality.[80,197]

The **most common severe congenital disorder of neutrophil function is *chronic granulomatous disease (CGD).*** CGD results from a mutation impairing NADPH oxidase, which is responsible for the normal oxidative burst within neutrophil phagosomes, rendering them unable to kill ingested bacteria or fungi.[25] Classic CGD is inherited in an X-linked recessive manner and primarily affects male infants, and less common variant forms of CGD are inherited in an autosomal recessive manner. **CGD is characterized by development of recurrent severe infections, primarily with catalase-positive organisms** (e.g. *Staphylococcus aureus, Pseudomonas aeruginosa,* Aspergillus) despite a normal absolute neutrophil count. The **presence of certain types of unusual infections** (e.g. *Burkholderia cepacia, Serratia marcescens, Nocardia*) **should raise suspicion for CGD.** The types of infections typically seen include pneumonias, abscesses, adenitis, and, less commonly, bacteremias.

Leukocyte adhesion deficiency (LAD) may also present during the neonatal period with recurrent bacterial infections of the skin and mucosa, impaired wound healing, absence of pus formation, and delayed separation of the umbilical cord.[43] LAD usually results from a deficiency in the integrins that are involved in the adhesion of neutrophils so they cannot migrate out of the endothelium to the site of infection in the tissue. Laboratory evaluation typically demonstrates neutrophilia with an elevated white blood cell count.

Data Collection

HISTORY

History should include questioning about maternal gestational complications, hypertension, collagen vascular disorders, and medications. Family history of previously affected infants and information about predisposition to or death during childhood from infections are important.

SIGN AND SYMPTOMS

Signs and symptoms of neutropenia follow primarily from related secondary infections. Although older infants may manifest fevers and aphthous ulcers with neutropenia, these are rarely apparent in newborn infants. **Delayed umbilical cord separation can be seen in LAD.**

LABORATORY DATA

The CBC should be obtained with attention to all cell lines. The peripheral smear should be carefully inspected for evidence of abnormal neutrophil morphology. **A bone marrow aspirate and biopsy may be needed** in certain circumstances if there is a high clinical suspicion of severe congenital neutropenia. **Testing of maternal blood for neutrophil antibodies can help confirm the presence of neonatal isoimmune neutropenia.** In patients with suspected neutrophil dysfunction, **a dihydrorhodamine test may be performed to measure the neutrophil oxidative burst.**[98] LAD can be diagnosed based on peripheral blood flow cytometry demonstrating decreased CD18 expression.

Treatment

Infants with neutropenia must be evaluated for sepsis and other infections and **treated with appropriate antimicrobial agents while cultures are pending.**

Immune neutropenia usually does not require any specific therapy in the absence of severe or invasive infections. **Granulocyte–colony stimulating factor (G-CSF) may be used in patients with severe neutropenia who have serious or recurrent infections to increase the absolute neutrophil count.**[37] **CGD is primarily treated with prophylactic antibiotics and antifungals, along with administration of-γ interferon.**[25] Replacement IVIG has a role in defects that also affect the lymphocyte production of antibodies. The role of transfused granulocytes is controversial, and its use is mostly indicated for overwhelming infections with gram-negative organisms in severely neutropenic infants.

Prevention and Parent Teaching

The sequelae of some severe genetic neutropenias can be prevented with bone marrow transplantation. Important **adjuvant approaches for all neutropenic babies include careful attention to hygiene when touching babies, infant skin care to prevent infections and avoid skin trauma, and recognition of early signs.** Most acquired neutropenias in neonates are of short duration. Parents of babies with congenital neutropenia must be instructed about the diagnosis, underlying defect, available treatments, and long-term prognosis.

21 NEONATAL HYPERBILIRUBINEMIA

BEENA D. KAMATH-RAYNE, PATRICIA A. FROESE, AND ELIZABETH H. THILO

Unconjugated hyperbilirubinemia is the most common condition requiring evaluation and treatment in neonates, but for most newborns, it is a benign postnatal transitional phenomenon. Neonatal hyperbilirubinemia manifests as jaundice, the yellow-orange tint usually detected visually in the sclera and skin of infants with total serum bilirubin (TSB) concentration between 6 and 7 mg/dL. Despite the cause-and-effect relationship, the terms *neonatal hyperbilirubinemia* and *neonatal jaundice* are used fairly interchangeably. All infants experience a rise in their serum bilirubin concentration after birth because of brisk red cell turnover and bilirubin formation paired with an immature liver that cannot adequately clear the bilirubin from the blood. It is estimated that about 60% to 80% of normal newborns will appear clinically jaundiced during the first week of life.[55,77] Despite this, the incidence of extreme hyperbilirubinemia and kernicterus is low[17,99] (Box 21.1).

Severe hyperbilirubinemia, defined as TSB above the 95th percentile for age in hours, occurs in 8% to 9% of infants during the first week of life.[14,15] Experience has shown the dangers of excessive concentrations of unconjugated bilirubin, such as the development of bilirubin encephalopathy and the devastating and irreversible effects of kernicterus. An understanding of the pathophysiology and clinical significance of hyperbilirubinemia is critical in the care of newborn infants. This chapter provides the reader with a basic overview of the multiple causes and contributing factors in the development of hyperbilirubinemia; describes the diagnosis, clinical significance, and complications of hyperbilirubinemia; and discusses current treatment modalities and their complications.

PATHOPHYSIOLOGY

Understanding the pathophysiology and clinical significance of hyperbilirubinemia requires an appreciation of normal bilirubin metabolism in the newborn (Fig. 21.1). A newborn produces bilirubin at a rate of 8 to 10 mg/kg/24 hr, which is 2 to 2.5 times the rate in adults. Red blood cells in newborns have a shortened life span of 70 to 90 days, compared with 120 days in adults, and the newborn has a higher red cell mass per kilogram weight compared with the adult. Because the catabolism of *1 g of hemoglobin yields 35 mg of bilirubin,* this accelerated red blood cell breakdown

BOX 21.1 PREVALENCE OF EXTREME HYPERBILIRUBINEMIA AND KERNICTERUS

- TSB >15 mg/dL: 8%–10% of newborns
- TSB >20 mg/dL: 1.2% of newborns
- TSB >25 mg/dL: 1/770 (0.13%) newborns
- TSB >30 mg/dL: 1/10,000 (0.01%) newborns
- Kernicterus (approx.): 1/100,000 (0.001%)
  - TSB >25 mg/dL: 1/18 (5%)
  - TSB >30 mg/dL: 1/7 (15%)
  - TSB >35 mg/dL: all have sequelae (100%)

TSB, Total serum bilirubin.

Data modified from Bhutani VK, Johnson LH, Keren R. BLUE type highlights content that is particularly applicable to clinical settings.

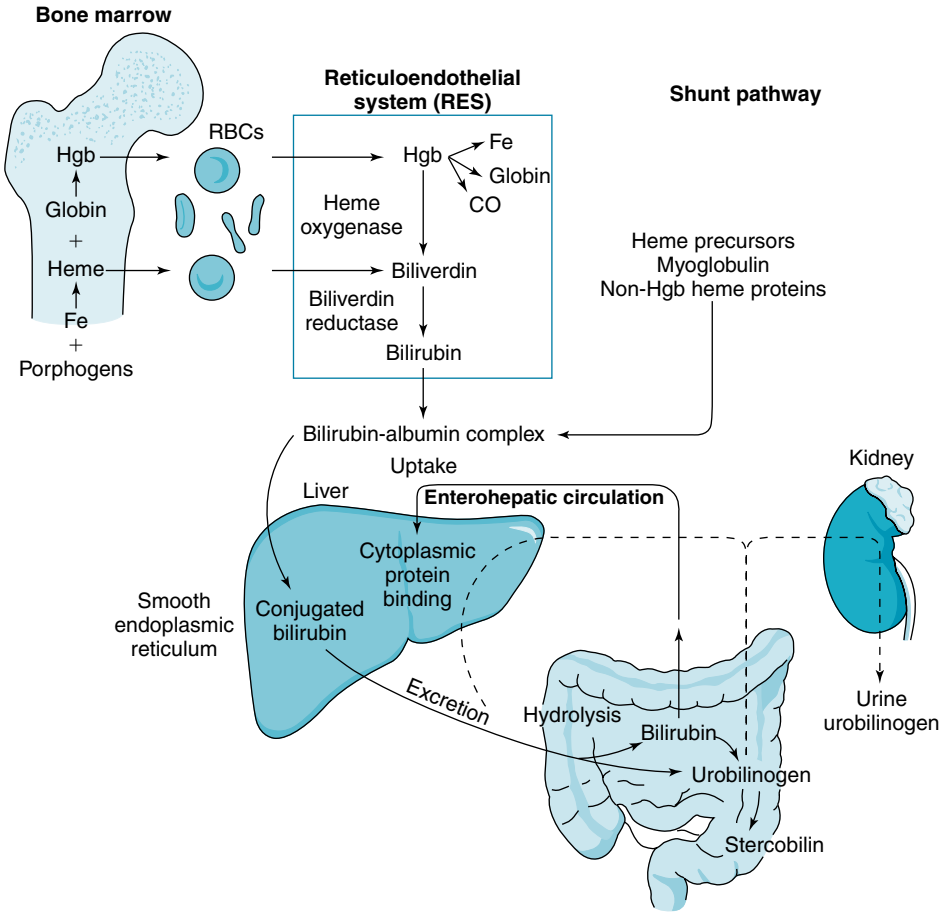

FIGURE 21.1 Bilirubin physiology: pathways of bilirubin production, transport, and metabolism. *Fe,* Iron; *Hgb,* hemoglobin; *RBC,* red blood cells; *CO,* carbon monoxide. (Modified from Gartner LM, Hollander M. Disorders of bilirubin metabolism. In: Assali NS, ed. *Pathophysiology of Gestation.* Vol 3. New York, NY: Academic Press; 1972.)

produces most of the bilirubin (75% to 85%) in newborns. The remaining 15% to 25% of bilirubin is derived from nonerythroid heme proteins found principally in the liver, and heme precursors in the marrow and extramedullary hematopoietic areas that do not go on to form red blood cells (referred to as "early peak" or "shunt" bilirubin).

Bilirubin metabolism begins in the reticuloendothelial system, principally in the liver and spleen, as senescent or abnormal red blood cells are removed from the circulation. The enzyme *heme oxygenase* acts on heme to produce biliverdin, and *biliverdin reductase* then converts biliverdin into bilirubin. This **bilirubin, in its unconjugated or indirect-reacting form, is released into the plasma**, where it is bound to albumin for transport. Exhaled carbon monoxide is a by-product of these pathways.

At a normal plasma pH, bilirubin is very poorly soluble and binds tightly to the circulating carrier protein albumin. Albumin contains one high-affinity site for bilirubin and one or more sites of lower affinity. **Bilirubin binds to albumin in a molar ratio of between 0.5 and 1 mole of bilirubin per mole of albumin. A bilirubin/albumin molar ratio of 1 corresponds to approximately 8.5 mg bilirubin/g of albumin. This ratio is likely to be lower in a sick very-low-birth-weight (VLBW) infant, who is also likely to have a lower serum albumin concentration**[26] than a healthy term newborn. It is important to note that the TSB is

the concentration of albumin-bound bilirubin; the concentration of unconjugated, unbound bilirubin ("free bilirubin") is potentially more important in prediction of neuronal injury, but measurement is not yet commercially available.[4]

Bilirubin bound to albumin is carried to the liver and dissociates from circulating albumin before entering the liver cell. The process of entering the liver cell occurs partly by passive carrier-mediated diffusion involving the sinusoidal transporter SLCO1B, and partly by mediation of organic anion transporter proteins (OATPs). In the liver cell cytoplasm, the unconjugated bilirubin binds to glutathione-S-transferase A, also known as *ligandin,* or with B-ligandin (Y protein). These are major intracellular transport proteins, and their bilirubin binding ability helps keep the potentially toxic unbound portion low. Z protein, another hepatic cytoplasmic carrier, also binds bilirubin, but with lower affinity.[96] Conjugation occurs within the smooth endoplasmic reticulum of the cell. This reaction, catalyzed by the enzyme *uridine diphosphate glucuronosyltransferase (UGT-1A1),* leads to the formation of water-soluble compounds called *bilirubin glucuronides.* UGT-1A1 is the predominant isoenzyme and arises from the *UGT1* gene complex on chromosome 2 (2q37).[95] In addition to UGT-1A1, conjugation requires glucuronic acid synthesized from glucose. Conjugated bilirubin is then actively secreted into bile and passes into the small intestine.

Conjugated bilirubin is not reabsorbed from the intestine, but the mucosal brush border of the newborn contains the enzyme *beta-glucuronidase,* which can convert conjugated bilirubin back into glucuronic acid and unconjugated bilirubin, which may then be absorbed. This pathway constitutes the enterohepatic circulation of bilirubin and contributes significantly to an infant's bilirubin load.

Factors That Affect Bilirubin Levels

A number of different factors affect the ability of albumin to bind bilirubin, including plasma pH, free fatty acid concentrations, and certain drugs, particularly sulfonamides and ceftriaxone. Albumin binding of unconjugated bilirubin may be important in the prevention of bilirubin toxicity, by limiting the amount of unbound, unconjugated bilirubin available for causing neuronal damage.[4,60,73] Consequently, serum albumin concentration may be measured as an estimate of available binding capacity, perhaps allowing a better estimation of the concentration at which aggressive phototherapy and exchange transfusion should be considered in a particular infant.[8]

A rise in bilirubin levels shortly after birth is partially attributable to a relative deficiency of UGT-1A1 activity (0.1% of adult levels at 30 weeks of gestation, 1% of adult levels by 40 weeks of gestation). Enzyme activity increases rapidly after birth independent of the infant's gestational age, achieving adult concentrations by 14 weeks of age.[95] Newborn monkeys have been shown to be deficient in the intracellular Y and Z proteins for the first few days of life, and this also may occur in the human newborn. The hormonal (estrogen) environment of the infant may also inhibit liver function and bilirubin secretion.

Certain ethnic groups, including Eskimo, Asian, and Native American, have an increased incidence and severity of hyperbilirubinemia for reasons that are not completely understood, but are likely related to genetic polymorphisms involving UGT-1A1 activity.[43,96] The presence of *beta-glucuronidase* in the bowel lumen during fetal life enables bilirubin to be reabsorbed and transported across the placenta for excretion by the maternal liver; its presence in the neonate, however, contributes to an excessive enterohepatic circulation of bilirubin.

Physiologic Jaundice

Debate and controversy remain over efforts to define normal or physiologic ranges of TSB concentrations in full-term newborn infants, because the data are affected by multiple variables. Traditionally, a distinction has been made between physiologic jaundice and hyperbilirubinemia that is either pathologic in origin or severe enough to warrant further evaluation and intervention. **Data from multiple studies consider that the 97th percentile of maximal TSB concentration in healthy mature newborns is 12.4 mg/dL for formula-fed infants and 14.8 mg/dL for breastfed infants.[6,9,65] Any TSB elevation exceeding 17 mg/dL should be presumed pathologic and warrants investigation** for a cause and possible therapeutic intervention, such as phototherapy.

In the normal full-term newborn, the clinical course of physiologic jaundice is characterized by a progressive increase in TSB concentration from about 2 mg/dL in cord blood to a mean peak of 5 to 6 mg/dL between 3 and 4 days of life *(phase I physiologic*

jaundice). This is followed by a decline to about 3 mg/dL toward the end of the first week of life and then continues with a period of very slowly declining TSB concentration until reaching the normal adult level of less than 2 mg/dL at the end of the second week of life *(phase II physiologic jaundice)*. **Several criteria have been proposed that can be used to exclude the diagnosis of physiologic jaundice in a full-term infant: (1) clinical jaundice in the first 24 hours of life, (2) TSB concentration that increases more than 0.2 mg/dL per hour, (3) TSB concentration exceeding the 95th percentile for age in hours, (4) direct-reacting bilirubin levels exceeding 1.5 to 2 mg/dL, or (5) clinical jaundice persisting for more than 2 weeks.** However, absence of these criteria does not guarantee that the jaundice is physiologic.

ETIOLOGY OF HYPERBILIRUBINEMIA

Excessive bilirubin concentrations occur in newborn infants by three main mechanisms: increased production (accelerated red blood cell breakdown), decreased excretion (transient UGT-1A1 insufficiency),[80] and increased reabsorption (enterohepatic circulation) (Box 21.2). The normal pathways of bilirubin metabolism described earlier account for much of the increase in bilirubin concentrations in newborn infants; however, there are circumstances that deserve evaluation in infants who have a more prolonged hyperbilirubinemia.

From a management perspective, **it is helpful to describe nonphysiologic hyperbilirubinemia according to its time of onset, early (first 24 to 48 hours) or late (after 48 to 96 hours), to determine its specific etiology.** In general, early-onset nonphysiologic hyperbilirubinemia is associated with increased bilirubin production, whereas later-onset hyperbilirubinemia is often associated with delayed bilirubin elimination with or without increased bilirubin production (Fig. 21.2).[50]

Overproduction of Bilirubin

HEMOLYTIC DISEASE OF THE NEWBORN

Hemolytic disease of the newborn may occur when blood group incompatibilities in Rh,

BOX 21.2 CAUSES OF HYPERBILIRUBINEMIA

Overproduction
- Hemolytic disease of the newborn (antibody-mediated hemolysis: Rh, ABO, Kell, Duffy)
- Hereditary hemolytic anemia
  - Membrane defects (spherocytosis, elliptocytosis, pyknocytosis)
  - Hemoglobinopathies
  - Enzyme defects (G6PD deficiency)
- Polycythemia
- Extravascular blood
  - Swallowed
  - Bruising or enclosed hemorrhage (e.g., cephalohematoma)
- Increased enterohepatic circulation (prematurity, delayed feedings, bowel obstruction)

Slow Excretion
- Decreased hepatic uptake
  - Decreased sinusoidal perfusion
  - Ligandin deficiency and SLCO1B1 deficiency
- Decreased conjugation
  - UGT-1A1 deficiency (Crigler-Najjar syndrome, Gilbert syndrome)
  - Enzyme inhibition, such as Lucey-Driscoll syndrome
- Inadequate transport out of hepatocyte
- Biliary obstruction (Dubin-Johnson syndrome, Rotor syndrome, biliary atresia)

Combined (Overproduction and Slow Excretion)
- Bacterial infection
- Congenital intrauterine infection

Breastfeeding
- Breastfeeding jaundice ("lack of breast milk" jaundice)
- Breast milk jaundice

Physiologic

Miscellaneous
- Galactosemia
- Hypothyroidism
- Infant of diabetic mother

FIGURE 21.2 Differential diagnosis of severe neonatal hyperbilirubinemia based on pathophysiology and timing at presentation. *G6PD,* Glucose-6-phosphate dehydrogenase; *TSB,* total serum bilirubin. (Modified from Smitherman H, Stark AR, Bhutani VK. Early recognition of neonatal hyperbilirubinemia and its emergent management. *Semin Fetal Neonatal Med.* 2006;11(3):214.)

ABO, or minor blood groups exist between a mother and her fetus (see Chapter 20). The classic example of hemolytic disease of the newborn has been erythroblastosis fetalis occurring as a result of Rh incompatibility. Fifteen percent of the white population is Rh negative. When an Rh-negative mother is sensitized to the Rh antigen after a blood transfusion or a fetal-maternal sensitization during pregnancy, delivery, abortion, or amniocentesis, the presence of the Rh antigen induces maternal antibody production. **Because prior sensitization with the Rh antigen is necessary for maternal antibody production, the first Rh-positive infant usually is not affected. Once a mother is sensitized, an anamnestic response to further exposure causes maternal immunoglobulin G (IgG) to cross the placenta into the fetal circulation, where it reacts with the Rh antigen on fetal erythrocytes. These antibody-coated cells are recognized as abnormal and destroyed by the fetal spleen.** This results in increased production of heme requiring metabolic degradation. As the destruction of erythrocytes and production of bilirubin progress, severe anemia and congestive heart failure can ensue, progressing to hydrops fetalis. **Fortunately, the use of anti-D gamma globulin (RhoGAM), particularly antenatal administration at 26 to 28 weeks of gestation to prevent sensitization of nonsensitized pregnant Rh-negative women, has markedly decreased the incidence of Rh isoimmunization in newborn infants.**

After the widespread use of RhoGAM, the most frequent cause of hemolytic disease of the newborn is now ABO blood group incompatibility. ABO incompatibility is limited to mothers of blood group O and affects infants of blood group A or B. All group O individuals

have naturally occurring anti-A and anti-B (IgG) antibodies, so specific sensitization is not necessary. The resulting hyperbilirubinemia in the newborn is highly variable and generally milder than that seen with Rh incompatibility. Although some 15% of pregnancies are a "set-up" for ABO incompatibility (mother O, baby A or B), only 33% of these infants show a positive direct antiglobulin test (DAT), and only 15% of these have clinically significant hemolysis and hyperbilirubinemia. If the DAT is negative, these infants, as a group, do not have an increased incidence of significant hyperbilirubinemia compared with non–ABO-incompatible infants.[95]

HEREDITARY HEMOLYTIC ANEMIAS

Erythrocytes with abnormal membranes or containing abnormal hemoglobin variants have increased rates of destruction. Individuals with *membrane defects,* such as spherocytosis, elliptocytosis, stomatocytosis, and pyknocytosis, cannot maintain the integrity of red blood cells because of abnormal osmotic fragility (generally increased) and an increased rate of splenic destruction (see Chapter 20). A mean corpuscular hemoglobin concentration (MCHC) greater than 36.5 to 37 g/dL or a ratio of MCHC:MCV (the HS index) greater than 0.36 may be clues to the diagnosis of hereditary spherocytosis.[27,95]

***Glucose-6-phosphate dehydrogenase (G6PD) deficiency* is the most common enzyme defect and is more commonly found in certain racial and ethnic groups, including East Asian, Mediterranean, and African peoples.** Pyruvate kinase deficiency is much less common. G6PD deficiency affects some 400 million individuals worldwide.[19] **In areas where G6PD is prevalent, it is the most common and most severe risk factor for hyperbilirubinemia.[5] G6PD deficiency is also common in the United States, with an estimated overall incidence of 3.4%.** Up to 12.5% of African-American males and 4% of African-American females are G6PD deficient.[20] Although G6PD deficiency is an X-linked recessive disease affecting primarily males and homozygous females, heterozygous females may also be phenotypically deficient as a result of X chromosome inactivation. **Affected infants may occasionally present with acute hemolysis and severe hyperbilirubinemia in response to exposure to an oxidative trigger (infection, starvation, or drug exposure, notably sulfonamides), but more commonly present with later-onset (end of first week of age) hyperbilirubinemia without significant anemia.**[100] The combination of G6PD deficiency with Gilbert's disease (another common genetic variation involving partial UGT-1A1 deficiency) makes infants especially prone to the development of later-onset severe hyperbilirubinemia without significant hemolysis or anemia.[47,94]

Individuals with *hemoglobinopathies,* which can be diagnosed by hemoglobin electrophoresis, may also have increased splenic destruction of red blood cells, although most of these do not manifest clinically in the newborn period. The exceptions are the alpha-thalassemia syndromes wherein three or four of the four alpha globin genes are affected, resulting in hemoglobin H disease (three genes affected) or homozygous alpha-thalassemia (absence of all four genes). Hemoglobin H disease can manifest as hemolysis and anemia in the neonate, and homozygous alpha-thalassemia regularly causes severe hemolysis, anemia, hydrops fetalis, and death.[95] Family history is positive in as many as 80% of cases.

POLYCYTHEMIA

In the presence of *polycythemia (a central venous hematocrit greater than 65%),* an increased red blood cell mass, coupled with the shortened life span of red blood cells in newborns, results in an increased bilirubin load. Polycythemia may be idiopathic, or it may occur as a result of a placental transfusion, twin-to-twin transfusion, or chronic in utero hypoxia.

EXTRAVASCULAR BLOOD

Enclosed hemorrhage includes cephalohematoma, subgaleal hemorrhage, cerebral hemorrhage, adrenal hemorrhage, intraabdominal or retroperitoneal bleeding, or extensive bruising. As these enclosed hemorrhages resolve, red blood cells trapped within are broken down and add to bilirubin production. Swallowed maternal blood is another possible source of increased bilirubin load.

INCREASED ENTEROHEPATIC CIRCULATION

As mentioned earlier, the intestinal brush border contains the enzyme *beta-glucuronidase,* which can convert conjugated bilirubin back into its unconjugated (absorbable) form plus glucuronic acid. **Meconium contains a substantial amount of bilirubin, estimated at 1 mg of bilirubin per 1 g of meconium, or a total load of 100 to 200**

mg. Any delay in the passage of meconium, as can occur with prematurity, delayed feedings, or bowel obstruction, increases the bilirubin load that must be metabolized. Hyperbilirubinemia requiring treatment due to these causes is rarely evident in the first 24 to 48 hours of life.

Slow Excretion of Bilirubin

Infants with normal bilirubin production rates may be unable to excrete it efficiently for a variety of reasons, as described in the following conditions.

DECREASED HEPATIC UPTAKE OF BILIRUBIN

Diminished hepatic uptake of bilirubin may be a result of inadequate perfusion of hepatic sinusoids or of deficient carrier proteins (Y and Z). *Inadequate perfusion* of hepatic sinusoids occurs when there is a shunt through a persistent ductus venosus or there is an extrahepatic portal vein thrombosis, or with hyperviscosity, hypovolemia, or severe congestive heart failure. *Functional deficiency* of the transporter proteins may be caused by certain drugs and compounds (e.g., steroid hormones, free fatty acids, chloramphenicol) that competitively bind to them. Although Y and Z proteins are decreased in some newborn primates, no actual deficiency has yet been demonstrated in the human newborn.

DECREASED BILIRUBIN CONJUGATION

Decreased bilirubin conjugation may be a result of *UGT-1A1 deficiency,* as in Crigler-Najjar syndrome or Gilbert syndrome.[86] These disorders are caused by defects in the *UGT-1A1* gene complex on chromosome 2. These diseases may represent a continuous spectrum of severity. *Crigler-Najjar syndrome* is rare and exists in two forms with either complete (type I) or partial (type II) absence of enzymatic activity. Type I is an autosomal recessive disorder, resulting in an inactive UGT-1A1 enzyme, putting the infant at significant risk of bilirubin encephalopathy. Lifelong phototherapy becomes ineffective in preventing toxicity, and liver transplantation is the only possible cure. Type II Crigler-Najjar syndrome is characterized by low but detectable concentrations of the enzyme and more moderate degrees of hyperbilirubinemia.[95] It is inherited as an autosomal dominant disorder and responds to enzyme induction with phenobarbital.

Gilbert syndrome is a milder and very common autosomal dominant disorder with partial UGT-1A1 enzyme activity caused by a number of polymorphisms in the *UGT-1A1 promoter sequence,* usually involving the number of TA base pair repeats. As the number of TA repeats increases above the normal 6, UGT-1A1 activity declines.[94] Approximately 9% of the US population is homozygous for the promoter sequence polymorphism responsible for Gilbert's syndrome and shows a 50% reduction in UGT-1A1 activity, whereas 42% of the population is heterozygous and shows a 37% reduction in enzyme activity. **Although Gilbert syndrome generally manifests after the newborn period with mild bilirubin elevation during times of stress, fasting, or intercurrent illness, it is also an important contributing factor in cases of later-onset severe hyperbilirubinemia, even in the absence of significant hemolysis.[86]** In the neonate, where TSB is a delicate balance between production and elimination, even a small decrease in bilirubin elimination can have a major impact on degree of hyperbilirubinemia. **Although neither G6PD deficiency nor Gilbert syndrome alone is associated with an increased incidence of hyperbilirubinemia, both occurring together are associated with severe hyperbilirubinemia.[20,99]**

INADEQUATE TRANSPORT OUT OF THE HEPATOCYTE

Dubin-Johnson syndrome (DJS) and Rotor syndrome[82] are genetically inherited conditions that are both autosomal recessive and have a similar phenotype in which individuals can conjugate bilirubin normally but cannot excrete it, leading to a mixed hyperbilirubinemia. In DJS, there is impairment in the biliary excretion of organic anions (except bile acids). Rotor syndrome has a different underlying mechanism, with impaired hepatocellular storage of conjugated bilirubin. **Both conditions are considered benign and do not require treatment.** Liver biopsy is not recommended as it will be unlikely to show abnormalities. Urine coproporphyrin excretion is helpful to differentiate the two disorders: in DJS, coproporphyrin concentrations will be normal, but composed predominantly of coproporphyrin I, as opposed to coproporphyrin III as seen in normal individuals. In Rotor syndrome, the total urine coproporphyrin concentration is 2 to 5 times the normal amount, with the majority being coproporphyrin I.

BILIARY OBSTRUCTION

Biliary obstruction often presents a diagnostic challenge requiring differentiation between generalized hepatocellular damage and mechanical obstruction.

A variety of disorders can cause hepatocellular damage, including infections, such as hepatitis, and metabolic disorders, such as galactosemia. **In the neonatal intensive care unit (NICU), the most common cause of hepatocellular damage is the use of parenteral nutrition.** The mechanism is not well established, but the injury takes at least 2 weeks to develop and is especially prominent in VLBW infants. Biliary atresia or, much less frequently, a choledochal cyst, can cause mechanical obstruction to bile flow, resulting in a conjugated hyperbilirubinemia with *light-colored stools*.

Combined Overproduction and Slow Excretion

INFECTIONS

Bacterial infections (sepsis neonatorum, especially necrotizing enterocolitis and urinary tract infection caused by toxin-producing organisms such as certain strains of *Escherichia coli*) or intrauterine viral infections can result in increased bilirubin production and decreased hepatic clearance.

Intrauterine infections, including syphilis, toxoplasmosis, rubella, cytomegalovirus, herpes simplex, coxsackie B virus, and hepatitis virus, cause clinical jaundice with evidence for hepatocellular damage (elevated liver enzymes, poor synthetic function, coagulopathy). Infants with these infections often have additional clinical signs of their infection such as thrombocytopenia and rash.

INFANT OF A DIABETIC MOTHER

The cause of hyperbilirubinemia in an infant of a diabetic mother (IDM) appears to be multifactorial. **In addition to prematurity and a tendency to feed poorly, leading to delayed intestinal motility and enhanced enterohepatic circulation, an IDM may have an increased bilirubin load as a result of an expanded red blood cell mass.** Erythrocyte membrane composition may be altered, and macrosomic infants often are bruised during labor and delivery. Evaluation of exhaled carbon monoxide (CO) in IDM infants has consistently shown evidence for increased production of bilirubin.[82]

Jaundice Associated With Breastfeeding

Numerous studies have reported an association between exclusive breastfeeding and an increased incidence and severity of hyperbilirubinemia, both during the first few days of life and as a cause of prolonged neonatal jaundice.[8,41,95] Breastfed infants are several times more likely to have TSB concentrations greater than 12 mg/dL than infants who are formula fed (13% vs. 4%). As such, **exclusive breastfeeding, particularly if nursing is not going well and weight loss is excessive, is listed as a major hyperbilirubinemia risk factor. Promotion and support of successful breastfeeding constitute key elements of the American Academy of Pediatrics (AAP) clinical practice guideline on the management of hyperbilirubinemia.**[5] **Ideally, a trained observer should evaluate all breastfed infants within 48 to 72 hours of discharge in either a home or office setting.** Early discharge of breastfed infants with inadequate follow-up may result in extreme hyperbilirubinemia and kernicterus, even in the absence of hemolysis.[17]

Two separate patterns of jaundice in breastfeeding infants have been described. The first has been termed *breastfeeding-associated jaundice* and the second *breast milk jaundice*.

BREASTFEEDING-ASSOCIATED JAUNDICE

It is important to recognize that not all breastfed infants will receive optimal milk intake during the first few days of life; as many as 10% to 18% of exclusively breastfed newborns lose more than 10% of birth weight.[32] **It has been postulated that this early jaundice is related to decreased caloric and fluid intake from colostrum (sometimes called "lack of breast milk" jaundice)**[41] **and increased enterohepatic circulation resulting from low stool output and breast milk containing beta-glucuronidase.**[8,72] Many studies show a relationship between the degree of hyperbilirubinemia and the amount of weight lost by the infant after birth.[1,94] Breastfeeding-associated jaundice, however, is not caused by increased bilirubin production.

Optimal management of a breastfeeding mother and infant includes early (initiation in the first hour after birth) and frequent nursing

(8 to 12 times each day). If the infant is unable to feed this frequently, the mother should be instructed in the regular use of a mechanical breast pump to improve her milk supply, and the infant should be supplemented with expressed breast milk or formula to improve nutritional status and intestinal motility.

BREAST MILK JAUNDICE

Breast milk jaundice is a benign condition that resolves without treatment. Such infants have an unconjugated hyperbilirubinemia (less than 12 mg/dL) that becomes exaggerated and persistent toward the end of the first week of life.[71] **Infants with breast milk jaundice are otherwise healthy, with normal weight gain, normal stool and urine output, a normal physical examination, and no other underlying etiology for the hyperbilirubinemia.** If concentrations are higher than 12 mg/dL and persist for several weeks, or if there is an elevation of direct or conjugated bilirubin concentration, other causes of hyperbilirubinemia need to be investigated. For the vast majority of infants, it is not necessary to interrupt breastfeeding, even if the bilirubin increases to concentrations that require phototherapy.

Lactation failure is not present in affected infants, suggesting that other possible mechanisms may be operative in breast milk jaundice. No specific inhibitor or inhibitory substance has been identified in mother's breast milk, but animal models suggest that mature breast milk may increase unconjugated bilirubin concentration by enhancing the enterohepatic circulation. **Breast milk may act as an environmental modifier for selected genotypes (for example, those with Gilbert polymorphism and/or G6PD deficiency)** and thereby potentially predispose to the development of marked neonatal jaundice.[90,91,94]

HYPERBILIRUBINEMIA IN PREMATURE INFANTS LESS THAN 35 WEEKS' GESTATIONAL AGE

Preterm infants are at higher risk for hyperbilirubinemia because of increased bilirubin production, delays in bilirubin elimination, and altered bilirubin-albumin binding.[21,98] Immaturity of UGT-1A1 activity is the primary cause of hyperbilirubinemia in preterm infants.[48] UGT-1A1 is progressively less active with decreasing gestational age.[48]

Prematurity in association with bilirubin toxicity can lead to long-term neurodevelopmental impairments.[21,48] These impairments can be manifested by the syndrome of bilirubin-induced neurologic dysfunction (BIND), which includes auditory neuropathy and visuomotor processing disorders.[21] **Bilirubin may have a higher propensity to cross the blood-brain barrier in preterm infants than in term infants because of differences in albumin binding and lower concentrations of albumin, potentially leading to kernicterus, even with bilirubin levels below usual treatment thresholds.[48]**

Late-preterm infants are overrepresented in the Pilot USA Kernicterus Registry.[44] Neonatal hyperbilirubinemia in late-preterm newborns is more prevalent, more pronounced, and more protracted than in their term counterparts. Late-preterm gestation (34 0/7 to 36 6/7 weeks) is one of the most prevalent identified risk factors for the development of severe hyperbilirubinemia and kernicterus,[15, 25] because these infants have an approximately eightfold increased risk of developing a TSB greater than 20 mg/dL (5.2%) compared with those born at 41 or more weeks of gestation (0.7%). **Many late-preterm infants will also be breastfed, and they frequently are cared for in normal newborn nurseries,** despite the fact that they remain relatively immature compared with term newborns in their capacity to handle unconjugated hyperbilirubinemia.[16]

Miscellaneous Causes

The following causes of hyperbilirubinemia are uncommon but important to consider in infants who have no other clear etiology to explain their elevated bilirubin levels. These conditions include **hypothyroidism and galactosemia.** Newborn genetic screening now routinely includes these conditions, because early detection allows intervention before permanent adverse neurologic injury occurs. **Hyperbilirubinemia, unconjugated or mixed, may be the initial sign of these conditions.**

MECHANISMS OF BILIRUBIN NEUROTOXICITY

Identification of infants at risk for severe hyperbilirubinemia enables clinicians to provide timely intervention to prevent neuronal injury. The AAP has described risk factors for hyperbilirubinemia, which are shown in Box 21.3.[8] **The most**

BOX 21.3 RISK FACTORS FOR HYPERBILIRUBINEMIA IN NEWBORNS

Major Risk Factors

- Predischarge TSB or TcB level in the high-risk zone
- Jaundice observed in the first 24 hours of life
- Blood group incompatibility with positive direct antiglobulin test, other known hemolytic disease (e.g., G6PD deficiency), elevated ETCOC
- Gestational age 35 to 36 weeks
- Previous sibling received phototherapy
- Cephalohematoma or significant bruising
- Exclusive breastfeeding, especially if nursing is not going well and weight loss is excessive
- East Asian race*

Minor Risk Factors

- Predischarge TSB or TcB level in the high intermediate-risk zone
- Gestational age 37 to 38 weeks
- Jaundice observed before discharge
- Previous sibling with jaundice
- Macrosomic infant of a diabetic mother
- Maternal age ≥25 years
- Male gender

Decreased Risk

These factors are associated with decreased risk for significant jaundice, listed in order of decreasing importance.

- TSB or TcB level in the low-risk zone
- Gestational age ≥41 weeks
- Exclusive bottle feeding
- Black race*
- Discharge from the hospital after 72 hours

*Race as defined by mother's description.

ETCOC, End-tidal carbon monoxide corrected; *G6PD,* glucose-6-phosphate dehydrogenase; *TcB,* transcutaneous bilirubin; *TSB,* total serum bilirubin.

From American Academy of Pediatrics. Subcommittee on Hyperbilirubinemia. Clinical Practice Guideline. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics* 2004;114(1):297.

important determinants of brain injury caused by hyperbilirubinemia are the concentrations of unconjugated bilirubin and free bilirubin, the concentration of serum albumin and its ability to bind unconjugated bilirubin, the concentration of hydrogen ion (pH), and neuronal susceptibility.[78] Although the TSB concentration alone is of limited value in predicting neurologic impairment and kernicterus, the use of the bilirubin:albumin ratio does not appear to predict neurodevelopmental outcomes in preterm infants better than TSB alone.[95] Although levels of unbound or free bilirubin seem to be more associated with abnormal hearing tests and may prove to be a better predictor of bilirubin toxicity than TSB, this measurement is not available clinically.[3] There is also no agreement on a "threshold" above which injury always occurs.[4] Finally, photoisomers, which account for up to 25% of circulating TSB during phototherapy, may affect albumin binding and the amount of unbound bilirubin available to enter the central nervous system, but the presence and effects of these compounds are largely unknown.

Nevertheless, unbound bilirubin appears to induce a variety of cellular events that result in neurotoxicity. Unbound bilirubin affects neurons, astrocytes, microglia, and oligodendrocytes, resulting in increased apoptosis in all cell lines, decreased arborization by neurons, release of proinflammatory cytokines by astrocytes and microglia, and decreased myelin synthesis by oligodendrocytes.[23,96]

Interpretation of High Bilirubin Concentrations

All bilirubin concentrations should be interpreted according to the infant's age in hours. The AAP recommends a nomogram that designates risk for newborn infants at 35 weeks or greater according to TSB obtained at varying postnatal ages in hours. The nomogram (Fig. 21.3), based on work by Bhutani et al., designates whether an infant is at high, intermediate, or low risk for requiring further intervention for hyperbilirubinemia, based on the TSB concentration.[8,14] **Universal screening combined with use of the hour-specific bilirubin nomogram has been shown to accurately predict and prevent severe hyperbilirubinemia.[12]** However, the nomogram includes only infants at and above 35 weeks' gestational age from a single institution with a primary outcome of TSB greater than 20 mg/dL, not bilirubin encephalopathy.[39] More premature infants have a slightly later peak and are at risk for adverse neurologic outcomes at lower levels of bilirubin than mature infants.

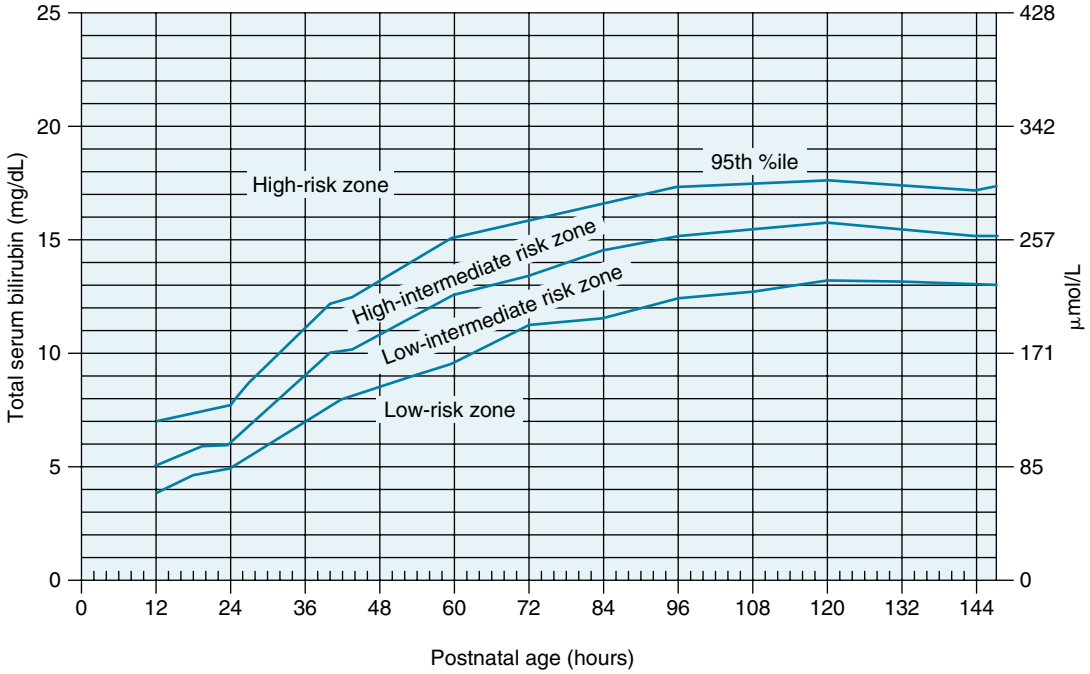

FIGURE 21.3 Nomogram for designation of risk in 2840 well newborns at 36 or more weeks' gestational age with birth weight of 2000 g or more or 35 or more weeks' gestational age with birth weight of 2500 g or more based on hour-specific serum bilirubin levels. The serum bilirubin level was obtained before discharge, and the zone in which the value fell predicted the likelihood of a subsequent bilirubin level exceeding the 95th percentile (high-risk zone). *%ile,* Percentile. (From Bhutani VK, Johnson L, Sivieri EM. Predictive ability of a predischarge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns. *Pediatrics.* 1999;103(1):6.)

PREVENTION OF HYPERBILIRUBINEMIA

Early Feeding

Compared with infants not fed during the first 24 to 48 hours of life, infants fed earlier have lower peak bilirubin levels, likely related to a decrease in intestinal transit time and decreased enterohepatic circulation. Early initiation of breastfeeding in the first hour helps establish lactation and set a pattern of frequent feeding.[51]

RhoGAM

As described earlier, widespread use of RhoGAM has proven effective in preventing the sensitization of Rh-negative mothers after delivery or abortion of Rh-positive infants. RhoGAM, or anti-D gamma globulin, provides passive protection by preventing maternal production of anti-Rh antibodies that might affect subsequent Rh-positive pregnancies, causing destruction of fetal red blood cells. Failures may occur if the amount of RhoGAM administered is insufficient compared with the load of fetal red blood cells received, or if a significant fetal-maternal hemorrhage occurred before prophylaxis. Routine management of the Rh-negative mother now includes the administration of antenatal RhoGAM in the second trimester (26 to 28 weeks), at the time of amniocentesis, and after delivery if the neonate is Rh positive.

Phenobarbital

Phenobarbital acts to induce microsomal enzymes, increasing the levels of UGT-1A1. It also stimulates bile secretion in infants with nonobstructive cholestasis and increases the concentration of ligandin. When used in conjunction with phototherapy, however, phenobarbital does not increase the rate of decline in bilirubin

levels.[29] Phenobarbital treatment is indicated in infants with Crigler-Najjar syndrome type II, but is otherwise not used on a routine basis.

Heme Oxidase Inhibitors

Metalloporphyrins, compounds that are potent competitive inhibitors of the enzyme *heme oxygenase,* the initial and rate-limiting step in bilirubin production, have been investigated as possible interventions for prevention of hyperbilirubinemia by modulating bilirubin production.[83] Only tin protoporphyrin (SnPP) and tin mesoporphyrin (SnMP) have been studied in humans for prevention of neonatal unconjugated hyperbilirubinemia. Although highly efficacious, SnPP had photosensitizing properties that made it less appealing. Although SnMP is also photosensitizing, its use at lower doses reduces photoreactivity. **Human trials with SnMP in preterm neonates have shown a dose-dependent reduction in peak bilirubin levels irrespective of gestational age and a reduction in the need for phototherapy.**[49,62,89] The efficacy of SnMP has been well described in patients with Crigler-Najjar syndrome. Other alternative metalloporphyrins and nonmetalloporphyrins are currently being investigated; however, further trials in humans to determine long-term safety and effectiveness are necessary before widespread use can be recommended.

EVALUATION OF THE INFANT WITH HYPERBILIRUBINEMIA

The history, physical examination, and laboratory data play an important role in the evaluation of the infant with hyperbilirubinemia (Box 21.4).

History

The evaluation of a jaundiced infant begins with a complete family, perinatal, and neonatal history. The family history should include the occurrence of disorders associated with hyperbilirubinemia in other family members, particularly siblings. **Need for phototherapy in a sibling is a risk factor for hyperbilirubinemia requiring intervention in the current child.** A family history of early gallstones, splenectomy, or chronic anemia may indicate inherited hemolytic diseases. The infant's course during labor and delivery should be assessed for possible infection during the pregnancy, the use of oxytocin induction for delivery, or the occurrence of an asphyxial episode during labor or delivery. A history of medications used and the infant's feeding and elimination patterns should also be obtained. **The time of onset of jaundice is important, because clinical jaundice in the first 24 hours of life is abnormal, and likely indicates a hemolytic process.**

BOX 21.4 EVALUATION OF UNCONJUGATED HYPERBILIRUBINEMIA IN THE NEONATE

History
- Family
- Perinatal and obstetric
- Neonatal

Physical Examination
- Pallor
- Hepatosplenomegaly
- Enclosed hemorrhage
- Petechiae
- Congenital anomalies

Laboratory Data

All Jaundiced Infants
- Maternal and infant blood type
- Coombs' test on cord blood
- Total/direct bilirubin (serial measurements)
- Complete blood count, including hematocrit, red blood cell indices, reticulocyte and platelet counts, white blood cell differential, and peripheral smear for red blood cell morphology
- Urinalysis, test for reducing substances
- Serum albumin concentration

Sepsis Evaluation
- IgM
- Urine cytomegalovirus culture and polymerase chain reaction
- Viral cultures

New Techniques
- Transcutaneous bilirubinometry
- Bilirubin-binding tests

Signs and Symptoms and Clinical Approach

A wide spectrum of signs and symptoms may occur in a jaundiced infant, often depending on the cause

of the jaundice. **Jaundice in a newborn usually can be detected visually at a level between 6 and 7 mg/dL. Visible icterus appears first on the head and face and progresses in a cephalocaudal manner.** The skin of the extremities, particularly the palmar and plantar surfaces, are the last skin surfaces to be affected; once the TSB approaches 15 mg/dL, all body surfaces are affected, and further elevation causes no difference in appearance. **However, multiple studies show the inaccuracy of visual estimation of the degree of jaundice, even by experienced health care workers; thus all newborns should be assessed for hyperbilirubinemia with a serum or transcutaneous measurement whenever concern exists.**

An infant with hemolytic disease of the newborn may show jaundice and pallor, or may appear entirely normal at birth. *Hepatosplenomegaly* resulting from congestion and extramedullary hematopoiesis may be present. **Infants affected by severe hemolytic disease of the newborn may also have pancreatic islet cell hyperplasia and an increased risk for hypoglycemia.** Physical examination may reveal the presence of a cephalohematoma or other lesion resulting from enclosed hemorrhage. The occurrence of petechiae or purpura raises the possibility of intrauterine infection or sepsis. Congenital anomalies or syndromic appearance should be noted, because an increased incidence of jaundice is noted in aneuploidy syndromes. Jaundice and umbilical hernia may be associated with congenital hypothyroidism.

SIGNS OF BILIRUBIN TOXICITY

Hyperbilirubinemia is of clinical concern because of the potential for brain injury. Neurons are the principal target of bilirubin toxicity. The spectrum of BIND ranges from acute bilirubin encephalopathy to the irreversible syndrome of kernicterus.[50] **More recently, the overarching term *kernicterus spectrum disorders (KSDs)* has been proposed to encompass all the neurologic sequelae of bilirubin neurotoxicity, with further subclassifications based on the principal disabling features (e.g., motor or auditory deficits).[53] KSDs include all of the following conditions:**

Acute bilirubin encephalopathy (ABE) describes the effects of hyperbilirubinemia seen during the hyperbilirubinemia and immediately thereafter. **Clinical signs of ABE include progressive changes to an infant's mental and behavioral status, including lethargy, poor feeding, and hypotonia, followed by hypertonia, a poor Moro reflex with incomplete flexion of the extremities, and a high-pitched cry.** Opisthotonos and retrocollis occur in the later stages.[19,77] As the symptoms of ABE worsen, apnea, seizures, and coma occur, which can result in death.

Kernicterus, or chronic bilirubin encephalopathy, is an irreversible and devastating brain injury[46] evidenced pathologically by yellowish staining in the deep nuclei of the central nervous system, particularly in the globus pallidus of the basal ganglia, central and peripheral auditory pathways, pontine and brainstem nuclei, subthalamic nuclei, cerebellum, and hippocampus. Compared with other forms of perinatal brain injury, kernicterus shows a clear correlation among etiology, pathogenesis, and symptomatology. **Based on multiple studies, kernicterus has a mortality rate of 10% and a 70% or higher risk of long-term morbidity.**[43] **The clinical signs of kernicterus include extrapyramidal movement disorder, including dystonia and choreoathetoid movements (rapid, highly complex, involuntary, spasmodic movements); gaze abnormalities (especially paralysis of upward gaze); auditory disturbances (deafness); dysplasia of the enamel of deciduous teeth; and mild cognitive defects.** The neuromotor abnormalities may be subtle, with the auditory abnormalities most apparent because the auditory pathways are the neural system most sensitive to bilirubin injury.[19]

Survivors with kernicterus may exhibit choreoathetosis, spastic cerebral palsy, cognitive delay, sensory and perceptual deafness, and visual-motor incoordination. Although it is not likely that significant cognitive delay alone, without the other features, is caused by bilirubin encephalopathy, it is possible, though not yet proven, that subtle neurologic signs may occur, including learning and behavioral problems, awkwardness, gait abnormalities, or minimal fine and gross motor incoordination.[44]

A syndrome of BIND can occur in the absence of classic kernicterus.[18] Bilirubin toxicity can result in neuronal cell death, astrocytic reactivity, and microglia activation that cause both subtle and obvious clinical manifestations.[24] These clinical manifestations can include abnormal neuromotor signs, muscle tone abnormalities, hyperexcitable neonatal reflexes, neurobehavioral manifestations, speech and language abnormalities, and central processing abnormalities (including sensorineural

audiologic and visuomotor dysfunction). There are concerns that vulnerable infants can acquire BIND, even without a history of severely elevated bilirubin levels, or with prolonged elevation of bilirubin levels that are subthreshold for treatment.[18]

Brain lesions identified on magnetic resonance imaging after extreme hyperbilirubinemia have been linked to dyskinetic cerebral palsy.[74] Newer imaging techniques, including diffusion tensor imaging or single-photon emission computed tomography allow for quantification of subtle white matter injury after exposure to unbound bilirubin.[74]

Bilirubin Toxicity in Very-Low-Birth-Weight Infants. Infants with hemolytic disease and premature (especially VLBW) infants should receive phototherapy and exchange transfusion at lower bilirubin concentrations than full-term and otherwise healthy infants. **Unfortunately, the "critical level" at which bilirubin toxicity occurs in either preterm or term infants has not been established. Preterm infants are more susceptible to elevated bilirubin concentrations because they have less efficient hepatic conjugation, lower albumin binding capacity, and increased central nervous system sensitivity to unbound bilirubin.** Some studies have shown significant neurodevelopmental impairment in preterm infants despite only modest elevations in bilirubin concentration. Such studies are difficult to interpret because of the many confounders (e.g., gestational age, concurrent illness) in this population of infants.

Laboratory Data

The TSB level remains the recommended test on which to base clinical decisions. *Transcutaneous bilimeters* are commonly used in newborn nurseries and outpatient settings to screen for hyperbilirubinemia and work by emitting light onto the skin and measuring the light reflected, which is not absorbed by bilirubin in the skin.[36] **Transcutaneous bilirubin measurements (TcB) have been shown to be valid and to result in reduced blood draws;[15,90] however, regular monitoring for quality assurance by comparison with TSB measurements is necessary. TcB measurements are not reliable during or after phototherapy because of the bleaching effect of the phototherapy on skin.[19]** Other studies indicate that discrepancies between TcB and TSB are increased in African-American and black African newborns.[67,86] In low-resource settings, TcB may identify a high proportion of false positives that may lead to unnecessary and burdensome treatment.[69]

Newer devices (e.g., the BiliCheck [Andover, MA] device by Phillips-Respironics or the JM-103 [Loganville, GA] device by Konica Minolta/Air-Shields) **are able to correct for skin melanin content and give results within 2 to 3 mg/100 mL of the TSB.** Although transcutaneous devices are currently approved and recommended for the evaluation of jaundice in infants greater than or equal to 35 weeks' gestational age, some studies indicate that TcB is also useful in premature infants, and consistently measures about 1 mg % less than TSB.[28]

Because TcB is not an exact measure of TSB, a TSB level should be obtained whenever therapeutic intervention is considered (Box 21.5). Other noninvasive methods of determining jaundice include jaundice color cards, or icterometers. In one study in China, measurements from the newborn's cheek had a correlation coefficient of 0.985 with TSB.[99] Another two-color icterometer (Bilistrip, Advanced Instruments, Norwood, MA) tested in Africa showed a sensitivity and negative predictive value for newborns requiring phototherapy of 95.8%.[68] These studies need to be replicated in larger and ethnically variable populations.

New complete bilirubin binding panels are under development and include plasma total bilirubin binding concentration, bilirubin binding capacity, and the concentration of nonalbumin bound or free bilirubin. A bilirubin-albumin equilibrium dissociation constant can be calculated from these variables that can be used in comparison with the other variables to determine the risk for bilirubin toxicity.[2] The additional use of the

BOX 21.5 INDICATIONS FOR TSB LEVEL TESTING[58]

- The TcB level is at 70% of the TSB level at which phototherapy would be instituted.
- The TcB value is above the 75th percentile on the AAP nomogram or the 95th percentile on the TcB nomogram.
- At follow-up after discharge, the TcB value is greater than 13 mg/dL.

TSB, Total serum bilirubin.

bilirubin:albumin ratio in jaundiced premature infants was evaluated in the Bilirubin Albumin Ratio Trial (BARTrial) but failed to demonstrate better correlation with neurodevelopmental outcome in preterm infants less than 32 weeks' gestational age assigned to the study group.[42]

ADDITIONAL LABORATORY EVALUATION

In addition to a bilirubin level, **the minimum laboratory evaluation of the newborn with significant jaundice requiring treatment should include the mother's and infant's blood types, Rh status, and antiglobulin testing on cord blood. A complete blood count (CBC), including hematocrit, reticulocyte count, red cell indices, platelet count, white blood cell count and differential, and peripheral smear for red blood cell morphology, should be performed, seeking evidence of hemolysis.** Microspherocytosis is characteristic of ABO incompatibility and hereditary spherocytosis (MCHC/MCV >0.36).[27]

Bilirubin concentration (TSB) should be measured serially, preferably at the same clinical laboratory facility because of significant interlaboratory variation, and interpreted based on the infant's age in hours at the time of measurement (see Fig. 21.3). **A fractionated bilirubin should be obtained if the jaundice is severe, prolonged, or associated with light-colored stools.** Serum albumin level may be helpful at higher bilirubin concentrations, with the bilirubin:albumin ratio considered as an additional factor in interpretation of bilirubin concentrations.

Evaluation for other potential causes of hyperbilirubinemia is essential when the etiology is not immediately clear. An elevated direct fraction of bilirubin, abnormal white blood cell count, left-shifted differential, or thrombocytopenia may suggest infection. Urinalysis, including evaluation for reducing substances, may be helpful. Infants suspected of having bacterial sepsis should receive antibiotic treatment and have a complete sepsis evaluation performed. Infants suspected of having intrauterine infection should have additional tests, including immunoglobulin M (IgM), as well as blood, cerebrospinal fluid, and/or exudate from skin vesicles for viral cultures and urine for cytomegalovirus as indicated.

Infants with hemolytic disease are at risk for late anemia after discharge from the nursery. These infants require close follow-up for anemia from their primary care provider, as they may require treatment with erythropoietin or transfusion.

TREATMENT

Treatment aims at lowering the concentration of circulating bilirubin or keeping it from increasing, thereby preventing acute bilirubin encephalopathy and kernicterus. In 2004, the AAP Subcommittee on Hyperbilirubinemia published clinical practice guidelines on the management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation that lend direction regarding the use of phototherapy and exchange transfusion (Table 21.1).[8] These guidelines and recommendations are outlined in Fig. 21.4 *(phototherapy)* and Fig. 21.5 *(exchange transfusion)*. Since the publication of these guidelines, several other studies suggested that combining clinical risk factors analysis with the predischarge measurements of TSB or TcB improves prediction of subsequent hyperbilirubinemia risk;[16,25,50,52,64] consequently,

TABLE 21.1 PHOTOTHERAPY AND EXCHANGE TRANSFUSION CRITERIA FOR VERY-LOW-BIRTH-WEIGHT AND EXTREMELY LOW-BIRTH-WEIGHT INFANTS

WEIGHT (G)	INITIATE PHOTOTHERAPY (mg/dL)	CONSIDER EXCHANGE TRANSFUSION (mg/dL)
500–750	5–8	12–15
751–1000	6–10	>15
1001–1250	8–10	15–18
1251–1500	10–12	17–20

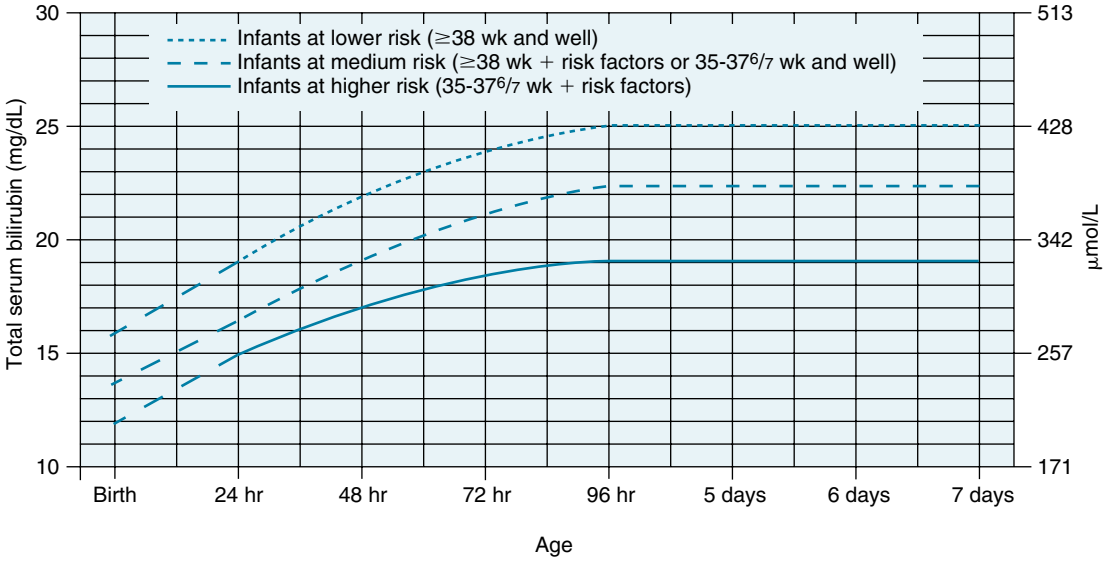
- Use total bilirubin. Do not subtract direct-reacting or conjugated bilirubin.
- Risk factors = isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin <3.0 g/dL (if measured).
- For well infants 35-37⁶/₇ weeks, can adjust TSB levels for intervention around the medium risk line. It is an option to intervene at lower TSB levels for infants closer to 35 weeks and at higher TSB levels for those closer to 37⁶/₇ weeks.
- It is an option to provide conventional phototherapy in the hospital or at home at TSB levels 2-3 mg/dl (35-50 mmol/L) below those shown, but home phototherapy should not be used in any infant with risk factors.

FIGURE 21.4 American Academy of Pediatrics (AAP) guidelines for phototherapy in hospitalized infants of 35 or more weeks' gestational age. (NOTE: These guidelines are based on limited evidence, and the levels shown are approximations. The guidelines refer to the use of intensive phototherapy that should be used when the total serum bilirubin [TSB] exceeds the line indicated for each category. Infants are designated as "higher risk" because of the potential negative effects of the conditions listed on albumin binding of bilirubin, the blood-brain barrier, and the susceptibility of the brain cells to damage by bilirubin.) *G6PD,* Glucose-6-phosphate dehydrogenase. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics* 2004;114(1):297.)

these recommendations were updated in a consensus-based guideline in 2009.[58] **The outlined *algorithm* in Fig. 21.6 represents the proposed consensus-based guidelines for the management and follow-up of hyperbilirubinemia in the newborn infant 35 or more weeks' gestational age, according to predischarge bilirubin measurements, gestation, and risk factors. Similarly, a consensus-based guideline has been developed for the suggested use of phototherapy in infants less than 35 weeks' gestational age.**[59] Subsequently, in 2013 Wallenstein and Bhutani published an expanded form of **these recommendations for the management of hyperbilirubinemia in the moderately preterm infant of 32 to 34 weeks' gestational age (Fig. 21.7).**

Phototherapy

Phototherapy is the most frequently used treatment for hyperbilirubinemia. The widespread availability and use of phototherapy in high-resource



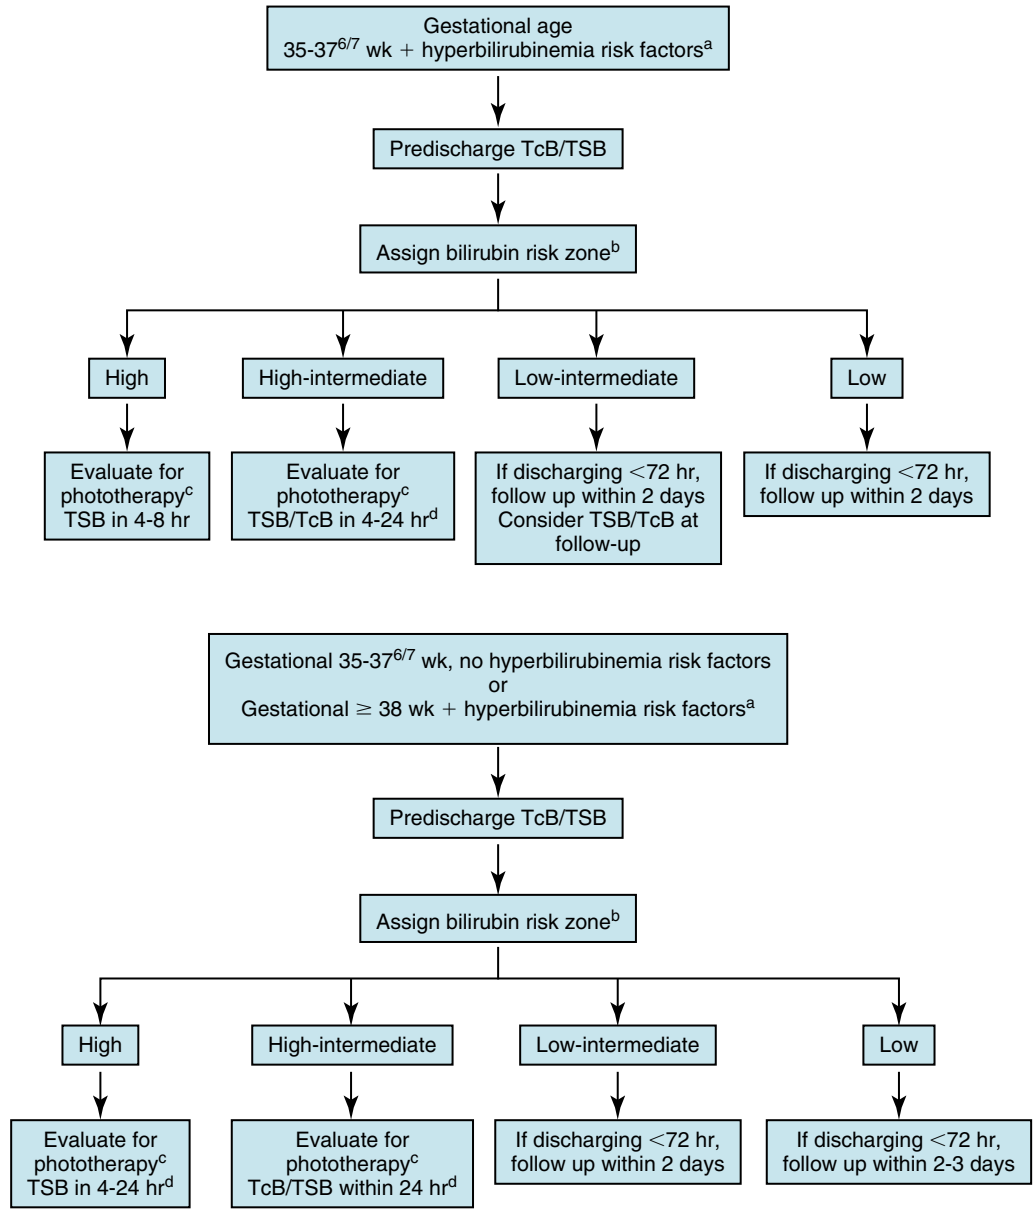
- The dashed lines for the first 24 hours indicate uncertainty due to a wide range of clinical circumstances and a range of responses to phototherapy.
- Immediate exchange transfusion is recommended if infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocollis, opisthotonos, fever, high-pitched cry) or if TSB is ≥5 mg/dl (85 μmol/L) above these lines.
- Risk factors: isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis.
- Use total bilirubin. Do not subtract direct-reacting or conjugated bilirubin.
- If infant is well and 35-37⁶/₇ weeks (median risk), can individualize TSB levels for exchange based on actual gestational age.

FIGURE 21.5 American Academy of Pediatrics (AAP) guidelines for exchange transfusion in infants of 35 or more weeks' gestational age. (NOTE: These suggested guidelines represent a consensus of most of the American Academy of Pediatrics Subcommittee on Hyperbilirubinemia but are based on limited evidence, and the levels shown are approximations. During birth hospitalization, exchange transfusion is recommended if the total serum bilirubin [TSB] rises to these levels despite intensive phototherapy. For readmitted infants, if the TSB level is above the exchange level, repeat TSB measurement every 2 to 3 hours and consider exchange if the TSB remains above the levels indicated after intensive phototherapy for 6 hours.) *G6PD,* Glucose-6-phosphate dehydrogenase; *TSB,* total serum bilirubin. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics.* 2004;114(1):297.)

settings have nearly eliminated the need for exchange transfusion in infants with nonhemolytic hyperbilirubinemia. Hospital-based studies in the United States have shown that 5 to 40 infants per 1000 term and late-preterm infants receive phototherapy before discharge from the nursery, and an equal number are readmitted for phototherapy after discharge.[55] The decision to initiate phototherapy must be individualized for each newborn and should be based on the AAP guidelines (see Fig. 21.4).

RATE OF BILIRUBIN DECLINE UNDER PHOTOTHERAPY

With effective phototherapy, the infant's bilirubin level should drop at a rate of 0.5 to 1 mg/dL (8.5 to 17 mmol/L) per hour, and by 30% to 40% after 24 hours of treatment, when applied at several days of age. **The rate of decline of bilirubin in the first days (early hyperbilirubinemia, likely the result of increased bilirubin production) will not be as brisk, but the rate of rise will be significantly slowed.** Bilirubin best absorbs light in the blue-green spectrum, particularly in the blue region near 460 nm[55]; light at 425 to 475 nm is therefore most effective. **The light energy supplied by phototherapy changes the shape and structure of bilirubin, converting it to photoisomers that can be excreted in the bile and urine without conjugation.[55]** Configurational isomers are formed most rapidly (Z, E and E, Z isomers), but the reaction



- Recommendation for timing of repeat TSB measurement depends on age at measurement and how far the TSB level is above the 95th percentile (Figure 21-3). Higher and earlier initial TSB levels require an earlier repeat TSB measurement.
- (a) Risk factors, (b) Figure 21-3, (c) Figure 21-4, (d) in hospital or as outpatient, (e) follow-up recommendations can be modified according to level of risk for hyperbilirubinemia.

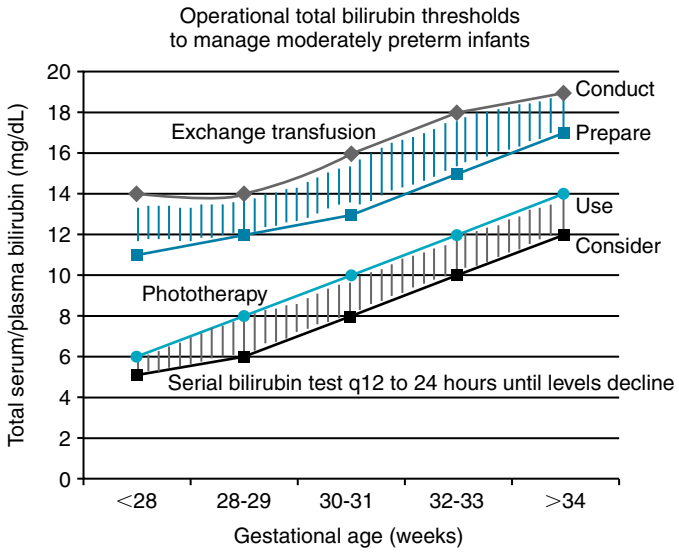

FIGURE 21.7 Suggested use of phototherapy and exchange transfusion in preterm infants less than 35 weeks' gestational age. The operational thresholds have been demarcated by recommendations of an expert panel. The *shaded bands* represent the degree of uncertainty. Recommended threshold to prepare for exchange transfusion assumes that these infants are already being managed by effective phototherapy. Increase in exposure of body surface area to phototherapy may inform the decision to conduct an exchange transfusion based on patient response to phototherapy. (From Wallenstein MB, Bhutani VK. Jaundice and kernicterus in the moderately preterm infant. *Clin Perinatol* 2013;40(4):679. Modified with permission from Maisels MJ, Watchko JF, Bhutani VK, et al. is reversible.[41] The most important of these isomers is ***lumirubin,*** **a stable structural photoisomer. Lumirubin does not require conjugation and is rapidly excreted in both bile and urine. The production of lumirubin is an irreversible reaction that appears to be dose-related,** but occurs more slowly than formation of the configurational isomers. Photo-oxidation of bilirubin occurs much more slowly and is not as important as photoisomerization.

The efficacy of phototherapy depends on the energy output *(irradiance)* of the light source (measured with a radiometer in units of microwatts per square centimeter per nanometer of light over a given wavelength band), **the distance of the light source from the infant, and the surface area of the skin exposed to the light. Intensive phototherapy consists of 30 μW/cm²/nm or more.[8]** Of concern, several studies show that irradiance of phototherapy devices worldwide may be suboptimal.[22] Barriers to appropriate irradiance levels may include distance of infant from the light source, skin surface area exposed, type of light source used, and protocols to standardize correct phototherapy practices and equipment maintenance.[22] **Fiber-optic blankets deliver phototherapy from a high-intensity light source either alone or in conjunction with other sources of phototherapy;** alone they are unlikely to expose adequate surface area on a term infant to provide intensive phototherapy.[55]

LIGHT SOURCES

The AAP describes the most commonly used phototherapy units in its 2004 guidelines. These include daylight, cool white, blue, or "special blue" fluorescent tubes or tungsten-halogen lamps in different configurations, either freestanding or as part of a radiant warming device. Most of these devices deliver enough output in the blue-green region of the visible spectrum to be effective for standard phototherapy use. **The most effective light sources commercially available for phototherapy are blue fluorescent tubes or specially designed light-emitting diode (LED) lights** (Natus Inc., San Carlos, CA). The special blue fluorescent tubes are labeled *F20T12/BB* (General Electric, Westinghouse, Sylvania) or *TL52/20W* (Phillips, Eindhoven, The Netherlands). It is important to note that special blue tubes provide much greater irradiance than regular blue tubes (labeled *F20T12/B*) because they provide light predominantly in the blue-green spectrum. At these wavelengths, light penetrates skin well and is absorbed maximally by bilirubin.[8]

Currently, LEDs are more frequently used than florescent tubes.[34] Super LEDs are high-intensity blue lights grouped together in small capsules that emit a high intensity blue light with a narrow band that produces low heat.[78] One study showed a **significant reduction in TSB in hemolytic and nonhemolytic neonates treated with the super blue light when contrasted with similar patients treated with florescent phototherapy.[79]**

Fiber-optic phototherapy blankets (Wallaby Phototherapy System, Fiberoptic Medical Products, Inc., Allentown, PA; Biliblanket, Ohmeda, Columbia, MD) use a high-intensity halogen light source for transmission of light by fiber-optic bundles. Irradiance and efficacy appear comparable with those for standard phototherapy. **Purported advantages of these systems are elimination of the need for eye patches, exposure of greater surface area, and provision of phototherapy outside of the nursery or hospital with less interference in mother-infant bonding.**

Double-bank phototherapy has been shown to reduce the TSB significantly faster than single-bank phototherapy because of the increase in body surface area that is exposed.[33]

Physical and laboratory evaluation should be performed before initiating phototherapy in any infant. **Once phototherapy has been initiated, TSB must be monitored as TcB measurement is no longer valid.** Hematocrit also must be followed serially in infants with hemolytic disease.

There are conflicting data in the literature on whether continuous or intermittent administration of phototherapy is most effective. **Phototherapy may be interrupted during brief periods for feeding, laboratory draws, assessment of the eyes, visual stimulation, and parental contact. Intermittent phototherapy has been shown to be as effective as continuous phototherapy in nonhemolytic term and late-preterm neonates.[75]** Although it only takes a few nanoseconds for the photochemical reaction (isomerization) to occur, it may take several hours for the migration and elimination of bilirubin to occur; during this time, phototherapy's role is minimal.[75] Neonates with nonhemolytic hyperbilirubinemia in the intermittent phototherapy (12 hours on, 12 hours off) arm had bilirubin levels that fell faster and a shorter duration of phototherapy compared with neonates in the continuous phototherapy arm.[75] Table 21.2 outlines some of

TABLE 21.2 NURSING MANAGEMENT OF INFANTS UNDERGOING PHOTOTHERAPY

NURSING ASSESSMENT

AREA	PARAMETER
Physical status	Intake and output Color Location of jaundice Skin integrity Stools (character, consistency) Vital signs Infant/environmental temperature Hydration status Signs of phototherapy side effects Eye discharge and tearing Position Activity
Neurobehavioral status	Sleep-wake states Sensory threshold Behavioral responsiveness Feeding behaviors Consoling abilities Stress responses Interactive capabilities

NURSING MANAGEMENT

NURSING DIAGNOSIS	INTERVENTION
Deficient fluid volume (actual or potential)	Monitor intake and output. Monitor hydration status (weight, specific gravity, urine output). Monitor stooling pattern, character. Maintain adequate fluid intake (oral or parenteral).
Imbalanced nutrition: less than body requirements	Assess feeding behavior and activity. Monitor fluid and caloric intake, weight, and abdominal girth. Remove eye shields during feeding. Hold during oral feedings as health and thermal status permit. Bring to alert state before feeding. Feed on demand if possible.
Impaired skin integrity	Observe color, rashes, excoriation. Clean skin with warm water. Clean perineal area after stooling. Turn frequently (also increases skin exposure to phototherapy). Ensure Plexiglas shield is in place between light source and infant to reduce exposure to ultraviolet light.

Continued

TABLE 21.2 NURSING MANAGEMENT OF INFANTS UNDERGOING PHOTOTHERAPY—CONT'D

NURSING MANAGEMENT	
NURSING DIAGNOSIS	**INTERVENTION**
Risk for injury	Observe for side effects associated with phototherapy. Observe for signs of sepsis. Provide care to minimize side effects of phototherapy. Shield eyes from lights with opaque patches. Ensure eyelids are closed when shield is applied to prevent corneal injury. Remove eye shield and observe eyes regularly. Monitor position of eye shield to prevent occlusion of nose. Avoid tight headband on eye shield to reduce risk of increased intracranial pressure, especially in preterm infants. Observe for eye discharge and tearing. Shield testes and possibly ovaries (data unclear about need to do this) with diaper.
Ineffective thermoregulation	Place in warm, thermoneutral environment. Monitor environmental and infant temperature. Observe for hypothermia and hyperthermia. Reduce heat losses from environmental sources. Use servocontrol for infants in incubator or under radiant warmer. Shield servocontrol thermistor from direct exposure to phototherapy lights.

From Blackburn S. Hyperbilirubinemia and neonatal jaundice. *Neonatal Netw.* 1995;14(7):15.

the nursing assessments and management to be performed in infants undergoing phototherapy.

REBOUND

After phototherapy is discontinued, TSB should be followed for at least 24 hours to assess for significant rebound. Infants most likely to experience significant rebound are those less than 37 weeks' gestational age, those with a hemolytic process, and those treated with phototherapy for early hyperbilirubinemia during the birth hospitalization, because the bilirubin is still rising at the time phototherapy is discontinued.[55]

SAFETY

Despite widespread use since 1958, questions about the safety and side effects of phototherapy remain. However, reports of clinically significant toxicity are rare.[57] Animal studies have demonstrated a potential retinal toxicity of light. Although it is not established that this occurs in the human newborn, the **infant's eyes should be covered while phototherapy is in use.** Patches should completely cover the eyes without placing excessive pressure on the eyes and should be carefully positioned to avoid occluding the nares. **Eye patches should be removed every 4 hours to permit evaluation of the infant's eyes. The patches should be left off during feedings and parental visits.**

HEAT BALANCE

Infants exposed to phototherapy, particularly low-birth-weight infants and infants under a radiant warmer, may have significant increases in their insensible water losses. Infants in incubators or servocontrolled care centers may become overheated. **The servocontrol probe should be shielded by an opaque covering.**

Infants treated in open cribs may become cold stressed. Fluid balance must be monitored carefully in an infant receiving phototherapy. Infants under phototherapy may also have increased stool water losses and may develop temporary lactose intolerance. **The infant's temperature, weight,**

and intake and output should be monitored frequently. Liquid stools containing reducing substances can be treated with a non–lactose-containing formula.

PHOTOTHERAPY IN PREMATURE INFANTS

Little evidence exists for management of hyperbilirubinemia in preterm infants less than 35 weeks' gestational age.[21,70] Consensus-based management continues to be the recommendation (see Fig. 21.7).[21,70] Extremely low-birth-weight (ELBW) infants have thinner and more translucent skin. The light from phototherapy interacts with bilirubin, but can also interact with many other molecules in the ELBW infant's tissues. Because the head represents a large expanse of their total body surface area, brain tissue is one of the most concerning areas of interaction.[84] **Therefore, generalizing the safety and efficacy of phototherapy to ELBW infants may not be appropriate.**

Because the concentration of bilirubin that is detrimental to ELBW preterm infants has not been well defined, a randomized controlled trial attempted to determine whether aggressive versus conservative phototherapy led to improvement in neurodevelopmental outcome at 18 to 22 months for infants between 501 and 1000 g.[62] **Although there was no difference in survival between groups overall, of the surviving infants, the aggressive phototherapy group had significant decreases in rates of neurodevelopmental impairment.** Of concern, however, was that in a **subgroup analysis of the smallest infants, 501 to 750 grams, the mortality rate was increased by 5% in the aggressive versus conservative phototherapy group.** Although not statistically significant, this increased mortality rate was worrisome to the authors and may offset any potential benefit of aggressive phototherapy in this weight category. Future directions may include evaluation of other novel interventions for prevention or treatment of hyperbilirubinemia in these most vulnerable infants.[10]

CHOLESTATIC JAUNDICE AND PHOTOTHERAPY

Infants who have cholestatic jaundice and are exposed to phototherapy may develop the "bronze baby syndrome," presumably caused by a breakdown product of bilirubin produced by phototherapy, although the mechanism is unclear. **An infant with bronze baby syndrome develops a dark gray-brown discoloration of the skin, urine, and serum.** There are generally no other clinical symptoms, but at least one death has been reported. After phototherapy ceases, the bronzing gradually resolves.

TRANSIENT SIDE EFFECTS

Transient skin rashes and tanning resulting from increased melanin production have been reported, as have bullous skin eruptions in infants treated with SnMP who are subsequently exposed to sunlight or daylight fluorescent bulbs.[55] A study published in 2008 suggested that intensive phototherapy might increase the number of melanocytic nevi identified at school age.[55] Other potential problems include **interference with biologic (circadian) rhythms and maternal-infant bonding.** Although there may be some transient, short-term growth effects, long-term growth effects and development appear unaffected by phototherapy.

PHOTOTHERAPY IN LOW-RESOURCE SETTINGS

Optimal phototherapy can be difficult to achieve in settings with limited resources and leads to higher rates of exchange transfusion in these settings. Barriers to optimal phototherapy include light sources that deliver a suboptimal light emission spectrum and irradiance level, maintenance constraints, lack of consistent electricity, and lack of education and awareness among medical staff administering phototherapy about how it works or the requirements for effective treatment.[13] A recent randomized, controlled, noninferiority trial was performed in a maternity hospital in Lagos, Nigeria, to determine if filtered sunlight and conventional phototherapy produced similar reductions in mild-to-moderate hyperbilirubinemia.[80] The study showed that filtered sunlight was noninferior to conventional phototherapy, that filtered sunlight achieved higher means of irradiance, but also that higher numbers of infants had elevated temperatures with filtered sunlight compared with conventional phototherapy. A subsequent study confirmed noninferiority of filtered sunlight for moderate to severe hyperbilirubinemia as well.[81] Although this is promising for future management of hyperbilirubinemia in low-resource settings, more evidence is needed on how to do this safely and effectively.

Intravenous Immunoglobulin

When immune-mediated hemolysis is present and the TSB is rising, despite intensive phototherapy or is approaching the exchange level, intravenous immunoglobulin should be administered to the infant to decrease the severity of hemolysis. The dose of 500 mg/kg to 1 g/kg IV over 2 to 4 hours may be repeated one time after 12 hours. This intervention has been shown in multiple trials to decrease the need for exchange transfusion by approximately 70% and is recommended for Rh isoimmunization as soon as the diagnosis is established, and for ABO isoimmunization if the TSB continues to rise despite intensive phototherapy.[8,9] Immunoglobulin is of no benefit in non–antibody-mediated hyperbilirubinemia such as occurs in G6PD deficiency, Gilbert syndrome, or spherocytosis.

Exchange Transfusion

An exchange transfusion is indicated for correction of anemia and removal of antibody-coated red blood cells in severe hemolytic disease, or for treatment of signs of acute bilirubin encephalopathy regardless of its cause or TSB level. Phototherapy cannot be used in place of an exchange transfusion in such infants, although use of intensive phototherapy while preparing for exchange transfusion is essential.

It must be stressed that the decision to perform an exchange transfusion is individualized for each patient. Particularly in VLBW infants, evidence-based guidelines are lacking. **The recent AAP guidelines for performing exchange transfusion in infants of 35 or more weeks of gestation are shown in** Fig. 21.5 **(see discussion in legend). Similar guidelines have recently been proposed for the preterm infant, as shown in** Fig. 21.7. Exchange transfusions are much more commonly performed in low- and middle-income countries; however, the criteria for making this decision have not been systematically explored nor a guideline written.[66]

A double-volume exchange transfusion is performed using 160 mL/kg of appropriate whole-blood product. If fresh whole blood is not available, reconstituted whole blood can be requested that can be mixed to a desired hematocrit. ABO type–specific Rh-negative blood should be used in cases with Rh incompatibility. Type O Rh-specific cells are indicated when ABO incompatibility exists. **Whereas a single-volume exchange (80 mL/kg) will replace 63% of the infant's blood, a double-volume exchange will replace 86%.** Further increase in the amount exchanged gives little additional benefit.

The blood bank can prepare reconstituted whole blood for the infant with a predetermined hematocrit, usually 50% to 55%. **An exchange transfusion will reduce bilirubin levels by approximately 45% to 85%,** according to various sources. Administration of 1 g/kg of 25% albumin 1 hour before the exchange transfusion has been shown in some studies to increase the efficiency of exchange by about 40%. **As plasma and tissue bilirubin levels equilibrate post-transfusion, the bilirubin rises to about 60% of the pre-exchange level.**

PROCEDURE

Exchange transfusion trays are commercially available and include a four-way stopcock, necessary tubing and syringes, a vial of 10% calcium gluconate, and a plastic bag for discarded blood.

The infant should be in the NICU for close observation during and immediately after the procedure. **Feedings should be held for 2 to 3 hours before the procedure and for some time afterward.** The procedure is performed by removing small aliquots of the infant's blood and replacing similar small aliquots of transfused blood product through the umbilical vein while blood pressure, heart rate, and general condition are monitored. Generally, 5 mL to 20 mL aliquots of blood are used, depending on the size and condition of the infant. Each aliquot should be 5% to 8% of the estimated blood volume or 5 mL/kg, withdrawn or infused at a rate of approximately 5 mL/kg/min. **The entire procedure should take 60 to 90 minutes and encompass 30 to 35 cycles of withdrawal and infusion.[38] In general, a slower exchange will result in less rebound of TSB than a rapid exchange because the extravascular bilirubin may equilibrate with the plasma bilirubin more extensively during the procedure.[38]** The initial aliquot should be withdrawn and sent to the laboratory for determination of bilirubin, hematocrit, and calcium. Blood used in the exchange must be warmed in a carefully controlled fashion to prevent "cold heart syndrome," which may cause arrhythmia and cardiac arrest, or overheating.[38]

The final aliquot from an exchange should be sent for determination of CBC, fractionated bilirubin, calcium ion, and electrolytes. In addition to the individuals performing the exchange, another person must keep an accurate record of time, volumes withdrawn and infused, vital signs, and medications administered.

POTENTIAL COMPLICATIONS

Exchange transfusion is a procedure with many potential complications and carries a mortality risk of about 0.5%. For this reason and because so few exchange transfusions are performed in highly resourced countries today (estimated at 3/100,000 live births in the United States),[64] this procedure should be done only by personnel who are familiar with the technique and its complications, preferably in a tertiary care unit. Vascular complications are related to the use of umbilical catheters (discussed in Chapter 7). **Necrotizing enterocolitis has been reported as a postexchange complication, probably as a result of bowel ischemia during the procedure,** and may be related to a more rapid exchange and use of larger aliquots of blood.[38,63]

Electrolyte and glucose disturbances are related to the blood preparation used for the exchange. Citrate used as part of the anticoagulant solution binds divalent ions such as calcium and magnesium; thus laboratory evaluation of calcium and magnesium during the procedure is essential. **The infant should be evaluated for hypocalcemia after each 100 mL of the exchange has been completed.** Although symptomatic hypocalcemia is rare, clinical signs and symptoms include irritability, tachycardia, or prolongation of the Q-Tc interval. **If hypocalcemia is detected, 1 mL of a 10% calcium gluconate solution is infused slowly through the umbilical vein catheter under continuous electronic cardiac monitoring.**

Acid-citrate-dextrose and citrate-phosphate-dextrose blood have high levels of sodium and glucose and sometimes potassium. **Initial hyperglycemia may be followed by reactive hypoglycemia as a result of an insulin response.** Although the blood is acidic at the time of infusion, a postexchange alkalosis may occur as citrate is metabolized to bicarbonate in the liver. Many of the electrolyte and acid-base disturbances may be avoided by the use of fresh, heparinized whole blood. **Bleeding may occur in an overheparinized infant but is reversible with protamine sulfate.**

Thrombocytopenia is very likely to occur after any exchange transfusion, but especially in the infant needing repeated exchange transfusions. Bacterial infection is rare, and routine antibiotic prophylaxis is not indicated. Most complications, other than thrombocytopenia, are avoidable if careful attention to technique is observed.

LONG-TERM OUTCOMES

Apart from kernicterus, recent studies have looked at other long-term outcomes associated with hyperbilirubinemia itself and with phototherapy treatment. Prediction of outcome is difficult, although a recent study evaluated the use of a 9-point BIND score that assesses mental status, muscle tone, and cry patterns and demonstrated that a BIND score greater than or equal to 4 had a specificity of 87.3% and a sensitivity of 97.4% for predicting poor neurologic outcome at 3 to 5 months.[35]

Several observational studies have suggested a possible association between hyperbilirubinemia and other conditions, such as autism spectrum disorder or childhood allergic diseases, although these studies also caution that further prospective evaluation of such links is needed.[7,31,54]

Recent studies have raised concerns that both conventional and intensive phototherapy are associated with DNA damage that could result in adverse long-term outcomes and that duration of phototherapy was positively correlated with markers of genotoxicity.[73] Several studies indicate a possible increased risk of cancer, although results are attenuated when confounding variables are eliminated.[65]

PARENT TEACHING

Providing parents with written information about jaundice and its treatment may be a beneficial adjunct to verbal explanations and forms a key element of the AAP guidelines on management of hyperbilirubinemia (Box 21.6). Because early discharge policies (less than 48 hours of age) have increased the need for outpatient evaluation or management of neonatal hyperbilirubinemia, it is important that **parents feel empowered to ask questions about hyperbilirubinemia and its symptoms so that they can bring any concerns to the attention of health care providers.[93]** This is especially true for the nursing mother, who may be

BOX 21.6 KEY ELEMENTS OF AAP CLINICAL PRACTICE GUIDELINE (2004): MANAGEMENT OF HYPERBILIRUBINEMIA IN THE NEWBORN INFANT 35 OR MORE WEEKS OF GESTATION

Important Points for the Management of Jaundice

- Promote and support successful breastfeeding.
- Establish nursery protocols for the identification and evaluation of hyperbilirubinemia.
- Measure the total serum bilirubin (TSB) or transcutaneous bilirubin (TcB) level on infants jaundiced in the first 24 hours.
- Recognize that visual estimation of the degree of jaundice can lead to errors, particularly in darkly pigmented infants.
- Interpret all bilirubin levels according to the infant's age in hours.
- Recognize that infants at less than 38 weeks' gestation, particularly those who are breastfed, are at higher risk of developing hyperbilirubinemia.
- Screen all infants before discharge with a TSB or TcB measurement, combined with clinical risk factors, to guide the need for additional testing to identify a cause for hyperbilirubinemia and for additional TSB measurements.
- Provide parents with written and verbal information about newborn jaundice.
- Provide appropriate follow-up based on the time of discharge and risk assessment.
- Treat newborns, when indicated, with phototherapy or exchange transfusion.

From American Academy of Pediatrics. Subcommittee on Hyperbilirubinemia. Clinical Practice Guideline. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics.* 2004;114(1):297.

questioning her ability to provide adequate nourishment for her infant. **Indeed, early discharge of infants has led to hyperbilirubinemia being the most common cause for hospital readmission in term infants.**

Providing parents and families with consistent information, reassurance, and support is essential. **The use of phototherapy can be distressing for parents and should be explained to them before they see their infant under phototherapy lights for the first time.**

In addition, **incubators, bili-masks, and phototherapy lights can all contribute to a sense of separation between parents and their infant by creating a physical and emotional barrier.** Parents may avoid coming to the nursery to be with their infant. If they do come to their infant's bedside, they may be reluctant to touch or participate in care for fear of interfering with phototherapy and potentially hindering their infant's progress.

As with many disorders in newborn infants, time and energy spent providing parents with information and support can alleviate much fear, guilt, and anger. It also can help facilitate the development of a healthy family relationship in a time of stress. **Signs and symptoms of jaundice should be explained in a manner that is understandable and meaningful for parents, emphasizing that neonatal hyperbilirubinemia is usually a transient condition and one to which all infants must adapt after birth.**

HEALTH SYSTEMS APPROACH TO BILIRUBIN

Recently, rising rates of kernicterus have called attention to potential systems failures in neonatal services, because most infants currently developing kernicterus are term and late-preterm babies who have been discharged postnatally and return to a pediatrician or emergency department with symptoms of kernicterus.[11,16,46] For this reason, the Joint Commission on Accreditation of Healthcare Organizations issued Sentinel Event Alerts on kernicterus in 2001 and again in 2004.[17,37,44,45,93] However, neither hyperbilirubinemia nor kernicterus has been a reportable disease, and no reliable information source exists to produce national annual estimates.[17] Most estimates range from 0.4 to 2.7 cases per 100,000 live births among infants born at or after 35 weeks of gestation in the United States[59,60] (see Box 21.1).

The root cause analysis for the reappearance of kernicterus revealed several factors. First, **multiple providers at multiple sites** deliver health services, and some providers may not have sufficient understanding of bilirubin and its potential for toxicity. **Early discharge of newborn infants in the first 72 hours after birth** occurs before the natural peak of bilirubin rise in term infants and before the establishment of adequate breastfeeding; these risks are potentiated even more in the late-preterm infant. **Limited parental and provider knowledge regarding hyperbilirubinemia and the early symptoms of acute bilirubin encephalopathy, and failures within health care systems to provide appropriate predischarge screening of at-risk infants,**

only serve to complicate issues.[16,87] Inadequate screening, the inability to measure TSB easily, and a high prevalence of medical conditions that increase the risk of severe hyperbilirubinemia (UGT-1A1 polymorphisms and G6PD deficiency) may cause infants at risk for significant hyperbilirubinemia to be overlooked.[79] In addition, issues related to patient referrals, challenges with implementation of phototherapy, limited availability of whole blood, or lack of experienced personnel to perform exchange transfusions may cause delays in the treatment of infants with acute bilirubin encephalopathy.[98]

The overall aim of the published guidelines[8,58] was to promote an approach that would (1) reduce the frequency of severe hyperbilirubinemia and bilirubin encephalopathy, (2) minimize the risk for unintended harm (e.g., increased anxiety, decreased breastfeeding, unnecessary treatment for the general population), and (3) avoid excessive cost and waste. **These guidelines emphasize the importance of universal predischarge screening combined with clinical risk assessment, close follow-up, and prompt intervention when indicated.** By obtaining a TcB or TSB on all infants before discharge, a systems-based approach to reducing the occurrence of acute bilirubin encephalopathy is achievable. **Infants with bilirubin levels above the 75th percentile for age in hours can be identified, and ongoing tracking of those with rapid rates of rise (greater than 0.2 mg/dL/hr)[19] can be arranged.** Although evidence that universal predischarge screening will reduce the incidence of kernicterus is lacking, published data suggest that predischarge screening can reduce the incidence of TSB levels of 25 mg/dL or greater by facilitating the early recognition of those infants at greatest risk, but may lead to overuse of phototherapy. Furthermore, universal screening is not associated with an increase in neonatal length of stay or postdischarge hospital use.[30] When possible overuse of phototherapy is balanced against the permanent and devastating, though rare, occurrence of kernicterus, such a widespread approach may be seen as conferring a small, but still worthwhile, benefit.[56,58]

The 10 key elements of the 2004 AAP practice guidelines are listed in Box 21.6. Bhutani and Johnson[16] went further to recommend a **five-step nationwide strategy to prevent severe neonatal hyperbilirubinemia:**

- An institutional curriculum for the systems approach, including universal prenatal, predischarge, and postdischarge risk assessment for severe neonatal hyperbilirubinemia
- Advocacy for on-site services that promote breastfeeding in the context of supervised and seamless health care delivery during the first month of life
- Effective parent-provider partnerships for safer management of neonatal jaundice
- Statewide (or regional) reporting of birthing institution outcome assessment for severe neonatal hyperbilirubinemia along with outcomes for neonatal screening for other inherited disorders
- Nationwide surveillance in which all cases of severe neonatal hyperbilirubinemia are reported

On a global scale, research is needed to better define the burden and causes of severe neonatal jaundice and its consequences, along with aggressive educational programs for families and health personnel to facilitate timely care-seeking, accurate diagnosis, and effective phototherapy.[40]

22 INFECTION IN THE NEONATE

MOHAN PAMMI, M. COLLEEN BRAND, AND LEONARD E. WEISMAN

A newborn infant is uniquely susceptible to infectious diseases. This chapter presents causes of infectious diseases with particular emphasis on prevention, history, presenting signs and symptoms, laboratory data, treatment, and parent teaching methods of prevention applicable to the care of the neonate. Abbreviations for this chapter are listed in Box 22.1.

PATHOPHYSIOLOGY AND PATHOGENESIS

An infection occurs when a susceptible host comes in contact with a potentially pathogenic organism. When the encountered organism proliferates and overcomes the host defenses, infection results. **Sources of infection in a newborn can be divided into three categories: (1) transplacental acquisition (intrauterine infection), (2) perinatal acquisition during labor and delivery (intrapartum infection), and (3) hospital acquisition in the neonatal period (postnatal infection) from the mother, hospital environment, or hospital personnel.**

In general, most infecting organisms can, under the proper circumstances, cross the placenta or ascend from the birth canal and invade the at-risk neonate. These infections may result in abortion, stillbirth, and disease present at birth or in the neonatal period.

The main goal is to prevent infections in the fetus and newborn. Unfortunately, few proven measures exist for the prevention of infections acquired via the placenta or in the perinatal period. Preventive measures are important, because most nonbacterial infections (except syphilis and possibly toxoplasmosis, cytomegalovirus [CMV] infection, and herpes simplex) do not respond to current therapy.

ETIOLOGY

Thorough data collection for the diagnosis of infectious diseases includes a review of the perinatal history, signs and symptoms, and laboratory data. Intrauterine, intrapartum, or neonatal disease may be caused by a wide variety of organisms, many of which are discussed in this chapter.

SPECIFIC INFECTIOUS DISEASES

The following specific infectious diseases are grouped according to their source of infection.[119]

Transplacental (Intrauterine) Acquisition

HUMAN IMMUNODEFICIENCY VIRUS INFECTION AND ACQUIRED IMMUNODEFICIENCY SYNDROME

Prevention. **The primary risk to infants for infection with human immunodeficiency virus (HIV), the causative agent of acquired immunodeficiency syndrome (AIDS), is intrauterine, intrapartum, and postpartum exposure to a mother with HIV infection.** HIV has been isolated from blood and many body fluids. Epidemiologic evidence has implicated only blood, semen, vaginal secretions, and breast milk

BLUE type highlights content that is particularly applicable to clinical settings.

BOX 22.1 ABBREVIATIONS

AIDS	Acquired immunodeficiency syndrome
CF	Complement fixation (test)
CIE	Counterimmunoelectrophoresis
CRP	C-reactive protein
CRS	Congenital rubella syndrome
CSF	Cerebrospinal fluid
DFA	Direct fluorescent antibody
DNA	Deoxyribonucleic acid
ELISA	Enzyme-linked immunosorbent assay
FA	Fluorescent antibody (test)
FAMA	Fluorescent antibody to membrane antigen
FTA-ABS	Fluorescent treponemal antibody absorption (test)
GBS	Group B *Streptococcus*
HBsAg	Hepatitis B surface antigen
HIV	Human immunodeficiency virus
IAHA	Immune adherence hemagglutination
IFA	Indirect fluorescent antibody (test)
IHA	Indirect hemagglutination inhibition (test)
IPV	Inactivated poliovirus vaccine
IUGR	Intrauterine growth restriction
LA	Latex agglutination (test)
MHA-TP	Microhemagglutination test for *Treponema pallidum* infection
NAAT	Nucleic acid amplification test
OPV	Oral poliovirus vaccine
PCP	*Pneumocystis jiroveci* pneumonia*
PCR	Polymerase chain reaction
RNA	Ribonucleic acid
RPR	Rapid plasma reagin (test)
RT-PCR	Reverse transcriptase PCR
VDRL	Venereal Disease Research Laboratory (test)

*Formerly *Pneumocystis carinii* pneumonia.

in transmission. **Some recommendations consider breast milk feedings contraindicated in developed countries where safe alternatives are available.[9,11,155] However, the most recent recommendations from the World Health Organization address exclusive and nonexclusive breastfeeding in mothers receiving anti-retroviral therapy (see Table 18.4).** HIV testing should be recommended and encouraged to all pregnant women.[9,10,155]

Because the medical history and examination cannot reliably identify all patients infected with HIV (or other blood-borne pathogens) and because during delivery and initial care of the infant, perinatal care providers are exposed to large amounts of maternal blood, **standard precautions (e.g., gloves) should be consistently used for all patients when handling the placenta or infant until all maternal blood has been washed away.**[9137]

Data Collection

History. HIV infection in the mother is acquired primarily sexually or by intravenous (IV) drug abuse. **Infection may be asymptomatic. Transmission from an untreated infected mother to the fetus or infant occurs in 13% to 39% of births. Approximately 40% of transmissions occur before birth, and the rest occur around the time of delivery.** Two-thirds of infections occurring before delivery are caused by transmission within the 14 days before delivery.[9] A high maternal plasma viral load, high cervicovaginal viral load, low $CD4^+$ lymphocyte count, advanced maternal illness, an increase in exposure of the fetus to maternal blood, premature delivery, prolonged labor, longer duration of rupture of membranes before delivery, and mode of delivery all increase perinatal transmission of HIV infection.[1079] Globally there has been a 48% reduction in pediatric HIV infection.[154] The rate of perinatal transmission of HIV has decreased to 1% or less in Europe and the United States.[155]

Signs and Symptoms. **Infants with perinatally acquired HIV infection uncommonly have symptoms in the neonatal period,** but the majority of these infants present with clinical illness by 24 months of life (median age at onset of symptoms is 11 to 12 months). One-fifth of infants infected with HIV perinatally develop serious disease or die in the first year of life.[149] Symptoms include failure to thrive, developmental disabilities, neurologic dysfunction, hepatosplenomegaly, generalized lymphadenopathy, parotitis, persistent oral candidiasis (thrush), and chronic or recurrent diarrhea. Lymphoid interstitial pneumonia is frequently seen in these infants. HIV-infected infants commonly have osteomyelitis, septic joints, pneumonia, sepsis, meningitis, and otitis media with common organisms (e.g., *Streptococcus pneumoniae, Haemophilus influenzae* type b), and these infections may be recurrent.[79,149]

Laboratory Data. **HIV nucleic acid detection by polymerase chain reaction (PCR) of DNA extracted from peripheral blood mononuclear cells is the gold standard for early diagnosis of infected infants, and results are available within 24 hours.**[149] About 30% of HIV-infected infants have a positive DNA PCR assay from samples obtained within 48 hours of age; 93% have detectable HIV DNA by 2 weeks; and almost all have it by 1 month of age. The primary serologic laboratory test for HIV antibody is the enzyme-linked immunosorbent assay (ELISA). The Western blot test is used for confirmation of positive ELISA results. **Differentiation of the child with passively acquired antibody from the infant with active infection is critical but difficult.** Acquired antibody is undetectable in 75% of infants by 12 months of age and in most infants by 15 to 18 months of age. Infants have also been described with negative serology but active infection. Virus isolation by culture is difficult and expensive, and p24 antigen detection is less sensitive.[79,86] The plasma HIV RNA PCR assay is currently used for quantifying the viral load but not routinely used for diagnosis. Although hypogammaglobulinemia has been reported (less than 10% of patients), hypergammaglobulinemia usually is present.

Treatment. **Antiretroviral therapy with zidovudine (ZDV) or highly active antiretroviral therapy (HAART), a combination of three or more drugs, reduces viral replication and is recommended for pregnant women to reduce perinatal HIV transmission (to <2% of births by women with HIV).**[10,28] Antiretroviral medications are administered for prophylaxis, for intravenous empirical therapy, and for treatment of newborns with documented HIV infection.[32]

ZDV should be given to infants of infected women beginning as soon as possible after birth (i.e., within 6 to 12 hours) and should be continued for 4 to 6 weeks.[10,32,155] **ZDV is administered orally at 2 mg/kg body weight/dose twice daily for 2 weeks and then increased to 3 mg/kg for next 4 weeks for infants born before 35 weeks of gestation. For infants born after 35 weeks of gestation, give a 4 mg/kg/dose twice daily for 6 weeks.**[79]

Infants born to untreated HIV-infected women should receive ZDV for 6 weeks, and three doses of nevirapine (NVP) in the first week of life (at birth, 48 hours later, and 96 hours after the second dose), beginning as soon after birth as possible. NVP is administered orally at 8 mg/dose (for infants 1.5 to 2 kg) or 12 mg/dose (infant >2 kg). If the infant is confirmed to be HIV positive, ZDV is changed to a multidrug antiretroviral regimen. Management guidelines for multidrug antiretroviral regimens are available online.[155] Infants who are perinatally infected with HIV are at high risk for developing *Pneumocystis jiroveci* pneumonia (PCP, formerly known as *Pneumocystis carinii* pneumonia) early in the first year of life. Guidelines recommend initiating prophylaxis for the prevention of PCP for all HIV-exposed infants at 4 to 6 weeks of age, regardless of their $CD4^+$ cell count. For infants receiving ZDV, PCP prophylaxis should begin after completion of the 6-week course of ZDV. The recommended PCP prophylaxis may be provided by 150 mg/m^2/day (5 mg/kg/day) of trimethoprim (TMP) and 750 mg/m^2/day (25 mg/kg/day) of sulfamethoxazole (SMX) administered in two divided doses for 3 consecutive days in a week.[10,79] TMP/SMX prophylaxis should be continued through the first year of life or until HIV infection is reasonably excluded.[6]

Parent Teaching. **Care of an infant at risk for HIV requires close and long-term follow-up. Involvement of the parents is essential to this process.** Education of the parents will maximize the success of such a care plan, and utilization of all available community resources should provide additional support. In addition to the rationale for and importance of the medical management just outlined, the parents should be counseled concerning the need for the following:

- Immunizations following the American Academy of Pediatrics schedule
- Rapid consultation with the infant's physician if he or she is exposed to varicella (may need treatment with varicella-zoster immune globulin [VariZIG]) within 96 hours of exposure) or measles (needs immune globulin intramuscularly regardless of immunization status)
- Rapid consultation with the physician for tetanus-prone wounds (requires tetanus immune globulin irrespective of immunization status)
- Rapid consultation with the physician for thrush, a diaper rash, or any other signs or symptoms of illness

Prevention of infections is important, and this requires good handwashing, regular bathing, appropriate food preparation skills (wash bottles, nipples, and pacifiers), and good skin care (changing diapers and moisturizing skin in other areas to prevent drying and cracking).[79]

CYTOMEGALOVIRUS INFECTION

Prevention. There are no practical methods for preventing CMV infection. Avoiding exposure is virtually impossible because of the ubiquitous and asymptomatic nature of the infections. **Avoiding unnecessary blood transfusions or using CMV-seronegative blood donors, white blood cell–depleted blood products, or frozen deglycerolized blood cells has proved to be important in minimizing the occurrence of postnatally acquired CMV, particularly in premature infants.[9,79]** Short-term or Holder pasteurization of mother's milk (if CMV positive) may be considered for infants born before 32 weeks of gestation.[79]

The question frequently arises about assignment of staff to infants with a possible diagnosis of CMV infection. Staff members who may be pregnant have heightened concern about this issue. Staff members should be aware that many infants with CMV infection are asymptomatic and therefore not identified while in the hospital. **To avoid any problems, staff members should employ good handwashing technique with all infants. Wearing gloves when handling urine and other secretions is a strategy that can also be employed by staff members who are working in the neonatal intensive care unit (NICU) and are pregnant or of childbearing age.** The actual risk for an infected infant's transmitting disease to a susceptible health care worker is unknown but probably small.[79]

Data Collection

History. **Congenital infections are represented by a wide spectrum of disease from asymptomatic disease to profoundly symptomatic disease.** CMV infection in the mother is usually asymptomatic.[92,125]

Signs and Symptoms. **An infant with CMV infection is usually asymptomatic.** Infants less than 32 weeks' gestational age are at greater risk of symptomatic CMV than term infants.[79] Congenital manifestations include intrauterine growth restriction (IUGR), neonatal jaundice (increased direct fraction), purpura, hepatosplenomegaly, microcephaly, seizures, intracerebral calcification, chorioretinitis, and progressive sensorineural hearing loss.[92,125]

Laboratory Data. CMV may be cultured from urine, pharyngeal secretions, and peripheral leukocytes. **Isolation of the virus within 3 weeks of birth indicates transplacental acquisition.** A paired sera demonstration of a fourfold titer rise or histopathology demonstration of characteristic nuclear inclusions in certain tissues can confirm infection. Examining the urine for intranuclear inclusions is not helpful. **PCR detection of viral DNA in tissues and cerebrospinal fluid is available.**[79]

Treatment. Ganciclovir, foscarnet, valganciclovir, and cidofovir are the only licensed antiviral agents effective against CMV. These drugs are approved only for treatment of life- and sight-saving disease. In a randomized controlled trial (RCT) that evaluated 42 neonates with congenital CMV infection involving the central nervous system (CNS), 6 weeks of IV ganciclovir therapy prevented hearing deterioration at 6 months. However, two-thirds of neonates treated with ganciclovir had significant neutropenia.[92,125] **Antiretroviral therapy for congenital CMV infection with antiviral agents is recommended in infants with evidence of CNS involvement, including sensorineural hearing loss, and should be considered in infants with serious end-organ disease (hepatitis, pneumonia, thrombocytopenia).**[92,125]

Parent Teaching. The need for good handwashing technique by parents and caregivers of infants with suspected CMV should be included in discharge instructions.

RUBELLA

Prevention. Medical personnel should ensure that all mothers have a protective hemagglutination titer before conception. If the woman is susceptible, vaccinate her with rubella vaccine before conception, and advise her that she should avoid conception for 28 days after receiving the vaccine.[79,91] If a woman is found to lack immunity to rubella during pregnancy, she should receive rubella immunization in the postpartum period, even if she is breastfeeding.[91]

All perinatal health care workers should have rubella titers drawn to identify immunity status, and they should be re-immunized if this is not adequate. Women of childbearing age who do not have protective immune titers should be encouraged to have rubella immunization.[9,79]

Data Collection

History. **Rubella in the first 4 to 5 months of pregnancy is associated with a high incidence of sequelae in the infant.**[9] A mother with rubella may be relatively asymptomatic or mildly ill with respiratory symptoms with or without a rash.[79]

Signs and Symptoms. Congenital manifestations of rubella include IUGR, sensorineural deafness, cataracts, neonatal jaundice (increased direct fraction), purpura, dermal erythropoiesis, hepatosplenomegaly, microcephaly, chronic encephalitis, chorioretinitis, and cardiac defects (especially patent ductus arteriosus and peripheral pulmonic stenosis). Less frequent manifestations include bone lesions and pneumonitis.[79]

Laboratory Data. The virus may be isolated from the throat, blood, urine, and cerebrospinal fluid (CSF). A paired sera demonstration of a fourfold rise in titers, such as an indirect hemagglutination (IHA) inhibition test or an indirect fluorescent antibody (IFA) test, is diagnostic. The IHA test generally has been replaced by one of several more sensitive methods, including ELISA, or latex agglutination, and reverse transcriptase polymerase chain reaction (RT-PCR) assays.[27,79]

Treatment. Supportive care is needed for transient manifestations such as hepatitis, jaundice, and thrombocytopenia. Cardiovascular and CNS abnormalities should be followed by the appropriate specialists. The infant should be monitored for failure to thrive. Serial hearing screens are indicated as deafness may develop or increase over time. Developmental follow-up should be included in the plan of care as psychomotor difficulties may develop, including autism.[126]

Parent Teaching. **Infants with congenital rubella syndrome may secrete the virus for many years. This requires that discharge instructions include preventive strategies that should be employed to decrease the chance of contact of susceptible pregnant women with the infant. Parents should be informed of their responsibility to ensure that potentially seronegative women of childbearing age avoid direct contact with the infant.**[79] The challenge arises to impress this on the family and at the same time avoid ostracizing the infant or negatively affecting the parent-infant attachment process. In discharge planning with these families, a collaborative approach should be employed, using community health, medical, nursing, and social work input and support. Another challenge is to impress on parents that an infant exposed to rubella during pregnancy may appear normal at birth, but the first appearance of some CNS symptoms may extend into childhood. Thus families and clinicians should keep a watchful eye on these children during the early childhood years.[91]

SYPHILIS

Prevention. Pregnant women should avoid exposure to syphilis. Monitor the serum early and late in pregnancy, and treat the mother for the appropriate stage of disease. Erythromycin, previously used in penicillin-sensitive women, is not considered adequate treatment during gestation because of 30% treatment failure rates in adults and failure to establish a cure in newborns as a result of poor transplacental passage of erythromycin. **Infants born to women treated with erythromycin should be considered at high risk for infection and appropriately evaluated and treated.** If penicillin allergy is confirmed in the pregnant woman, acute desensitization is necessary. Desensitization can be accomplished using increasing doses of oral penicillin over 4 to 6 hours.[151]

Data Collection

History. **A congenital infection may be manifested by a multisystem disease.** A primary syphilitic chancre on the cervix or rectal mucosa in a mother may be unnoticed.[151]

Signs and Symptoms. An infant exposed to syphilis may be asymptomatic at birth, or virtually all organ systems may be involved. Clinical findings may include hepatitis, pneumonitis, bone marrow failure, myocarditis, meningitis, nephrotic syndrome, rhinitis (snuffles), a rash involving the palms and soles, and pseudoparalysis of an extremity.[79,151]

Laboratory Data. The microscopic darkfield examination identifies spirochetes from nonoral lesions.

Nonspecific, nontreponemal reaginic tests, such as Venereal Disease Research Laboratory (VDRL) tests and rapid plasma reagin (RPR) tests, followed serially with a rise or absence of fall after birth, are useful for screening.[79,151] Specific treponemal antibody serologic tests, such as a fluorescent treponemal antibody absorption (FTA-ABS) test or a microhemagglutination test for *Treponema pallidum* (MHA-TP), provide diagnostic confirmation of a reactive nontreponemal test, but an FTA-ABS immunoglobulin M (IgM) test is unreliable.[79] False-positive results may occur with nontreponemal tests secondary to other medical conditions or other spirochetal diseases. Therefore confirmation of diagnosis is necessary.[79] **A long-bone x-ray examination showing metaphysitis or periostitis may help in diagnosing syphilis. VDRL tests on CSF are mandatory in all infants suspected of having congenital syphilis.** When the diagnosis of active congenital syphilis is equivocal, often it is best to treat and ascertain the diagnosis by serial serologic determinations.[79]

Treatment. Table 22.1 outlines the treatment of syphilis.[79]

Parent Teaching. Adequate follow-up of both symptomatic and asymptomatic neonates is very important. A physical evaluation should be conducted at 1, 2, 3, 6, and 12 months. Serologic testing should be performed at 3, 6, and 12 months after completion of therapy regimen, or until titer decreases fourfold. Noninfected or adequately treated infants' titers should be decreased by 3 months and nonreactive by 6 months. If titers fail to decline or if they increase or are still present after 6 to 12 months of age, the infant should be reevaluated and retreated. Infants with neurosyphilis should have a repeat CSF examination every 6 months until it is normal and VDRL nonreactive. If CSF VDRL is still reactive at 6 months or CSF white cell count is not decreasing at each reexamination or is abnormal at 24 months, retreatment is indicated.[79]

TOXOPLASMOSIS

Prevention. Women should avoid unnecessary exposure to raw meat, cat feces, and eating fruits or vegetables not peeled or washed thoroughly. Using a pair of gloves when emptying the litter box may provide protection if the pregnant woman (or a woman attempting to become pregnant) must empty the litter box.[79] A pregnant woman (or woman attempting to become pregnant) should use hot soapy water to wash her hands immediately after exposure to any infectious source, even after wearing gloves.[26]

Data Collection

History. Congenital infections are represented by a wide range of disease, from asymptomatic disease to profound symptomatic disease, and all require treatment.[66,79,139] Mothers may have noted an influenza-like illness or posterior cervical adenitis. Toxoplasmosis should be considered in the differential diagnosis if chorioretinitis is present, even if there are no other symptoms. A history of exposure to cat feces or ingestion of raw meat may occasionally be obtained.[66,79,139]

Signs and Symptoms. Manifestations in a newborn may be prematurity, IUGR, hydrocephalus, chorioretinitis, seizures, cerebral calcifications, hepatosplenomegaly, thrombocytopenia, jaundice, generalized lymphadenopathy, and rash.[66,79,139]

Laboratory Data. Isolating *Toxoplasma gondii* from blood or body fluids is difficult and tedious. Cysts may be found in the placenta or tissues of a fetus or newborn.[66,139] Most congenitally infected infants have a Sabin-Feldman dye test titer greater than 1:1000 at birth.

Treatment. Table 22.1 outlines the treatment of toxoplasmosis.[79]

Parent Teaching. Parents of infants with congenital toxoplasmosis should know that the majority of neurologic problems are identified in early infancy and will need ongoing management and follow-up for visual impairment.[55]

ZIKA VIRUS

Prevention. Women who are contemplating pregnancy should avoid travel to areas known to have Zika virus (ZKV) present and avoid intercourse with male partners who are at risk for exposure to ZKV. Pyriproxyfen, a mosquito larvicide, has been introduced into drinking water in Brazil and is considered nontoxic at recommended levels.[156]

Data Collection

History. Zika virus is an arbovirus transmitted by Aedes mosquitos (particularly *Aedes Aegypti* mosquitoes, known for spreading yellow fever

TABLE 22.1 RECOMMENDED THERAPY FOR INDICATED CONDITION

CONDITION	TREATMENT
Sepsis and/or Meningitis	
Initial Therapy	
Early onset	IV ampicillin and gentamicin or IV amikacin (if gentamicin-resistant organisms are present in nursery, ampicillin plus cefotaxime is a suitable alternative, particularly if meningitis is present).
Late onset	IV vancomycin plus cefotaxime or IV aminoglycoside (see "Early onset").
Once Specific Organisms Are Identified	
Group B *Streptococcus*	IV ampicillin and gentamicin for 10-14 days (gentamicin may be discontinued if strain is susceptible to ampicillin or with penicillin G alone once identified and shown to be susceptible).
Coliform species	IV ampicillin and gentamicin for 10-14 days (cefotaxime may replace gentamicin).
Listeria monocytogenes	IV ampicillin and IV gentamicin for 14-21 days.
Enterococcus	Same as for *Listeria monocytogenes*. For ampicillin resistance, use vancomycin.
Group A *Streptococcus*	IV penicillin G for 10-14 days.
Group D *Streptococcus* (non-enterococcus)	Same as for group A *Streptococcus*.
Staphylococcus aureus	IV nafcillin for 10-14 days; IV vancomycin for methicillin-resistant strains.
Staphylococcus epidermidis	IV vancomycin for 10-14 days.
Pseudomonas aeruginosa	IV ceftazidime and aminoglycoside for 10-14 days.
Anaerobes	IV metronidazole, clindamycin, or meropenem.
Pneumonia	
Group B *Streptococcus*	Same as for sepsis (respiratory distress syndrome may mimic pneumonitis and vice versa).
Staphylococcus aureus	Same as for sepsis.
Chlamydia trachomatis	PO erythromycin for 14 days or with azithromycin for 3 days.
Pneumocystis jiroveci	PO or IV trimethoprim and sulfamethoxazole, or IV pentamidine isethionate.
Pertussis	PO or IV azithromycin for 5 days (clinical course is unchanged, but shedding of organism is diminished significantly).
Ureaplasma spp.	PO or IV azithromycin 20/kg/day for 3 days
Other organisms	Same as for sepsis.
Skin and Soft Tissue Infections	
Impetigo	IV or IM nafcillin; PO cephalexin for 7 days (depending on clinical severity). For methicillin resistance, use vancomycin. Also consider topical mupirocin.
Group A *Streptococcus* infections	IV penicillin G for 7 days.
Breast abscess	IV nafcillin and gentamicin for 7 days pending identification of etiologic agent (change to IV penicillin if *Streptococcus* is etiologic agent; IV ampicillin or gentamicin should be used for coliform species pending sensitivities); value of surgical drainage is individualized; vancomycin for methicillin-resistant strains.
Omphalitis and/or funisitis	Cefotaxime or gentamicin, and clindamycin for ≥10 days (penicillin may be used if infection is caused by group A or B streptococci); if gram-negative rods, consider gentamicin or cefotaxime also.

TABLE 22.1 RECOMMENDED THERAPY FOR INDICATED CONDITION—CONT'D

Gastrointestinal Infections	
Salmonella species	IV ampicillin for 7-10 days; or IV cefotaxime or ceftriaxone for 7-10 days depending on sensitivities (focal complications of meningitis and arthritis should be monitored closely).
Shigella species	PO trimethoprim/sulfamethoxazole or PO or IV ampicillin, depending on susceptibilities.
Necrotizing enterocolitis	IV ampicillin and IV gentamicin for 2-3 weeks, (if *Pseudomonas* is isolated, IV ceftazidime or piperacillin/tazobactam combination may be substituted for ampicillin); supportive measures (gastrointestinal suction) are appropriate.
Osteomyelitis or Septic Arthritis	
Group B *Streptococcus*	IV penicillin G or ampicillin for 21 days minimum.
Staphylococcus aureus	IV oxacillin for 21 days minimum. Vancomycin for methicillin-resistant strains.
Coliform species	IV gentamicin for 21 days (IV ampicillin for 21 days minimum if organism is sensitive).
Gonococcus species	IM, IV ceftriaxone for 7-14 days
Unknown	IV oxacillin and gentamicin or cefotaxime for 21 days minimum.
Urinary tract infections	Suspect predisposing anatomic defect if urinary tract infection; individualize workup and follow-up.
Enterococcus species	Ampicillin, 150 mg/kg/day divided q 8 hr for 10 days.
Miscellaneous Conditions	
Congenital syphilis	If more than 1 day of treatment is missed in either of the following regimens, the entire course should be restarted.
Without central nervous system (CNS) involvement	IM procaine penicillin G (50,000 units/kg) daily for 10-14 days (follow-up Venereal Disease Research Laboratory [VDRL] test results should revert to negative if treatment is adequate by 1 year).
With CNS involvement	IV aqueous crystalline penicillin 50,000 units/kg/dose q 12 hr for the first 7 days of life and then q 8 hr for 10 days. Repeat lumbar puncture about every 6 months until results are normal.
Toxoplasmosis	PO sulfadiazine, 100 mg/kg/day divided q 12 hr and PO pyrimethamine, 2 mg/kg/day for 2 days then 1 mg/kg/day for 2-6 months, then 3 times weekly for up to 1 year. Dose is divided q 12 hr (supplemental folic acid, 1 mg/day, should be added). Ocular, CNS, or HIV involvement may require additional therapy.
Herpes simplex infections	IV acyclovir, 20 mg/kg/dose q 8 hr for 14 days if skin or mucous membrane involvement; 21 days if CNS involvement. If eye involvement, add trifluridine 1% ophthalmic or ganciclovir 0.15% ophthalmic.
Conjunctivitis	
Chlamydia species	PO erythromycin for 10 days (topical may be ineffective) or azithromycin for 5 days
• Gonococcus species	IM, IV ceftriaxone 25-50 mg/kg as a single dose and azithromycin for 5 days (cefotaxime if hyperbilirubinemia present)
Otitis Media	
• In otherwise normal neonate	PO amoxicillin/clavulanic acid (Augmentin), 40 mg/kg divided q 8 hr for 10 days.
• In neonate with nosocomial infection	PO or IV ampicillin and IV gentamicin (if there is no response to treatment, consider diagnostic tympanocentesis; *Staphylococcus aureus* and coliform species may be present).

CNS, central nervous system; *HIV,* human immunodeficiency virus; *hr,* hour; *IM,* intramuscular; *IV,* intravenous; *PO,* oral.

Data from Bradley JS, Nelson JD, eds. *Nelson's Pediatric Antimicrobial Therapy.* 24th ed. Elk Grove Village, IL: American Academy of Pediatrics and Redbook; 2018.

and dengue fever) or through sexual transmission. First identified in 1947 in Rhesus monkeys in the Zika forest of Uganda, Zika infection was reported in Brazil in 2015 and has spread rapidly.[62,127] The virus generally occurs close to sea levels and has been identified in Central/South America, Central Africa, Southeast Asia, the Pacific Islands, the Caribbean, Puerto Rico, New York, and in the gulf coast region of the United States.[14,156]

Signs and Symptoms. A careful maternal history is important. Zika may be asymptomatic or result in a subtle flulike illness.[62,156] Maternal symptoms may include fever, rash, pruritis, lymphadenopathy, edema of extremities, myalgia, arthralgia, headache, vertigo, retro-orbital pain, vomiting, diarrhea, or mucous ulcers.[127,156]

Infants may have a number of neurologic symptoms including microcephaly (if present on prenatal ultrasonography, testing is recommended). Encephalomyelitis, cerebral calcifications, ventriculomegaly and lissencephaly, mild cardiac defects (ASD, PDA, and VSD), ocular defects (colobomatous chorioretinal atrophy of the macula and pigmentary changes), arthrogryposis, and talipes have all been reported.[62,108,157]

Laboratory Data. **Viral particles have been detected by reverse-transcriptase polymerase chain reaction (RT-PCR) in blood, urine, amniotic fluid, semen, saliva, and in neuronal tissue.** Serologic testing with IgM, ELISA, or immunofluorescence assay may detect Zika virus in acute infections.[84,127] A plaque reduction neutralization test can help eliminate cross-reactivity to other *Flaviviridae* viruses in serology.

Treatment. Vaccine development is in progress using both DNA and inactivated viruses.[14]

Parent Teaching. **Parents should be aware of the need for developmental follow-up,** as microcephaly may result in developmental delay. Eye abnormalities may result in visual impairment. Progressive sensorineural hearing loss may be detected by serial hearing screens.[157]

Perinatal Acquisition During Labor and Delivery

CHLAMYDIA TRACHOMATIS INFECTION

Prevention. **Eye prophylaxis with erythromycin (preferred) or tetracycline ophthalmic ointment minimizes the development of conjunctivitis but has no effect on the subsequent development of pneumonitis.**[79,109]

Data Collection

History. A mother with a *Chlamydia trachomatis* infection is usually asymptomatic during her pregnancy.[9,109]

Signs and Symptoms. **Conjunctivitis may be manifested as congestion and edema of the conjunctiva, with minimal discharge developing 1 to 2 weeks after birth** and lasting several weeks with recurrences, particularly after topical therapy. **Infants with pneumonitis usually do not have a fever but have a prolonged staccato cough,** tachypnea, mild hypoxemia, and eosinophilia. Otitis media and bronchiolitis also may occur.[79,109]

Laboratory Data. Definitive diagnosis is made by isolating the organism in tissue culture and by nucleic acid amplification tests (NAATs) (e.g., PCR). Direct fluorescent antibody method or enzyme immunoassay is less sensitive and specific. **To enhance the likelihood of obtaining an adequate sample, scrape the lower conjunctiva (for conjunctivitis), or obtain deep tracheal secretions or a nasopharyngeal aspirate (for pneumonia).** NAATs are not recommended for nasopharyngeal aspirates unless the laboratory is Clinical Laboratory Improvement Amendments (CLIA) certified to perform the test. Scraping conjunctival epithelial cells and demonstrating characteristic intracytoplasmic inclusion bodies by a Giemsa stain is diagnostic. **Although serologic tests for conjunctivitis are unreliable, a significant titer rise in IgM-specific antibody may be reliable in cases of pneumonia. Eosinophilia (greater than 300 eosinophils/mm3) may suggest chlamydial pneumonia**. Cell culture and nonculture methods, such as DFA, can be used to diagnose neonatal chlamydial ophthalmia and neonatal chlamydial pneumonia although with less sensitivity and specificity than culture.[79,109]

Treatment. Table 22.1 **outlines the treatment of chlamydia.**

Parent Teaching. The mother and any sexual partners should be treated. The infant should be observed for emesis as hypertrophic pyloric stenosis has occurred in infants receiving oral erythromycin and azithromycin.[79]

ENTEROVIRUS (COXSACKIEVIRUS A, COXSACKIEVIRUS B, ECHOVIRUS, AND POLIOMYELITIS) INFECTIONS

Enterovirus infections are the most commonly diagnosed viral infections in the NICU, and coxsackievirus B1 was the most common in 2007 by the National Enterovirus Surveillance System.[31,77]

Prevention. To prevent poliomyelitis, it is essential to maintain poliomyelitis immunity with active immunization before conception. Passive protection with pooled human serum globulin may help in selected exposures (0.2 mL/kg body weight, given intramuscularly). **Routine nursery infection control procedures must be observed. It is recommended that only inactivated poliovirus vaccine (IPV) be used in the nursery.** The IPV is administered intramuscularly and contains no live virus, whereas oral poliovirus vaccine (OPV) (no longer available in the United States) is administered orally and contains live but attenuated virus, which has been reported to cause infection in immunocompromised patients.[79]

Data Collection

History. Infection may occur year-round but is more prevalent from June to December in temperate climates. Most enterovirus infections are asymptomatic. Poliomyelitis is rare because of a high level of vaccine-induced immunity in most of the world.[79]

Signs and Symptoms. Mothers with enteroviral infections are usually mildly ill, with fever or diarrhea. **Infants may be asymptomatic or have fever or diarrhea. Infants who acquire the infection without maternal antibody have severe disease and high mortality rates.** Fever, irritability, lethargy, and rash are common. Severe disease with sepsis, meningoencephalitis, myocarditis, pneumonia, hepatitis, or coagulopathy may occur.[2] Prematurity, early onset of illness (less than 7 days), maternal history of illness, high white blood cell count (15,000/mm^3 or greater), and low hemoglobin (less than 10.7 g/dL) have been shown to be risk factors of severe infection.[87]

Laboratory Data. The virus may be isolated from the throat, rectum, or CSF. Isolating coxsackie virus A may require suckling mouse inoculation. Serologic screening is impractical because of the large number of serotypes. PCR assay for enterovirus RNA in CSF and other specimens is available and is more sensitive than viral isolation.[79]

Treatment. **A randomized, double-blind, placebo-controlled trial of the antiviral agent *pleconaril* in 61 newborns with enteroviral sepsis characterized by hepatitis, coagulopathy, or myocarditis suggests that pleconaril decreases duration of culture and PCR positivity and increases survival. Further development and evaluation of pleconaril therapy for neonates is warranted.**[3] Pleconaril prevents viral attachment and entry into the host cells and seems to be well tolerated in neonates.[2,67] Hand hygiene is paramount to control spread of enteroviral infections.[79] Intravenous immunoglobulin may be effective in severe enteroviral infection.[3]

GROUP B STREPTOCOCCUS INFECTION

Prevention. **Group B *Streptococcus* (GBS) sepsis is associated with significant morbidity and mortality risks. A recent worldwide systematic review and meta-analysis found the risk of early onset GBS infection in neonates of colonized mothers to be 1% to 2%.**[132]

In 2019 the American Academy of Pediatrics (AAP) and the American College of Obstetricians and Gynecologists (ACOG) reaffirmed universal antenatal culture screening for the detection of GBS colonization and intrapartum antibiotic prophylaxis in colonized women to prevent early onset sepsis.[22, 122] Implementation of this strategy has decreased the incidence of early onset GBS in the United States form 1.8 cases/1000 live births in 1990 to 0.23 cases/1000 live births in 2015.[102]

Pregnant women who are GBS positive are treated with penicillin or ampicillin during labor or treated with cefazolin if they are allergic to penicillin. **Intrapartum prophylactic antibiotics are also indicated if the GBS status of the mother is unknown and one or more intrapartum risk factors exist (see History in the next section).**

Treatment with antibiotics for less than 4 hours is inadequate to prevent the transmission of GBS.[122] Use of these guidelines results in an 80% reduction in the number of neonates affected by early-onset GBS sepsis.[9,79,132]

Data Collection

History. **Maternal history of any risk factors that include (1) gestation less than 37 weeks, (2) rupture of membranes for 18 hours or longer, (3) a maternal temperature of 38°C (100.4°F) or higher, (4) a history of GBS bacteriuria during the current**

TABLE 22.2 MATERNAL AND INFANT CLINICAL CHARACTERISTICS OF EARLY-ONSET GBS DISEASE

GBS STATUS	ROM >18 HR	ANY FEVER	FEVER >100.4° C	INTRAPARTUM ANTIBIOTICS	TERM	PRETERM	ILL-APPEARING	ABNORMAL WBC COUNT	CRITICALLY ILL/DIED
Negative (*n* = 16)	7 (44)	8 (50)	3 (19)	2 (12)	14 (88)	2 (12)	11 (69)	12 (75)	5 (31)
Positive (*n* = 5)	3 (60)	2 (40)	1 (20)	2 (40)	2 (40)	3 (60)	4 (80)	2 (40)	2 (40)
Unknown (*n* = 4)	0 (0)	2 (50)	1 (25)	0 (0)	1 (25)	3 (75)	4 (100)	4 (100)	4 (100)
			5 (20)	4 (16)	17 (68)	8 (32)	19 (76)	18 (72)	11 (44)

Numbers in parentheses indicate percentage of total for each category (GBS negative, positive, or unknown and total cases). ROM indicates rupture of membranes; abnormal WBC count. *GBS,* Group B *Streptococcus; ROM,* rupture of membranes; *WBC,* white blood cell.
Modified from Puopolo KM, Madoff LC, Eichenwald EC. Early-onset group B streptococcal disease in the era of maternal screening. *Pediatrics* 2005;115(5):1240.

pregnancy, or (5) a previous infant with GBS infection warrants intrapartum antibiotics.[12,122]

Signs and Symptoms. Symptoms of early-onset GBS are seen within the first 24 hours of life. Table 22.2 depicts clinical and laboratory findings of early-onset GBS infection.

Laboratory Data. New screening tests have been developed and validated for rapid identification of GBS, including pigmented enrichment broths, chromogenic agars, DNA probes, and NAATs, such as PCR. A survey of antepartal and intrapartal use of NAATs found that only 18.7% of laboratories offered NAATS for rapid GBS screening.[52] Another study of the impact of rapid PCR to test for GBS in women at term with ruptured membranes found a clinically significant reduction in the use of prophylactic antibiotics.[57]

A full sepsis evaluation, including a lumbar puncture (LP), is indicated for any newborn who demonstrates signs of infection.

Treatment. Table 22.1 outlines the antibiotic treatment of GBS infection.

As outlines in the current guidelines there are three strategies for risk assessment of infant greater than or equal to 35 weeks' gestation: 1 categorical risk assessment (see Figure 22.1A), use of the Neonatal Early Onset Sepsis Calculator (see Figure 22.4 and 3) enhanced observation (see Figure 22.1B) For Infants less than or equal to 34 weeks' gestation the early onset risk assessment is outlined in Figure 22.2.

Use of the updated treatment algorithms have reduced the number of early onset sepsis evaluations ans antibiotic exposure without increasing the rate of GBS infection.[4, 23, 79, 144]

Complications. Although GBS prophylaxis has been shown to be effective for early onset sepsis, neonatal GBS disease remains a significant health problem.[135,140,144] Concerns for antibiotic resistance exist and the incidence of late onset GBS has not declined, but in fact is now more common than early onset GBS.[44,102] GBS contaminated breast milk may be a source of late onset GBS sepsis.[17, 168]

Parent Teaching. See Early Onset Bacterial Disease, Parent Teaching on p. 24 and Parent Teaching on p. 31.

HEPATITIS B

Prevention. Prenatal screening of women for hepatitis B surface antigen (HBsAg) is indicated and is cost-effective. **Use of active and passive immunization in infants born to HBsAg-positive mothers is recommended by the Advisory Committee on Immunization Practices[134]** (Tables 22.3 and 22.4). **Within 24 hours of birth, universal vaccination of medically stable newborns weighing greater than or equal to 2000 g born to HBsAg-negative women is recommended.[134]** Additionally, the new recommendations also include: (1) testing of HBsAg-positive pregnant women for

hepatitis B virus DNA, (2) postvaccination serologic testing for infants whose mother's HBaAg status is indefinitely unknown (when a parent relinquishes a newborn), (3) single-dose revaccination for infants born to HBsAg-positive mothers who are not responding to the initial dose, and (4) removal of permissive language for delaying the birth dose until after hospital discharge.[134] HepB vaccine or HBIG given together or alone are 75% and 71% effective, respectively, in preventing perinatal transmission of HBV. Combined, their efficacy is 94%. Vaccination produces seroprotection in 98% of healthy term neonates, with a better vaccine response in infants less than 2000 g birth weight at 1 month of age.[134]

Data Collection

History. **Mothers who are HBsAg positive because of the chronic carrier state or acute disease before delivery may pass the infection to their infants at delivery.**[9] Women at high risk include those of Asian, Pacific Islander, or Alaskan Eskimo descent; women born in Haiti or sub-Saharan Africa; and those with a history of liver disease, IV drug abuse, or frequent exposure to blood in a medical-dental setting.

Signs and Symptoms. **A neonate with hepatitis B is usually asymptomatic.** Occasionally, infected infants demonstrate elevated liver enzymes or acute fulminating hepatitis.[79] **Neonatal infection with subsequent chronic carriage has been implicated in the development of primary hepatocellular carcinoma later in life.**

Laboratory Data. Most infants at risk for acquiring hepatitis from their mother are HBsAg negative at birth. Many untreated infants become HBsAg positive 4 to 12 weeks after birth and become lifelong asymptomatic carriers or develop hepatitis B.[79]

Treatment. **Infants born to mothers who are Hepatitis B positive or are of unknown status should receive Hepatitis B vaccine and HBIG within 12 hours of life. In general, all stable newborns weighing 2000 g and over should receive Hepatitis B vaccine in the first 24 hours of life. Infants weighing less than 2000 grams should be immunized at 1 month of age or before hospital discharge.** Only single-antigen hepatitis B vaccine should be used for newborns. If inflammatory liver disease is present, referral to a hepatologist is advised.[79,134]

Parent Teaching. **Risk of chronic hepatitis B infection is increased in infants exposed prenatally or in the first year of life.** Up to 25% of infants who acquire chronic hepatitis B infection will develop HBV hepatocellular cancer or cirrhosis.[79] **Stable premature infants should get Hepatitis B immunizations at the same chronologic age and in the same dose as term infants throughout the complete series. Serologic testing for immunity is recommended** for infants born to HBsAG-positive women and to women with unknown status.[79,134]

HEPATITIS C

Prevention. **Neonates acquire hepatitis C virus (HCV) infection mostly through vertical transmission from the mother** and rarely through transfusion of hepatitis C–contaminated blood products. **Vertical transmission rates from the mother to the infant vary (approximately 5%), and risk factors associated with increased transmission are HCV viral load, coinfection with HIV, rupture of membranes more than 6 hours, and internal fetal monitoring.**[47,110,118] Reducing viral load by maternal antiviral therapy, especially in HIV-coinfected women, and avoiding internal fetal monitoring are interventions that can reduce transmission but have not been evaluated. **Breastfeeding is not associated with increased rates of transmission and is not contraindicated.**[79,118] Screening of blood products for HCV is mandatory for prevention of transfusion-related HCV infection.

Data Collection

History. **Approximately 1% to 2% of pregnant women in the United States are seropositive for HCV, but vertical transmission occurs only if the mother is HCV RNA positive at the time of delivery.**[79] HCV RNA titers rise many weeks after birth in infants, indicating a perinatal acquisition rather than an intrauterine transmission.[118]

Signs and Symptoms. **Neonates with perinatal acquisition of HCV infection are usually asymptomatic** without jaundice and with normal or only mildly elevated liver transaminase levels.[79] **Progression to chronic hepatitis is common and occurs in approximately 80% of infected infants. Liver biopsies in infants with perinatally acquired HCV during follow-up show evidence of chronic inflammation.** A small percentage (20%) of infants may spontaneously resolve their infection.[49]

Laboratory Data. **The essential diagnostic feature is HCV RNA positivity on at least two occasions by PCR.** Sensitivity of the PCR is 22% in infants younger than 1 month of age and 97% after 1 month of age.[45] Maternal antibodies may persist in the infant for 13 to 18 months and are not useful for

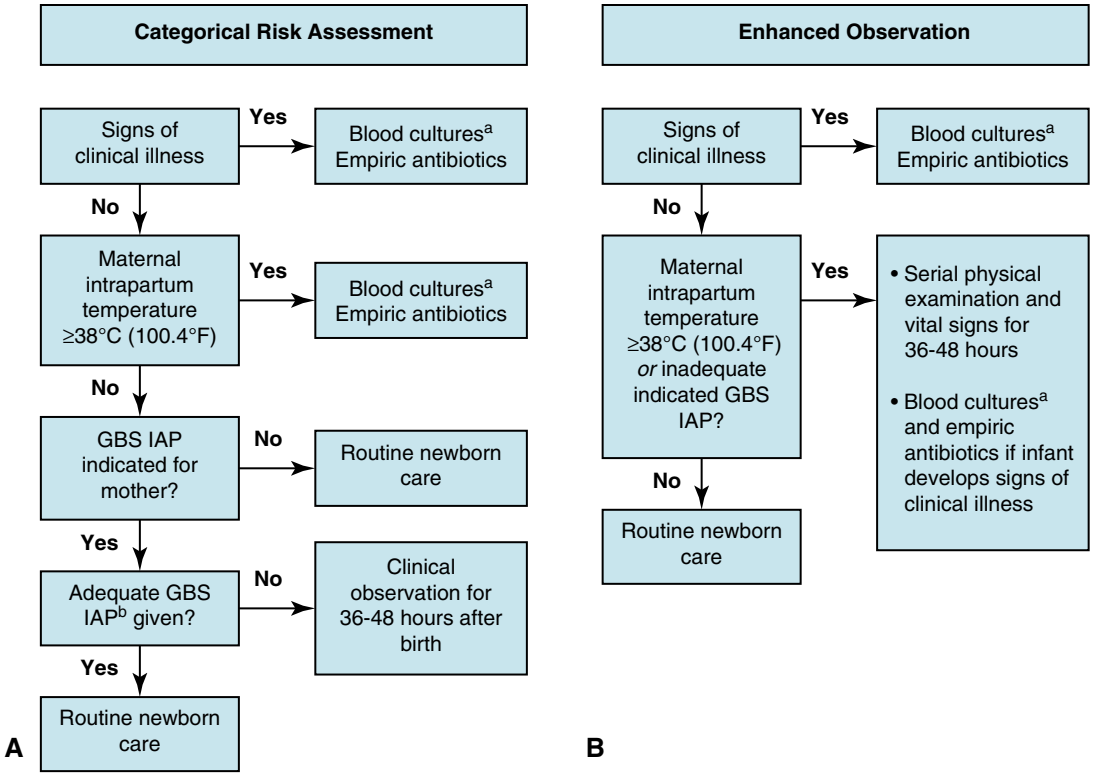

FIGURE 22.1 Options for EOS risk assessment among infants born ≥35 weeks' gestation. A, categorical risk assessment. B, Enhanced observation.[a] Consider lumbar puncture and CSF culture before initiation of empiric antibiotics for infants who are at the highest risk of infection, especially those with critical illness. Lumbar puncture should not be performed if the infant's clinical condition would be compromised, and antibiotics should be administered promptly and not deferred because of procedure delays.[b] Adequate GBS IAP is defined as the administration of penicillin G, ampicillin, or cefazolin ≥4 hours before delivery.

diagnosis. Following liver transaminase levels may help monitor the course of hepatic inflammation.

Treatment. Ribavirin and interferon alfa are used in the treatment of adults. A systematic review and meta-analysis of ribavirin and interferon for the treatment of chronic hepatitis C in children found that the combination therapy is both safe and effective.[43] One study found a 98% sustained viral response in children 1 to 5 years of age treated with interferon and ribavirin for chronic hepatitis C.[167] A 5-year follow-up of ribavirin/pegylated interferon found significant impairment in height; within the next 5 to 10 years, interferon-free regimens may become available.[65]

Parent Teaching. Transmission among family contacts is rare unless there is direct or mucosal exposure to blood. **Breastfeeding is safe as long as the mother's nipples are not cracked or bleeding.** Children with hepatitis C generally do not need to be excluded from child care settings.[79]

HERPES SIMPLEX (TYPES 1 AND 2) INFECTION

Prevention. The key to preventing herpes simplex is avoiding exposure. In the third trimester, use of maternal prophylaxis with antiviral agents for herpes decreases recurrence of maternal lesions and decreases the incidence of cesarean delivery. However, there is insufficient evidence that this strategy prevents neonatal herpes.[68] **Mothers with active lesions or in prodrome should have a cesarean delivery preferably within 4 to 6 hours of membrane rupture. Treatment with acyclovir should begin at the first sign of neonatal disease or when infants have been exposed to an active lesion.[9,79]**

Communication is necessary between obstetric and neonatal staff to determine the status of a family

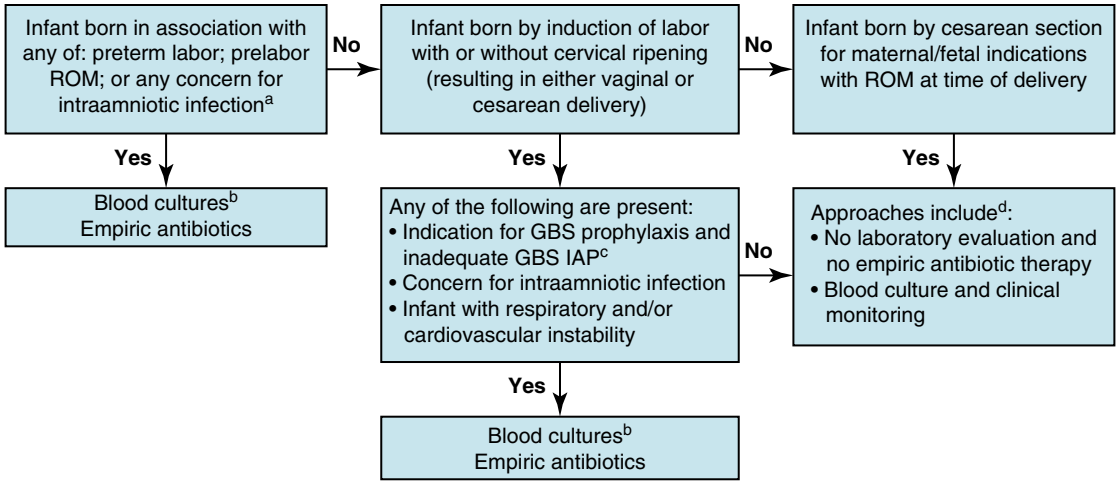

FIGURE 22.2 EOS risk assessment among infants born ≤34 week's gestation.[a] Intraamniotic infection should be considered when a pregnant woman presents with unexplained decreased fetal movement and/or there is sudden and unexplained poor fetal testing.[b] Lumbar puncture and CSF culture should be performed before initiation of empiric antibiotics for infants who are at the highest risk of infection unless the procedure would compromise the infant's clinical condition. Antibiotics should be administered promptly and not deferred because of procedural delays.[c] Adequate GBS IAP is defined as the administration of penicillin G, ampicillin, or cefazolin ≥4 hours before delivery.[d] For infants who do not improve after initial stabilization and/or those who have severe systemic instability, the administration of empiric antibiotics may be reasonable but is not mandatory.

TABLE 22.3 ACCEPTABLE METHODS OF PASSIVE IMMUNIZATION IN NEWBORNS

DISEASE	INDICATIONS	WHEN TO USE	PRODUCT	DOSE
Hepatitis A	Active infection in mother or close family contacts	As soon as possible	IGIM	0.02–0.04 mL/kg body weight given IM
Hepatitis B	Mothers with acute type B infection or who are antigen (+)	As soon as possible (within 12 hours)	HBIG*	0.5 mL IM
Tetanus	Inadequately immunized mothers with contaminated infant (e.g., dirty cord)	As soon as possible	TIG	250 units given IM (optimal dose not established)
Varicella	Administer as soon as possible to infant born to a mother who develops lesions <5 days before delivery, within 7 days after delivery, or when/if infant is exposed to varicella-zoster virus any time during the initial hospitalization.	Within 10 days	VariZIG	125 units/10 kg body weight up to a maximum of 625 units (62.5 units if ≤2 kg)

*Should be used in conjunction with active immunization with hepatitis B virus (HBV) vaccine (see Table 22.4).
HBIG, Hepatitis B immune globulin; *IGIM*, immune globulin for intramuscular injection; *IM*, intramuscularly; *TIG*, tetanus immune globulin (human); *VariZIG*, varicella zoster immune globulin.
Modified from Wilson C, Nizet V, Maldonado Y, Remington J, Klein J, eds. *Remington and Klein's Infectious Diseases of the Fetus and the Newborn Infant.* 8th ed. Philadelphia, PA: Elsevier Saunders; 2016; with addition from Updated recommendations for use of VariZIG—United States, 2013. *MMWR* 2013;62(28):574–576.

with a history of herpes. **Unnecessary restrictions should not be placed on postpartum mothers who are not actively infected.**[9] Health professionals should employ all family-centered strategies used in their institutions with families unless such strategies are precluded by the need for the infant's treatment.

Data Collection

History. Disease caused by type 1 herpes simplex usually is spread by the oral route, whereas disease caused by type 2 herpes simplex is usually spread by the genital route.[79] **Many mothers who transmit herpes simplex to their newborn infants are**

TABLE 22.4 ACCEPTABLE METHODS OF ACTIVE IMMUNIZATION IN NEWBORNS

DISEASE	INDICATION	WHEN TO USE	PRODUCT	DOSE
Hepatitis B	HBsAg positive or HBsAg negative	3 separate doses: at birth*; at 1 month; and at 6 months	Recombivax HB	0.5 mL given IM
			Engerix-B	0.5 mL given IM
Pertussis	To control outbreak in nursery	As soon as possible	TDaP†	0.5 mL given SC
Tuberculosis	Selected infants at risk for contracting tuberculosis	As soon as possible	BCG	0.1 mL or 0.2-0.3 mL of half-strength dilution given intradermally as a single dose

*As soon as possible (within first 24 hours of life).
†Pregnant mothers may provide passive immunity against pertussis if they receive TDaP between the 27th and 36th weeks of pregnancy.
BCG, Bacillus Calmette and Guérin; *HBsAg*, hepatitis B surface antigen; *IM*, intramuscularly; *SC*, subcutaneously; *TDaP*, tetanus, diphtheria, and pertussis vaccine.

asymptomatic.[71] The risk to the infant from recurrent lesions is minimal.[79]

Signs and Symptoms. Infants with herpes simplex have a spectrum of illnesses ranging from localized skin lesions (i.e., vesicular rash) to generalized infections involving the liver, lungs, and CNS (i.e., seizure).[38,159] A recent study found that 84% of infants presented with seizure, vesicular rash, or critical illness, and a subset (16%) lacked classic signs at admission but manifested HSV signs within 24 hours of admission.[38] Disseminated HSV has high morbidity and mortality rates.[71,79,159]

Laboratory Data. A cytologic examination of the base of skin vesicles with a Giemsa stain (Tzanck test) may reveal characteristic but nonspecific giant cells and eosinophilic intranuclear inclusions. The virus may be readily identified on a tissue culture within 48 hours from the respiratory and genital tracts, blood, urine, and CSF.[79] Rapid viral diagnosis by direct fluorescent antibody tests is widely available.[79] Detection of virus in CSF by PCR assay is preferred, if available.[28] Although tests of paired serology such as complement fixation (CF) test, ELISA, and neutralization are available, they are of little value in an acute clinical situation.[79] Elevated liver transaminases and thrombocytopenia may indicate herpes infection.[24]

Treatment. Table 22.1 outlines the treatment of herpes simplex infection.

Parent Teaching. Families with herpes simplex require consistent and detailed teaching about prevention of transmission of herpes to the infant. Breastfeeding mothers can be reassured that they may continue to breastfeed as long as no lesions are on their breasts. Emphasis should be placed on the need for breastfeeding mothers to check their breasts for lesions.[9]

Parents with active herpes simplex should employ good handwashing technique while caring for their infants. Parents with oral herpes should avoid kissing their infants while lesions are open and draining.[79]

LISTERIA MONOCYTOGENES INFECTION

Prevention. Pregnant women should avoid unpasteurized dairy products (i.e., milk and cheese) to prevent Listeria monocytogenes infection.[89]

Data Collection. See Laboratory Data on p. 20.

Treatment. Table 22.1 outlines the treatment of *L. monocytogenes* infection.

Parent Teaching. See Early Onset Bacterial Disease, Parent Teaching on p. 24 and Parent Teaching on p. 31.

MYCOBACTERIUM TUBERCULOSIS INFECTION

Prevention. Mothers at risk for Mycobacterium tuberculosis infection may be identified with a tuberculin test during pregnancy. If the mother is a tuberculin converter (has had a positive skin test result within the past 2 years), a radiographic examination of the chest and lungs should be performed. If the mother has active tuberculosis, she should be treated with isoniazid plus rifampin and ethambutol for at least 9 months. Safety of pyrazinamide in

pregnancy is not well established, and this drug is not used routinely in pregnant women. **Pyridoxine (vitamin B6) always should be given with isoniazid during pregnancy and breastfeeding because of the increased requirements for this vitamin.** If the mother does not have active tuberculosis, household contacts should be screened. **If the disease is identified in the mother or household contacts, the infant is at high risk for developing tuberculosis.**[79]

Separate infants of mothers with active disease from the mother until the mother is not contagious (usually negative sputum). Treat high-risk infants with isoniazid (10 mg/kg/day) or a tuberculosis vaccine (BCG) (see Table 22.4).[9,79]

Data Collection

History. **A strong history of maternal contact with tuberculosis favors the diagnosis.** This is especially true in high-risk populations (Southeast Asians, American Indians, and families with a known cavitary disease). **Mothers with HIV infection are at an increased risk for developing active tuberculosis.**[79] Mothers infected with tuberculosis have an 80% greater risk of pregnancy complications than noninfected mothers.[40]

Signs and Symptoms. Mothers may be relatively asymptomatic or have signs and symptoms that are generalized (fever and weight loss) or localized to the respiratory tract.[79] **A congenital infection is extremely rare.**[9] **Nonspecific signs and symptoms such as failure to thrive and unexplained hypothermia or hyperthermia are the most common manifestations in the neonatal period.**

Laboratory Data. **Acid-fast organisms found on smears of gastric aspirates, sputum, CSF, or infected tissues strongly suggest tuberculosis in the neonate.** Isolating *M. tuberculosis* by culture is diagnostic and should be sought aggressively. The tuberculin skin test result usually is positive (greater than 10-mm induration) in active tuberculosis. However, a positive skin test result requires 3 to 12 weeks after infection to manifest itself, and the test result is usually negative in a neonate. A chest radiograph examination also usually yields a negative result in a neonate.[79]

Treatment. Because congenital tuberculosis is such a rare condition, optimal therapy has not been established. However, most recommendations suggest four-drug therapy: isoniazid, rifampin, pyrazinamide, and ethambutol or an aminoglycoside (streptomycin or kanamycin).[79]

Parent Teaching. **Infants who are treated with isoniazid or breastfed infants whose mothers are treated with isoniazid should receive pyridoxine supplementation.**[79]

NEISSERIA GONORRHOEAE INFECTION

Prevention. Screening high-risk mothers before delivery may identify asymptomatic gonorrhea. Treating positive mothers before delivery or exposed infants at delivery is necessary.[79]

Administering silver nitrate, erythromycin, or tetracycline in the eyes is mandatory in all vaginal deliveries.[79,99]

Data Collection

History. Mothers with previous venereal disease are a high-risk group, because 80% of the infected women may be asymptomatic.

Signs and Symptoms. The predominant manifestation of gonorrhea is *ophthalmia neonatorum,* although a systemic bloodborne infection may rarely occur involving the joints, lungs, endocardium, and CNS. **Conjunctivitis usually begins 2 to 5 days after birth. Eye prophylaxis minimizes but does not guarantee freedom from infection. Scalp abscess resulting from fetal monitoring has been reported.**[79]

Laboratory Data. **A Gram stain of purulent eye discharge revealing gram-negative intracellular diplococci is diagnostic.** Culture confirmation using fermentation or fluorescence establishes the diagnosis of gonorrhea. The organism is labile, so specimens for culture should be taken to the laboratory and plated immediately. When gonorrhea is diagnosed, other sexually transmitted diseases may be present concomitantly (especially chlamydial infection).[79]

Treatment. Table 22.1 outlines the treatment of *Neisseria gonorrhoeae* infection.

Parent Teaching. Eye prophylaxis should be provided within 1 hour of birth.[79,99]

VARICELLA

Prevention. Tables 22.3 and 22.4 outline prevention of infection.[79]

Data Collection

History. A history of varicella in the mother before conception virtually excludes the diagnosis. Varicella manifests in the mother with a fever, respiratory symptoms, and characteristic vesicular rash primarily on the trunk. **If this occurs within 5 days of**

delivery, the newborn is at risk for infection.[79] Preventive measures should be instituted as soon as possible.[9] **Acute perinatal varicella is frequently a devastating systemic disease.** Nosocomial acquired transmission of varicella is a potentially significant problem for high-risk infants: premature infants born to susceptible mothers; infants who are severely premature regardless of maternal status; and immunocompromised patients of all ages (Table 22.5).

Signs and Symptoms. **Congenital varicella is rare but has followed maternal varicella in the first trimester of pregnancy. Congenital manifestations include limb atrophy, skin scars, and CNS and eye abnormalities.**[7,79]

Laboratory Data. Varicella can be identified from a scab or vesicular fluid using PCR. Viral culture and DFA are less sensitive.[79]

The demonstration of multinucleated giant cells containing intranuclear inclusions in skin scrapings on Giemsa stain is nonspecific but helpful. Virus can be isolated from scrapings of vesicle base during the first 3 to 4 days of the eruption by direct fluorescent antibody test or isolation of virus in tissue culture.[30,32] Isolating the virus from the respiratory tract is difficult. A number of serologic tests such as the fluorescent antibody to membrane antigen test, immune adherence hemagglutination test, ELISA, and neutralization test are available but are not helpful in the acute clinical situation. CF serologic tests are relatively insensitive.[79]

Treatment

Parent Teaching. **Contact and airborne precautions are needed to prevent the spread of varicella to susceptible individuals. The infant must remain separated from exposed individuals for 8 to 10 days** and separated from the mother until the mother's vesicles have dried. **VariZIG can be given to decrease the possibility of infection of the infant, however the infant needs to remain isolated from susceptible individuals for 28 days, and the pediatrician's office should be notified of the risk before any visits.** Expressed breast milk can be provided by the mother with varicella if there are no lesions on the breast.[79]

EARLY-ONSET BACTERIAL DISEASE

Prevention. For GBS only, see p. 10.

Data Collection

History. Early-onset disease is almost always acquired perinatally and is discussed here. Late-onset disease is discussed in the Postnatal Acquisition Late-Onset Bacterial Disease section later in this chapter. **Early-onset disease presents as a fulminant multisystem illness during the first days of life (less than 72 hours of age). Significant risk factors for early-onset disease include prematurity, low birth weight, premature onset of labor, rupture of membranes for 18 hours or more, maternal intrapartum temperature higher than 38°C (100.4°F), and chorioamnionitis.**[,79] Bacteria responsible for early-onset disease are acquired from the birth canal before or during delivery and are listed in Box 22.2. Although the advent of intrapartum antibiotic prophylaxis for **GBS infections has generally reduced early-onset disease of this pathogen, it has not been universally eliminated, and black preterm infants remain at considerably greater risk than do white preterm infants and both black term infants and white term infants.**

Also, **since the practice of intrapartum prophylaxis began, a predominance of gram-negative organisms has been noted in infants weighing less than 1500 g at birth,** and concern for this continued trend remains.[,135] **Gram-negative infections now account for more than one-half of the instances of early-onset sepsis.**[,135,140,143,144] Data from the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network, which comprises 16 major neonatal units, showed an increase in *Escherichia coli* infections in very-low-birth-weight (VLBW) infants from 1998 to 2000 compared with 1991 to 1993 that persisted during the 2002 to 2003 period.[143] A more recent study of the epidemiology of early-onset sepsis found that from 2005 to 2014, GBS prevention with intrapartum antibiotics has not increased the incidence of early-onset *E. coli* infections.[135] Data from the Norwegian National Cohort demonstrated that **in infants born at less than 28 weeks' gestational age and with birth weight less than 1000 g, *E. coli* was the most common organism isolated on the first day of life.**[130] **Early-onset bacterial disease is associated with a high (11%) mortality rate and significant morbidity (6.3% with sequelae at discharge).**[135,140,144]

Signs and Symptoms. **Neonatal bacterial sepsis is characterized by systemic signs of infection associated with bacteremia. Meningitis in a neonate can be a sequela of bacteremia or can occur in 15% to 38% of neonates with negative blood culture.**[79,128] In addition, bloodborne bacteria may localize in other tissues, causing focal disease. Both

BOX 22.2 CRITICAL FINDINGS
ORGANISMS CAUSING EARLY-ONSET BACTERIAL SEPSIS

Common Organisms
Group B Streptococcus
Escherichia coli
Coagulase-negative *Staphylococcus*

Unusual Organisms
Staphylococcus aureus
Neisseria meningitidis
Streptococcus pneumoniae
Haemophilus influenzae (type B and nontypable)

Rare Organisms
Klebsiella pneumoniae
Pseudomonas aeruginosa
Enterobacter species
Serratia marcescens
Group A *Streptococcus*
Anaerobic species
Listeria monocytogenes

patterns of bacterial disease, early onset and late onset, have been associated with systemic infections during the neonatal period.[79,128]

In general, signs, particularly in early-onset disease, are nonspecific and nonlocalizing.[79] Signs and symptoms may include temperature instability (hypothermia or hyperthermia), respiratory distress (apnea, cyanosis, and tachypnea), lethargy, feeding abnormalities (vomiting, increased residuals, and abdominal distention), jaundice (particularly increased direct fraction), seizures, or purpura (Fig. 22.3).[128]

Quantification of risk of early-onset neonatal sepsis using maternal risk factors and neonatal clinical examination may significantly decrease antibiotic use in neonates early after birth.[48,121] From this initial research, the Kaiser Newborn Sepsis Calculator was developed (Fig. 22.4). **National and international, single-center studies to evaluate the safety and efficacy of the calculator have been conducted with their outcomes listed in** Box 22.3. Additionally, potential benefits of the calculator's use include a reduction in health care costs, fewer painful procedures,

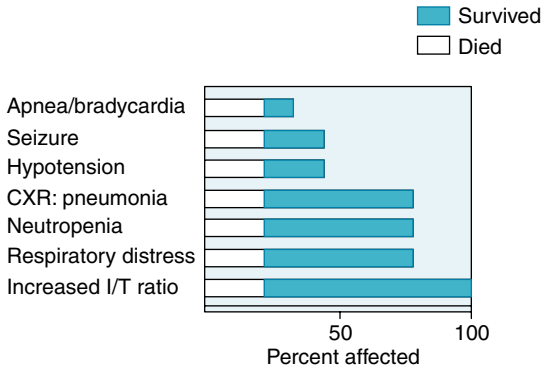

FIGURE 22.3 Clinical and laboratory findings in nine infants with signs and symptoms of early-onset group B streptococcal disease. *CXR,* Chest x-ray; *I/T,* ratio of immature to total neutrophils. (From Nelson SN, Merenstein GB, Pierce JR. Early onset group B streptococcal disease. *J Perinatol.* 1986;6:234.)

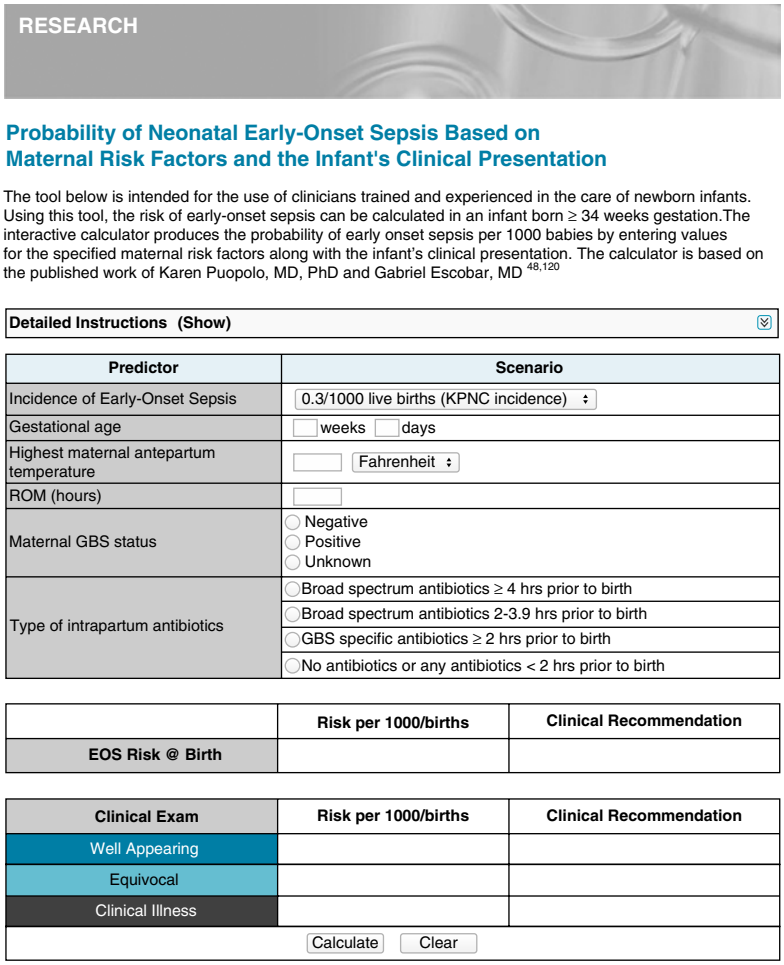
promotion of breastfeeding by avoiding unnecessary separation of mother and baby, and a strategy for promotion of antibiotic stewardship.[54,160] **Continuous, competent, clinical observation must accompany use of the calculator** because in one study some neonates with culture-proven early-onset sepsis would have been missed using the calculator alone,[23] and in another study some neonates with initial low sepsis scores deteriorated after 12 hours of life.[76] Multicenter multinational RCTs to evaluate the systematic use of the sepsis calculator and the effects on clinical practice and outcomes are warrented.[4,23,54,76,83,98,160]

Laboratory Data. **Isolating bacteria from a nonpermissive site (blood, CSF, urine, closed body space) is the most valid method of establishing the diagnosis of bacterial sepsis.[162]** Surface cultures (including ear and gastric aspirates) do not establish the presence of active systemic infection but merely indicate colonization. Bacterial antigens or endotoxins may be demonstrated in sera, CSF, urine, or body fluids by a variety of methods (counterimmunoelectrophoresis, latex agglutination, and limulus lysate tests). Such a demonstration is not totally definitive, nor does it allow the determination of the antibiotic sensitivity of the offending organism.[128] False-positive reactions may be caused by skin surface contamination or gastrointestinal absorption of antigen.[13] Because the sensitivity of blood cultures is very low (i.e., high false-negative results),[58,95] other laboratory methods to identify bacterial sepsis in neonatal blood are being researched. Methods such as rapid PCR testing[146] and amplification/analysis of ribosomal DNA in bacterial



RESEARCH

Probability of Neonatal Early-Onset Sepsis Based on Maternal Risk Factors and the Infant's Clinical Presentation

The tool below is intended for the use of clinicians trained and experienced in the care of newborn infants. Using this tool, the risk of early-onset sepsis can be calculated in an infant born ≥ 34 weeks gestation.The interactive calculator produces the probability of early onset sepsis per 1000 babies by entering values for the specified maternal risk factors along with the infant's clinical presentation. The calculator is based on the published work of Karen Puopolo, MD, PhD and Gabriel Escobar, MD [48,120]

Detailed Instructions (Show)

Predictor	Scenario
Incidence of Early-Onset Sepsis	0.3/1000 live births (KPNC incidence)
Gestational age	weeks days
Highest maternal antepartum temperature	Fahrenheit
ROM (hours)	
Maternal GBS status	Negative Positive Unknown
Type of intrapartum antibiotics	Broad spectrum antibiotics ≥ 4 hrs prior to birth Broad spectrum antibiotics 2-3.9 hrs prior to birth GBS specific antibiotics ≥ 2 hrs prior to birth No antibiotics or any antibiotics < 2 hrs prior to birth

	Risk per 1000/births	Clinical Recommendation
EOS Risk @ Birth		

Clinical Exam	Risk per 1000/births	Clinical Recommendation

FIGURE 22.4 Kaiser newborn sepsis calculator: probability of neonatal early-onset sepsis based on maternal risk factors and the infant's clinical presentation. (From Kaiser Permanente Division of Research. Available at: https://neonatalsepsiscalculator.kaiserpermanente.org. ©2019 Kaiser Permanente Division of Research. Accessed March 9, 2019.)

genes and electrophoresis[58,145] show promise in rapid identification of the organism and diagnostic accuracy.

The CSF is examined in most infants suspected of sepsis, because meningitis is a frequent manifestation of sepsis in neonates, especially in symptomatic infants and infants with GBS sepsis and with late-onset disease (Table 22.6).[81,128] Low yield and potential adverse effects from LP have resulted in examination of CSF being deferred in asymptomatic infants being evaluated for maternal risk factors or respiratory distress.[128] **Meningitis is difficult to exclude without an LP, and its diagnosis affects therapy and follow-up in the neonate.[81,128,135] In VLBW preterm infants with late-onset sepsis, 1.4% of all VLBW and 5% of those who had LP had meningitis.[142] One-third of the VLBW preterm infants with meningitis had negative blood cultures. In VLBW infants, meningitis was associated with lower gestational age, prior sepsis, longer mechanical ventilation, longer length of stay, seizures, and death.[142]** More recent research into early and late onset neonatal sepsis shows variation in the use of LP: (1) low use for late-onset sepsis (21% in a single-center study),[166] (2) variable use from country to country (higher in Denmark than in Sweden) for early-onset sepsis,[42]

Classification of Infant's Clinical Presentation (Hide)

Clinical Exam	Description
Clinical Illness	1. Persistent need for NCPAP / HFNC / mechanical ventilation (outside of the delivery room) 2. Hemodynamic instability requiring vasoactive drugs 3. Neonatal encephalopathy /Perinatal depression ▪ Seizure ▪ Apgar Score @ 5 minutes < 5 4. Need for supplemental O_2 ≥ 2 hours to maintain oxygen saturations > 90% (outside of the delivery room)
Equivocal	1. Persistent physiologic abnormality ≥ 4 hrs ▪ Tachycardia (HR ≥ 160) ▪ Tachypnea (RR ≥ 60) ▪ Temperature instability (≥ 100.4°F or <97.5°F) ▪ Respiratory distress (grunting, flaring, or retracting) not requiring supplemental O_2 2. Two or more physiologic abnormalities lasting for ≥ 2 hrs ▪ Tachycardia (HR ≥ 160) ▪ Tachypnea (RR ≥ 60) ▪ Temperature instability (≥ 100.4°F or <97.5°F) ▪ Respiratory distress (grunting, flaring, or retracting) not requiring supplemental O_2 Note: abnormality can be intermittent
Well Appearing	No persistent physiologic abnormalities

FIGURE 22.4, cont'd

and (3) neither C-reactive protein (CRP) or IT ratio are predictive in identifying neonates with confirmed or suspected meninigitis.[59,147] These researchers recommend that the **decision to perform an LP be focused on the individual presentation of the infant and a positive blood culture.**[59,147]

Several laboratory aids are used in assessing neonatal sepsis, but it must be realized that these tests are not sensitive or specific enough to influence clinical decisions on their own.[34,46,79] *Leukocyte indices* predict sepsis with sensitivities ranging from 17% to 90% and specificities from 31% to 100%.[34] **CRP is an acute-phase reactant synthesized in the liver in the first 6 to 8 hours of the infective process with a low sensitivity (60%) early in sepsis. However, serial CRP measurements at 24 and 48 hours improve sensitivity to 82% and 84%, and specificity and positive predictive values range from 83% to 100%.**[103] Negative predictive values for CRP are extremely high. **Serial CRP patterns have been found to be useful to follow resolution of infection and guide antibiotic therapy.**[70,95,136] **CRP levels do not seem to be affected by gestational age and have better sensitivity and negative predictive values compared with leukocyte indices.**[39] CRP response has been found to be better in gram-negative infections compared with infections with coagulase-negative *Staphylococcus*. The use of CRP in neonatal sepsis has recently been reviewed.[69,95,136]

Procalcitonin, **another acute-phase reactant, which rises within 4 hours of exposure to**

bacterial endotoxin, has a sensitivity and specificity ranging from 83% to 100%. The serum profile of procalcitonin has been claimed to be superior to that of CRP in the diagnosis of sepsis, after resolution of infection, and may differentiate between sepsis and other inflammatory processes (e.g., trauma).[113] Procalcitonin may have sufficient diagnostic accuracy in differentiating invasive fungal infections from bacterial infections and uninfected individuals.[41] Recent systematic reviews found that procalcitonin has moderate accuracy in diagnosing neonatal sepsis, is more accurate than CRP, and should be used within the context of other clinical parameters and relevant investigations.[123,165] **Another meta-analysis and systematic review found that a combination of CRP and procalcitonin improves the accuracy of the diagnosis of neonatal sepsis.**[131]

Serial measurements may be more useful, as is a combination of tests.[95,103,104,131] Radiographic examination of the chest and other specific areas indicated by clinical concerns may also be helpful.[128]

Several other nonspecific laboratory abnormalities may accompany neonatal sepsis, including hyperglycemia, hypoglycemia, and unexplained metabolic acidosis. Molecular techniques for diagnosis of infection are fast and reliable and may be very useful, especially in infants whose mothers have received intrapartum antibiotics.

Treatment. **Antibiotics are the cornerstone of treatment for presumed or confirmed infections in neonates. However, the indiscriminate or inappropriate use of systemic antibiotics may cause undesirable side effects[82,150] (increased risk of NEC, ROP, BPD and mortality, especially in VLBW premature infants),[21,22,37,150] favor the emergence of resistant strains of bacteria, and alter the microbiome of the newborn.**[29] Antibiotic stewardship for appropriate therapy and duration of therapy is

BOX 22.3 USE OF THE KAISER NEWBORN SEPSIS CALCULATOR: RESEARCH EVIDENCE

- Fewer sepsis workups
  - 14.5% (before calculator use) versus 4.9% (after calculator use)[83]
- Reduction in empirical antibiotics
  - 5% (before calculator use) versus 2.6% (after calculator use)[83]
  - 4.8% to 2.7% (prospective use of calculator with existing protocols)[4] resulting in a 44% reduction without delay or prolongation of therapy
  - 92% (using CDC 2010 guidelines) versus 23% (use of sepsis calculator)[160]
  - 50% reduction in antibiotic use[76]
  - 99% (in neonates whose mothers had chorioamnionitis before use of calculator) versus 2.5% (after calculator use)[98]
  - Fewer days of antibiotics (2.08 days to 0.05 days)[98]
- Reduction in invasive, costly laboratory testing[160]
- Improved antibiotic stewardship[160]
- No increase in adverse effects (i.e., readmission, meningitis, or death)[83]

of paramount importance in improving neonatal outcomes.[21,94,98,115,124,158]

Adequate and appropriate specimens for culture should be obtained before antibiotic therapy is initiated. Emergence of antibiotic resistance in gram-negative organisms is a major clinical concern.[18] In the data from the NICHD Neonatal Research Network, 85% and 75% of early-onset *E. coli* infections were ampicillin resistant in the 1998 to 2000 and the 2002 to 2003 cohorts, respectively.[140,143] Plasmid-mediated extended-spectrum beta-lactamases (produced by *Klebsiella* spp., *E. coli,* and *Serratia*) that confer resistance to a variety of β-lactam agents (penicillins and cephalosporins) and chromosomally mediated AmP-C–type beta-lactamase (*Enterobacter* and *Citrobacter* spp.)–producing gram-negative organisms have been isolated from the NICU.[63,64,116] **Exposure to third-generation cephalosporins (e.g., cefotaxime) and being a VLBW infant are noted risk factors for the acquisition of resistant organisms.**

Broad-spectrum antibiotic coverage, usually with ampicillin and an aminoglycoside for early-onset sepsis, is commonly initiated pending culture and sensitivity results. Once causative organisms are identified and antibiotic sensitivities are established, **the most appropriate and least toxic antibiotic or antibiotic combination should be continued for an appropriate period by a suitable route.** If adequate cultures are negative after a reasonable period (24 to 48 hours), antibiotic therapy may be discontinued in most situations.

Antibiotics are not the entire solution to treating the infected newborn. Meticulous attention to the treatment of associated conditions, such as shock, hypoxemia, thermal abnormalities, electrolyte or acid-base imbalance, inadequate nutrition, anemia, or presence of pus or foreign bodies, may be as important as choosing the proper antibiotic. IV immunoglobulins are not recommended because they do not reduce the length of stay, mortality, or major disability at 2 years of age in infants with suspected or proven neonatal infection.[107] Table 22.1 **provides guidelines for choosing the proper antibiotic for indicated conditions;** Table 22.7 **gives the proper dose, route, and frequency of administration of commonly used antibiotics in the newborn nursery.** Table 22.8 **describes the passage of antibiotics across the placenta, and** Table 22.9 **describes their passage into breast milk.**

Parent Teaching. Transplacental infection often results in fetal abnormality or death. Newborns who survive may have long-term sequelae such as developmental, neurologic, motor, sensory, growth, and physical abnormalities.

Before antibiotic use, the mortality rate from bacterial sepsis was 95% to 100%, but antibiotics and supportive care have reduced the mortality rate to less than 50%; however, survival is highly variable and depends on the organism and underlying or associated conditions. **Debilitated infants (preterm and sick neonates) are at greater risk and have a higher incidence of morbidity and mortality than term healthy neonates. The most common complications of bacterial sepsis are meningitis and septic shock.** The outcome is influenced by early recognition and vigorous treatment with appropriate antibiotics and supportive care.

POSTNATAL ACQUISITION LATE-ONSET BACTERIAL DISEASE

Prevention. The CDC defines *nosocomial* as **all neonatal infections acquired in the intrapartum period or during hospitalization. Infants requiring the specialized care of NICUs are highly susceptible to infection.** Prematurity, stress, immature immune systems, and complicated medical and surgical problems contribute to their increased susceptibility. In addition, most **infants in the NICU require a variety of invasive diagnostic, therapeutic, and monitoring procedures; many of these procedures bypass natural physical barriers, which may allow colonization to occur and a nosocomial (late-onset) infection to develop.[56]**

A recent *Cochrane* review states that lactoferrin supplementation to enteral feedings (either with or without probiotics) decreases late-onset sepsis and severe NEC in preterm infants without adverse effects (see Chapter 17).[112] Although current evidence is of low quality, when ongoing trials of >6000 preterm infants are completed, new data may enhance the quality of evidence.

Central line–associated bloodstream infections (CLABSIs), also called catheter-related bloodstream infections, are the most frequent hospital-acquired infections and are of particular concern in the NICU because of the prevalence of indwelling catheter lines needed for fluids, nutrition, and medications. Infection occurs via the insertion site with migration of microorganisms along the

TABLE 22.7 ANTIBIOTIC, ANTIVIRAL, AND ANTIFUNGAL AGENTS: DOSAGES FOR NEONATES

ANTIBIOTIC, ANTIVIRAL, OR ANTIFUNGAL	ROUTE	DAILY DOSAGES AND INTERVALS	
		0–7 DAYS OF AGE	MORE THAN 7 DAYS OF AGE
Acyclovir†	IV	20 mg/kg/dose q 8–12 hr depending on weight and age	Same
Amikacin sulfate	IV, IM	15 mg/kg/dose q 24–48 hr depending on gestation and age	15–17.5 mg/kg/dose q 24 hr
Amoxicillin	PO	15 mg/kg every 12 hr	Same
Amoxicillin/clavulanic acid	PO	Not recommended	25–45 mg/kg/day divided q 12 hr
Ampicillin			
• Meningitis	IV	100–150 mg/kg/day divided q 8–12 hr For GBS 200–300 mg/kg/day divided q 8 hr	150–200 mg/kg/day divided q 6–8 hr For GBS, 300 mg/kg/day divided q 6 hr
• Other indications	IV, IM, PO	50 mg/kg/day divided q 12 hr	75 mg/kg/day divided q 8 hr
Azithromycin	IV, PO	10 mg/kg/day q 24 hr	Same
Cefazolin*	IV, IM	50 mg/kg/day divided q 12 hr	75 mg/kg/day divided q 8–12 hr
Cefotaxime	IV, IM	100 mg/kg/day divided q 12 hr	150 mg/kg/day divided q 8 hr
Ceftazidime*	IV	100 mg/kg/day divided q 12 hr	150 mg/kg/day divided q 8 hr
Ceftriaxone	IV, IM	25–50 mg/kg q 24 hr	Same
Clindamycin	IV, PO	15–21 mg/kg/day divided q 8 hr	15–27 mg/kg/day divided q 8 hr
Erythromycin ethyl succinate (EES)	PO	40 mg/kg/day divided q 6 hr	40 mg/kg/day divided q 6 hr
Ganciclovir†	IV	6 mg/kg/dose q 12–24 hr	Same
Gentamicin	IV, IM	4–5 mg/kg/dose q 24–48 hr depending on gestation and age	4–5 mg/kg/dose q 24–36 hr depending on gestation and age
Meropenem*	IV	40–60 mg/kg/day divided q 8–12 hr depending on gestational age and weight	60 –90 mg/kg/day divided q 8 hr (higher doses may be needed in meningitis)
Metronidazole	IV, PO	15–22.5 mg/kg/day divided q 8–12 hr	15–30 mg/kg/day divided q 8–12 hr
Nafcillin	IV	50–75 mg/kg/day divided q 8–12 hr	75–150 mg/kg/day divided q 6–8 hr
Nystatin‡	PO	400,000 units divided q 6 hr	Same
Penicillin G			
• GBS Meningitis	IV	250,000 to 450,000 units/kg/day divided q 8 hr	450,000–500,000 units/kg/day divided q 6 hr
• Other indications	IV	100,000 units/kg/day divided q 12 hr	150,000–200,000 units/kg/day divided q 6–8 hr
Penicillin G, benzathine	IM	50,000 units/kg (1 dose only)	Same
Penicillin G, procaine	IM	50,000 units/kg/day once daily	Same
Pentamidine isethionate*	IV	4 mg/kg/day for 14 days	Same
Piperacillin/tazobactam	IV	300 mg/kg/day divided q 8 hr	320 mg/kg/day divided q 6 hr
Rifampin	IV, PO	10 mg/kg/day q 24 hr	Same
Ticarcillin	IV	150 mg/kg/day divided q 12 hr	150 mg/kg/day divided q 8–12 hr

TABLE 22.8 PASSAGE OF ANTIBIOTICS ACROSS THE PLACENTA*

PERCENTAGE OF ANTIBIOTIC IN INDICATED CATEGORY	ANTIBIOTIC
Equal to serum concentration	Amoxicillin Ampicillin Carbenicillin Chloramphenicol Methicillin Nitrofurantoin Penicillin G Sulfonamides
50% of serum concentration	Aminoglycosides
10%–15% of serum concentration	Amikacin Cephalosporins Clindamycin Nafcillin Tobramycin
Negligible (<10% of serum concentration)	Dicloxacillin Erythromycin

*Several factors determine the degree of transfer of antibiotics across the placenta, including lipid solubility, degree of ionization, molecular weight, protein binding, placental maturation, and placental and fetal blood flow.

TABLE 22.9 PASSAGE OF ANTIBIOTICS INTO BREAST MILK*

PERCENTAGE OF ANTIBIOTIC IN INDICATED CATEGORY	ANTIBIOTIC
Equal to serum concentration	Isoniazid Metronidazole Sulfonamides Trimethoprim
50% of serum concentration	Chloramphenicol Erythromycin Tetracyclines
<25% of serum concentration	Cefazolin Kanamycin Nitrofurantoin Oxacillin Penicillin G Penicillin V

*Data on concentrations of antibiotics in human breast milk are sparse. Because most antibiotics are present in breast milk in microgram amounts, they are normally not ingested by the infant in therapeutic amounts.

catheter/catheter hub, seeding from another site of infection, and infusion of contaminated fluids.

Longer dwell times for catheters are also associated with increased CLABSIs. Rates of infection increase over the first 2 weeks and then remain elevated for the duration of the line. In the first 40 days from placement, coagulase-negative staphylococci are the most prevalent organisms. After 50 days, the risk of gram-negative infection is increased.[16,96,106,137]

A systematic and multidisciplinary approach to reducing CLABSIs should be included in the infection control policies of every NICU. Evidence-based guidelines or "bundles" (of specific evidence-based interventions) are packaged together to reduce variability in insertion and catheter maintenance and have been shown to reduce CLABSIs. "Bundles" can be developed by individual NICUs or obtained through collaborative practice organizations.[117,163] **Strategies to prevent CLABSIs generally include (1) education for all health care providers, (2) need for adequate nurse staffing, (3) meticulous hand hygiene, (4) strict aseptic technique, (5) limitation of line manipulations, and (6) limitation on dwell time.** For line placement, use of maximum sterile barriers (i.e., hat, mask, sterile gown and gloves) and a full sterile body drape is recommended. Other strategies include the use of ultrasonography to limit placement attempts, avoiding the femoral vein for percutaneous placement, and proper disinfection of hubs, connectors, and injection ports.

Dressings should be changed every 7 days and/or when the dressing is loose, damp, or visibly soiled. Lines should be removed immediately when signs of infection or phlebitis are present. The need for line continuation should be evaluated daily and the line removed as soon as possible. A process for tracking CLABSIs is essential so that causes are identified and intervention quickly occurs when rates increase.*

Infection control principles and practices for the prevention of these nosocomial infections are outlined in Table 22.10. **Table 22.5 outlines infection control measures and isolation techniques for specific diseases.**[19,79,137]

Data Collection

History. Late-onset disease may occur as early as 3 days of age but is more common after the first week of life. Affected infants may have a history of obstetric complications, but they are less common than obstetric complications in early-onset disease. Bacteria responsible for late-onset sepsis and meningitis include those acquired from the maternal genital tract and organisms acquired after birth from human contact or from contaminated equipment or material (Box 22.4).[9] **Gram-positive organisms predominate in late-onset sepsis, and gram-negative organisms account for about one-third of late-onset cases of sepsis in VLBW infants.**[141] **Although prematurity remains the most significant factor, invasive procedures performed on a neonate, such as intubation, catheterization, and surgery, also increase the risk for bacterial infection.**[78,111,141]

Signs and Symptoms. Similar to those of early-onset sepsis, signs and symptoms are nonspecific. Heart rate variability, the acceleration and deceleration of heart rate that occurs as a result of activity and neonatal states, has been researched as a sign of sepsis. **Decreased heart rate variability (from baseline) and transient decelerations have been noted to occur up to 24 hours before symptoms of sepsis occur.**[61,100] **Therefore decreased heart rate variability is an early sign of late-onset sepsis.**

Decreased baseline variability also occurs in systemic inflammatory response syndrome, necrotizing enterocolitis, intraventricular hemorrhage, and chronic lung disease. Medications also affect variability. Paralytics, anesthetics, and anticholinergics decrease variability, whereas dexamethasone improves variability.

As noninvasive screening tools for late-onset sepsis, algorithms that highlight changes in baseline heart rate variability have been developed. These algorithms are adjuncts to clinical assessment/observation and laboratory data in decision making regarding sepsis evaluation and need for empirical antibiotics. The most recent research into alterations of heart and respiratory rates and oxygen saturations before overt signs of late-onset sepsis have found: (1) trending of heart rate (bradycardia) and oxygen saturations (desaturations) in preterm infants with developing infection[101] and (2) VLBW premature infants in two NICUs showed a high correlation of heart rate and oxygen saturations in relation to respiratory rate (i.e., periodic breathing or apnea that resulted in bradycardia and desaturation) in the 24 hours before overt sepsis symptoms.[50] Translating metrics

TABLE 22.10 INFECTION CONTROL PRINCIPLES AND PRACTICES TO PREVENT NOSOCOMIAL INFECTION

PRINCIPLE	PRACTICE
Handwashing	
Handwashing is the most important procedure for controlling infection in the NICU.	1. Before each shift, wash hands, wrists, forearms, and elbows with antiseptic. Scrub hands with a brush or pad for 2–3 minutes, and rinse thoroughly. Chlorhexidine, hexachlorophene, and iodophors are the preferred products. 2. Wash hands for 10–15 seconds between infant contacts. Soap and water are adequate unless the infant is infected or contaminated objects have been handled. 3. Use an antiseptic for handwashing before surgical or similar invasive procedures. 4. Alcohol-based disinfectants are effective when used before and after patient contact.
Cell Phone	
Cell phones and other handheld electronic devices are a potential vector for bacteria.[15,80] Bacteria may be transmitted from phone to hands.	1. Clean phones with a hospital-approved wipe. 2. Clean hands after using a cell phone.
Patient Placement	
Overcrowding in the NICU increases the risk for cross-contamination.	1. Provide 4- to 6-foot intervals between infants.
SKIN AND CORD CARE	
The skin, its secretions, and its normal flora are natural defense mechanisms that protect against invading pathogens (see Chapter 19). No single method of cord care has been identified to prevent colonization or limit disease.	1. The American Academy of Pediatrics suggests using a dry technique: a. Delay initial cleansing until temperature is stable. Manipulating an infant's skin must be minimized. b. Use sterile cotton sponges and sterile water or mild soap to remove blood from face and perineal area. c. Do not touch other areas unless they are grossly soiled. 2. Local application of alcohol, triple dye, and various antimicrobials may be used in areas where the risk of omphalitis is high.
MEDICAL DEVICES	
Medical devices facilitate infections by the following: 1. Bypassing normal defense mechanisms, providing direct access to blood and deep tissues 2. Supporting growth of microorganisms and becoming reservoirs from which bacteria can be transmitted with the device to another patient 3. Providing a "protected site" when placed in deeper tissue, so phagocytosis or defense mechanisms cannot eradicate the organisms 4. Using sterile medical devices that are occasionally contaminated from the manufacturer or central supply	1. IV infusion devices predispose infants to phlebitis and bacteremia. Preventive measures include preparing the site with tincture of iodine (2% iodine in 70% alcohol), an iodophor, or 70% alcohol, or 2% chlorhexidine in infants with mature skin,[78] anchoring the IV securely; performing frequent site assessment, rotating the IV site when clinically indicated;[161] changing the IV administration set every 48–96 hours on IVs that do not contain lipids or blood products;[153] and discontinuing the IV at the first sign of complication. 2. Central lines are common in the NICU and are a common locus of infection. Central lines should be placed under sterile conditions.[111] The use of evidence-based CLABSI bundles that include sterile tubing changes and continuous monitoring is necessary to prevent infection. 3. Arterial lines predispose infants to bacteremia. Preventive measures include aseptically inserting the catheter using gloves, inspecting the site and performing site care every 24 hours, treating the catheter and stopcocks as sterile fields, and minimizing manipulation by drawing all blood specimens at the same time. 4. Intravascular pressure–monitoring systems predispose infants to septicemia. Preventive measures include replacing the flush solution every 24 hours and replacing the pressure transducer according to manufacturer's recommendations and hospital policy. 5. Respiratory therapy devices increase the risk for contamination. Preventive measures include using aseptic technique during suctioning; dating opened solution for irrigation, humidification, and nebulization, and discarding after 24 hours; ensuring routine replacement and cleaning of all respiratory equipment, including Ambu bags, cascade nebulizers, endotracheal tube adaptors, and tubing.

TABLE 22.10 INFECTION CONTROL PRINCIPLES AND PRACTICES TO PREVENT NOSOCOMIAL INFECTION—cont'd

Specimen Collection	
Improperly collected specimens cause infection at the site of collection or erroneous diagnosis, leading to the administration of the wrong antibiotic or delayed administration of the appropriate antibiotic.	1. Wash hands before collecting specimen. 2. Observe aseptic technique to reduce risk for infection and to avoid contamination of specimen. 3. Deliver specimens to the laboratory immediately. 4. Do not use femoral sticks.
Nursery Attire	
Personal clothing and unscrubbed skin areas of personnel should not touch infants.	1. Short-sleeved scrub gowns accommodate washing elbows. 2. Long-sleeved gowns should be worn and changed between handling of infected or potentially infected infants. 3. Sterile gowns are necessary for sterile procedures.
Employee Health	
Transmission of disease among patients and employees can occur bidirectionally. Each NICU must establish reasonable guidelines for restriction of assignments based on the employee's potential to transmit disease and the potential risk for acquiring disease.	1. Conditions that commonly restrict personnel from patient care in the NICU are skin lesions and draining wounds, acute respiratory infections, fever, gastroenteritis, active herpes simplex (oral, genital, or paronychial), and herpes zoster. 2. Conditions that are transmitted from infants to personnel are the following: a. Rubella: Obtain rubella titers from women of childbearing age; if a protective level is not present, they should be vaccinated. b. Cytomegalovirus is a potential threat to pregnant women. Adherence to good infection control practices may reduce this threat. c. Hepatitis B is usually not a major problem in the NICU, because host vaccine is available and may be considered for high-risk individuals (see Tables 22.3 and 22.4). d. Use of gloves with body fluid contact will decrease the risk for transmission of hepatitis B virus and human immunodeficiency virus.
Cohorting	
Cohorting is an important infection control measure used primarily during outbreaks or epidemics in the NICU. The object of cohorting is to limit the number of contacts of one infant with other infants and personnel.	1. Group together infants born within the same time frame (usually 24–48 hours) or who are colonized or infected with the same pathogen. These infants should remain together until discharged. 2. Provide nursing care by personnel who do not care for other infants. 3. After all infants in cohort are discharged, clean the room before admittance of a new group of infants.

Preventing Transmission of Infectious Agents in Healthcare Settings. Available at: https://www.cdc.gov/infectioncontrol/guidelines/isolation/. Accessed February 27, 2019.

into real-time bedside displays and conducting randomized clinical trials to determine their efficacy in clinical care and impact on outcomes are the next research directions.[50]

Laboratory Data. **A complete set of culture specimens should be obtained,** but limitations are similar to those in early-onset infection.

Treatment. **Broad-spectrum antibiotic coverage, usually vancomycin and an aminoglycoside or a third-generation cephalosporin, is commonly initiated pending culture and sensitivity results. However, vancomycin resistance remains a potential problem in the care of sick neonates.**[29,36,90] To minimize the development of these

BOX 22.4 CRITICAL FINDINGS
ORGANISMS CAUSING LATE-ONSET BACTERIAL SEPSIS

- Coagulase-negative *Staphylococcus*
- *Escherichia coli*
- *Klebsiella* species
- *Enterobacter* species
- *Candida* species
- *Malassezia furfur*
- Other enteric organisms
- Group B *Streptococcus*
- Methicillin-resistant *Staphylococcus aureus*

resistant organisms, the CDC has recommended prudent vancomycin use, education of medical personnel about the problem of vancomycin resistance, early detection and prompt reporting of organisms, and immediate implementation of appropriate infection control measures (see Table 22.10).

Complications. CLABSIs increase morbidity and mortality rates, length of stay, and cost of care.

Parent Teaching. Parents should be taught to wash their hands on entering the nursery and before touching their infant and between siblings. Parents should also be told that it is acceptable to remind others to wash their hands before touching their infant.

FUNGAL INFECTION

Fungal infections have been a significant cause of neonatal morbidity and mortality.[33,88] Fungal infections are the third most common infection after 72 hours of life in infants weighing less than 1500 g.[33,88,141] Prevalence rates vary from 33% in the NICHD cohort[141] to 35% in a more recent 15 year retrospective Italian study.[88] Candida species are the most common in Europe and America[20] (44% in a recent Italian epidemiologic study),[88] and other species predominate in Asia.[20] Of the 4% to 8% of ELBW infants who develop candidemia, there is a 30% mortality rate.[148] Both the incidence and mortality rate of invasive fungal infection is inversely related to birth weight and gestational age.[75] Survivors of invasive fungal disease have long-term neurodevelopmental impairments.[5,14]

In addition, fungal infections are usually seen in infants with congenital anomalies requiring surgery or infants who require multiple or prolonged vascular catheterization.

Prevention. Because these infants are often colonized at birth, strict adherence to aseptic technique when dealing with central catheters is essential. Use of broad-spectrum antibiotics (e.g., cephalosporins), administration of histamine$_2$ (H2) receptor blockers, and use of corticosteroids are significant risk factors, and their use should be minimized.[33,75,133]

One study of 322 NICUs found the incidence of invasive fungal infections decreased from 3.6 episodes/1000 infants in 1997 to 1.4 episodes/1000 infants in 2010.[8] This reduction is attributed to reduced use of broad-spectrum antibiotics, fluconazole prophylaxis, fewer CLABSIs, and empirical antifungal therapy.[8,75]

Intravenous fluconazole prophylaxis reduces the incidence of invasive fungal infection in very preterm or VLBW neonates; however the meta-analysis does not show a statistically significant effect on mortality.[35] Antifungal prophylaxis should be used for preterm infants < less than 27 weeks' gestational age and less than 1000 g birth weight because intravenous fluconazole (at 3 mg/kg twice a week) and nystatin are effective in the prevention of invasive candida sepsis, improving survival and neurodevelopmental outcomes.[74,114,129] The lowest dose of fluconazole is recommended as higher dosing does not increase efficacy and increases the risk of toxicity and costs.[85]

A recent systematic review and meta-analysis of RCTs showed that the use of enteral probiotics is associated with a lower risk of candida colonization.[69] When one of the seven studies was removed from meta-analysis because of high baseline fungal infections, only limited data showed that probiotic supplementation prevented invasive fungal infection in preterm neonates.[69]

Data Collection

History. Prematurity (less than 32 weeks' gestational age), Apgar score less than 5 at 5 minutes, shock, antibiotic therapy, parenteral nutrition for longer than 5 days, use of lipids for longer than 7 days, presence of a central catheter, length of hospital stay longer than 7 days, use of H2 blockers, and intubation are risk factors for fungal infections.[33,88,72,133]

TABLE 22.11 ANTIFUNGAL THERAPY

DRUG	DOSAGE	COMMENTS
Amphotericin B	1 mg/kg/day IV	Nephrotoxicity
Amphotericin B lipid complex	5 mg/kg/day IV over 2 hr	Thrombocytopenia Anemia Hypokalemia
5-Fluorocytosine (5-FC)	100 mg/kg/day PO divided q 6–8 hr	Hepatotoxicity Bone marrow suppression
Fluconazole	3–6 mg/kg/day IV, PO divided q 6 hr	Liver toxicity Adjust for renal function

hr, Hour; *IV,* intravenously; *PO,* orally.

Signs and Symptoms. **Signs and symptoms may be nonspecific, nonlocalizing, and difficult to differentiate from those of bacterial sepsis. Skin and oral infections in high-risk infants, especially in VLBW infants, can become invasive and should be treated.**

Laboratory Data. Routine laboratory data, as may be collected based on clinical signs and symptoms, are rarely helpful in differentiating fungal from bacterial infection. **A positive culture result from urine, blood, CSF, or a skin biopsy indicates systemic infection.** A recent study comparing platelet counts in fungal and bacterial infections found: (1) a significant decrease in platelet count and a higher CRP level in the early stage of fungal infection when compared with bacterial infection and (2) no difference in platelet and CRP counts in the acute stage of fungal and bacterial infections.[164] These researchers found **a high accuracy in the early diagnosis of fungal infection when the platelet count was less than 157.0 × 10^9/L and an effective predictor of invasive fungal infections in preterm infants.**[164]

Urine for analysis and culture, ophthalmologic examination, imaging of the brain by computed tomography scan or magnetic resonance imaging, echocardiogram for endocarditis, and renal ultrasonography for fungal mycetomas are mandatory in disseminated fungal infections.[105]

Treatment. **Supportive care and removal of foci of infection (i.e., infected catheters or fungal mycetomas) are important. Antifungal therapy with amphotericin B is the mainstay of treatment for invasive fungal infections in the neonate.**[114,79] For CNS candidiasis using monotherapy with amphotericin B, if the CSF does not become sterile within a few days or the neonate becomes more ill, 5-fluorocytosine (5-FC) is added. 5-FC has excellent CSF penetration and is reserved for use in combination with amphotericin B in neonates with CNS candidiasis[51] (Table 22.11).

Lipid formulations of amphotericin are available that are less toxic and may be the choice in infants who cannot tolerate standard amphotericin.[6] A recent drug utilization review of liposomal amphotericin B use in neonates cited the weakness of the studies and recommended additional RCTs to determine the true benefits of the drug.[138] **Fluconazole therapy may have efficacy similar to amphotericin but without the toxicity.**[60]

PARENT TEACHING

Parents who have an infant with viral or bacterial infection require support and information about their infant's condition. Questions arise about treatment and prognosis, as well as about possible long-range effects of the infection. Parents experience significant guilt feelings based on misperceptions about what role they had in causing the infection. Health care professionals should remain sensitive to the crisis that parents are experiencing and address the issues of etiology as well as treatment and prognosis. Valid and factual

data, as well as information about complications and long-term effects, should be shared with parents in a timely manner.

Controlling infection in the nursery is of prime importance but does not exclude parents from caring for their sick infant. Everyone must adhere to proper handwashing, gowning, and isolation techniques.[137] Educating the parents and siblings about the **importance of these procedures, along with appropriate reminders, ensures cooperation. With proper precautions, there is no evidence of increased incidence of infection with parent and sibling visits.**

All those entering the nursery must be screened for the presence of illness. Anyone (including staff) with a fever, respiratory symptoms (cough, runny nose, sore throat), gastrointestinal symptoms (nausea, vomiting, diarrhea), or skin lesions should not come in contact with the infant. People with communicable disease (e.g., varicella) or recent exposure to a communicable disease also should not come in contact with the sick neonate.[19,137] Daily cord care should be demonstrated, and a demonstration by the parents should be observed before discharging the infant. ***Every* parent should be taught the signs and symptoms of neonatal illness, because early recognition of signs and symptoms expedites prompt treatment. Parents must be taught to take axillary temperatures and to read a thermometer. They should be aware that both hypothermia and hyperthermia may be signs of neonatal illness.**[19,137]

ACKNOWLEDGMENT

Dedicated to the memory of Gerry Merenstein, MD, FAAP.

23 RESPIRATORY DISEASES

SANDRA L. GARDNER, MARY ENZMAN-HINES, AND MICHAEL NYP

Despite the marked improvement over the past years in the survival of premature newborns with respiratory distress, significant mortality and high morbidity rates persist. Much of the improvement in neonatal mortality has been the result of successful treatment and management of respiratory diseases in the neonate.

This chapter presents an overview of some of the common respiratory diseases and their treatments and outcomes. General principles and concepts related to respiratory physiology, etiologic factors, and symptomatology are presented, followed by specific disease processes and their management.

GENERAL PHYSIOLOGY

Any discussion of general respiratory physiology must include some elements of anatomy and embryology and their significance to the clinician (Table 23.1).

Surface-active compounds such as phosphatidylcholine and phosphatidylglycerol stabilize the alveoli. Surface tension forces act on air-fluid interfaces, causing a water droplet to "bead up." The surface-active compound (e.g., soap added to a water droplet) reduces the surface tension and allows the droplet to spread out in a thin film. **In the lung, surface tension forces tend to cause alveoli to collapse. A compound such as surfactant reduces surface tension and allows the alveoli to remain open.**

However, the situation is more complicated than just described. Laplace detailed the magnitude of the pressure (p) exerted at the surface of an air-liquid interface as equaling twice the surface tension (st) divided by the radius (r) of curvature of the surface ($p = 2\ st \div r$). In the absence of surfactant, an alveolus with a small radius of curvature has a greater magnitude of pressure at its surface (tending to collapse it) than does an alveolus with a larger radius of curvature. **Therefore smaller alveoli tend to collapse and empty contained gas into larger alveoli.**

Surfactant modifies surface tension by decreasing surface tension when the radius of curvature is small and increasing surface tension when the radius of curvature is greater. An alveolus with a larger radius of curvature has a greater-than-expected pressure (tending to reduce its volume), and an alveolus with a smaller radius of curvature has less-than-expected pressure. Therefore the alveoli are stabilized at a uniform radius of curvature (uniform volume).

Surfactant provides a number of useful properties in addition to reducing surface tension, which increases lung compliance, provides alveolar stability, and decreases opening pressure. It also enhances alveolar fluid clearance, decreases precapillary tone, and plays a protective role for the epithelial cell surface. **Surfactant is constantly being formed, stored, secreted, and recycled. Conditions that interfere with surfactant metabolism include acidemia, hypoxia, shock, overinflation, underinflation,**

BLUE type highlights content that is particularly applicable to clinical settings.

TABLE 23.1 LUNG DEVELOPMENT

STAGE AND MAJOR EVENTS	SIGNIFICANCE
Embryonic (Up to 5 Weeks)	
Single ventral outpocketing quickly divided into two lung buds.	Airways begin to differentiate.
Mesenchyme surrounds endodermal lung buds, which continue to divide and extend into the mesenchyme.	
Branching of the airways begins.	Branching anomalies (e.g., pulmonary agenesis and sequestered lobe) occur early in fetal life.
Pulmonary arteries invade lung tissue following the airways and divide as the airways divide. Pulmonary veins arise independently from the lung parenchyma and return to the left atrium, thus completing the pulmonary circuit.	
Pseudoglandular (5-16 Weeks)	
Progressive airway branching begins; bronchi and terminal bronchioles form.	All subdivisions that will form airways are complete by the sixteenth week.
Muscle fibers, elastic tissue, and early cartilage formation can be seen along the tracheobronchial tree. Mucous glands are found at 12 weeks and increase in number until 25-26 weeks, when cilia begin to develop.	
Diaphragm develops.	Herniation of the diaphragm occurs.
Canalicular (13-25 Weeks)	
Airway changes from glandular to tubular and increases in length and diameter.	Air-conducting portion (bronchi and terminal bronchioli) continues luminal development.
20 Weeks	
Fetal airways end in blind pouches lined with cuboid epithelium; a relatively large amount of interstitial mesenchyme is present; few pulmonary capillaries are present, and they are not closely associated with the respiratory epithelium.	
22-24 Weeks	
Rapid proliferation of the pulmonary capillary bed, an increase of the surface area of the respiratory epithelium, and formation of alveolar ducts and sacculi occur.	Development of gas exchange portion (the respiratory bronchi and alveolar ducts) begins; pulmonary vasculature develops most rapidly.
Respiratory epithelium contains cells that become differentiated into type I and type II pneumocytes.	
Type I pneumocytes produce an extremely thin squamous epithelial layer that lines the alveoli and fuses to the underlying capillary endothelial cells.	By the late fetal period, the resulting membrane between the alveoli and capillaries allows sufficient gas exchange to support independent life.
Type II pneumocytes (cuboid cells) are the site of surfactant synthesis and storage.	At 22 weeks, surface-active phospholipids (lecithin) can first be detected.
Terminal (24-40 Weeks)	
Lung differentiation: proliferation of the pulmonary vascular bed, creation of new respiratory units (alveolar ducts and alveoli), decrease in amount of mesenchyme, and fusion of the gas-exchange epithelium to the pulmonary capillary epithelium occur.	Before this time, the fetal lungs are incapable of supporting adequate gas exchange because of insufficient alveolar surface area and inadequate pulmonary vasculatur.

TABLE 23.1 LUNG DEVELOPMENT—CONT'D

STAGE AND MAJOR EVENTS	SIGNIFICANCE
34-36 Weeks	
Phosphatidylglycerol appears, and a dramatic increase in the principal surfactant compound phosphatidylcholine occurs.	Adequate amounts of surface-active material protect against the development of respiratory distress syndrome.
Alveolar (Postnatal Lung Development: Late Fetal Life to 8-10 Years of Age)	
At term, the number of airways is complete; there is sufficient respiratory surface for gaseous exchange, and the pulmonary capillary bed is sufficient to carry the gases that have been exchanged.	Although the infant is capable of sustaining respiratory effort and the lung is able to provide oxygenation and ventilation at birth, lung development is still incomplete.
Alveoli continue to increase in number, size, and shape; they enlarge and become deeper to maximize the exposed surface area for gas exchange.	Ongoing lung development implies that infants who have suffered severe lung disease at birth need not have lifelong pulmonary compromise.

pulmonary edema, mechanical ventilation, and hypercapnia. Surfactant production is delayed in infants of diabetic mothers (IDMs) of classes A, B, and C; infants with erythroblastosis fetalis; and infants who are the smaller of twins. Surfactant production is accelerated in the following:

- IDMs of classes D, F, and R
- Infants of heroin-addicted mothers
- Premature rupture of membranes of greater than 48 hours' duration
- Infants of mothers with hypertension
- Infants subjected to maternal infection
- Infants suffering from placental insufficiency
- Infants affected by administration of corticosteroids
- Infants affected by abruptio placentae

The fetal lung is filled with a volume of liquid (20 to 30 mL/kg) equal to the functional residual capacity. This fluid is not amniotic fluid but rather a liquid that has been produced in the lung and discharged through the larynx and mouth into the amniotic fluid. **Lung fluid is continuously produced at a rate of approximately 2 to 4 mL/kg/hr.**

The movement of lung fluid and its components (notably lecithin) into amniotic fluid has become a notable clinical tool as the lecithin-sphingomyelin (L/S) ratio. Noting a sharp increase in the L/S ratio, Gluck and Kulovich[185] found they could predict which infants were at risk for respiratory distress syndrome (RDS). In general, **L/S ratios of more than 2:1 are not associated with RDS, whereas ratios of less than 2:1 are associated with it.** Phosphatidylglycerol (PG), the second most common phospholipid in surfactant, appears at about 36 weeks' gestation and increases until term. **The presence of PG is associated with a very low risk for RDS, whereas its absence is associated with the development of RDS.** Unlike the L/S ratio, **PG determination is valid in the presence of blood-contaminated amniotic fluid.**

During vaginal delivery, approximately one third of the lung fluid may be removed during the thoracic "squeeze" as the infant passes through the birth canal; the remainder of the fluid is removed mainly by the pulmonary lymphatics, although pulmonary capillaries may play a role. After a cesarean section, all of the lung fluid will be removed by the pulmonary lymphatic system, capillaries, and reversal of the sodium and chloride pumps.

The *first breath of life,* a response to tactile, thermal, chemical, and mechanical stimuli, initiates respiratory effort. The fluid-filled lungs, surface forces, and tissue-sensitive forces are obstacles to the first breath. At birth, gas is substituted for liquid to expand the alveoli. Lung ultrasounds at the **first breath(s) of life in neonates born (by vaginal and C-section) at 35 or more weeks' gestation found 89% fluid clearance at the 1 to 10 minute examination and complete fluid clearance at the 11 to 20 minute examination in all the infants.**[57] After the alveoli are "opened" during the first few breaths, a film of surfactant-active material stabilizes the alveoli.

The first breath of life requires an opening pressure of 60 to 80 cm H_2O to overcome the effects of the surface tension of the air-liquid interface, particularly the small airways and alveoli. Thus on each subsequent breath, less pressure is necessary to allow for a similar increase in air volume in the lung. The effort of breathing is lessened with subsequent breaths.

GENERAL ETIOLOGIC FACTORS

Respiratory disease **may be defined as a progressive impairment of the lungs to exchange gas at the alveolar level.** Although the pathologic process causing respiratory distress in the neonate may occur in any portion of the respiratory system, **the final common pathway in respiratory disease is impairment of gas exchange.**

Prematurity is the single most common factor in the occurrence of RDS. Its incidence is inversely proportional to gestational age (GA) and occurs most frequently in infants of less than 1200 g and 30 weeks' gestation. **RDS occurs in male infants twice as frequently as in female infants (2:1). The principal factor operating in the development of RDS in very premature infants is surfactant deficiency.**

Multiple gestations increase the risk for respiratory disease related to lung maturity in the second, third, or more siblings. The second and subsequent infants may experience perinatal asphyxia, malpresentation, or mode of delivery (e.g., cesarean section) that contributes to respiratory disease. Grand multiparity is associated with increased risk for respiratory disease, particularly when other siblings have had RDS.

Prenatal maternal complications increase the risk for respiratory disease in the infant. Maternal illnesses such as cardiorespiratory disease, hypoxia, hemorrhage, shock, hypotension, or hypertension result in decreased uterine blood flow with subsequent hypoxia or ischemia at the placental level. Severe maternal anemia causes fetal cardiac depression and respiratory depression. Maternal diabetes may result in preterm delivery because of fetal and maternal indications. There is also a greater incidence of false-positive L/S ratios in diabetic populations. There has been a propensity of IDMs to develop RDS despite documentation of L/S ratios greater than 2:1. (A combination of an L/S ratio of 2:1 or greater and the presence of PG confirms fetal lung maturity.) Abnormal placental conditions (compressed umbilical cord caused by prolapse or breech delivery, placental disease such as infarcts or syphilis, or hemorrhage as a result of placenta previa or abruption placentae) affect oxygen transfer from mother to fetus and result in asphyxial insult to the developing fetal lung. Premature rupture of the membranes predisposes the fetus or newborn to the development of infections such as pneumonia, sepsis, or meningitis. **Premature or prolonged rupture of the membranes not associated with neonatal infection accelerates fetal lung development and thereby lessens the incidence of RDS.** Maternal toxemia and maternal drug addiction also hasten fetal lung maturation. **Antenatal administration of glucocorticoids[372] results in less severe RDS and fewer doses of surfactant, fewer cases of patent ductus arteriosus (PDA) and intraventricular hemorrhage (IVH), and lower mortality rates.**

Factors affecting the fetus during the birth process may lead to respiratory distress. Depression of the respiratory center can occur as a result of maternal medications that cross the placenta. An infant delivered shortly after analgesics, anesthetics, or magnesium sulfate is administered to the mother may have only minimal respiratory efforts at birth. Excessive uterine activity, usually as a result of oxytocin induction or augmentation of labor, may result in decreased uterine blood flow, late fetal heart deceleration, and respiratory depression in the infant at birth. Respiratory distress may be the result of direct trauma to the respiratory center or a cerebral hemorrhage in proximity to it. Fetal shock caused by difficult labor or dystocia, tight nuchal cord, cerebral hemorrhage, or hemorrhage from the fetal side of the placenta results in central nervous system (CNS) depression and hypoxia. Bleeding results in a generalized hypovolemic condition characterized by decreased oxygen-carrying capacity. Fetal or neonatal asphyxia and blood loss lead to progressive respiratory distress. After cesarean birth, retention and slower absorption of lung fluid through circulatory and lymphatic channels contributes to a higher incidence of transient tachypnea of the newborn.

The timing of cesarean section influences the incidence of RDS. Recent studies noting the increased risk of late-preterm infants and RDS in elective cesarean sections are cited in Chapter 5.

Obstruction of the airway caused by aspiration of meconium or amniotic fluid occurs before

birth, spontaneously at birth, or during resuscitative efforts. Although the lungs initially fill with air, subsequent atelectasis occurs as airway obstruction prevents further entrance of air. Conversely, a "ball-valve" or "air-trapping" effect may occur as air is allowed in but is unable to escape because of intermittent obstruction. The presence of amniotic debris, vernix, lanugo, and meconium in the respiratory tract increases the incidence and severity of pulmonary infection. Diaphragmatic paralysis occurs after phrenic nerve injury during birth (usually in a large-for-gestational-age [LGA] infant) and is often associated with brachial plexus injuries. The paradoxic movement of the paralyzed diaphragm during inspiration and expiration results in inadequate tidal volume and impaired gaseous exchange.

Existing neonatal conditions increase the risk for respiratory distress. Congenital defects that prevent transmission of the stimulus to or from the respiratory center, prevent normal respiratory effort, reduce gas-exchange surface area, or hamper the delivery of oxygen to the site of exchange will predispose the infant to respiratory compromise. Such defects include heart or great vessel anomalies, diaphragmatic hernia and hypoplastic lung, respiratory tract anomalies (e.g., choanal atresia or tracheoesophageal fistula), chest wall deformities, and CNS defects.

Diseases of the infant also can lead to respiratory distress. Hemolytic disease, such as ABO and Rh incompatibility, results in anemia and, if severe, in hypovolemic shock. Blood incompatibilities may cause respiratory distress by decreasing the oxygen-carrying capacity of the blood. Infections stress the body's systems, increase oxygen requirements, and contribute to an impairment of surfactant production. Chronic lung disease in the form of bronchopulmonary dysplasia (BPD) occurs as a result of therapies used to treat respiratory disease. Prolonged treatment of RDS may be necessitated by the severity of the disease but may increase the risk for developing chronic lung disease.

GENERAL PREVENTION

Antepartum

Prevention of respiratory disease begins with prevention of the conditions that predispose to respiratory distress. These conditions that constitute "reproductive risks" have been identified and can be categorized as psychosocial, genetic, biophysical, or economic in nature. Once an individual is identified as being in a high-risk category, comprehensive prenatal care with immediate attention given to maternal complications that arise is crucial (see Chapter 2).

Intrapartum

Fetal well-being is assessed by use of electronic monitoring of uterine activity, fetal heart rate, and fetal scalp blood sampling. Electronic fetal heart rate monitoring enables instantaneous fetal heart rate tracings that provide coincident correlation between uterine contractions and fetal response. These tools enable the practitioner to evaluate how well the fetus withstands the stresses of labor and to make decisions about the laboring course.

Fetal cardiac response to stress is unlike an older child's or adult's response to hypoxia, hypercapnia, and acidosis with tachycardia from sympathetic nervous system discharge. A fetus responds to these same stresses with an initial increase in heart rate that is quickly followed by bradycardia from parasympathetic stimulation when the hypoxia, hypercapnia, and acidosis persist (see Chapter 2).

Postpartum

After delivery, an infant should be maintained in an environment that minimizes stress and thereby minimizes oxygen requirement. All infants, but particularly at-risk infants, should be maintained within the narrow parameter of physiologic homeostasis (as outlined in Unit Two, Support of the Neonate).

GENERAL DATA COLLECTION

Because the clinical manifestations of many neonatal illnesses include respiratory symptoms (cardiac, metabolic, neurologic, and hematologic), a systematic and thorough approach to data collection is essential in evaluating an infant in respiratory distress.

History

The perinatal history (antepartum, intrapartum, and postpartum) should be reviewed for risk factors (see Chapter 2).

Signs and Symptoms

Vital signs such as temperature, pulse, respiration, and blood pressure should be evaluated. Hypothermia and hyperthermia increase oxygen requirements by altering the basal metabolic rate. Hypotension is often associated with respiratory distress.

RESPIRATORY EXAMINATION

Respiratory effort is normally irregular in rate and depth and is chiefly abdominal, rather than thoracic, with a **rate of 30 to 60 breaths/min.** A recent study of the respiratory rates of healthy term infants at 2 hours of age found: (1) median rates of 46 breaths/min, (2) at the 95th percentile, rates of 65 breaths/min, and (3) at the 5th percentile rates of 30 to 32 breaths/min.[531] In this study, respiratory rates increased with being awake, being a boy, and being born after heavy meconium-stained amniotic fluid. There was **no difference in respiratory rates between vaginal and cesarean births.**

Bradypnea is characterized by a rate below 30 breaths/min that is regular (as opposed to periodic or apneic) and may be caused by an insult to the respiratory center of the CNS. **Tachypnea, a rate of 60 breaths/min or greater after the first hour of life, is the earliest sign of respiratory (and often other) diseases.** As a compensatory mechanism, tachypnea attempts to maintain alveolar ventilation and gaseous exchange. As a decompensatory mechanism, tachypnea increases oxygen demand, energy output, and the "work" of breathing.

Periodic respirations are cyclic respirations of apnea (5 to 10 seconds) and ventilation (10 to 15 seconds). The average respiratory rate is 30 to 40 breaths/min. Periodic breathing is a common occurrence in small preterm infants as a result of an immature CNS. **Apnea is a nonbreathing episode lasting longer than 20 seconds and accompanied by physiologic alterations.** The syndrome of apnea is discussed under Apnea later in this chapter.

Use of accessory muscles of respiration is indicative of a marked increase in the work of breathing. Retractions reflect the inward pull of the thin chest wall on inspiration. Retracting is best observed in relation to the sternum (substernal and suprasternal) and the intercostal, supracostal, and subcostal spaces. The increased negative intrathoracic pressure necessary to ventilate the stiff, noncompliant lung causes the chest wall to retract. This further compromises the lung's expansion. **The degree of retraction is directly proportional to the severity of the disease.**

Nasal flaring is a compensatory mechanism that attempts to take in more oxygen by increasing the size of the nares and thus decreasing the resistance (by as much as 40%) of the narrow airways. **Grunting is forced expiration through a partially closed glottis.** The audible grunt may be heard with or without the aid of a stethoscope. **As a compensatory mechanism, grunting stabilizes the alveoli by increasing transpulmonary pressure and increases gaseous exchange by delaying expiration.**[212]

Color is normally pink within the first 10 minutes of life. *Acrocyanosis,* **which is peripheral cyanosis of the hands and feet in the first 24 hours of life, is normal. Pallor** with poor peripheral circulation may indicate systemic hypotension. **Ruddy, plethoric skin color** may indicate hyperviscosity, polycythemia, or both as the cause of respiratory symptoms. However, the lack of a deep-red coloring does not rule out polycythemia or hyperviscosity.

Cyanosis, a late and serious sign, is a blue discoloration of the skin, nail beds, and mucous membranes. Differentiation between **peripheral cyanosis** (of hands and feet) and **central cyanosis** (of mucous membranes of mouth and generalized body cyanosis) is essential. **Because a large decrease in PaO_2 may be tolerated without detectable cyanosis, the lack of cyanosis does not ensure a healthy infant.** When hypoxemia reaches a level that produces frank cyanosis, the insufficiency is usually in advanced stages (see Chapter 8). Therefore cyanosis or its lack is not a reliable sign in neonates.

Symmetry of the newborn chest is characterized by a relatively round or barrel shape, because the anteroposterior diameter equals the transverse diameter. With prolonged respiratory distress, there is an increase in the anteroposterior diameter, so the neonate becomes *pigeon-chested.*

Auscultation of a newborn's chest includes comparing and contrasting one side with the other and noting the quality of breath sounds and the presence or absence of rales, rhonchi, or other abnormal sounds. Because of the relatively small size of the newborn's chest, it is hyperresonant, so breath sounds are widely transmitted. **Therefore one cannot always rely on auscultation to detect**

pathologic conditions (e.g., pneumothorax). Percussion of the chest to determine the presence of air, fluid, or solids may not be useful in the neonate because of small chest size and hyperresonance. Palpation of the neonatal chest wall while the infant is crying may detect gross changes in sound transmission through the chest. **Palpation of crepitus in the neck, around the clavicles, or on the chest wall suggests the complication of air leak.**

NONRESPIRATORY EXAMINATION

Hypotonia is characterized by a froglike positioning and a lax, open mouth. Progressing from flexion to flaccidity indicates progression of hypoxia and exhaustion from the work of breathing. Cardiac and related findings such as a murmur, absence of pulses, bounding pulses, palmar or calf pulses, weight gain, hepatosplenomegaly, cyanosis, edema, bradycardia, or tachycardia indicate congestive heart failure or congenital heart defects. **A scaphoid abdomen indicates a diaphragmatic hernia.**

Laboratory Data

Because the clinical presentation of many respiratory and nonrespiratory diseases is the same, a **chest x-ray examination** may be the only way to differentiate cause and establish the proper diagnosis. X-ray evaluation helps eliminate congenital anomalies (e.g., diaphragmatic hernia with lung hypoplasia, masses, and obstruction) as the cause when acquired respiratory disease (e.g., RDS, transient tachypnea of the newborn, and pneumonia) is the cause of the distress. X-ray films confirm the presence of pneumothorax or other pulmonary air leaks.

Measurement of arterial blood gases is used to demonstrate alterations in oxygenation and acid-base balance and to differentiate between respiratory and metabolic components. Initial baseline values are followed by serial observations at least every 15 to 30 minutes after any change in therapy during the acute phase of illness. **Pulse oximetry enables immediate evaluation of oxygenation status and is an adjunct to arterial blood gas sampling.**[15] **A *shunt study* may differentiate between lung origin and cardiac origin of respiratory distress.** The symptoms of pulmonary disease (cyanosis and low PaO_2) are often alleviated with crying, increased FiO_2, or continuous positive airway pressure. If the same symptoms are cardiac in origin, they remain unchanged or worsen with these interventions. Administration of 100% FiO_2 for 10 minutes or longer may result in an increased PaO_2 (greater than 100 mm Hg), whereas in cardiac disease caused by right-to-left shunting, there is no change in PaO_2 after 100% FiO_2 administration.

CAUTION: In the presence of severe lung disease with significant right-to-left shunting, cyanosis and PaO_2 may not be changed with 100% FiO_2.

The **hematocrit value is used to rule out anemia or polycythemia** as the cause of the respiratory distress. In anemia, inadequate oxygen content promotes tissue hypoxia. In polycythemia, increased viscosity and sludging of blood flow adversely affect tissue oxygenation.

The white blood cell count, differential, and C-reactive protein (CRP) (see Chapter 22) aid in diagnosing sepsis as the cause of distress. A blood culture is an invaluable aid when infection is suspected and should be obtained before antibiotic therapy is initiated. **Blood glucose** determination to rule out hypoglycemia as a cause is particularly important in IDMs, small-for-gestational-age (SGA) infants, LGA infants, and preterm appropriate-for-gestational-age (AGA) and late-preterm infants. An **electrocardiogram (ECG), echocardiogram, and cardiac catheterization** are used to rule out cardiac abnormalities.

An electroencephalogram (EEG) and ultrasonographic examination of the brain help rule out CNS abnormalities. **Serum electrolytes** (calcium, sodium, and potassium) aid in eliminating metabolic aberration as the cause of the distress.

GENERAL TREATMENT STRATEGIES

Treatment of any condition should be directed at correction of its underlying cause. In meconium aspiration syndrome, the presence of meconium damages the neonatal lung. No therapeutic measure is available at present to augment the healing process. Therapy is thus directed at preventing or alleviating the consequences of neonatal lung diseases, such as hypoxemia and acidemia, allowing healing to take place and reducing the potential for iatrogenic complications.

Respiratory support is the hallmark of treatment of neonatal respiratory disease. Respiratory support involves increasing inspired oxygen tensions and providing ventilation, if necessary.

Supplemental Oxygen

Oxygen is a *drug*, the most commonly used drug in neonatal care. Historically, the policy of unrestricted and unmonitored oxygen therapy was accompanied by potential harm (e.g., RDS, chronic lung disease [BPD/CLD], retinopathy of prematurity [ROP] [discussed in Chapter 31], PDA [see Patent Ductus Arteriosus later in this chapter], necrotizing enterocolitis [NEC] [discussed in Chapter 28], and IVH/periventricular leukomalacia, hypoxic-ischemic encephalopathy [PVL, HIE] [discussed in Chapter 26]) from oxygen free radicals without clear benefits).

Free radicals are continuously produced in all cells as a byproduct of cell metabolism. Free radicals have positive effects in normal physiologic processes as follows: (1) biologic defense against bacteria, viruses, and cancer cells; (2) vasodilation; (3) neurotransmission; and (4) the up-regulation of some genes.[28] However, free radicals may also have harmful effects. **Free radicals, highly reactive atomic molecules with unpaired electrons, regain their stability by quickly reacting with other molecules in proximity to obtain the molecules they need. Reaction with free radicals causes damage to these close molecules by changing their structure and function.** To maintain homeostasis, the human body either uses or counters free radical activity with endogenous and exogenous antioxidants. Neonates, especially preterms, have maturational deficiencies in endogenous antioxidant systems, nutritional issues altering exogenous dietary intake of antioxidants, and diseases/conditions requiring interventions that preclude control of free radical–generating stimuli in their environment.[28] **Therefore the neonatal period is an especially vulnerable time for free radical damage and injury.[526] Neonates, especially preterms and sick term infants, depend on care providers to use strategies that emphasize the prudent use of oxygen therapy (e.g., use of the minimum amount of oxygen to provide the desired therapeutic effect),[28,193,526] because the proper concentration of supplemental oxygen, especially for extremely preterm infants, remains to be established.[20,61,503]** Neonatal animal modeling of hyperoxia lung injury shows a direct relationship between oxygen concentration and severity of alveolar simplification.[369]

When the neonate cannot maintain adequate oxygenation, supplemental oxygen must be provided. Because oxygen is a drug, it must be treated as such and given only for specific indications (Box 23.1). Institutional protocols for ordering, delivering, monitoring, and documenting oxygen therapy are recommended.[15]

BOX 23.1 CRITERIA THAT INDICATE A NEED FOR SUPPLEMENTAL OXYGEN

Biochemical

Hypoxemia: PaO_2 <60 mm Hg

Asphyxia: progressive hypoxemia, hypercarbia, and acidosis

Clinical

Respiratory distress: Tachypnea
- Grunting
- Flaring
- Retractions
- Apnea

Activity: decreased/no response to painful stimuli; lack of spontaneous activity

Hypotonia and saturation: PO <90%

Hypoperfusion: low blood pressure and/or prolonged CRT >3 seconds

Central cyanosis: perioral, mucous membranes of gums/lips, skin, periorbital

CRT, Capillary refill time; *PO*, pulse oximetry.

Regardless of the mode of delivery (hood, nasal cannula or prongs, endotracheal tube [ETT], bag, or mask), safe and effective oxygen administration follows certain principles outlined in Table 23.2.

OXYGEN TARGETING FOR THE VERY-LOW-BIRTH-WEIGHT PRETERM INFANT

Because an infant who is hyperoxic (PaO_2 greater than 80 mm Hg) clinically looks no different from an infant whose PaO_2 is normal, **monitoring of oxygen saturations and partial pressure of oxygen with arterial blood gases is mandatory whenever oxygen is administered.** Because PO gives immediate and continuous data, fewer PaO_2 values are obtained, so interpretation of PO readings and their relationship to PaO_2 values is critical. **Because PO saturations higher than 92% can often be associated with hyperoxia (e.g., PaO_2 greater than 80 mm Hg),** cohort[540] studies demonstrated a significant reduction in the incidence of ROP and BPD/CLD in preterms when their oxygen saturations were maintained in the lower (SpO_2 89% to 94%) rather than the higher range (SpO_2 96% to 99%).

TABLE 23.2 PRINCIPLES OF OXYGEN ADMINISTRATION

PRINCIPLE	RATIONALE
No concentration of oxygen has been proved to be "safe."	A concentration (e.g., 30%, 50%, 80%, 100%) that is therapeutic for one infant may be toxic for another.
Oxygen blenders must be available wherever oxygen is being administered (e.g., delivery room, transition nursery, level I, II, III, IV nursery).	Enables the delivery of different amounts of inspired oxygen concentrations[28,193]
Oxygen must be titrated to the individual needs of each newborn so that the infant is maintained in a normoxic state, avoiding both hypoxemia and hyperoxemia.[276] Acutely ill neonates requiring supplemental oxygen therapy also should have blood pH and $PaCO_2$ measured.[15]	Maintaining normoxia results in effective pulmonary vasodilation, thus preventing PPHN.[292] Normoxia is measured preductally by: Arterial PaO_2 levels between 60 and 80 mm Hg Pulse oximetry levels between 92% and 94% or as high as 90% -97%[292] (see section on oxygen targeting: 90%-95%) If a newborn has a *diagnosed* cyanotic congenital heart defect, a PO level below 90% or a PaO_2 level below 60 mm Hg is "tolerated" because the shunting in the heart and the admixture of oxygenated and unoxygenated blood prohibit a higher PO or PaO_2 level.
Titrate inspired oxygen concentrations to the individual neonate's need by continuous noninvasive pulse oximetry wherever oxygen is being administered (e.g., delivery room, transition nursery, level I, II, III, IV nursery).	**Oxygen administration without some form of continuous monitoring of the individual infant's oxygenation level is dangerous and not recommended.**[15]
Evaluation of the color of a neonate (e.g., pink or cyanotic) as an indicator for the need for or lack of need for oxygen was used prior to the development of modern monitoring devices. The practice of "eyeballing oxygen"—administering oxygen in concentrations just sufficient to abolish cyanosis—was used to titrate oxygen between blood gases in facilities without blood gas capability and prior to pulse oximetry.	**Because of the presence of fetal hemoglobin, the neonate's color is a poor indicator of oxygenation status: cyanosis is a *late* sign of hypoxemia and being pink in color does not mean that a newborn is well oxygenated.** **Central cyanosis of the mucous membranes of the mouth, around the eyes (periorbital cyanosis), and generalized cyanosis (blue discoloration of the skin and nailbeds) is pathologic and must be distinguished from peripheral cyanosis (acrocyanosis of the hands and feet).** **Central cyanosis is a *late* and serious sign because a large decrease in PaO_2 may be tolerated by the neonate (with fetal hemoglobin) without detectable cyanosis. When hypoxemia reaches a level that produces frank cyanosis, the insufficiency of oxygen is at an advanced stage.** For example: a neonate with a PaO_2 of 35 mm Hg will have an oxygen saturation of only 80% and be pink, even though he or she is hypoxic and in need of supplemental oxygen. (See The 30-60-90 rule in Chapter 8.) Lack of cyanosis or the presence of pink skin is not a reliable sign in neonates and does not ensure a healthy, well-oxygenated neonate. **Oxygen administration without some form of continuous monitoring of the infant's oxygenation (e.g., arterial blood gases or pulse oximetry) is dangerous and not recommended.**[15]
Delivered oxygen should be humidified (30% to 40%).	Dry gases are irritating to mucous membranes of the neonatal airway; humidity decreases insensible water loss. To prevent respiratory therapy equipment from becoming a source of infection, humidifiers and tubing should be replaced per institutional and product protocols.
Oxygen should be warmed (31-34° C; 87.8-93.2° F]) so that the temperature at the delivery site is the same as the incubator temperature. **Oxygen delivered by ETT should be warmed to core temperature (i.e., 36.5-37° C [97.7-98.6° F]).**[193]	Warming oxygen prevents cold stress and increased oxygen consumption from blowing cold air in the infant's face or down the ETT.[496] A recent integrative review of the literature of mechanical ventilation in premature infants found that recommended levels of heat and humidification were not maintained.[420]

Continued

TABLE 23.2 PRINCIPLES OF OXYGEN ADMINISTRATION—CONT'D

PRINCIPLE	RATIONALE
The oxygen concentration delivered to the neonate must be monitored by continuous or intermittent sampling (at least every hour) and recorded. Additionally, hourly documentation of the following parameters should also be recorded: • PO saturation values • Mode of oxygen delivery (e.g., hood, nasal cannula, CPAP, CMV HFV) • Amount of oxygen being delivered (e.g., FiO_2, liter flow/minute)[14]	The concentration of the drug, oxygen, its mode of delivery, and PO saturations are documented interventions.
Oxygen monitors and analyzers should be calibrated according to the manufacturer's recommendations.[15]	Assure accuracy of readings from devices.
Wean cautiously from supplemental oxygen.[496] Adjust FiO_2 in small increments (2%-5%) to avoid hypoxemia and/or hyperoxemia. Adjustment of supplemental oxygen, particularly lowering the oxygen, must be done slowly to avoid the *flip-flop phenomenon.*	*For every 1% decrease in FiO_2 there is a 10 mm Hg decrease in PaO_2.* See Chapter 8 for a discussion of the "rule of seven" which states that the estimated percentage change in inspired oxygen is equal to the desired change in PaO_2 divided by 7. A stable concentration of oxygen is necessary to maintain PaO_2 and PO levels within the desired normal limits. The neonate responds to changes in supplemental oxygen with a *flip-flop phenomenon*—a sudden increase or decrease in oxygen concentration may result in a disproportionate increase or decrease in PaO_2 or PO value caused by vasodilation (increased oxygen) or vasoconstriction (decreased oxygen) in response to oxygen.[496] The closer to term gestation the more developed the musculature around the pulmonary vessels, and the more labile these infants are to deceases in supplemental oxygen and/or receiving oxygen that keeps their PO below 90%.[537] When more mature infants are not given enough oxygen to keep their pulmonary vasculature dilated or have a sudden drop in their oxygenation level—handling, bathing, weighing, discontinuing oxygen to take baby from delivery room to nursery, examinations—a hypoxic insult occurs. Any hypoxic insult may result in: • Pulmonary vasoconstriction, which causes hypoperfusion and increased pulmonary vascular resistance • Opening of the ductus arteriosis • Right-to-left shunting at the DA and the FO • Hypoxemia, hypercarbia, and acidosis • Essentially these changes represent the reversion to fetal circulation—without the presence of the placenta as the organ of gaseous exchange. This persistence or reversion to fetal circulation is the pathophysiology of PPHN. In this population of sick neonates (late-preterm/early term/term), the risk of developing PPHN is higher than the risk of ROP, so that the PO saturation ranges from at least 92%-94% (or 90%-97%)[292] should be maintained to prevent PPHN.
Observe and document color, respiratory effort, activity, and circulatory response in addition to PO saturations and PaO_2 values	Clinical response aids in determining the need for oxygen therapy and for appropriate adjustments.
Clinical observations, FiO_2 concentrations, and time of adjustments must be described, documented, and reported.	Oxygen concentrations should be returned to previous levels if clinical observations of distress and inability to tolerate decreased levels of oxygen occur.

TABLE 23.2 PRINCIPLES OF OXYGEN ADMINISTRATION—CONT'D

PRINCIPLE	RATIONALE
Prone positioning with the head of the bed elevated to a 45 degree angle promotes oxygenation Prone positioning skin-to-skin care with mother/father	See Chapter 13; Box 13.11: Effects of prone positioning on page ***. Gravity assists the abdominal organs to be dependent and not pushing upwards and compromising respiratory excursion. Improves gaseous exchange, especially in preterm infants <1000 g (see Chapter 13)
Place cardiorespiratory monitor and/or pulse oximeter.	PO required for every baby on oxygen and prone positioning requires monitoring device(s) for safety.
Minimize internal stress:	
Maintain in neutral thermal environment and in thermal neutrality to minimize oxygen consumption and oxygen demand.	Hypothermia increases oxygen demand and oxygen consumption in an already stressed neonate needing oxygen.
Maintain adequate blood glucose levels.	Hypoglycemia causes respiratory distress that increases the need for oxygen.
Handle gently and minimally (DO NOT BATHE) to prevent iatrogenic hypoxic episodes that can precipitate PPHN (see PPHN section in this chapter).	Handling a sick neonate for any reason causes a fall in PaO_2 and PO saturations. With handling the PaO_2 variations in the neonate are:[113,161] • At rest ±15 mm Hg variation • Crying: decrease in PaO_2 by as much as 50 mm Hg • Routine care: decrease in PaO_2 by as much as 30 mm Hg
Minimize external stress:	
Minimize painful procedures.	Pain increases heart and respiratory rates and blood pressure and decreases PaO_2 and PO.
Use nonpharmacologic (comfort) interventions for painful procedures that are necessary.	See Chapter 12: Nonpharmacologic (comfort) interventions on page *** for neonatal pain.

C, Centigrade; *CMV,* conventional mechanical ventilation; *CPAP,* continuous positive airway pressure; *DA,* ductus arteriosus; *ETT,* endotracheal tube; *F,* Fahrenheit; *FiO_2,* fraction of inspired oxygen; *FO,* foramen ovale; *HFV,* high frequency ventilation; *PO,* pulse oximetry; *PPHN,* persistent pulmonary hypertension of the newborn; *ROP,* retinopathy of the newborn.

A systematic review and meta-analysis in 2011 found a 50% reduction in severe ROP and a 20% to 25% reduction in BPD/chronic lung disease when the lower rather than higher oxygen saturation range was used.[453] Two studies (STOP-ROP[519] and BOOST[21]) that randomized preterm infants (several weeks after birth) to a lower or higher saturation range also found that **higher saturations resulted in (1) more BPD/CLD, (2) no difference in the progression to threshold ROP, (3) more days on oxygen supplementation, and (4) a higher use of health care resources**.

Five multicenter, multinational trials (SUPPORT,[503] three BOOST II trials,[61] and the COT trial[459]) randomized a total of 4965 premature infants of less than 28 weeks of gestation to low (Spo_2 85% to 89%) or high (Spo_2 91% to 95%) ranges. Outcomes at 2 years corrected age (CA) of preterm infants included in the BOOST-II trial who were randomized to the *lower* saturation group included: (1) nonsignificantly higher rates of death or disability in each trial analyzed separately and (2) a significantly higher rate of death or disability and death alone when both trials were analyzed together.[61] Results of all five trials have recently been systematically reviewed and a final meta-analysis (the NeOProM) performed to determine optimal oxygen saturation targets for preterm infants (mean GA of 26 weeks; mean birth weights of 820 to 850 g).[20] **At 18 to 24 months CA, there was no significant difference between the lower and higher saturation groups in mortality or major disability.**[20] Secondary analysis of the data found **that the *lower* saturation group had: (1) more death prior to 36 weeks' postmenstrual age (PMA), before discharge from the neonatal intensive care unit (NICU) and before reaching 18 to 24 months' CA, (2) a significantly higher risk of severe NEC, and (3) a significantly higher risk of PDA requiring ligation. Preterm infants randomized to the *higher* saturation group had a significantly higher risk of BPD and ROP requiring treatment but no increase in blindness.**[20]

Based on these studies, a survey of 193 NICUs in 27 European countries[234] and the NeOProM systematic review,[20] guidelines for oxygen targeting in preterm infants less than 28 weeks' GA recommend[112,260,454,506]:

- **Target Spo2 between 90% and 95%**

Maintaining ranges between 90% and 95% to avoid hypoxemia/hyperoxemia is an enormous challenge to care providers, especially neonatal nurses. A recent systematic review found that the proportion of time that preterm infants spent outside of designated ranges varied from 8.2% to 22.4%.[331] The narrower target range (90%–95%) is associated with an increase in median SpO_2 and a right shift in the distribution,[542] but there was no change in the time spent between 90% and 95%.

Maintaining oxygen saturations within narrow ranges is labor intensive, with one study finding that **the fraction of inspired oxygen (FiO_2) concentration was adjusted between 16 and 41 times per day, with an average of one adjustment every hour. These researchers noted an increased frequency of prolonged hyperoxia when nurses were each caring for more than one neonate.**[318] Factors influencing clinical decision making about oxygen titration include poor staffing, nursing shortage, and lack of knowledge about oxygen use.[251] A recent study evaluated the incidence of hypoxemia episodes (SpO_2 <75) in 24 mechanically ventilated premature infants to compare the difference between day and night frequency and severity.[241] During the nighttime hours (2100 to 0500), the frequency of mild hypoxemia (SpO_2 <85) and severe and prolonged hypoxemia was less when compared to daytime hours (0900 to 1700). Frequency of severe hyperoxemia (SpO_2 >95%) was greater during the nighttime hours, whereas the mean FiO_2 did not vary between the day and night hours. The researchers concluded that fewer hypoxemia episodes were due to less handling and sensory stimulation at night.

New mechanical devices such as a closed-loop automatic control (CLAC) reduce nursing workload, improve oxygen administration, and automatically control FiO_2 to preterm infants receiving CPAP or mechanical ventilation.[206] **In ventilated preterm infants, automated control of inspired oxygen reduced episodes of hypoxemia and hyperoxemia while maintaining better oxygen saturation ranges.**[296]

Fluctuations of PaO_2 (e.g., hypoxemia and hyperoxemia episodes) in the very-low-birth-weight (VLBW) preterm may be a more significant risk factor than hyperoxia alone for the development of threshold ROP.[587] These episodes of hyperoxia and/or hypoxia may result from the underlying respiratory pathology or the result of care providers' interventions (e.g., positioning; suction; "chasing desaturations by increasing FiO_2"; surfactant administration).

DELIVERY METHODS

For instructions on the bag-and-mask resuscitation method, see Chapter 4. **An oxygen hood is a clear plastic hood that fits over the infant's head to deliver a constant concentration of oxygen.** If the infant has sufficient ventilation to maintain a normal arterial carbon dioxide tension, oxygenation by increased inspired oxygen tensions through an oxygen hood may be the only respiratory support that is necessary. This degree of support is particularly applicable in cases of mild RDS, transient tachypnea of the newborn (TTN), meconium aspiration, or neonatal pneumonia.

A **blender system** is the most reliable way to administer a fixed oxygen concentration via a hood. An appropriate-size hood should be used. If it is too large, the infant may slip out of the hood and FiO_2 may be diluted by leaks; if it is too small, pressure points may develop, especially around the neck. **Another source of oxygen must be provided when the infant's head is removed from the hood because of feeding, being held, or suctioning.** This secondary source may be set up from the blender source so that the infant's PaO_2 remains constant during suctioning or feedings. The infant may need increased FiO_2 from the secondary source. This can be adjusted easily according to assessments made with pulse oximetry, and these changes should be recorded.

For both home and hospital use, a **nasal cannula** (NC) is used to administer oxygen to the dependent infant who is developing social and motor skills:

- **Choose the appropriate-size cannula for the infant**—a cannula that is too large obstructs the nares, prevents air leak thus enabling an increase in CPAP, irritates the nasal mucosa, and is uncomfortable for the baby.[283]
- **Position the cannula across the infant's upper lip.** Secure it to the infant's face by first applying hydrocolloid barrier or transparent dressings directly to the infant's cheeks and taping the cannula to it to prevent skin irritation.

- Oxygen tubing should be long enough to provide opportunities for social and gross motor skill development.

CAUTION: Neonates are obligatory nasal breathers, so nasal obstruction (mucus or milk) will decrease the amount of oxygen actually received. Therefore nares should be suctioned as needed. **Because the exact concentrations of oxygen delivered by cannula cannot be measured, flow rates are titrated by monitoring PaO_2 or pulse oximetry readings and by evaluating the clinical course.**

Two thirds of neonatal centers in the United States, Australia, and New Zealand have adopted **heated, humidified, high-flow (greater than 1 L/min) nasal cannula (HHHFNC) therapy** as **primary respiratory therapy for preterms with RDS, apnea of prematurity, and postextubation respiratory care, including weaning from nasal continuous positive airway pressure (NCPAP).**[154,283,332,430,570] Use of NCs with oxygen rates above 0.5 L/min may result in inadvertent administration of continuous distending (positive) pressure.[326] **HHHFNC generates CPAP to the preterm airway that may be excessive** given the conditions of (1) closed mouth, (2) tightly fitting NC, (3) rate of flow, and (4) infant size (less than 1500 g).[283]

Commercial HHHFNC devices currently in use can achieve flow rates of 4 to 8 L/min.[167] Unlike CPAP devices that are equipped with a pressure gauge and a pop-off safety valve, **HHHFNC devices do not have a direct measure of the pressure applied to the infant's airway** or a pop-off valve to prevent the accumulation of excessive pressure; **flow rates as high as 6 L/min have been used without measurement of the level of CPAP delivered.**[167] **CPAP generated with HHHFNC depends on flow rate and weight; the smallest infants with the highest flow rates and a completely closed mouth may achieve clinically significant and unpredictable levels of CPAP.**[283,571] Several more recent studies have compared HHHFNC and NCPAP by examining the breathing patterns, work of breathing, lung mechanics, gas exchange, pulse oximetry saturations and thoracoabdominal synchrony in a total of 40 preterm infants (27–31 weeks' gestation) and found no significant differences.[305,471]

Improved ventilation and oxygenation with HHHFNC (at flow rates above 2 L/min) with comparable efficacy to use of NCPAP in preterms with RDS have been demonstrated in several observational and retrospective studies.[332,451,475] **Newer studies of the use of HHHFNC versus NCPAP for primary respiratory support in preterm infants with mild to moderate RDS show conflicting results in** Box 23.2. Because of the conflicting research, **a consensus panel issued a report about high-flow nasal therapy use, found in** Box 23.3.

As primary therapy for RDS, HHHFNC has also been compared to nasal intermittent positive-pressure ventilation (NIPPV) in preterms (<35 weeks' gestation and >1000 g birth weight). There was no significant difference in the need for endotracheal intubation/ventilation or the rate of morbidities (i.e., pneumothorax, BPD, IVH, NEC, PDA, or nasal trauma) between the preterms randomized to the HHHFNC or the NIPPV treatment groups.[285] This randomized pilot study also found a longer duration of respiratory support when compared to NIPPV.

NOTE: The use of HHHFNC for postextubation care is discussed under the heading Weaning from the Ventilator later in this chapter.

Continuous Distending Pressure

Continuous distending pressure (CDP) is used for the prevention and treatment of RDS, apnea of prematurity, and weaning from intermittent positive-pressure ventilation. CDP results in less respiratory failure and mortality but an increased rate of pneumothorax.[225] Application of a continuous distending pressure (CDP) to the lungs increases functional residual capacity and PaO_2. Oxygenation is improved by decreasing intrapulmonary shunting and by improving the match of ventilation and perfusion. The application of CDP improves compliance of the lung and lessens the work of breathing.[194] **Early application of CDP in preterms with RDS reduces the subsequent use of intermittent positive-pressure ventilation (IPPV) with its accompanying adverse effects.**

In RDS, in which the functional residual capacity is reduced, increased respiratory oxygen tensions through an oxygen hood (oxyhood) may not be sufficient to maintain an adequate arterial oxygen tension. More invasive techniques may be necessary.

CPAP and continuous negative pressure (CNP) are two methods of delivery of CDP. If the infant cannot maintain a PaO_2 of 60 mm

BOX 23.2 USE OF HEATED, HUMIDIFIED HIGH-FLOW NASAL CANNULA (HHHFNC) AS PRIMARY RESPIRATORY SUPPORT FOR PRETERM INFANTS: RESEARCH EVIDENCE

Advantages

- For preterm infants >28 weeks' gestation, there is no difference in treatment failure (i.e., need for intubation and mechanical ventilation) and no difference in secondary outcomes (i.e., duration of respiratory support, need for surfactant, incidence of pneumothorax or BPD/CLD)[304,593]
- Less nasal trauma and damage[217,337,430,593]
- Stable preterm infants with mild respiratory dysfunction have comparable diaphragm thickness and chest excursion with NCPAP and HHHFNC[157]
- HHHFNC is a safe and efficacious alternative to NCPAP for primary respiratory support for mild to moderate RDS,[216,217,304,593] in treatment of apnea of prematurity,[448] for weaning from CPAP,[485] and for post-extubation failure[484]
- Systematic reviews of the evidence for use of HHHFNC in preterm infants agree that there is no difference in death or BPD/CLD and other morbidities except a need for longer therapy[173,332,570]
- No difference in achieving full oral feedings among VLBW (<1500 g) randomized to HHHFNC or NCPAP[184]

Disadvantages

- Inability to measure pressure of HHHFNC with possibility of air leak and lung injury[337]
- Few studies of HHHFNC use in ELBW infants[337]
- Less effective than NCPAP overall, but effective for the majority of preterms of at least 28 weeks' gestation without surfactant therapy. The HIPSTER trial was halted because of treatment failure (25.5% HHHFNC vs. 13.3% NCPAP failure) that was significant in preterm infants <32 weeks and >32 weeks gestation. There was longer duration of use (4 days vs. 3 days) and more use of supplemental oxygen with HHHFNC.[430]
- Longer use, longer exposure to positive pressure and oxygen[216,227]
- More treatment failures (need for intubation/mechanical ventilation) as a result of more hypoxia among preterm infants (30–35 weeks' gestation) randomized to HHHFNC compared to NCPAP. No difference in respiratory or clinical outcomes and complications between groups.[472]
- Significantly higher treatment failure (need for higher level of respiratory support) among preterm infants with both moderate and severe respiratory distress in the HHHFNC (26.3%) compared to the NCPAP group (7.9%) when used as primary respiratory support[362]
- Case report of tension pneumocephalus as a complication of HHHFNC use[235]
- Chart review of pre and post use of HHHFNC: higher rates of ROP and a trend toward higher rates of BPD/CLD; delayed oral feedings and fewer infants orally feeding at discharge, higher use of intermediate care and longer length of stay among those who used HHHFNC[227]
- Lack of adequately powered RCTs: (1) comparing HHHFNC to other forms of primary respiratory support, (2) for weaning from other forms of noninvasive support, and (3) use varying populations (i.e., ELBW; mildly preterm) populations.[570]
- Lack of evidence that HHHFNC is superior to NCPAP and that it is cost effective[173]
- Lack of large prospective RCTs so that "HHHFNC should not be a routine or first choice of neonatal respiratory support for RDS."[81] (The HUNTER trial in Australia and New Zealand may provide answers because it will be a multicenter [eight non-tertiary centers] RCT of the use of HHHFNC versus NCPAP for primary respiratory support in preterm infants ≥31 weeks' gestation to evaluate safety, efficacy, and cost-effectiveness.[335])

BPD/CLD, Bronchopulmonary dysplasia/chronic lung disease; *CPAP,* continuous positive airway pressure; *ELBW,* extremely low-birth-weight; *HHHFNC,* humidified, high-flow nasal cannula; *NCPAP,* nasal CPAP; *RCT,* randomized controlled trial; *RDS,* respiratory distress syndrome; *ROP,* retinopathy of prematurity; *VLBW,* very-low-birth-weight.

Hg in 0.6 FiO_2, a trial of CPAP through the nasal route is indicated. Initial levels of CPAP should be in the range of 4 to 5 cm H_2O. CPAP should be increased to 8 to 10 cm H_2O by 1 to 2 cm increments if necessary to raise the infant's PaO_2 (as measured by arterial blood gas determinations, noninvasive monitoring, or both).

Not all CPAP application techniques are equal. Neonates receiving "bubble" CPAP experience chest wall vibrations (similar to those seen in high-frequency ventilation [HFV]) that contribute to gaseous exchange. Two studies of the mechanics of bubble CPAP are important for information about maintenance of an adequately functioning system. **Lung volume recruitment and breathing efficiency during bubble CPAP are influenced by the size and depth of submergence of the expiratory limb of a CPAP circuit, the diameter of the bubble generator bottle, and lung compliance.[578] Condensation in the exhalation limb of a patient circuit during bubble CPAP accumulates at the rate of 3.8 mL/hr.[588] When this condensation reaches volumes greater than 10 mL, the oscillating fluid increases airway pressure and results in significant increases in mean tracheal pressure.** These researchers recommend **frequent (i.e., every 2 to 3 hours) emptying of the exhalation tube, continuous monitoring of**

BOX 23.3 CONSENSUS BY CLINICIANS ABOUT ASPECTS OF HHHFNC USE[434,586]

- Adequate heating (37° C)[78] and humidification (100% relative humidity)[82]
- Prevention of nasal occlusion (a nasal prong-to-nares ratio of 50% to 80%)[82]
- Initial flow rates in the range of 4 to 6 L/min with a minimal flow rate of 2 L/min[82] and a maximum flow rate of 8 L/min
- Criteria for escalation or weaning of therapy includes work of breathing and assessment of amount of supplemental oxygen
- Equivalence of high-flow nasal cannula with NCPAP for noninvasive respiratory therapy for preterm infants >28 weeks' gestation with RDS (both initial therapy and resolving RDS)
- Equivalence of high-flow nasal cannula for noninvasive support of stable infants on NCPAP
- No consensus on discontinuation of high-flow therapy

HHHFNC, Humidified, high-flow nasal cannula; *NCPAP,* nasal continuous positive airway pressure; *RDS,* respiratory distress syndrome.

pressure at the nasal airway interface, and using an adjustable pressure-relief valve in the circuit (set to 5 cm H_2O pressure above the desired mean pressure).[588]

***Bubble CPAP* compared with ventilator-derived nasal CPAP (NCPAP) in VLBW infants with moderate RDS has comparable failure rates (need for intubation) with no difference in complication rates (i.e., IVH and mortality).**[4] When 170 preterm infants (<34 weeks' gestation) were randomized to jet CPAP or bubble CPAP, failure rates at 72 hours were similar between the two groups.[56] Another comparison of bubble and jet CPAP in preterm infants under 34 weeks' GA found that those using bubble CPAP had more nasal injury.[268] Bubble CPAP is a low-cost device for developing countries that decreases neonatal mortality.[258,339,363,444]

High-amplitude bubble NCPAP (called Seattle PAP) provides different support from conventional bubble CPAP by changing the angle of the exhalation limb and decreasing the work of breathing.[563,564] The esophageal pressures of 40 preterm infants under 32 weeks' gestation were measured after 2 hours of conventional bubble NCPAP and then after 2 hours of Seattle PAP. Use of the high-amplitude Seattle PAP resulted in a lowered effort of breathing with no adverse effects (pneumothoraces or nasal trauma).[564] Whether a lowered effort of breathing translates to less morbidity and mortality awaits further study.

In one center, use of bubble CPAP from birth in 401 to 1000 g preterms has resulted in (1) fewer delivery room intubations, (2) fewer days on mechanical ventilation, (3) less use of postnatal steroids, (4) better weight gain, and (5) no increase in complications, including the incidence of CLD/BPD.[367] In a randomized controlled trial (RCT), larger preterms (mean GA of 36 weeks; mean birth weight of 2900 g) with respiratory distress were treated with either supplemental oxygen in an oxygen hood or with bubble CPAP through nasal prongs.[70] Only 23% of the larger preterms who were treated with CPAP were transported to a higher-level NICU compared with 40% of the preterms who were treated with oxygen in a hood. Also, cost savings were realized and there was no increase in oxygen use or mortality rate. However, there was a clinically—not statistically—significant increase in the incidence of pneumothorax in the CPAP group; the **24-hour presence of a neonatal nurse practitioner or physician to relieve air leaks is mandatory with the use of CPAP.**

More recent studies of bubble CPAP continue to demonstrate cost effectiveness and better outcomes of preterms with RDS, including extremely low-birth-weight (ELBW) and VLBW preterms.[258,339,363,444] A 7-year retrospective review of respiratory outcomes in 633 VLBW infants found a significant reduction in BPD/CLD (43% lower chance), less mechanical ventilation, and fewer discharged with diuretics and supplemental oxygen after use of bubble CPAP.[174] A subset analysis of the outcomes of ELBW preterms receiving bubble CPAP found a faster extubation rate, fewer days of mechanical ventilation (more ELBW off mechanical ventilation at 1 week of age), less ROP, fewer PDA ligations and deaths, and an increase in low-grade IVHs.[174] Another study found a 27% improvement in survival in a developing country with the use of bubble CPAP, especially in VLBW preterms, those with RDS, or those with sepsis.[258] A small trial (n = 18) of bubble NCPAP verus ventilator NCPAP found no differences in short-term outcomes (vital signs, oxygen saturation) and a nonsignificant difference in decreasing respiratory rate and cerebral fractional oxygen extraction while on bubble NCPAP.[196] A meta-analysis of seven RCTs of nasal bubble CPAP found a reduced failure rate and length of stay.[555] A systematic review of the

use of CPAP in low-and middle-income countries showed that it was safe and effective, and that it reduced mortality, the need for invasive mechanical ventilation, and transfer to a higher level facility, but higher quality evidence and the need for larger studies was recommended.[523]

Large, multicenter RCTs of NCPAP starting at birth include the COIN trial,[355] the SUPPORT trial,[497,503] the VON Delivery Room Management trial,[146] the CURPAP,[448] Colombian Network,[436] and South American Neocosur Network[511] trials. The COIN trial[355] compared NCPAP with intubation and ventilation of 25 to 28 weeks' gestation preterms breathing spontaneously by 5 minutes of age with respiratory distress. Within the first 5 days of life, 46% of those randomized to NCPAP were intubated, at a median of 6.6 hours of life. Outcomes at 36 weeks were no different for either group in the combined outcome of death or oxygen dependence. A nonsignificant trend toward less CLD/BPD occurred in the more mature preterms, whereas there was a trend toward increased mortality rates in the less mature preterms randomized to NCPAP. Unlike other studies, only 77% of the infants randomized to intubation received surfactant, and surfactant use was halved in the NCPAP group.[355] The SUPPORT trial compared immediate CPAP to intubation, surfactant, and mechanical ventilation in 24 to 27⅙ weeks gestation preterms and found fewer ventilator days, less postnatal steroid use, and no difference in air leaks, BPD/CLD, or death.[503] **In the SUPPORT trial, the most immature (24 to 25 weeks' gestation) preterms benefited the most from the early initiation of NCPAP**[503] and had less respiratory morbidity at 18 to 22 months' CA.[497] The CURPAP[448] and Colombian Network[436] trials demonstrated no difference in the rate of BPD/CLD with early CPAP versus prophylactic surfactant. **From these data the American Academy of Pediatrics (AAP) policy statement on respiratory support in preterm infants at birth recommends initiation of NCPAP at birth as an alternative to routine intubation and early surfactant therapy.**[14] **The AAP policy and the evidence-based recommendations of the EPICE group recommends combining early NCPAP with selective surfactant therapy in extremely preterm infants,** which results in lower BPD/CLD and death rates compared with early/prophylactic surfactant therapy.[14,590] (see also later section under Surfactant Replacement Therapy and Box 23.15). A more recent study shows that early NCPAP in preterm infants 32 weeks' gestation or under decreased the need for mechanical ventilation and surfactant use but had no significant effect on the development of BPD/CLD.[79]

Alternate methods of delivering continuous distending pressure in neonates include biphasic NCPAP and NIPPV. NIPPV use as the initial respiratory support for preterm infants (26 to 32 weeks' GA) has been shown to result in less need for surfactant or invasive ventilation in the first 72 hours of life, while reducing the incidence of moderate to severe BPD/CLD.[388,447]

However, a meta-analysis of the rates of death or BPD/CLD in preterm infants randomized to NIPPV with a conventional mechanical ventilator or bilevel device found no significant difference between the two in BPD/CLD or death.[347] Biphasic CPAP delivers two alternating levels of distending pressure at specific rates independent of the neonate's own respiratory rate. Biphasic is similar to CPAP but possibly better at maintaining an appropriate functional residual capacity (FRC). An RCT comparing biphasic CPAP and NCPAP of 540 preterm infants under 30 weeks' gestation and under 2 weeks of age found no significant difference in preventing extubation failure or in BPD/CLD, death, IVH, NEC requiring surgery, or pneumothorax.[549] Other trials have found that noninvasive ventilation strategies such as biphasic positive airway pressure (BiPAP) and nasal synchronized intermittent positive-pressure ventilation (NSIPPV) reduced the risk of failure in VLBW infants when compared to CPAP[447] and that Bi-NCPAP was superior to regular NCPAP for apnea of prematurity.[239] Even though biphasic CPAP delivery seems promising, specific volume drivers are required for its use, thus potentially limiting access.

Indications and complications in the use of CPAP are listed in Table 23.3. If the infant maintains ventilation as indicated by normal arterial carbon dioxide tension, no further respiratory support may be necessary. CPAP may be delivered by facemask, nasal pharyngeal tubes, nasal prongs, or ETT. Delivery of CPAP by nasal prongs is the most common method used; use of short binasal prongs is the most effective.[133] However, a more recent RCT and a systematic review both found that use of a mask for CPAP is as effective as nasal prongs, with less nasal trauma and pulmonary interstitial emphysema (PIE) and fewer CPAP failures.[186,243]

TABLE 23.3 CONTINUOUS POSITIVE AIRWAY PRESSURE

INDICATIONS	COMPLICATIONS
Premature infant who breathes spontaneously yet has mild to moderate respiratory distress syndrome; primary, initial respiratory support after birth	Respiratory difficulty secondary to narrowing of the nasal passage with prongs or of the trachea with the presence of an endotracheal tube
Very-low-birth-weight infant with primary or secondary apnea	Pneumothorax and other air leaks
Support during weaning from mechanical ventilation	Nasal and/or septal irritation, trauma, deformity, obstruction[488]; gastric and abdominal distention; perforation; infection (tracheal colonization on day 5 of nasal continuous positive airway pressure [NCPAP] use also associated with longer need for respiratory support)[12]

Advantages to the use of NCPAP include[174,193]:

- Less invasive than ETT
- Decreased incidence, duration, and complications of intubation and mechanical ventilation
- Earlier extubation
- Decreased incidence and morbidity of BPD/CLD
- Improved oxygenation and decreased work of breathing
- Decreased need for surfactant and second doses of surfactant
- Reduced mortality rate

Disadvantages include (1) gaseous distention of the bowel or gastrointestinal (GI) perforation[176] (both are rare occurrences),[532] (2) increased rate of pneumothorax,[70,355] (3) difficulties keeping prongs in the nose and maintaining patency, (4) infant agitation, and (5) alteration in appearance (dilation of the nares).[488] **The nutritional approach to neonates on noninvasive respiratory support must be individualized** so that pulmonary function and nutritional support are optimized without compromising either one.[64]

Nasal CPAP is labor intensive for the neonatal nurse.[172] Choosing the correct size of nasal prong is important to avoid movement and erosion of nasal tissue. A recent systematic review found an incidence of 20% to 100% for nasal trauma with the incidence highest in preterms under 30 weeks' gestation.[236] **The risk of nasal injury is also increased with longer duration of NCPAP, the type of device used, and longer NICU stay.[268,563]** Box 23.4 **lists important aspects of care of the neonate on NCPAP (or any other device using the nasal route) to optimize safety and efficacy.**

Criteria that indicate improvement on CPAP are listed in Box 23.5. Failure of CPAP is associated with (1) birth weight less than 1500 g, (2) GA 30 weeks or less, (3) "whiteout" chest x-ray, (4) FiO_2 50% or greater at 20 minutes of CPAP, and (5) positive end-expiratory pressure (PEEP) 5.5 cm H_2O or greater.[207,508] When the infant's PaO_2 is consistently over 70 mm Hg, inspired oxygen concentration or CDP may be lowered. Oxygen concentration is usually lowered in 5% to 10% increments to a level of 40% to 60%. CDP is lowered in increments of 1 cm H_2O to a level of 2 cm H_2O before discontinuation.[242] Results in weaning from NCPAP are seen when the pressure is lowered, then stopped, rather than removed for a number of hours during the day.[242] The infant may then be placed into an oxygen hood with the same FiO_2. Neonates should be monitored closely with pulse oximetry and arterial blood gases.

Pulmonary Hygiene

Pulmonary hygiene is normally maintained by ciliary activity, a covering of mucus, and narrowing and dilation of the bronchi with respiration and coughing. Anatomic and physiologic variations in the neonate alter these normal pulmonary mechanisms. **The small airway of the neonate has a diameter that is four times smaller than that of the normal adult.** Debris that causes only a moderate obstruction for the adult airway causes a disproportionately greater obstruction of the smaller airway of the neonate. Also, **a neonate normally has an underdeveloped cough reflex.** A sick neonate with insufficient respiratory effort and a weak or nonexistent cry has underventilated lungs. If a neonate who is attached to multiple life-support systems is cared for in the same position, secretions localize in the dependent pulmonary tree and predispose to hypostatic pneumonia.

BOX 23.4 CARE OF INFANTS RECEIVING NASAL THERAPIES* TO OPTIMIZE SAFETY AND EFFICACY

Prongs

- Nasal prongs should fill the entire nares without distending or causing blanching of the nares
- Presence of a small space (at least 2 mm) between the nares and prong base
- Lateral straps are used to secure the prongs by providing gentle, equal tension
- Assess prongs and NCPAP device at least every hour to ensure proper positioning and functioning
- Remove NCPAP device q 2–4 hr to assess skin integrity (e.g., color, perfusion, pressure, excoriation) and massage nasal septum
- Alternate use of nasal prongs with mask at least twice a day[77] to remove pressures on nares

Hat

- Use the appropriate size hat to avoid prong movement; change hat size with neonatal head growth
- Position just above the eyebrows, with the back of the hat extending to the base of the neck and completely covering the infant's ears
- Use ties on the hat to secure tubing, thus decreasing movement and/or upward pull of CPAP system

Nose

- Suction nares only PRN to maintain nasal patency
- Avoid deep nasal suctioning unless absolutely necessary for individual infant
- Use a hydrocolloid dressing[582] or silicone gel[198] over the nose and philtrum to provide a barrier layer for skin protection

Mouth

- Place orogastric tube for decompression of the stomach
- Encourage closed mouth by use of pacifier and/or prone positioning

Comfort Measures

- Positioning prone, swaddled, or contained (to promote flexion) (see Chapter 13) decreases movement and pulling/dragging of the device on the nares
- Minimal handling and position change q 2–4 hr and/or with infant agitation and developmental positioning
- Skin-to-skin care with parents (see Chapters 12 and 13)
- Pacifier, nonnutritive sucking, sucrose
- Environmental management—decrease light/noise (see Chapter 13)
- Use neonatal pain scale and administer pharmacologic sedation and/or pain relief (see Chapter 12)

*Noninvasive nasal therapies include *NBiPAP,* Nasal biphasic positive airway pressure; *NCPAP,* nasal continuous positive airway pressure; *NHFOV,* nasal high-frequency oscillator ventilation; *NIPPV,* nasal intermittent positive-pressure ventilation; *NSIPPV,* nasal synchronized intermittent positive-pressure ventilation.

Prevention of nasal injuries secondary to NCPAP application in the ELBW infant. *Neonatal Netw.* 2009;28(1):13; Flanagan KA. Noninvasive ventilation in preterm neonates. *Adv Neonatal Care.* 2016;16(2):91.

Pulmonary hygiene consists of two major components: chest physiotherapy (CPT) and suctioning. The goals of pulmonary hygiene are:

- To maintain a patent airway by clearing secretions
- To promote optimal pulmonary oxygenation and ventilation
- To prevent pulmonary infection from accumulated secretions
- To facilitate removal of pulmonary debris by loosening and mobilizing secretions into the mainstem bronchi for suctioning

Pulmonary hygiene has been used as a treatment for intubated patients with conditions associated with atelectasis, increased secretions, and pulmonary debris (pneumonia, meconium aspiration, RDS, and BPD).

CHEST PHYSIOTHERAPY

CPT consists of positioning, percussion, and vibration. Postural changes use gravity to facilitate the movement of pulmonary debris from smaller to larger bronchi. Postural changes used with pediatric and adult respiratory patients have been used for neonatal CPT. **However, most ill neonates, especially VLBW and ELBW infants, do not tolerate multiple positioning and repositioning.** Periodic (every 2 to 4 hours with care) repositioning changes the ventilation-perfusion matching in dependent lung areas and improves oxygenation. Prone positioning improves lung mechanics and lung volumes and improves oxygenation (see Chapter 13).

Percussion of the chest wall creates a suction action that loosens secretions. Percussion should

BOX 23.5 CRITICAL FINDINGS

CRITERIA THAT INDICATE IMPROVEMENT ON CONTINUOUS POSITIVE AIRWAY PRESSURE

Blood Gases

- Decrease or stabilization of oxygen requirement FiO_2 ≤0.60 with PaO_2 >50 mm Hg or pulse oximetry >90%
- Maintenance of adequate ventilation
  - $PaCO_2$ ≤50 to 60 mm Hg
  - pH 7.25 to 7.45

Clinical

- Decreased work of breathing—decreased respiratory rate, grunting, flaring, and retracting
- Improved lung volumes and appearance on chest x-ray films
- Improved patient comfort

occur through gently tapping over the affected lung. **In infants with BPD, rib fractures have been documented that resulted from vigorous percussion[417] and vibrator use.[576]** Vibration of the neonate's chest may follow percussion. Even though vibration must be done on expiration to move secretions with the exhalation of air, this is very difficult to accomplish with the neonate's rapid, shallow breathing cycle.

Any manipulation of the sick neonate has the potential for decreasing oxygenation and precipitating hypoxia (see Chapter 13). During CPT, bradycardia, cyanosis, hypotonia, fighting, struggling, and alterations in oxygenation are signs of stress. There is also an increase in plasma epinephrine and norepinephrine levels with CPT and endotracheal suctioning; this stress response is decreased in sedated preterm infants.[195] CPT is no better than standard care for clearing secretions in ventilated neonates and is accompanied by hypoxia and increased oxygen requirements. Postextubation CPT has also shown no differences in preventing atelectasis, decreasing the number of apnea/bradycardia episodes, the need for reintubation, or the duration of supplemental oxygen.[30]

The most severe complications reportedly resulting from CPT are an increased risk for IVH (see Chapter 26) and cerebral encephalopathy. An increased incidence of severe intraventricular/periventricular hemorrhage has been reported in preterm infants treated with early CPT.[423] In 1992, a previously unrecognized and distinct pattern of severe, late-onset brain injury was reported in 15 neonates (24 to 32 weeks' GA; 600 to 1270 g birth weight). The pattern of brain injury was of extensive, dense, and cystic lesions involving the periphery of the brain bilaterally. This full-thickness cortical necrosis, called *encephaloclastic porencephaly,* resulted in 14 deaths and severe neurologic deficit in the only survivor.[111] This nursery changed its protocol to include holding the baby's head steady during CPT; no further cases of brain injury have occurred.[422]

Another study of 454 babies found 13 babies (24 to 27 weeks' GA; 680 to 1100 g birth weight) with lesions similar to the encephaloclastic porencephaly just described. The lesions in these infants were described as cystic with cortical and subcortical destruction and peripheral rather than periventricular; they occurred between 2 and 3 weeks of life. These hemorrhagic infarcts are consistent with the pathologic changes in older infants from *shaken baby syndrome.*[277,572] The extremely immature brain of the VLBW infant may be particularly vulnerable to the shaking movements of CPT. Five of these infants died; seven of the eight surviving infants had disabilities (e.g., mild hemiplegia to severe spastic quadriplegia; cognitive delay) at 6 to 16 months of age. For longer than 3 years, no VLBW infant in this NICU has received CPT in the first month of life; no further cases of this brain injury have occurred.[277,572]

The techniques, efficacy, complications, outcomes, safety, and frequency of CPT have not been studied sufficiently.[230] Given the lack of data, the lack of clear evidence of benefit, and the concerns of safety for VLBW infants, recommendations include[422,572,577]:

- Use CPT cautiously.
- Do not use CPT on VLBW infants in the first month of life.
- Keep the infant's head steady during CPT.
- CPT should be used only for definite indications when the infant is fit and able to tolerate the procedure.
- CPT should never be done "routinely," but should be applied on an individual basis after careful and thorough assessment.

- Percussion should be used only when secretions are not cleared by suction alone.
- Use of CPT in the delivery room lacks evidence-based research.
- CPT should not be included in pulmonary hygiene until research clearly substantiates its benefits.

SUCTIONING

Once secretions are loosened and mobilized, they must be removed through the nose, mouth, or trachea with suctioning.

Naso-oropharyngeal Suctioning. When an infant has no artificial airway, **suctioning the naso-oropharynx serves two purposes: removing secretions and initiating a cough reflex that mobilizes secretions**. With either a suction bulb or catheter, the infant is suctioned when secretions are produced. Providing an oxygen source during the procedure is necessary. **Because stimulation of the nares causes reflex inspiration with possible inhalation of oropharyngeal contents, first the *mouth* and then the *nose* should be suctioned.** The results should be documented.

CAUTION: Suctioning should be avoided for 30 minutes to 1 hour after feeding unless it is necessary to establish a patent airway. The catheter should be gently inserted upward and back into the nares, never forced. If the catheter is hard to pass or the nares seem blocked, this procedure should be abandoned to prevent swelling or trauma. **Frequent nasal suction creates trauma and edema. The catheter may initiate vasovagal stimulation with alterations in heart rate[37] and/or resultant bradycardia.**

Endotracheal Suctioning. An artificial airway prevents normal warming, humidifying, and cleansing of the air by the upper airway. The presence of the foreign body (the tube) also increases pulmonary secretions. **To maintain a patent airway, sterile endotracheal suction should be performed on an individual basis, *never* on a routine basis (e.g., on a schedule of every 2, 3, or 4 hours).**[17] A *Cochrane* review states that there is insufficient evidence to identify the ideal frequency of ETT suctioning in mechanically ventilated neonates.[68] **Individual assessment criteria to establish that the infant "needs" suction are listed in** Box 23.6. Knowledge of the infant's respiratory diagnosis suggests the need and the frequency of suction. The acute phase (first 72 hours) of RDS is a restrictive disease; few secretions are produced, so minimal suctioning (every 12 to 24 hours) is necessary. **Studies have found no increase in occluded tubes when suction frequency was changed from every 6 to every 12 hours (during the first 72 hours of RDS)[574] and from every 4 to every 8 hours.**[106] Disease processes noted for secretion production (e.g., the chronic phase of RDS, CLD/BPD, meconium aspiration syndrome, or pneumonia) may require early and frequent suctioning.

ETT suctioning is not an innocuous procedure. **ETT suction is associated with numerous physiologic alterations and complications** (Box 23.7). Hypoxia and changes in heart rate and blood pressure alter cerebral blood flow, increase intracranial

BOX 23.6 CRITICAL FINDINGS
INDIVIDUAL ASSESSMENT CRITERIA FOR SUCTION

Evidence of Secretions
- Visible secretions in tube
- Audible coarse, wet, or decreased breath sounds
- Palpation of wet, coarse vibrations through chest wall

Alterations in Vital Signs
- Changes in respiratory pattern:
  - Increased work of breathing (retractions, grunting, flaring)
  - Tachypnea or apnea
- Change in cardiac pattern; tachycardia or bradycardia

Alterations in Neonatal State
- Increased agitation, irritability, restlessness
- Hypertonic or hypotonic
- Listless, lethargic

Alterations in Oxygenation and Ventilation
- Desaturations (<90%) or labile saturations on pulse oximeter
- Skin color changes—pale, dusky, cyanotic
- Changes in arterial blood gas values—increased pCO_2, decreased PaO_2, respiratory acidosis
- Increased peak inspiratory pressure on mechanical ventilation and increased high-pressure alarms
- Decreased chest wall vibration with high-frequency ventilation (HFV)

BOX 23.7 PHYSIOLOGIC ALTERATIONS AND COMPLICATIONS ASSOCIATED WITH ENDOTRACHEAL TUBE SUCTION

- Hypoxia/hypoxemia[162,416]
  - Caused by disconnection from the ventilator and oxygen and presence of suction catheter and application of negative pressure, which partially occludes the airway; handling during the procedure; desaturations on the PO
- Alterations in heart rate[37,162,428]
  - Bradycardia, dysrhythmias, and asystole are precipitated by hypoxemia
- Alterations in blood pressure
  - Hypertension/hypotension
- Alterations in cerebral blood flow[403,428]
  - Changes in oxygenation, heart rate, and blood pressure increase cerebral blood flow, both during and after the procedure (late [6 minutes]/prolonged [25 minutes] elevations of CBF),[252] and intracranial pressure, which increase the risk for intraventricular hemorrhage
- Increase in plasma epinephrine and norepinephrine levels[195]
- Tissue damage
  - Granuloma formation within airways; increased severity of CLD/BPD associated with colonization of lungs with gram-negative bacilli; lobar emphysema and atelectasis; bronchial stenosis
- Atelectasis
  - Marked increase in opening (inflation) pressures of the lungs; adequate lung recruitment and PEEP may prevent lung collapse and deterioration in arterial oxygenation; atelectasis
- Pneumothorax
  - From aggressively ventilating neonate above baseline pressures
- Infection
  - Airway colonization with gram-positive cocci and gram-negative bacilli by 2 weeks of life despite the method of suction
- Unplanned extubation

CBF, Cerebral blood flow; *CLD/BPD,* chronic lung disease/bronchopulmonary dysplasia; *PEEP,* positive end-expiratory pressure; *PO,* pulse oximetry.

pressure, and predispose the preterm to an increased risk for IVH (see Chapter 26). **Pulse oximetry is a valuable tool in assessing oxygenation status during and after suctioning. The infant may be preoxygenated before suctioning, or if oxygen saturation falls (below 90%) during suctioning, the infant may be hyperventilated.** *Preoxygenation* is the increase of FiO_2 above baseline concentration before ETT suction to prevent/reduce hypoxemia.[17] **To avoid exposing the preterm to hyperoxic events that may predispose to ROP, the FiO_2 is increased by 10% to 20% above baseline when clinically indicated for an individual infant. For ELBW/VLBW infants, FiO_2 increases may be from 2% to 5%.** Using 100% oxygen only if it is clinically indicated for the individual infant prevents hyperoxia. *Hyperventilation* (e.g., increasing respiratory rate) with a bag or the manual breaths on the ventilator after each catheter pass minimizes hypoxia and contributes to shortened time of stabilization and recovery. More research is needed on the optimal timing of increasing the FiO_2 and the amount of oxygen to use.[416]

Administration of intermittent doses of morphine during endotracheal suctioning has not been shown to reduce pain scores in ventilated preterms. In this same RCT, multisensory stimulation after suctioning also was not associated with reduced pain scores.[93] **Comfort measures (e.g., nonnutritive sucking, expressed breast milk, sucrose, swaddling, facilitated tucking) are recommended during suction to provide pain relief[87,136] and to reduce bradycardia and desaturations (see Chapter 12).**

Most of the physiologic alterations and complications of ETT suction are the result of decreases in PEEP, lung volume, and oxygen during disconnection of the ETT from the ventilator for use of the open suction procedure. Use of closed suction systems (e.g., an adapter to suction without disconnection from the ventilator) decreases associated hypoxemia and bradycardia by enabling oxygenation and ventilation to continue during suction.[106,512] However, closed suction interferes with ventilator function (i.e., substantial negative intratracheal pressure during suction; the potential for higher airway pressures and tidal volumes after suctioning).[274] Closed suction is associated with smaller decreases in cerebral oxygenation, smaller variations in cerebral blood volume, and related hemodynamic changes, particularly in ventilated preterms.[253,357] Use of a four-handed closed suction technique was recently found to have no advantages in baseline heart rate, oxygen saturation, or salivary cortisol levels.[103] However, in this randomized crossover design, four-handed suction was associated with fewer stress-related and more self-regulatory behaviors.[103] A small study comparing the effects of open versus closed suction for mechanically (conventional and high-frequency) ventilated ELBW preterms ($n = 19$) found decreases in cerebral blood flow and heart rate during suction

and return to baseline after suctioning ceased; both of these changes were independent of the kind of ventilation and the type of suction used.[428] Two studies comparing open and closed suction had conflicting results: (1) no differences in an RCT of 39 neonates 34 weeks' GA or older[395] and (2) a significant decrease in hypoxemia and drop in Spo_2 with a higher Spo_2, mean arterial Po_2, and mean oxygenation ratio after closed versus open suction.[408] A more recent study comparing open and closed ETT suctioning found no significant difference in respiratory or heart rates, arterial PaO_2 values, or pain of the ventilated neonates between the two suction procedures.[73]

Closed suction removes secretions as effectively as open suction with no increase in the rate of bacterial airway colonization (with catheter change every 24 hours), suction frequency, reintubation, duration of mechanical ventilation, length of hospitalization, incidence of nosocomial pneumonia or sepsis, severity of BPD/CLD, or mortality rate in 175 low-birth-weight (LBW) infants.[105] Enclosure of the catheter in a clear sheath decreases the possibility of cross-contamination and environmental pollution of objects and personnel with bacterial and viral pathogens. Closed suction systems are easier to use, less time consuming, better tolerated by the neonate, cost effective, and well accepted by neonatal nurses.[106] **Closed suction improves short-term outcomes but needs more research to be recommended as the only method of ETT suction by *Cochrane* reviews,[512] but it is suggested for neonates by the American Association of Respiratory Care.[17]** Another study comparing open and closed suctioning found less time and staffing were necessary when closed suctioning was used and that there were fewer physiologic disturbances (e.g., less reduction in SpO_2, fewer heart rate and mean airway pressure increases).[163] **Closed ETT suction has been identified as "best practice" in reducing nosocomial sepsis in the NICU.[96]**

The actual procedures used in closed and open suction often are not supported by research data. Table 23.4 **outlines common suction techniques, research data, and recommendations to alter clinical practice.**

Procedure for Closed Suction

Equipment to Be Prepared.

- Inline suction catheter (changed daily)
- Sterile normal saline (without preservative)
- Suction canister and tubing (60 to 80 mm Hg negative pressure)

Procedure.

- Unlock the inline suction catheter. Press suction control valve and check suction pressure.
- Place saline solution syringe on the proximal port of the adapter to irrigate the catheter before suction, place normal saline syringe or bullet at the distal port or adapter, and squeeze saline solution into the port while applying suction.
- Slide the catheter through the plastic cover down the ETT to the predetermined distance.
- Apply suction while withdrawing the catheter tip to the catheter window (the plastic cover will inflate from ventilation if the catheter is pulled back too far; the catheter will completely or partially occlude the ventilatory circuit if not pulled back far enough). Only one suction attempt should be made before the infant is again ventilated. Assess tolerance of the procedure by observing pulse oximeter and infant's color, heart rate, tone, and activity. Hyperventilate the lungs with appropriate FiO_2 for 6 to 8 breaths or until adequate oxygenation has been established.
- To irrigate the catheter after suction, place a normal saline syringe at the distal port adapter and squeeze saline solution into the port while simultaneously applying suction. Remove the saline solution and close the port when the catheter has been rinsed thoroughly.
- Rotate and lock the suction control cap to discontinue suction.
- Suction the nasopharynx and oropharynx as needed with a suction bulb or separate suction catheter and tubing. Do *not* disconnect the closed suction catheter from its suction line—this contaminates the setup for ETT suction.
- Check respirator settings, including alarm system in "on" position. Check tube position to be sure the tracheal tube is not strained or bent.
- Note amount and type of secretions obtained.

Procedure for Open Suction

Equipment to Be Prepared.

- Sterile suction catheter of appropriate size (discard after each suctioning)
- Sterile gloves
- Sterile normal saline solution (without preservative)
- Stethoscope

TABLE 23.4 SUCTION PROCEDURE: RESEARCH BASIS AND RECOMMENDATIONS

COMMON TECHNIQUES	RECOMMENDATIONS	RESEARCH DATA
Instillation of 0.25–0.5 mL sterile NS before suction *Purpose:* Mobilize and thin secretions; aid in catheter passage	Mucus is not miscible with saline solution so bolus saline does not thin or liquefy secretions[17]; vaporized or nebulized NS thins secretions.[17] Bolus saline accumulates at the end of the ETT; <20% of the saline solution is retrieved with suction and remainder is absorbed by the body. Use of NS associated with increased hypoxia, deterioration of lung mechanics, and infection.[17] Maintenance of adequate humidification (100%) and warming oxygen to core temperature keep secretions loose and lubricate the ETT and the surrounding tissues. Routine use of NS instillation before suction should not be performed.[17]	*Closed suction:* Irrigate catheter before suction; place NS syringe at distal port adapter and squeeze saline solution into port while simultaneously applying suction. *Open suction:* Dip or moisten catheter tip in sterile NS or water-soluble jelly to facilitate sliding down the small-diameter ETT.
Head turned from side to side with suction *Purpose:* To advance catheter down contralateral bronchus	Suction causes fluctuations in cerebral blood flow, which increases ICP and the risk for intraventricular hemorrhage.[403] Sharply turning head to the side occludes the jugular vein and increases ICP, which is at its lowest when the head is in the midline or slightly elevated.[403]	*Turned head position:* Contraindicated because of data on increased ICP, jugular vein occlusion, and anatomic impossibility of passing catheter into bronchi using this strategy. Do not turn the infant's head during suction; keep head in midline for suction.
Catheter inserted until resistance (touching the carina) is met, withdrawn slightly; then suction applied	Application of negative pressure with suction and touching the bronchial mucosa with catheter cause irritation, tissue damage, and significant oxygen desaturations.[193]	Shallow suction does not touch the carina with the catheter tip[17,181]: Using the ETT markings and the length of the adapter, insert the catheter no more than 1 cm beyond the total distance (e.g., if the ETT is inserted 10 cm and the length of the adapter is 1.5 cm, the suction catheter should be inserted 11.5 cm to no farther than 12.5 cm).
Catheter is inserted and removed several times	One small study ($n = 16$) evaluated nurses' subjective reports of amount of secretions obtained with one and two suction passes; no difference was noted.	Limit number of catheter passes to the number needed to adequately remove secretions. Do not use up-and-down motion while removing the catheter because this decreases oxygenation and promotes hypoxia and tissue damage. Only one suction attempt should be made before the neonate is again ventilated; every catheter passage is considered a suction event; occlude ETT with catheter for no longer than 5–10 sec.
Use as large a suction catheter as will easily go down the lumen of the ETT	Use suction catheter that occludes less than 70% of the lumen of the ETT.[17]	Impedance to gas flow occurs in an ETT when more than 70% of the lumen is occluded.[17]
No use of developmental care adjustments during the stressful procedure of suction	Body containment significantly decreases the magnitude of the preterm's response (e.g., pain, desaturations and bradycardia) to suctioning.[162]	Use the developmental care technique of containment (swaddling or facilitated tucking), NNS, or sucrose during suction (see Chapters 12 and 13).

ETT, Endotracheal tube; *ICP,* intracranial pressure; *NNS,* nonnutritive sucking; *NS,* normal saline.

- Suction machine and tubing (60 to 80 mm Hg negative pressure)

Procedure.

- The sterile catheter and glove package are opened. Sterile normal saline solution (0.25 to 0.5 mL) is drawn up in a 1 mL syringe. The resuscitation bag is connected to oxygen, and the patency is checked so that if the neonate becomes apneic or bradycardic during the procedure, resuscitation equipment is immediately available. If the infant is on a ventilator equipped with a bag, this may be used for resuscitation if necessary.
- Disconnect and dip the suction catheter in or wet the tip of the suction catheter with the sterile normal saline.
- Put gloves on and attach sterile catheter to suction tubing. With nondominant hand, disconnect ETT from ventilator.
- Gently pass catheter down the ETT to premeasured length.
- Occlude suction hole in catheter and withdraw. Use continuous suction so that secretions are not "released" with intermittent suction. Only one suction attempt should be made before the infant is again ventilated. Assess tolerance of procedure by observing pulse oximeter and infant's color, heart rate, tone, and activity.
- Reconnect ETT to ventilator and hyperventilate with appropriate FiO_2 for 6 to 8 breaths or until adequate oxygenation has been established. Check ventilator settings including alarm system in "on" position. Check tube position to ensure that the tube is not bent or strained. Note amount and type of secretions obtained.

NOTE: When two persons are available for suction, one remains "sterile" and does the suctioning while the other detaches the ETT from the ventilator and hyperventilates the infant between suctionings.

Because ETT suctioning compromises the neonate's physiologic homeostasis, adequate recovery time is necessary after the procedure.[162] For ETT suction, an average of 4.4 minutes of recovery time is necessary (6 of 25 infants in one study never returned to baseline during the observation). Use of containment such as swaddling or facilitated tucking, expressed breastmilk, or oral sucrose has been shown to decrease pain response and improve oxygenation after suctioning.[136] **These infants may need a significant rest period after suctioning before other aspects of care such as feeding are attempted.**

Endotracheal Intubation

Endotracheal intubation may be accomplished by the orotracheal route or the nasotracheal route. An ETT diameter that approximates the diameter of the infant's fifth digit generally fits snugly into the trachea. **To measure for an ETT, the distance from the oral orifice to midway between the glottis and carina may be calculated by multiplying the crown–heel length by 0.2. In an emergency, the distance from the lips to midway between the glottis and carina may be approximated by the *7-8-9-10 rule.* The distance is 7 cm in a 1 kg infant, 8 cm in a 2 kg infant, 9 cm in a 3 kg infant, and 10 cm in a 4 kg infant.**

Premedication for intubation is recommended for any nonemergent intubation.[287] **Intubation is a painful procedure associated with unfavorable physiologic side effects such as bradycardia, desaturation, and increased blood pressure, intracranial pressure, and pulmonary pressure. Increases in intracranial pressure in the ELBW infant are of particular concern because this population already is predisposed to IVH.** Medications listed in Table 12.13 with rapid onset and short duration of action are ideal. The agitation and pain of intubation are relieved with analgesia and sedation; vagolytics and muscle relaxants reduce the cardiovascular side-effects of intubation. Premedication also decreases the number of attempts, the amount of airway trauma and significantly contributes to more rapid intubation, regardless of the experience of the intubating professional.[341] **The neonate should be pretreated for pain with a more rapid, short-acting opiate such as fentanyl or remifentanil rather than morphine because it has no more effect on the severity of hypoxemia or bradycardia at intubation than placebo.**[313] Benzodiazepines should not be used alone for intubation because of an increase in desaturations during the procedure and a need for cardiopulmonary resuscitation after intubation.[341] Midazolam may be used for additional sedation or to potentiate the effect of the opiate so smaller doses of each medication can be administered.

Table 23.5 **is a protocol for premedication for elective endotracheal intubation.** One study of 166 infants (24 to 44 weeks' GA) being premedicated

TABLE 23.5 PREMEDICATIONS FOR ELECTIVE ENDOTRACHEAL INTUBATION

DRUG	DOSAGE	COMMENTS
Analgesia: Remifentanil	2 mcg/kg IV: Dose with medication pump over 3 minutes to prevent chest wall rigidity from rapid administration Onset: 1 minute Half-life: 5.4 minutes	Excellent conditions for intubation (ease of laryngoscopy, vocal cord position, jaw relaxation, lack of limb movement and cough) and short procedure time when compared to morphine[401,565]
Sedation: Midazolam	0.1 mg/kg IV: Dose with medication pump over 2 minutes to prevent chest wall rigidity from rapid administration Onset: 1–2 minutes Half-life: 6.3 hours	Use for preterm infants ≥34 weeks' corrected GA Do *not* use for preterm infants <34 weeks' corrected GA because of systemic and cerebral hypotension with resulting brain injury with bolus doses[19]
Vagolytic: Atropine	0.02 mg/kg IV: Rapid IV push Onset: 1 minute 0.02 mg/kg IM Onset: 15–30 minutes	Blocks vagal response and bradycardia to placement of laryngoscope blade/ETT; minimizes oral secretions; increases heart rate
Muscle Relaxants*:	1 mg/kg IV push	
Rocuronium	Onset: 1–3 minutes Duration: 40–60 minutes Treat chest wall rigidity with: 1 mg/kg IV push.	Intermediate duration non-depolarizing neuromuscular blocking agent. Stable in IV solution—does not require reconstitution like vecuronium. Higher first attempt success rate of intubation when compared to no muscle relaxing agent used.[165]
Succinylcholine	2 mg/kg IV[40] Onset: 20–40 seconds[343] Duration: 6–8 minutes[343] 4 mg/kg IM Onset: 4–16 minutes	More rapid intubation and elimination of intracranial hypertension.[40] Associated with 50% fewer attempts at intubation and improved first attempt success (58% verus 18%).[311] Adverse effects: Use with caution in neonates with baseline hyperkalemia as medication may increase serum potassium levels. Extra caution in neonates receiving medications that may cause hyperkalemia: B-adrenergic blockers and angiotensin-converting enzyme inhibitors. May trigger malignant hyperthermia.

*Only ordered by NICU attending or fellow. Neonate must be supportable by bag/mask ventilation before paralytic administration.
Adapted from McPherson C. Premedication for endotracheal intubation in the neonate. *Neonatal Network*. 2018;37(4):238.

for elective endotracheal intubation found that **only the combination of fentanyl and midazolam significantly decreased pain scores and the stress response of an increase in blood glucose.**[72] Even though this study found that the most immature preterms responded similarly to infants of older gestational ages, **the most immature infants were less likely to receive premedication.**[72]

INTUBATION PROCEDURE

ETT placement must be immediately verified by auscultation and confirmed by a chest x-ray examination; ultrasound imaging may also be used for secondary confirmation. Findings on auscultation and what they suggest are listed in Table 23.6. **End-tidal carbon dioxide ($ETCO_2$)**

TABLE 23.6 CHEST AUSCULTATION ABNORMALITIES AND UNDERLYING CAUSES

FINDING	POSSIBLE CAUSE
No air entry bilaterally	Air leak Plugged endotracheal tube
Diminished air entry	Air leak Endotracheal tube too high
Air entry over stomach	Unplanned extubation
Air entry unequal	Air leak Endotracheal tube too low
Cardiac point of maximum intensity shifted	Air leak with tension

detectors are available to immediately verify tube placement and have been tested in the delivery room and NICU.[27] In the presence of exhaled CO_2 (after six breaths), the $ETCO_2$ detector changes color from purple to yellow. The time necessary to detect proper ETT placement with these detectors is 4 to 12 seconds versus 0 to 90 seconds by clinical evaluation. This significantly faster time enables quicker extubation and reintubation if the ETT is in the esophagus.[27] **Use of $ETCO_2$ detection devices to confirm proper ETT placement is recommended by the AAP in the Neonatal Resuscitation Program (NRP) Guidelines.**[561] This device also is useful for ongoing assessment of ETT placement.[129] Other available devices are capnometry, with a numeric display, and capnography, with both a numeric and waveform display (see Chapter 7).[129]

For long-term stability, commercially available ETT anchors prevent accidental extubation. Some nurseries still prefer fixing tubes with tape or sutures.

EXTUBATION PROCEDURE

Assess the infant's condition by observing the heart rate, color, and respiratory rate and effort, and by auscultating the chest. If the infant's condition is stable, proceed with extubation. **Before extubating, do not feed the infant or empty stomach contents to prevent vomiting. Neonates are obligatory nasal breathers; the nasopharynx also must be suctioned and patent for extubation.**

Hyperinflate with deep breaths with the infant's head in the midline and remove the tube (1) on inflation (to provide adequate lung expansion and prevent atelectasis), (2) on expiration[194] (so that secretions that have accumulated around the tracheal tube are "blown away" on exhalation and tube removal), or (3) while suctioning (to remove secretions that have accumulated around the tube). Place the neonate in a warm, humidified oxygen hood at FiO_2 to keep pulse oximeter at 92% to 94%.

Reassess the infant's condition, especially for signs of increased work of breathing and distress. Document the tube removal and infant's tolerance to extubation. Check arterial blood gases 15 to 20 minutes after extubation to assess oxygenation and ventilation status. Perform a chest x-ray examination to document atelectasis or fully expanded lungs. Observe for complications of intubation (Table 23.10).

BOX 23.8 CRITICAL FINDING

CRITERIA THAT QUALIFY NEWBORNS FOR ASSISTED VENTILATION

Blood Gases

- Severe hypoxemia (PaO_2 <50 to 60 mm Hg with FiO_2 ≥0.60 or PaO_2 <60 mm Hg with FiO_2 >0.40 in infant weighing <1250 g)
- Severe hypercapnia ($PaCO_2$ >55 to 65 mm Hg with pH <7.20 to 7.25)

Clinical

- Apnea and bradycardia requiring resuscitation in infants with lung disease or unresponsive to CPAP or requiring theophylline therapy in preterm infants with normal lungs
- Inefficient respiratory effort, such as gasping respirations from asphyxia, narcosis, or primary cardiopulmonary disease
- Shock and asphyxia with hypoperfusion and hypotension
- RDS in infants weighing <1000 g, frequently making them incapable of maintaining ventilation

CPAP, Continuous positive airway pressure; *RDS*, respiratory distress syndrome.

MECHANICAL VENTILATION

Mechanical ventilation is used in neonates to correct abnormalities in oxygenation (decreased PaO_2), alveolar ventilation (increased $PaCO_2$), or respiratory effort (apnea, ineffectual respirations, or increased work of breathing) (Box 23.8). It may not be used to treat the primary disease but is frequently used to support the infant until the disease is treated or resolved.

Ventilator Settings. To individualize assisted ventilation, knowledge of the ventilator capabilities is essential.

Intermittent Mandatory Ventilation. Most mechanical ventilators in common use today allow for intermittent mandatory ventilation (IMV). **IMV provides a continuous flow of gas that is available to the infant during spontaneous respirations. Periodic occlusion of the system diverts gas under pressure to the infant.** Because IMV provides for spontaneous and mechanical ventilation, only the amount of ventilatory assistance that is needed by the individual infant is provided.

Using the noninvasive, nasal route to provide intermittent mandatory ventilation (NIPPV) as a primary ventilation strategy (rather than just for postextubation care) is common. An RCT of

40 infants with transient tachypnea of the newborn (TTN) found that nasal intermittent mandatory ventilation was well tolerated and as effective (i.e., similar duration of support, oxygen therapy, duration of TTN, and length of stay) as NCPAP.[132] A *Cochrane* review of 10 RCTs found that early NIPPV is superior to NCPAP alone for decreasing respiratory failure, the need for intubation, and invasive mechanical ventilation in 1061 preterm infants with RDS.[314]

Continuous Distending Pressure. **CDP is expressed in centimeters of water. CDP may be given without IMV (CPAP) or with it (PEEP).** The effects of CDP include increased alveolar stability, increased functional residual capacity, decreased risk for atelectasis, increased intrathoracic pressure, and impeded passage of fluid from lung capillaries to alveolar spaces, aiding in the prevention or treatment of pulmonary edema. Effects of changes in PEEP depend on severity of lung disease and degree of lung inflation. **High PEEP in the presence of relatively compliant lungs will cause overdistention, worsen PaO_2, and increase pulmonary vascular resistance (PVR). In addition, overdistention may increase the risk for barotrauma. However, the use of levels of PEEP that are too low contributes to hypoxia and pulmonary hypertension because of low lung volumes. Acute lung injury is actually worsened by the failure to recruit adequate lung volume by using insufficient PEEP.**

Peak Inspiratory Pressure. **Peak inspiratory pressure (PIP) is the maximum pressure measured during the delivery of gas (inspiration) during conventional mechanical ventilation. PIP reflects the effects of the amount of gas delivered to the lungs in a given breath (tidal volume: 4 to 6 mL/kg in preterms; 8 to 10 mL/kg in term infants) and the underlying mechanical properties of the lungs.** For example, if the same PIP is used in neonates with severe RDS (with stiff, noncompliant lungs) as in neonates ventilated for apnea with minimal lung disease, the tidal volume will be much greater in the latter group. Recent **studies suggest that overdistention of the lungs caused by excessive tidal volumes, and not pressure itself, worsens acute lung injury (so-called *volutrauma*).** Thus adverse effects of high PIP depend on the degree of lung disease.

When questioning whether **PIP or PEEP is more likely to cause air leaks, the answer is PIP. Both PIP and PEEP cause air leaks if they are excessive and are influenced by the lung compliance of the infant.** Evidence strongly suggests that lung injury results from excessive tidal volume (excessive PIP).[266] It would be difficult to overexpand the lungs with PEEP to the point of air leak. Too little PEEP is far more often the cause of air leaks.[266]

Rate. **The rate reflects how often a volume of gas in the system is delivered to the infant. It is expressed as breaths per minute.** Too rapid a rate, especially with a poorly inflated lung, can cause lung injury caused by gas trapping ("inadvertent PEEP").

Inspiratory-Expiratory Ratio. **The inspiration-expiration ratio (I/E ratio) reflects the relationship between time spent in inspiration and time spent in expiration.** When the rate is 60 breaths/min and the total respiratory cycle is 1 second, an I/E ratio of 1:1 means 0.5 second is inspiration and 0.5 second is expiration. If the I/E ratio is 1:2 with a rate of 60 and the total respiratory cycle is 1 second, inspiration is 0.33 second and expiration is 0.66 second.

Prolonged inspiration may be associated with more efficient ventilation, optimal arterial oxygenation, a higher risk for air leak, and impeding venous return. Prolonged expiration also improves oxygenation, especially in air-trapping conditions (e.g., rapid-rate ventilation or airway disease).[62]

Mean Airway Pressure. **Mean airway pressure (MAP) is the amount of pressure transmitted to the airway throughout an entire respiratory cycle.[62] *Any* change in ventilator settings affects the MAP.** MAP is most affected by changes in PEEP, inspiratory time, or I/E ratio.[62] **MAP is associated with optimal oxygenation (increased PaO_2) and ventilation (decreased $PaCO_2$) when pressures range between 6 and 14 cm H_2O.[62] When MAP exceeds 14 cm H_2O, there is a progressive deterioration of the blood gases (decreased PaO_2, increased $PaCO_2$).[62]** The effects of any given level of MAP depend on the changes in mechanical properties of the lung caused by the primary disease. For example, high MAP may be needed to improve oxygenation in severe RDS or meconium aspiration syndrome, especially in term neonates. Low MAP in this setting causes sustained hypoxemia and atelectasis. In contrast, use of high MAP in neonates in the presence of minimal lung disease causes overdistention and deterioration of arterial blood gas tensions. In general, the goal of increasing MAP is to improve PaO_2 and usually is achieved by small increases in

PEEP or prolongation of inspiratory time. Repeat chest x-ray examination and continuous monitoring of blood pressure and oxygenation (by pulse oximeter) help determine the optimal level of MAP.

Usual starting pressures for beginning ventilatory support are listed in Table 23.7. The inspired oxygen tension is adjusted to provide an adequate arterial oxygen tension. If the infant still has difficulty maintaining an adequate carbon dioxide tension, a faster rate or greater inspiratory pressure would be indicated. Table 23.8 **lists the usual effects to be expected from changing specific ventilator settings.**

TABLE 23.7 STARTING PRESSURES FOR BEGINNING VENTILATORY SUPPORT

PARAMETER	RANGE
FiO_2	At previous level or 10% higher than previously required concentration
PEEP	4–6 cm H_2O
PIP	16–20 cm H_2O
Rate	40–60
I/E ratio	1:1–1:2

I/E, Inspiration to expiration; *PEEP,* positive end-expiratory pressure; *PIP,* peak inspiratory pressure.

To evaluate the efficacy of mechanical ventilation and any adjustments made with the system, continuous monitoring with pulse oximeters (see Chapters 7 and 8**) must be maintained and/or blood gases obtained.** During the acute phase of illness, blood gases should be obtained 15 to 30 min after beginning ventilatory support or after any change in settings, every 4 to 6 hours if no change is made in ventilator settings, and as needed based on the clinical condition of the infant.

Arterial blood gases should be maintained in the following range (see Chapter 8**):**

- **PaO_2: 60 to 80 mm Hg**
- **$PaCO_2$: 35 to 45 mm Hg**
- **pH: 7.35 to 7.45**

Optimal arterial blood gas tensions are somewhat controversial. **To decrease the risk for acute lung injury by minimizing lung overdistention and barotrauma, some investigators advocate strategies that target lower PaO_2 and higher $PaCO_2$ ("permissive hypercapnia").**[75,442] The risks and benefits of such strategies depend on the specific clinical setting. If excessive ventilator settings are necessary to lower $PaCO_2$, allowing $PaCO_2$ to rise (to 50 to 60 mm Hg) (as long as the pH is greater than 7.25) is often accepted in an attempt to avoid lung injury. In addition, because the goal of respiratory care is to optimize

TABLE 23.8 USUAL EFFECTS OF CHANGING CONVENTIONAL MECHANICAL VENTILATOR SETTINGS

	CAUSES			
INCREASING	PAO_2	$PACO_2$	PH	COMPLICATIONS
FiO_2	↑	0	0	Oxygen toxicity (CLD/BPD, ROP); absorption atelectasis; FiO_2 may have no effect on oxygenation in the presence of severe R→L (right to left) shunt (PPHN), congenital heart disease, or marked intrapulmonary shunting as a result of severe parenchymal lung disease
CPAP/PEEP	↑	0/↑	0/↓	Hypoventilation with respiratory acidosis; decreased cardiac output with metabolic acidosis; air leaks
PIP	↑	↓	↑	Barotrauma with air leaks and CLD/BPD; respiratory alkalosis
Rate	↓	↓	↑	Respiratory alkalosis
I/E ratio (1:1–1:2)	↑	0	0	Increased intrapleural pressure; decreased venous return

CLD/BPD, Chronic lung disease/bronchopulmonary dysplasia; *CPAP,* continuous positive airway pressure; *I/E ratio,* inspiration to expiration ratio; *PEEP,* positive end-expiratory pressure; *PIP,* peak inspiratory pressure; *PPHN,* persistent pulmonary hypertension of the newborn; *ROP,* retinopathy of prematurity.

oxygen delivery to tissues, the effect of a given PaO_2 depends partly on cardiac function (see Chapter 24) and hemoglobin level (see Chapter 20). Accepting lower PaO_2 and O_2 saturation may lead to worse outcomes in the setting of systemic hypotension and poor cardiac function (e.g., sepsis). However, a recent follow-up study of the outcomes of ELBW preterm infants (24⅞ to 27⅞ weeks' gestation) from the SUPPORT trial found an association between higher $PaCO_2$ levels in the first 2 postnatal weeks and severe intraventricular hemorrhage and death, BPD and death, and neurodevelopmental impairment and death.[13]

Recognizing that aggressive ventilator management (e.g., intubation, high PIP, high MAP) is associated with increased lung injury and CLD/BPD, gentler ventilator techniques and management have been developed and are being used. Many gentler strategies incorporate relinquishment of traditional ventilator controls (from the health care provider) to patient control of ventilator parameters. Facilitated by computer-assisted technology, newer types of ventilators are being used. Volume-targeted versus pressure-limited ventilation results in significant reductions in death or BPD/CLD, duration of ventilation, pneumothorax, hypocarbia, and severe cranial ultrasound pathologies.[275]

Patient-Triggered Ventilation. Asynchrony between the infant's respiratory efforts and the ventilator is uncomfortable for the neonate and causes increased barotrauma, which contributes to lung injury (e.g., CLD/BPD). Altered cerebral blood flow may contribute to IVH. **Patient-ventilator synchrony occurs when patient-triggered ventilation (PTV) responds to the neonate's signal representing spontaneous respiratory effort and delivers a mechanical breath timed to the onset of inspiration.** PTV has been demonstrated to do the following[139,404]:

- Decrease asynchrony
- Improve gaseous exchange (e.g., oxygenation and carbon dioxide elimination)
- Create respiratory support that is more synergistic with the neonate's respiratory efforts
- Increase comfort for the infant, thus reducing the need for use of sedatives, narcotics, and paralyzing medications
- Decrease the need for ventilatory support

A recent systematic review of 22 studies comparing PTV with conventional mechanical ventilation (CMV) found fewer air leaks and a shorter duration of mechanical ventilation.[191]

Modes of PTV include the following:

- Synchronized intermittent mandatory ventilation (SIMV)
- Assist-control ventilation (ACV)—oxygenation, volume-guarantee ventilation (VGV), neurally adjusted ventilator assist (NAVA), and minute ventilation (V_{min})
- Pressure-support ventilation (PSV)
- Pressure-regulated volume control (PRVC)
- Proportional assist ventilation (PAV)

Synchronized Intermittent Mandatory Ventilation. **SIMV, a commonly used form of PTV, delivers mechanical breaths at a fixed rate. SIMV enables synchronization of ventilation breaths by sensing (through an airway or diaphragmatic sensor) the neonate's initiation of respiration and then triggering a mechanical breath.** Synchronized ventilation prevents the generation of excessive pressure within the respiratory tract when infant exhalation coincides with mechanical ventilation. Use of SIMV is associated with a decrease in (1) oxygen need, (2) duration of ventilator therapy, (3) incidence of BPD, and (4) severity of IVH and is more comfortable for the infant.[404] Use of SIMV is also associated with fewer episodes of hypoxia and better oxygenation as a result of improved ventilation-perfusion and increased resting lung volume (FRC) compared with IMV of VLBW infants.[168] Noninvasive ventilation strategies using synchronized nasal intermittent positive-pressure ventilation (SNIPPV) as a primary mode of support for preterm infants with RDS shows similar results compared with bilevel NCPAP.[446]

Assist-Control Ventilation. Newer neonatal ventilators are equipped with computer technology with rapid digital feedback circuits. **Computer-assisted control enables adjustments of FiO_2, PIP to control tidal volume, and ventilatory rate to control minute ventilation.** ACV is used in preterms with RDS, infants with a strong respiratory drive, and infants who are not heavily sedated. ACV is also more comfortable for the infant but may result in difficulty weaning from the ventilator because of diaphragmatic muscle atrophy.[404] Small studies have reported that

computer-assisted maintenance of target oxygen saturation is as effective as manual FiO_2 adjustments. Larger RCTs on safety and efficacy are warranted.

In volume-guarantee ventilation, a preset target tidal volume is maintained by the ventilator because the pressure limit varies inversely with lung compliance and the neonate's respiratory effort. Volume-targeted ventilation holds a significant advantage over pressure-targeted ventilation by delivering a physiologic tidal volume (about 4 to 5 mL/kg), potentially limiting excessive pressure and potential barotrauma. Historically, measuring physiologic tidal volume in the smallest infants, the location of flow sensor, and compensating for ET air leak had limited the utility of volume-targeted ventilation in the premature population.

Combining volume-guarantee with assist-control ventilation in the acute phase of RDS and SIMV in the weaning process results in less variable tidal volumes, shorter duration of ventilation, and a significant improvement in the combined outcomes of mortality and BPD/CLD rates in VLBW infants.[145] Another RCT of volume-guarantee SIMV ventilation and surfactant therapy found a shorter duration of ventilation and significantly fewer morbidities (i.e., ROP, BPD/CLD and IVH) in preterms with RDS.[204] Use of lower backup ventilation rates (i.e., 30 breaths/min rather than 50 breaths/min) enables greater triggering of ventilator inflations.[567] Certainly larger RCTs are necessary.

Neurally adjusted ventilator assist (NAVA) is a mode of ventilation that uses electromyographic (EMG) signaling from the diaphragm to match ventilator support to the infant's respiratory drive. EMG signaling from the diaphragm is acquired by electrodes embedded in a nasogastric tube and incorporated into a mechanical ventilator that converts the EMG signaling into a proportional assisted breath that is synchronized to infant-initiated breath. Diaphragm EMG activity is measured in magnitude (Edi signal). Ventilator support is adjusted by monitor Edi signal to optimize respiratory support. Early studies in neonates suggest improved patient ventilator interaction and synchrony with lower peak pressures.[48,67] Three studies compared NAVA to pressure-control ventilation[441,491] and to SIMV[308,441] in preterm infants and found that a lower PIP was required for adequate ventilation. Compared with pressure-control ventilation, NAVA also required the use of lower FiO_2, lower respiratory rate to achieve a lower pCO_2, and better compliance in five ventilated preterms less than 1500 g.[491] In the most recent study, 24 neonates receiving NAVA had higher respiratory rates, although their estimated work of breathing was improved.[441] Use of NAVA did not increase respiratory severity scores or resting energy expenditure.[441]

NAVA is available noninvasively by using nasal prongs, mask, or nasopharyngeal tube. An RCT of 15 premature infants under 32 weeks' gestation receiving noninvasive NAVA ventilation found improved patient-ventilator synchrony, even in the presence of large air leaks.[307] Premature infants may require a higher NAVA level[328] when transitioning from intubated to noninvasive NAVA. A *Cochrane* review of NAVA found no difference in rates of BPD/CLD, pneumothoraces, or IVH, and the duration of ventilation in one RCT. Well-designed trials to evaluate NAVA, a new type of triggered device, are needed.[440]

Minute ventilation (i.e., the volume of gas moving in and out of the lungs over time, expressed in mL per kg per minute) is a successful predictor of readiness to wean, extubate, and establish optimal pulmonary mechanics.[180] Mandatory minute ventilation (MMV), a new ventilator mode in the NICU, provides mechanically generated breaths only if the neonate's spontaneous breathing does not meet a minimum level of minute ventilation (chosen by the health care provider). If the infant's spontaneous pressure-supported breaths exceed the minimum minute ventilation, no additional breaths are delivered by the ventilator. If the infant fails to meet the specified minute ventilation, intermittent mandatory breaths are delivered at the preset tidal volume. **MMV enables the infant to control the rate, flow, and inspiratory time of the ventilator, which enhances synchrony and ensures a "backup" system to assume the work of breathing if the infant cannot maintain adequate minute ventilation.**[203]

Pressure-Support Ventilation. PSV complements the infant's respiratory effort by triggering a mechanical breath preset to a specific pressure. PSV decreases the work of breathing created by airway resistance (e.g., narrowed diameter of neonatal ETT) and ventilator circuit resistance.

PSV also decreases the work of breathing by assisting the activity of the infant's respiratory muscles. PSV is used alone (if the infant has effective respiratory drive) or in conjunction with SIMV. A recent systematic review found that SIMV + PS resulted in a longer duration of MV and more BPD/CLD when compared to high frequency oscillation.[191] PSV is useful in chronic and acute situations and in weaning chronically ventilator-dependent infants. When PSV was compared with SIMV, preterms exhibited better respiratory function (e.g., lower respiratory rates and less work of breathing), so PSV is effective for fatigued or weaning infants.[394] Another study comparing two levels of PSV with SIMV found that PSV increased total minute ventilation, stabilized breathing for preterms less than 32 weeks' gestation, and may be a useful strategy to wean preterms from mechanical ventilation.[202]

Pressure-Regulated Volume Control. PRVC delivers four breaths and modifies the ventilator's pressure to attain the prescribed tidal volume; breaths are both volume and pressure regulated. Studies show conflicting results: (1) safe and a lower incidence of air leaks and IVH[407] and (2) no benefit compared with SIMV in the treatment of RDS in preterm infants.[115]

Proportional-Assist Ventilation. In PAV, ventilator pressure increases in proportion to inspiratory volume (e.g., inspiratory flow varies to match the neonate's respiratory effort). Both volume and flow proportional assist relieve the neonate of both elastic (e.g., respiratory muscles) and resistive work of breathing. During PAV, the infant's breathing completely controls all variables of the ventilator breathing pattern through exceptionally fast computer-controlled feedback circuitry. In the initial trial using PAV in infants, lower MAP and transpulmonary pressure were used to effectively oxygenate and ventilate infants with mild to moderate respiratory insufficiency.[460] Respiratory rates were 50 to 80/min with a fast and shallow pattern and tidal volumes less than 5 mL/kg. A more recent RCT comparing PAV and PTV in ELBW preterms found that PAV safely maintained gaseous exchange at lower MAP compared with PTV. Although there were no adverse effects, the researchers concluded that backup conventional ventilation breaths must be provided during PAV to prevent apnea-related oxygen desaturations.[461] Two studies of PAV and SIMV for ventilation of neonates with RDS and MAS found that both were equally as effective with the infants on PAV having a shallower, more rapid breathing pattern with similar tidal volume and lower PIP and MAP.[579,580]

High-Frequency Ventilation. Barotrauma/volutrauma is a major contributing factor to the development of chronic lung disease or death from progressive lung injury in newborns treated with conventional mechanical ventilation. **The goal of HFV is to reduce barotrauma by the application of HFV early in the course of RDS or to reduce the progression of injury in infants who already have pulmonary interstitial emphysema, recurrent pneumothorax, or bronchopleural fistula. In addition to minimizing lung injury, the goal of HFV is to effectively enhance oxygenation over conventional ventilation.**

HFV differs from conventional modes of ventilator support, using smaller tidal volumes (less than anatomic dead space) at supraphysiologic frequencies and allowing for generation of lower intrathoracic pressure. At high frequencies, the calculated tidal volume is less than dead space. Thus the physics of gas flow and exchange are different from the traditional teaching of lung mechanics and are related to augmented diffusion. Reduction in barotrauma occurs by allowing for ventilation with very small pressure amplitude around the mean airway pressure in the distal airway. Therefore at high frequencies (commonly 10 to 15 Hz), the peak inspiratory and expiratory pressures approach MAP (i.e., lower downstream pressures). Because of this effect, higher MAP can be used to improve oxygenation without worsening lung injury.

HFV can be achieved by jet ventilators, oscillators, or high-frequency flow interrupters. Jet ventilators and HFV deliver short bursts of high-flow gases directly into the proximal airway via a small cannula and have a passive exhalation cycle. This ventilatory mode is usually augmented with a backup rate by a conventional ventilator that gives sigh breaths. The frequency range of high-frequency jet ventilation (HFJV) is 240 to 660 breaths/min (4 to 11 Hz).[139]

Oscillators vibrate columns of air and have active exhalation cycles. The usual frequency is 600 to 900 breaths/min (10 to 15 Hz). Oscillators (high-frequency oscillatory ventilation [HFOV]) are used both as a rescue therapy when

CMV is unsuccessful and electively as a primary mode of ventilation. The HFOV ventilator most commonly used is the SensorMedics 3100A, which uses a piston with a diaphragm to actively move gas into and out of the lung. Systematic reviews of early elective use of HFOV, compared with CMV, in preterm, late-preterm, and term infants found the following[104]:

- No effect on mortality rate at 28 to 30 days of life or at term equivalent age
- Significant reduction in risk of BPD/CLD at term equivalent age but effect was inconsistent across studies
- More air leaks and pulmonary interstitial emphysema
- Short-term neurologic morbidity (found in some studies; not statistically significant)
- No significant difference in rates of severe IVH (grades 3 or 4) and PVL
- Overall reduction of ROP
- No significant difference in long-term neurodevelopmental outcomes; one recent trial found significant reduction in the risk of cerebral palsy (CP) and poor mental development

Reviewers concluded that there was a small reduction in the incidence of CLD with the use of elective HFOV, but this result is weakened by its inconsistency across trials and is offset by an increased incidence of air leaks.[104]

An RCT comparing HFOV and SIMV in preterms with RDS found better early oxygenation, reduction in oxygenation index, and shorter length of stay in the HFOV-treated group; survival and complication rates were similar.[478] One small (n = 19 preterms 30 weeks' gestation or less) retrospective cohort study of HFOV with low oscillatory frequency found benefits (i.e., improved oxygenation, reduced MAP, survival) in preterms with PIE.[489]

When HFOV was compared with PSV plus volume guarantee (VG), early use of HFOV treatment was associated with a reduction in lung inflammation in preterms less than 30 weeks' gestation[117]; another study found VG to result in lower inflammation markers than HFOV.[320] A more recent RCT of HFOV versus SIMV-PSV in 366 preterm infants with severe RDS found (1) significantly higher mortality and BPD/CLD rates in the SIMV-PSV group; (2) fewer days of mechanical ventilation and hospitalization, as well as less ROP and need for surfactant with HFOV; and (3) less moderate to severe neurologic disability at 18 months in the HFOV group.[502] Discordance in study findings may be attributed to (1) maturity/immaturity of preterm infants, (2) time to initiation of HFOV, (3) use of antenatal steroids, (4) use of surfactant replacement, (5) differences in techniques used (e.g., presence or absence of lung volume recruitment strategy), (6) level of MAP, (7) duration of use, and (8) variations in cerebral blood flow (CBF) secondary to changes in pCO_2.[352] **Some researchers recommend that CMV be the first choice in treatment of preterm infants with RDS and HFOV be reserved for rescue therapy** if CMV is unsuccessful.[352] Further research is needed to clarify which ventilator should be used initially.

BOX 23.9 MINUTE VENTILATION (V_{min})

$$CV{:}V_{min} = TV \times RR$$

$$HFOV^{*}{:}V_{min} = fx\left(\text{Amplitude}, \text{Hz}^{-1}\right)$$

*There is a paradoxic effect with HFOV in which an increase in the frequency (Hz) actually decreases ventilation and therefore increases pCO_2. Conversely, decreasing Hz increases ventilation and decreases pCO_2.

CV, Conventional ventilation; *HFOV,* high-frequency oscillating ventilation; *Hz,* hertz; *RR,* respiratory rate; *TV,* tidal volume (PIP-PEEP).

Data from Donn SM, Sinha S. Invasive and noninvasive neonatal mechanical ventilation. *Respir Care.* 2003;48(4):426.

Remember that the rate of carbon dioxide removal is determined by minute ventilation. **Minute ventilation is the product of tidal volume and respiratory rate (TV × RR).** In CMV, the tidal volume and rate can both be adjusted by increasing or decreasing the breaths per minute (rate) and by increasing or decreasing the PIP or PEEP for tidal volume (TV = PIP − PEEP). In HFV, the same minute ventilation equation holds true, but the rate is set by breaths/min (hertz) and the tidal volume is determined by the amplitude (Box 23.9).

In HFOV, tidal volume is adjusted primarily by changing the amplitude setting. Amplitude is the amount of pressure oscillation that occurs around the MAP. **Increasing the amplitude will increase the tidal volume and therefore decrease pCO_2.** Conversely, decreasing the amplitude will

decrease the tidal volume and therefore increase the pCO_2. Amplitude is initially set when chest rise is adequate and then slowly adjusted up or down in increments of one or two.

The respiratory rate in HFV is determined by the hertz setting. One hertz equals 60 breaths per minute. Therefore 10 hertz equals 600 breaths/min. The rate is initially set between 10 and 15 Hz. **There is a paradoxic effect of high-frequency breaths in the bronchi of the lungs so that when the hertz setting is increased, the pCO_2 increases. The opposite is also true.** Whereas HFOV has an active expiration phase, HFJV has a passive expiration phase and therefore uses a low CMV backup rate to deliver intermittent sigh breaths to prevent air trapping and augment pCO_2 removal.

Oxygenation in CMV and HFV is determined by the FiO_2 and the MAP. With use of HFOV in the rescue mode, the MAP is initially set 1 to 2 cm H_2O above the previous CMV setting. Adjustments for oxygenation (MAP, FiO_2) and ventilation (amplitude, Hz) can be made independently and can therefore be done simultaneously (Table 23.9). Chest x-ray studies are helpful in determining optimal lung volume. **As lung compliance improves—and it can improve quite rapidly after surfactant administration—there is a risk for overinflating the lungs with too much MAP.**[546] This increase in MAP leads to an increase in intrathoracic pressure that may result in air leaks or IVH or may impede venous return, which can in turn lead to hypotension. MAP is generally slowly increased or decreased in increments of 1 or 2. Chest x-ray studies, blood gases, and blood pressure should be monitored closely during HFV.

Synchronized mechanical ventilation, delivered as high-frequency positive-pressure ventilation (HFPPV), is another mode of oxygenation and ventilation in which positive airway pressure and spontaneous inspiration occur simultaneously. Adequate gas exchange should be achievable at lower peak airway pressures. HFPPV results in a reduction of air leaks and ventilator duration.

Nasal high-frequency oscillator ventilation (NHFOV) is a relatively new method of combining the benefits of high-frequency and noninvasive technologies.[359] A survey of European NICUs found that NHFOV, with binasal prongs, is used for preterm infants under 1500 g who fail NCPAP or NIPPV.[170] The most common adverse effects of NHFOV were abdominal distension, highly viscous secretions, and upper airway obstruction due to the secretions. A retrospective case series of 79 cases of NHFOV found: (1) 73% used as a rescue after failing another noninvasive therapy and for postextubation prophylaxis, (2) 58% transitioned to another noninvasive mode without needing intubation, and (3) there was a significant reduction in apnea, bradycardia and desaturations without any complications.[360] In a pilot study, NHFOV was compared to biphasic NCPAP in preterm infants

under 1250 g who failed CPAP and was found not to be superior to the biphasic NCPAP.[361] Large, multicenter trials of NHFOV are needed.

Inhaled Nitric Oxide. Vascular endothelial cells endogenously produce a potent vasodilator substance ("endothelium-derived relaxing factor"), later identified as nitric oxide. **Nitric oxide (NO), delivered as a gas, causes potent, selective, and sustained pulmonary vasodilation in the perinatal pulmonary circulation.**[271] The vasodilator response occurs as a result of inhaled nitric oxide (iNO) stimulation of soluble guanylate cyclase activity, increasing cyclic guanosine monophosphate (cGMP) in vascular smooth muscle and causing vasorelaxation. Selectivity of iNO for the pulmonary circulation is based on direct delivery of NO into the lung; because NO is avidly bound by hemoglobin in red blood cells and inactivated after metabolism to nitrite and nitrate, there are no direct effects on systemic arterial pressure.[271] In laboratory studies, iNO also reduces oxidative stress and pulmonary inflammation and enhances pulmonary alveolization and growth.[273] Potential toxicities include decreased platelet aggregation, hemorrhage, and methemoglobinemia.

Inhaled NO has been approved by the U.S. Food and Drug Administration (FDA) for treatment of late-preterm (>34 weeks' GA) and term neonates with persistent pulmonary hypertension of the newborn (PPHN)[271] **(see Persistent Pulmonary Hypertension of the Newborn later in this chapter). Use of iNO in term and late-preterm neonates with PPHN and respiratory failure decreases the need for extracorporeal membrane oxygenation.**[292] **Use of iNO in preterm infants (<34 weeks' GA) remains controversial with a National Institutes of Health (NIH) consensus statement recommending against the routine use of iNO in preterms (<34 weeks' GA).**[99]

Extracorporeal Membrane Oxygenation/Extracorporeal Life Support. Extracorporeal membrane oxygenation/extracorporeal life support (ECMO/ECLS) is a modification of cardiopulmonary bypass that allows more prolonged therapy than is traditionally performed in the operating room for cardiac surgery.[164] **ECMO/ECLS establishes a pulmonary bypass circuit, allowing gas exchange to occur outside the lung by perfusion of blood through a membrane oxygenator.** Blood is drawn from a catheter in the right internal jugular vein or right atrium, oxygenated as it crosses the membrane, and then returned to the patient via the right common carotid artery (venoarterial ECMO/ECLS) or the femoral vein (venovenous ECMO/ECLS). The pump produces a continuous, nonpulsatile flow through the membrane oxygenator as the patient is kept heparinized and continues to be ventilated at low pressures, rates, and oxygen tensions. **The goal of this therapy is to "buy time" for the severely injured lung to heal while attenuating ongoing lung injury by decreasing exposure to hyperoxia and barotrauma.** Therapy can be continued for several days until lung recovery appears sufficient to maintain adequate gas tension without ECMO/ECLS.

ECMO/ECLS therapy improves survival in term neonates with severe hypoxemic respiratory failure and PPHN. **ECMO/ECLS is used as a treatment of last option when neonates are unresponsive to maximum conventional support.** ECMO/ECLS criteria include the following[164]:

- GA 34 weeks or older, weight 2000 g or more
- Mechanical ventilation less than 10 to 12 days
- No significant coagulopathy or uncontrollable bleeding
- No major intracranial hemorrhage
- Reversible lung disease
- No lethal malformations
- No major uncorrectable cardiac lesions
- No severe asphyxia
- Failure of optimal medical management
- PaO_2 less than 50 mm Hg for 4 hours; Oxygenation Index (MAP × FiO_2 × 100/ PaO_2) of 25 to 40

Conditions treated with ECMO/ECLS include meconium aspiration syndrome, congenital diaphragmatic hernia, sepsis, pneumonia, PPHN, and air leak syndromes.

In the past two decade, the number of neonates being treated with ECMO/ECLS has declined by 40% to 50%.[492] Because ECMO/ECLS is invasive, labor intensive, costly, and involves risks associated with systemic anticoagulation (e.g., intracranial hemorrhage), alternative therapies (e.g., surfactant replacement, iNO, HFV, and pharmacotherapies) are used initially and have reduced the need for ECMO.[374] These therapies have changed the population being treated with ECMO/ECLS, shortened

length of stay, reduced costs, and raised concerns in delay of use of ECMO/ECLS.

Complications of ECMO/ECLS depend on initial disease process, pre-ECMO/ECLS factors (e.g., asphyxia, coagulopathy, hypoventilation, hyperventilation), and type of ECMO/ECLS used (e.g., venoarterial vs. venovenous). **The most common complications are hemorrhagic and nonhemorrhagic CNS insults.** A retrospective cohort study of data reported to the ECLS Organization from 7190 neonates receiving ECMO found 20% with neurologic complications and increased mortality.[413] Neonates who develop intracranial hemorrhage are at highest risk for mortality and poor neurodevelopmental outcomes. There is a high (74%) survival rate with ECMO/ECLS in neonates with PPHN; survival for congenital diaphragmatic hernia is 50%.[36] A recent cohort study of 130 neonates and children with pulmonary artery hypertension found that only 1.4% were treated with ECMO. Of those treated with ECMO, there was a higher risk of acute kidney injury, neurologic complications, sepsis, thrombotic conditions, and higher mortality rate.[370]

Partial Liquid Ventilation. Although prenatal administration of steroidal agents, use of surfactant, and HFOV therapies have improved the clinical course of sick preterm newborns with respiratory failure, the morbidity of severe RDS persists. Based on 40 years of experimental (animal) studies, perfluorocarbon (PFC) liquids have been found to improve gaseous exchange, lung mechanics, and cardiopulmonary stability in various respiratory diseases.[110,192] PFC liquids are suitable for liquid ventilation because of their high solubility of respiratory gases, easy elimination by evaporation from the lungs, and lack of metabolism by the body.[192] Instillation of an FRC of PFC liquid into the lungs during gaseous ventilation constitutes partial liquid ventilation (PLV). The best ventilator management during PLV has not been determined and may differ with underlying lung pathology.[192]

PLV is applicable to the surfactant and structurally deficient preterm lung because it reduces or eliminates surface tension forces, optimizes lung recruitment, and reexpands atelectatic lung. In a term infant, PLV is applicable to structural lung disease (e.g., diaphragmatic hernia) or lung disease associated with airway debris (e.g., aspiration syndromes or pneumonia). A nonrandomized, nonblinded clinical study of 13 preterm infants with severe RDS who failed to improve with CMV showed improved oxygenation within 1 hour of initiation of PLV.[306] A case report of partial liquid ventilation accompanying HFV showed improved gas exchange with a decrease in oxygenation index.[345] In infants with respiratory failure, a combination of PLV, iNO, and surfactant may produce optimal response. The safety and efficacy of PLV are undergoing phase III trials in adults in the United States; trials are contemplated in infants and children in Europe.

WEANING FROM THE VENTILATOR

When the infant's condition improves, ventilatory support is slowly removed. **Evidence of improvement includes biochemical and clinical parameters as follows:**

- Arterial blood gases are stable and physiologic.
- Spontaneous respiratory efforts occur in addition to ventilator-generated respirations and if the infant is disconnected from the ventilator for suctioning.
- There is increased activity and muscle tone and progressively decreasing FiO_2 requirement.
- For extremely preterm infants[84,333]:
  - Higher gestational age
  - Not SGA
  - Higher 5-minute Apgar scores
  - Arterial blood gases: pH and lower pCO_2 prior to extubation
  - Lower peak FiO_2 within the first 24 hours of life

Weaning an infant as soon as possible from intubation and the ventilator is associated with a decrease in the complications of intubation (see Table 23.10) and the incidence of CLD/BPD resulting from barotrauma, volutrauma, and oxygen toxicity. With IMV, there is a gradual decrease in mechanical ventilation with a corresponding increase in spontaneous respiration. **One ventilator setting at a time is changed, and arterial blood gases and pulse oximetry values are evaluated to determine the infant's response before another adjustment is made.** Because each ventilator parameter has risks and benefits, each parameter must be evaluated before the decision is made as to which one will be lowered. **Because high concentrations of oxygen are toxic to lungs and hyperoxia damages eyes, oxygen is usually lowered first in 5% to 10% increments to a**

TABLE 23.10 COMPLICATIONS OF ENDOTRACHEAL INTUBATION

COMPLICATIONS	COMMENTS
Immediate	
Malposition	
Too low	Usually in right mainstem bronchus; no or diminished breath sounds in left chest or upper right lobe; asymmetric chest movement; atelectasis (withdraw tube until breath sounds are heard bilaterally and equally)
Too high	Inadequate ventilation bilaterally; especially at lung bases
Esophageal	Air movement auscultated in stomach with no or inadequate breath sounds
Obstruction	
Plug	Partial—no change or diminished breath sounds audible Complete—distant or no breath sounds audible
Kinking of the Tube	
Head position	Flexion or extension of the head results in diminished or blocked airflow
Perforation	
Vocal cords Trachea Pharynx Esophagus/gastric	
Pulmonary Hemorrhage	Rescue surfactant for respiratory failure accompanying pulmonary hemorrhage may be considered (see Box 23.15)
Infection	Colonization in the neonatal airway increases with the duration of intubation; presence of ETT longer than 72 hours is associated with colonization; this biofilm may contribute to the chondritis that precedes subglottic stenosis; MRSA tracheal infection causes subglottic stenosis. Late-onset sepsis is more common in VLBW infants with prolonged ventilation; mechanical ventilation is a risk factor for nosocomial infection.[310,336]
Air leak	ETT displacement (e.g., into the right mainstem bronchus or to the level of the carina) is a major factor in the development of air leaks.[378]
Increased intracranial pressure	Suctioning increases mean BP, which increases cerebral blood flow velocity and intracranial pressure, which increases the risk for IVH/PVL (see Box 23.7).
Postextubation	
Migratory lobar collapse	Prevent and treat with pulmonary hygiene.
Diffuse microatelectasis	In VLBW infants may be associated with apnea; treatable by pulmonary hygiene or nasal CPAP or both
Long-Term	
General	Vocal cord inflammation, stenosis, and eventual dysfunction; tracheobronchial fistula; subglottic stenosis; tracheal inflammation and stenosis; necrotizing tracheobronchitis; contributes to CLD/BPD
Specific to the Type of Tube	
Orotracheal	Abnormal dentition; gingival and palatal erosion; palatal grooves
Nasotracheal	Otitis media; erosion of alae nasi and nasal septum; nasal stenosis

BP, Blood pressure; *CLD/BPD,* chronic lung disease/bronchopulmonary dysplasia; *CPAP,* continuous positive airway pressure; *ETT,* endotracheal tube; *IVH,* intraventricular hemorrhage; *MRSA,* methicillin-resistant *Staphylococcus aureus; PVL,* periventricular leukomalacia; *VLBW,* very-low-birth-weight.

level below 80%. PIP is lowered in 1 to 2 cm increments to a level of 16 to 18 cm H_2O, and respiratory rate is lowered in increments of 1 to 5 breaths/min until the infant has a rate of 15 to 20 breaths/min.

Failure of extubation results in a reintubation rate of 25% to 50% in ELBW/VLBW infants.[146,355,503] An automated analysis of respiratory behavior during a short period of ETT CPAP is being studied as a tool to predict extubation readiness.[433,466] **Nasal CPAP is effective in preventing extubation failure and decreasing CLD/BPD by preventing atelectasis, improving oxygenation, decreasing apnea/bradycardia, and improving thoracoabdominal motion synchrony, which indicates improved breathing strategy.**[267] Using NCPAP pressures in the range of 7 to 9 cm H_2O, instead of 4 to 6 cm, has been shown to reduce extubation failure in an RCT of preterms with a birth weight of 500 to 1000 g and GA of 23 to 30 weeks.[71] **Weaning an intubated neonate to ventilator CPAP increases the work of breathing associated with ETT resistance and dead space (e.g., breathing through a straw).** A meta-analysis of three RCTs comparing use of ventilator CPAP with extubation to nasal CPAP showed a significant advantage (e.g., decreased the risk for reintubation and ventilation) for extubation to nasal CPAP, especially using nasal prongs.[127] **When weaning from invasive to noninvasive respiratory support, use of prone positioning of preterm infants has also been shown to increase end-expiratory lung volume and tidal volume.**[539]

Despite the large body of evidence supporting NCPAP in prevention of extubation failure,[128] there is increasing use of HHHFNC instead of NCPAP after extubation. The largest multicenter trial compared the reintubation rates of 303 preterms (<32 weeks' gestation) randomized to HHHFNC or NCPAP after extubation.[334] **Significantly less nasal trauma was noted, as well as a failure rate of 34.2% in the HHHFNC group and 25.8% in the NCPAP group and successful treatment of the HHHFNC failures with NCPAP.** The researchers concluded that the efficacy of HHHFNC was similar and noninferior to NCPAP in very preterm infants after extubation.[334] The most recent studies (by the same group) compared the time to wean from HHHFNC versus NCPAP and the use of HHHFNC and NCPAP after extubation of preterm infants under 32 weeks' gestation.[484,485] There was no difference in time to successfully wean from HHHFNC and NCPAP and no difference in morbidities or complications between the groups; there was significantly less nasal trauma in the HHHFNC group.[485] The second study of 49 preterm infants (<32 weeks' gestation) randomized to HHHFNC or NCPAP after extubation found no difference in reintubation rates (8.3% HHHFNC vs. 8% NCPAP) within 72 hours of extubation and no difference in morbidities and complications except for significantly less nasal trauma with HHHFNC.[484] **A *Cochrane* review states that HHHFNC is equally efficacious in preventing treatment failure, death, and BPD/CLD, as most of the evidence reviewed was use of HHHFNC after extubation.**[570] Although HHHFNC use is associated with fewer pneumothoraces and less nasal trauma than NCPAP, further adequately powered RCTs are needed.[570]

Extubation directly to nasal CPAP has also been shown to be more effective than extubation directly to supplemental oxygen in a hood. A meta-analysis of six RCTs comparing nasal CPAP (by any method) with use of an oxygen hood after extubation found that nasal CPAP (1) decreases adverse clinical events (e.g., apnea, bradycardia, respiratory acidosis, hypoxia), (2) decreases the incidence of CLD/BPD, and (3) decreases the incidence of reintubation.[128] These positive effects increase when nasal prong CPAP is used compared with nasopharyngeal CPAP, and the benefits are consistent across ranges of weight and GA.[128]

For weaning preterm infants from mechanical ventilation, prophylactic use of nasal CPAP (with nasal prongs) has been defined as the standard of care. However, variations in therapeutic methods and devices are associated with variations in outcomes. Although RCTs demonstrate a clear advantage of nasal prongs over nasopharyngeal administration, differences in design of nasal prongs may alter effectiveness. **Use of binasal prongs is more effective than a single nasal prong in weaning ELBW infants from the ventilator.**[134] Use of nasal biphasic positive airway pressure (NBiPAP) is no more effective than use of NCPAP in preventing extubation failures in preterms (<30 weeks' gestation and <2 weeks of age).[549]

Various clinical strategies for initiation, management, and weaning of NCPAP are used. Use of NCPAP with the Aladdin/Infant Flow System (i.e., residual gas pressure is provided by the constant flow

of gas) decreases the work of breathing by a more stable volume recruitment in the lungs and has been shown to facilitate extubation in VLBW infants compared with nasal pharyngeal CPAP.[109] Other studies show equal efficacy (e.g., no differences in apnea, bradycardia, or desaturation) when nasal prong CPAP is compared with nasal synchronized IMV.[134] An RCT comparison of bubble CPAP versus Infant Flow Driver CPAP for postextubation support found that use of bubble CPAP reduced the mean duration of CPAP use by 50%, and there was a higher rate of successful extubation in preterms ventilated for 14 days or less.[202]

If NCPAP fails, the nasal route may also be used to administer mechanical ventilation, which augments the effectiveness of NCPAP, reduces respiratory rate and the inspiratory work of breathing, improves rates of successful extubation, stimulates respiratory drive, increases ventilation, decreases $PaCO_2$, and is even being used as the initial method of respiratory support.[388] After extubation of preterm infants, use of NIPPV decreases the incidence of extubation failure (from 48 hours through the first week) more effectively than NCPAP.[312] However NIPPV has no effect on the incidence of BPD or mortality. NIPPV that is synchronized and the type of device used may also affect the effectiveness of NIPPV.[349] SNIPPV after extubation in VLBW infants improves gaseous exchange and decreases respiratory effort.[232] Use of nonsynchronized nasal intermittent positive-pressure ventilation (nsNIPPV) compared to NCPAP after extubation results in a significant reduction in the duration of noninvasive ventilation and oxygen supplementation and decreased rates of BPD/CLD.[244]

Once adequate oxygenation and ventilation on CPAP alone have been maintained, the infant may be placed in an oxygen hood or on an NC. **Oxygen should be adjusted by using targeted saturation ranges with pulse oximetry.**

During the recovery phase of RDS (approximately 72 hours), changes in lung compliance occur rapidly. Hyperoxia, air leaks, increased intracranial pressure, and decreased cardiac output easily occur if high pressures and high oxygen concentrations are not decreased as rapidly as the lung is recovering.

Infants who are difficult or impossible to wean from the ventilator may have CLD/BPD, PDA, or CNS damage that affects the respiratory control center.

BOX 23.10 COMPLICATIONS OF RESPIRATORY DISEASE

1. Acute
   a. Sudden deterioration of condition
   b. Air leaks
   c. Central nervous system
      Hypoxic-ischemic injury
      Increased intracranial pressure
      Hemorrhage
   d. Cardiac
      Patent ductus arteriosus
      Decreased cardiac output
   e. Infection
   f. Bleeding diathesis
   g. Tube
   h. Pulmonary hemorrhage
2. Chronic
   a. Oxygen toxicity and barotraumas (CLD/BPD)
   b. Hyperoxia (retinopathy of prematurity)
   c. Hypoxia
   d. Tube

CLD/BPD, Chronic lung disease/bronchopulmonary dysplasia.

GENERAL COMPLICATIONS

Acute Complications

Acute and chronic complications are the result of the disease process, treatment, or both. Beginning with the least invasive therapy and progressing to more complicated ones, only as needed, accomplishes two goals: It individualizes therapy and minimizes the risk for complications. Continuous monitoring of the individual infant's progress is vital to decrease complications from the disease and from the interventions used to support the infant or treat the primary condition. **Complications of respiratory diseases are listed in** Box 23.10.

Sudden deterioration of the infant's condition is an emergency, and the cause must be found and corrected as soon as possible to minimize further damage. Causes of sudden deterioration are listed in Box 23.11.

RESPIRATORY

Management of an infant who has suddenly deteriorated begins with a visual inspection. The

BOX 23.11 CAUSES OF SUDDEN DETERIORATION

1. Tube
   a. Accidental extubation
   b. Accidental disconnection
   c. Plug
2. Machine malfunction
   a. Ventilator or continuous positive airway pressure device
   b. Oxygen blender
   c. Tubing and connections
3. Alarm system "off"
4. Severe hypoxia
5. Metabolic factors
6. Air leak
7. Intraventricular hemorrhage

oxygen hood, CPAP, or ventilator must be properly connected and free of water. If all connections are intact, the infant must be disconnected from assisted ventilation and connected to a resuscitation bag (which is connected to an oxygen source and kept at the bedside). Manual ventilation matching pressure, rates, and FiO_2 to ventilator settings must be maintained. **If the infant improves with these interventions, mechanical failure of the ventilator should be suspected.** Assistance should be summoned to find the mechanical problem or replace the system. The infant's respiratory effort must be manually assisted until the problem is solved.

If the infant does not improve with manual ventilation, there is probably a problem with the tube. The infant's condition can be assessed by auscultating the chest for quality of breath sounds. Findings and what they suggest are listed in Table 23.11.

The ETT should be suctioned quickly. If there is no improvement in clinical condition or air entry, the tube should be replaced while the infant is supported with bag-and-mask ventilation. **If the tube is too low, it can be repositioned by pulling it back 0.5 to 1 cm. If air entry and clinical condition improve with auscultation, the tube must be secured in the new position and a chest x-ray examination done to confirm tube placement. If assessment of the chest leads to suspicion of accidental extubation, the tube must be removed, ventilation with bag and mask administered, and reintubation performed.**

TABLE 23.11 CRITICAL FINDINGS CHEST AUSCULTATION FOR ENDOTRACHEAL TUBE PLACEMENT

FINDING	CAUSE
No air entry bilaterally	Esophagus intubated; air leak; plugged endotracheal tube (ETT)
Air entry over left upper abdominal quadrant	Esophagus intubated; air entry heard over stomach
Diminished air entry	ETT too high; air leak
Air entry unequal; right chest better aerated than left chest	ETT too low; down right mainstem bronchus

If the infant does not improve with manual ventilation and the tube is in place, an air leak or IVH could be the cause.

Monitors and ventilators are equipped with alarm systems to warn care providers of sudden changes in the infant's condition or support systems. **It is imperative that all alarm systems be maintained in the "on" position. Turning the alarms "off" during care for such procedures as suctioning and weighing creates the risk for forgetting to turn them on again.** In a busy NICU or in a single-room NICU design, the compromised infant may not be visually noticed until the hypoxia is so severe that resuscitation is more difficult or impossible. Monitor parameters (both high and low alarm settings) must be individualized for each infant and recorded (see Chapter 7).

A sick neonate may experience a severe hypoxic insult when oxygen is too rapidly altered during caregiving procedures. **Feeding, weighing, or turning without an alternative oxygen source may cause a sudden decrease in PaO_2, pulmonary vasoconstriction, hypoperfusion, and an iatrogenic worsening of the condition.** Prolonged ETT suctioning (15 to 20 seconds) causes hypoxia and atelectasis. Care must be organized to conserve energy, minimize hypoxic insults, and maintain the infant in physiologic homeostasis. **Alternative oxygen sources must be provided when the usual method of oxygen delivery is disrupted for giving care.** Small alterations in FiO_2 prevent rapid increases or decreases in oxygen tension.

METABOLIC FACTORS

Hypoglycemia must never be overlooked as the cause of sudden collapse. Undetected infiltration

or disconnection of intravenous fluids may cause a precipitous drop in blood glucose, with respiratory irregularity, apnea, or seizures. Quickly checking the blood glucose with a glucometer is always warranted. If low blood glucose is not the cause of the sudden deterioration, it may be a complication of the asphyxial episode. After the infant is stabilized, screening for hypoglycemia and providing adequate fluids and glucose are appropriate (see Chapter 15).

Hypothermia and overwhelming sepsis with their associated metabolic derangements may be the cause of sudden deterioration. Muted response to cold stress is a consequence of asphyxial insult, and cold stress must be avoided after the acute episode. A high level of suspicion for infection should accompany sudden deterioration (see Chapters 6 and 22).

AIR LEAKS

Physiology. When air dissects from an alveolus, it follows the tracheobronchial tree and may accumulate in the mediastinum (pneumomediastinum), in the pleural space (pneumothorax), in the space surrounding the heart (pneumopericardium), in the peritoneal cavity (pneumoperitoneum), or subcutaneously (subcutaneous emphysema). **Air leaks are complications of respiratory diseases and treatment strategies.** When air continues to accumulate, pressure builds in the pleural space, compresses the lung, and pushes the mediastinum toward the unaffected side and a tension pneumothorax results.

The free air released from ruptured alveoli may lead to *pulmonary interstitial emphysema* (PIE) (Fig. 23.1). **PIE is associated with preterm infants who were resuscitated with high concentrations of oxygen and had higher PEEPs and higher need for surfactant.**[381] The free air of PIE intravasates into interstitial tissue and can compromise pulmonary vascular circulation and ventilation. Localized pulmonary interstitial emphysema sometimes resolves spontaneously. Frequently, it can continue for weeks or even months. Use of HFV has improved the outcome of these infants.

Etiology. Infants at increased risk for the development of air leaks fall into three specific categories: healthy term neonates, neonates with pulmonary diseases, and neonates receiving positive-pressure support (CPAP and IMV).

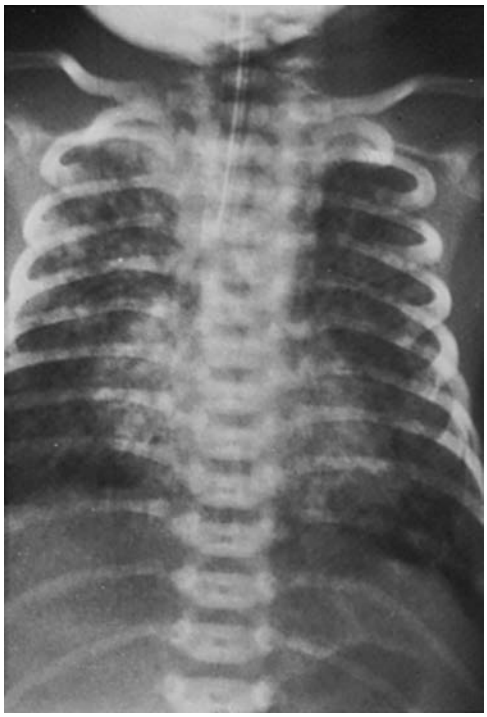

FIGURE 23.1 Pulmonary interstitial emphysema.

Healthy term neonates generate pressures of 40 to 80 cm H_2O for their first breath of life. Therefore a spontaneous air leak is more common in the neonatal period (2% to 10%) than at any other time of life.

Pulmonary diseases such as RDS result in stiff, noncompliant lungs requiring higher pressures for alveolar ventilation. Aspiration syndromes cause a ball-valve obstruction of debris with distal air trapping (meconium, milk, amniotic fluid, blood, and mucus). Hypoplastic lungs create a risk for air leaks because lung growth and development are abnormal and the lungs are stiff and noncompliant (diaphragmatic hernia and oligohydramnios syndrome). In either congenital lobar emphysema or PIE, alveolar rupture is associated with positive-pressure ventilation.

Positive-pressure ventilation, especially with excessive pressure, results in overdistention with alveolar rupture and air dissection. Air leaks occur in 16% to 36% of infants who are ventilated by CPAP or IMV or are resuscitated with a bag and mask or with an ETT and bag. **ETT displacement is a major factor in the development of air leaks** (see Table 23.10). Administration of surfactant

lowers the levels of ventilatory support necessary to ventilate the preterm infant's lungs adequately and results in a reduced incidence of pneumothorax.

Prevention. Using the least amount of positive pressure to obtain physiologic results decreases the chances of air leaks. The incidence of pneumothorax is reduced in surfactant-treated prematures and with the use of HFV. Scrupulously clearing the airway before resuscitation and using pressure gauges on resuscitation equipment may prevent aspiration and the possibility of inadvertently using pressure that is too high. Vigilance in positioning, securing, and maintaining ETT position may significantly reduce the incidence of air leaks.[378] Air leaks alter systemic hemodynamics and are associated with the development of IVH (see Chapter 26). Rapid recognition of at-risk infants, recognition of clinical manifestations and diagnosis, and rapid emergency treatment improve survival and decrease the long-term sequelae of hypoxia and ischemia.

Data Collection

History. Pneumothorax or other air leaks should be suspected when any one of the following infants takes a sudden turn for the worse:

- A preterm infant with RDS either with or without positive-pressure support
- A term or postterm infant with meconium-stained amniotic fluid
- An infant with a chest radiograph showing interstitial or lobar emphysema
- An infant requiring resuscitation at birth
- An infant receiving CPAP or positive-pressure ventilation

Signs and Symptoms. Asymptomatic air leaks occur in term neonates; these frequently require no treatment and resolve spontaneously in 24 to 48 hours. Gradual onset of symptoms is characterized by increasing difficulty in ventilation, oxygenation, and perfusion. Early clinical manifestations may include restlessness and irritability, lethargy, tachypnea, and use of accessory muscles including grunting, flaring, and retractions. These subtle clinical changes may be unnoticed until the infant progresses to a sudden, profound collapse.

Sudden and severe deterioration in clinical course is characterized by the following:

- **Profound generalized cyanosis**
- **Bradycardia**
- **Decrease in the height of the QRS complex on the monitor**
- **Air hunger, including gasping and anxious facies**
- **Diminished or shifted breath sounds**
- **Chest asymmetry**
- **Diminished, shifted, or muffled cardiac sounds and point of maximal intensity (PMI)**
- **Severe hypotension and poor peripheral perfusion**
- **Easily palpable liver and spleen**
- **Subcutaneous emphysema**
- **Cardiorespiratory arrest**

Laboratory Data. Arterial blood gas determinations reveal increasing hypoxemia (decreased PaO_2), increasing hypercapnia (increased $PaCO_2$), and a persistent metabolic acidosis with gradual onset of symptoms. Transillumination of the chest with a fiber-optic probe may reveal hyperlucency of the affected side compared with the other side. **A chest x-ray examination is the definitive diagnostic technique in air leaks. Ultrasound of the lung is highly accurate in diagnosing pneumothorax** and in one study was performed in 5.3 minutes (±5.6 minutes) versus 19 minutes (±11.7 minutes) for chest x-ray.[418] Because clinical manifestations of many other diseases may be similar to air leaks, the only way to be sure of the diagnosis is to perform a chest x-ray examination or chest ultrasound. **Anteroposterior and lateral films must be obtained, and a decubitus lateral x-ray film may be of value.** X-ray findings in pneumothorax, the most common air leak, include:

- Increased lucency, overall increase in size, and flattened diaphragm on the affected side
- Widened intercostal spaces
- Decreased or absent pulmonary vascular markings
- Sharp contrast of the cardiac border and diaphragm (sharp edge sign)

Tension pneumothorax results in mediastinal shifts with decreased volume, increased opacity of opposite lung, and deviation of heart and trachea to the other side.

Treatment. An air leak is a surgical emergency of the chest. Tension within the chest cavity compromises lung excursion and cardiac output; without prompt treatment, the infant will not survive. **Trained care providers must be available immediately to provide emergency management in any institution that provides positive-pressure ventilatory support.**

Evacuation of trapped air to decrease tension and allow proper organ function is the goal of treatment. Pneumomediastinum rarely needs to be treated, but pneumopericardium often results in cardiac tamponade and requires needle aspiration or tube drainage. Pneumoperitoneum must be differentiated from a perforated viscus.

A suggested conservative treatment is endotracheal intubation of the unaffected lung. The tube is advanced 1 to 2 cm beyond the carina to occlude the involved lung. This procedure is difficult to perform if the left lung is involved. If the pulmonary interstitial emphysema is localized to one lung or lobe of the lung, differential ventilation or surgical removal of the lobe may be curative. **Pneumothorax may be treated with needle aspiration of air. Tube thoracotomy with suction drainage is frequently necessary.**

Use of fibrin glue to treat persistent pneumothorax has been reported, with resolution within 24 hours of treatment.[450] Complications included (1) bradycardia requiring manual ventilation, (2) significant hypercalcemia, (3) diaphragmatic paralysis, (4) contralateral pneumothorax, and (5) localized tissue necrosis.

Immediate Supportive Care. **The head of the bed is elevated 30 to 40 degrees.** This decreases the work of breathing by using gravity to localize the air in the upper chest and to push the abdominal organs downward away from the diaphragm.

Oxygen at 100% concentration is administered. The two goals for using 100% oxygen for immediate care are to improve oxygenation in a severely compromised infant and to increase by as much as sixfold the rate of absorption of the trapped air by means of a nitrogen washout technique.

CAUTION: Prolonged administration of 100% oxygen to treat an air leak in term infants has been used. **Because of new understanding about the effects of oxidative stress from use of 100% oxygen, prolonged use for "nitrogen washout" should be used with caution** (see Supplemental Oxygen earlier in this chapter). Exclusive use of 100% oxygen to treat trapped air is contraindicated in preterm infants because of the risk for developing retinopathy of prematurity and the length of time necessary to obtain complete resolution.

A severely compromised infant requires immediate emergency procedures. A diagnostic and therapeutic thoracentesis may be necessary in life-threatening situations in which there is no time to wait for x-ray examination.

Needle Aspiration. **A scalp vein needle (23 to 25 gauge) or an Angiocath (24 gauge), a three-way stopcock, and a 10 to 20 mL syringe may be used for needle aspiration.** The equipment is connected (syringe-stopcock-needle/Angiocath), the chest is aseptically prepared, and the needle is inserted into the third intercostal space in the anterior axillary line. A slight pop may be felt when the pleura is entered. Air is withdrawn into the syringe and evacuated into the room by turning the stopcock. This procedure is repeated until no more air can be aspirated or a chest tube can be placed.

Chest Tube. **Chest tube thoracotomy is the definitive treatment for pneumothorax.** The insertion of a chest tube is an invasive procedure that requires strict surgical technique, with each operator wearing a gown, gloves, mask, and cap. The infant should be appropriately positioned, restrained, provided with a sucrose pacifier, and monitored before the chest is prepared for asepsis. Ideally, the anterior chest wall should be prepared with a scrub solution for a minimum of 3 minutes. If a special tray is not available, a minor suture tray will usually contain the necessary instruments.

Necessary equipment is as follows:

- Chest tube (8 to 12 Fr Argyle)
- Iodine or povidone-iodine (Betadine) scrub solution
- Gloves, gown, mask, hat
- Sterile drapes
- Syringes
- Sterile sponges (gauze)
- Medicine cups
- Lidocaine 1% without epinephrine
- Scalpel blades (no. 11 or 15)
- Hemostat (mosquito and Kelly clamps)
- Scissors
- Needle holder
- Sterile suture
- Sterile connectors (straight)
- Tubing
- Infant disposable underwater seal drainage system (two- or three-bottle or Pleur-evac system)
- Wall suction
- Sterile saline solution
- Tape, transparent dressing
- Chest tube clamp for emergency disconnection

The insertion site depends on the clinician's preference. In the lateral approach, the site is the fourth

to sixth intercostal space on or lateral to the anterior axillary line. In the superior approach, the site is the second or third intercostal space on or just lateral to the midclavicular line (Fig. 23.2). A case report of breast deformity, psychologic distress, and need for corrective surgery (in adolescent preterm girls) as a result of chest tube insertion for multiple pneumothoraces recommends a preventive strategy of using the anterior axillary line, maintaining a distance of 4 to 5 cm inferior to the nipple, and inserting the tube through the fifth or sixth intercostal space.[419]

After infiltration of the area with 1% lidocaine for pain control, a small incision is made. A purse-string suture should be placed around the incision with ends left loose. A curved hemostat is inserted into the incision and opened. The catheter is advanced through the interspace and into the pleural space. The most frequent error by an inexperienced operator is applying too little force to enter the pleural cavity. The purse-string suture is tightened and tied and then tied to the chest tube. The tube is connected to the underwater drainage system, which may then be connected to a continuous suction device (10 to 20 cm H_2O is most commonly recommended). The tube should be secured with tape. An x-ray examination is used to confirm placement of the tube and evaluate the effectiveness of the therapy. **Attention to pain control with opioids and/or nonnarcotic analgesics is also necessary after the procedure** (see Chapter 12).

Complications. In some instances, complications have arisen from the placement of chest tubes in neonates. These include hemorrhage, lung perforation, infarction, and phrenic nerve injury with eventration of the diaphragm. Clinical signs of eventration (elevation of the diaphragm into the thoracic cavity) include a shift of the umbilicus upward and toward the affected side.[338]

Care of Chest Tube and Drainage System. The chest tube drainage system removes air and fluid material from the pleural space to restore negative pressure and expand the lung. **Care providers must be familiar with the operation of the drainage system used in the nursery.** The single-bottle water seal system drains air and fluid by gravity and blocks atmospheric air from being drawn into the pleural space. In addition to the water seal, the multiple-bottle systems allow suction to be applied to facilitate drainage and expansion. The Pleur-evac system is a single plastic unit divided into three chambers: the collection, water seal, and suction chambers.

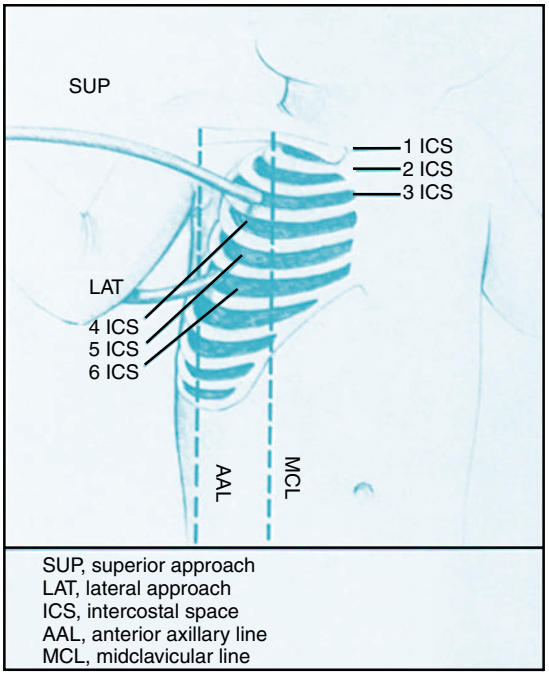

FIGURE 23.2 Chest tube insertion site. (From Oellrich RG. Pneumothorax: chest tubes and the neonate. *MCN Am J Matern Child Nurs.* 1985;10(1):31.)

Oscillation of fluid in the tube demonstrates effective communication between the pleural space and drainage bottle. In the small, sick infant, intrapleural pressure may cause only fluctuation in the tube at the chest wall. Fluctuation in either the tube or bottle should be observed. Fluctuation may cease as a result of fibrin or blood clots obstructing the tube, kinked or compressed tubing, or the suction apparatus not working properly. **Milking and stripping the chest tube generally are unnecessary if only air is being removed.** Presence of clots or debris may require gentle kneading of the tube. **Milking and stripping generate tremendously high pressures that may entrap and damage the lung in the chest tube eyelets.**

Bubbling in the drainage bottle indicates that air is being removed from the pleural space. Continuous bubbling may indicate an air leak in the system. To locate the source of the leak, the tube is momentarily clamped (beginning close to the chest and working toward the bottle) with a rubber-tipped hemostat. When the clamp is placed between the air leak and the water seal, the bubbling will stop. Patency of the tube, fluctuation, and bubbling should be observed and charted hourly.

Excessive or insufficient fluid in the drainage bottles may interfere with proper function of the drainage system. The bottle may have to be changed, or sterile saline may have to be added.

Frequent turning is important for maximum drainage and lung expansion. Proper stabilizing and positioning of the chest tube is necessary for function, comfort, and prevention of accidental removal. The tubing may be secured by encircling it with an adhesive tab, placing a safety pin through the tape (not the tube), and securing it to the bed. **If the tube becomes dislodged, the opening should be covered with sterile gauze and pressure applied until the tube can be replaced.**

When the infant is moved for such procedures as x-ray examination and weighing, the tube must be stabilized by holding it close to the chest. **If the closed system is disturbed (e.g., because of a broken bottle), the tube should be clamped with a rubber-tipped hemostat that always should be kept at the bedside.** The chest tube should be clamped for as short a time as possible. **After necessary clamping, vital signs and clinical conditions should be closely monitored.**

Bottles should be stabilized by being taped to an incubator or warmer so that they are not accidentally broken or picked up. **The bottles must always be below the level of the infant's chest to prevent water from being pulled into the pleural space.**

Removal of Chest Tubes. **The chest tube may be removed when bubbling has ceased for at least 24 hours and the chest x-ray films show no free air for 12 to 24 hours. Attention to pain relief during the removal process includes a sucrose pacifier and pharmacologic pain relief** (see Chapter 12). Rapid, sterile removal of the tube is followed by application of a petrolatum gauze pressure dressing.

CENTRAL NERVOUS SYSTEM INSULT

Acute insult to the CNS may result in increased intracranial pressure, hemorrhage, or hypoxic-ischemic brain injury (see Chapter 26).

CARDIAC COMPLICATIONS

CDP or IMV may exert sufficient pressure on the pulmonary capillary bed to raise pulmonary artery pressure and interfere with cardiac output. The effect of CDP or IMV on the pulmonary vascular bed and cardiac output may be alleviated by lowering the PIP or PEEP or both. At times, a fluid infusion to increase the intravascular volume may overcome the resistance to the pulmonary blood flow. The effect of MAP on cardiac output is difficult to monitor in most NICUs, because pulmonary artery or pulmonary wedge pressures are not routinely obtained. Until these measurements are routinely obtained, the best CPAP is determined only on clinical grounds.

PDA is the most common cardiac complication in neonates with respiratory disease. Most often it is manifested by an increasing oxygen requirement or increased dependency on ventilatory support (see Chapter 24).

INFECTION AND BLEEDING

Procedures such as intubation expose the neonate to the risk for acquired (nosocomial) infection. Scrupulous attention must be given to technique when caring for respiratory equipment, and performing procedures such as sterile suctioning of the ETT minimizes the risks for infection. **Handwashing before and after every contact with the neonate is the best method of preventing hospital-acquired infection in an already compromised, sick neonate.** Neonates who are severely ill with respiratory disease may exhibit bleeding diathesis at birth or during the acute phase of their disease. Early recognition and treatment is important (see Chapter 20).

Chronic Complications

CHRONIC LUNG DISEASE/ BRONCHOPULMONARY DYSPLASIA

Despite improvements in neonatal respiratory care, the incidence of BPD/CLD continues to be high and is the direct result of the survival of extremely premature infants (under 28 weeks' gestation).[125,303] **The incidence of CLD/BPD in mechanically ventilated preterm infants is inversely related to birth weight and GA. Need for mechanical ventilation at 7 days of life is associated with an increased risk for BPD.[303] The primary pathology of BPD/CLD is related to lung injury from positive-pressure ventilation and is a multisystem disease, and most of the treatment is supportive.**

BPD was first described by Northway and Rosan[380] as serial roentgenographic changes occurring in the lungs of premature infants who survived

hyaline membrane disease (HMD). **The clinical course of BPD is one of increasing respiratory distress and often is described as the chronic phase of RDS.** Although CLD is a more inclusive term, CLD occurs in a variety of conditions, including esophageal atresia, aspiration pneumonia, congenital heart disease, PDA, and meconium aspiration syndrome (MAS).

Recent changes in neonatal care have modified the classic stages of BPD as first described by Northway and Rosan.[380] In comparison with the infants in earlier studies, today's neonates with BPD are far more premature, have lower birth weights, and generally lack many of the radiographic changes of cystic lung disease. **The "new BPD" is characterized by arrested lung development resulting from interference with alveolarization, vascularization, and the development of excess tone and airway reactivity, primarily in preterm infants with birth weights under 1250 g.**[249]

The expanded definition and criteria for the diagnosis of BPD/CLD are listed in Table 23.12. A recent research study of infant (median age 52 weeks' PMA) pulmonary function testing in preterm infants (median GA at birth 25 weeks and median birth weight of 707 g) found that **severe BPD could be classified into obstructive (51%), restrictive (9%), and mixed (40%) types.**[470] Despite changes in care practices, the incidence of chronic lung disease in infants after NICU care remains a significant clinical problem, with an **incidence of 40% in extremely preterm infants (≤28 weeks' GA).**[125] Between 2009 and 2012, in ELBW (26 to 27 weeks' GA) born at US academic centers, the rate of BPD increased from 50% to 55%.[500] **The relative incidence of BPD/CLD is inversely related to GA:** (1) relative incidence of mild disease is 30.3%, (2) relative incidence of moderate disease is 30.2%, (3) relative incidence of severe disease of 16.4%.[2,149]

The incidence of BPD/CLD varies among NICUs[299] because of variations in respiratory management associated with oxygen toxicity and barotrauma and volutrauma. Although use of nasal CPAP is associated with lower BPD/CLD rates, increased use of intubation, mechanical ventilation, and high pressures (PIP and MAP) is associated with increased BPD/CLD rates. When mechanical ventilation is used, the shorter the duration, the less often BPD/CLD occurs.[76]

Pathophysiology. BPD/CLD is a disorder of primarily premature infants that is characterized by respiratory distress and impaired gas exchange. **The pathogenesis of BPD/CLD is one of chronic, constant and recurring lung injury with ongoing repair and healing of the injury.** Chronic injury and repair may itself prolong the need for the very factors that contribute to the development of BPD/CLD: oxygen therapy and

TABLE 23.12 DEFINITION AND CLINICAL CRITERIA OF BRONCHOPULMONARY DYSPLASIA (BPD)

GESTATIONAL AGE	<32 WEEKS	≥32 WEEKS
Time point of assessment	36 days PMA or discharge to home, whichever comes first	>28 days but <56 days postnatal age or discharge to home, whichever comes first
	TREATMENT WITH OXYGEN >21% FOR AT LEAST 28 DAYS PLUS	
Mild BPD	Breathing RA at 36 weeks' PMA or discharge, whichever comes first	Breathing RA by 56 days PMA or discharge, whichever comes first
Moderate BPD	Need* <30% oxygen at 36 weeks' PMA or at discharge, whichever comes first	Need* >30% oxygen at 56 days' postnatal age or at discharge, whichever comes first
Severe BPD	Need* ≥30% oxygen and/or positive pressure (PPV or NCPAP) at 36 weeks' PMA or at discharge, whichever comes first	Need* ≥30% oxygen and/or positive pressure (PPV or NCPAP) at 56 postnatal days or at discharge, whichever comes first

*A physiologic test confirming that the oxygen requirement at the assessment time point remains to be defined. This assessment may include a PO saturation range.
NCPAP, Nasal continuous positive airway pressure; *PMA*, postmenstrual age; *PPV*, positive-pressure ventilation; *RA*, room air (21%).

mechanical ventilation. In RDS, there is injury to the alveolar mucosa, airway mucosa, serum exudation membranes, and fibrin coagulation-forming hyaline membranes. If sufficient hypoxia occurs with resultant damage, the alveolar and airway epithelium and its basement membrane will hemorrhage and round cell infiltration will begin. Cellular and noncellular debris fill the alveoli and small airways. The obstruction causes microatelectasis, and unobstructed airways become hyperexpanded and emphysematous.

In the healing and repair process, type II alveolar cells or their precursors multiply and differentiate into type I pneumocytes, which provide alveolar epithelium. Cells of the basal layer of the pseudostratified, ciliated, columnar epithelium lining the airways multiply and migrate to cover the injured airway and rejuvenate the epithelium. During this healing phase, the rapidly multiplying and differentiating transitional cells are squamous or cuboidal and therefore appear "metaplastic." Epithelial metaplasia is one of the characteristics of BPD.

As healing occurs, increased inspired oxygen tensions, barotrauma, and infection continue to injure the cells that are taking part in the healing process.

Etiology. BPD/CLD is an iatrogenic disease caused by oxygen toxicity and barotrauma resulting from pressure ventilation. Even preterm infants with mild respiratory distress in the first week of life may develop **BPD/CLD. BPD/CLD is multifactorial, and prenatal predictors include prematurity (e.g., early GA and low birth weight), male gender, and maternal smoking and hypertension.**[356] A biomarker predictive of BPD/CLD has recently been identified by the presence or absence of microRNAs (miRNAs) in tracheal aspirates of preterm infants with severe BPD/CLD.[295] Reduction of miR-876-3p is associated with more severe BPD, whereas elevation of the same biomarker is protective. Combining a reduction in mi-876-3p with alteration in the neonatal airway (presence of Proteobacteria) strongly predicts premature infants who will develop BPD/CLD.[295]

Oxygen Toxicity. BPD/CLD has been documented in both long-term and short-term exposure to oxygen at both low and high levels (greater than 60% to 80%), as well as in infants treated with mechanical ventilation without supplemental oxygen. As a result of these findings, many units have instituted guidelines for oxygen use and monitoring of levels with pulse oximetry. **Avoidance of excessive oxygen exposure and careful attention to oxygen saturations and arterial PaO_2 may help reduce lung injury resulting from oxygen exposure.**[125] In high-risk, extremely low GA newborns, cumulative supplemental oxygen exposure is independently associated with BPD/CLD or death.[554]

Barotrauma/Volutrauma. Development of BPD/CLD is a result of barotrauma and volutrauma, almost exclusively in neonates receiving positive-pressure ventilation.[125] BPD/CLD has been described in infants who have received high PIPs and high PEEP[193] and neonates with pneumothorax and PIE.[125] The incidence of BPD/CLD is decreased when lower PIPs are used.[193] Although PIPs should be limited whenever possible, some infants with very noncompliant lungs require the use of high pressure for survival. Volutrauma (e.g., increased lung volume [stretch]) results in regional overdistention of lung units or airways, which may promote lung injury more than pressure itself.[125] **Using the smallest possible tidal volumes to inflate the lung avoids the overdistention and volutrauma that causes BPD/CLD.**[193,250]

Use of surfactant therapy and newer ventilatory techniques[75] has decreased the pressures necessary to adequately oxygenate and ventilate the neonate's lungs, as well as resultant air leaks. **A gentler ventilator strategy, "permissive hypercapnia" (e.g., accepting a $PaCO_2$ of 45 to 58 mm Hg) benefits the preterm by (1) use of lower PIP, MAP, rate, and tidal volume; (2) improving ventilation-perfusion matching; (3) decreasing days on ventilation, use of supplemental oxygen, and reintubation rates; (4) increasing oxygen availability at the tissue level; (5) increasing respiratory drive and decreasing apnea; (6) increasing cardiac output; and (7) decreasing BPD/CLD.**[75,442] An RCT in 16 tertiary centers in Germany studied the outcomes of ELBW infants with slight hypercapnia (pCO_2 values from 40–60 mm Hg) versus those with higher pCO_2 values (55–75 mm Hg).[521] The rates of BPD/CLD, death, IVH, ROP and neurodevelopmental outcomes did not differ between groups.[521,522] **Even though mild permissive hypercapnia is safe and has modest benefit, the optimal $PaCO_2$ level has not been determined.**

Use of HFV, HFV with surfactant replacement, and HFV with "high volume" technique are all associated with a decreased incidence of BPD/

CLD (see High-Frequency Ventilation earlier in this chapter).

Patent Ductus Arteriosus. **There is a high incidence of BPD among infants with PDA and congestive heart failure.** The amount of oxygen and peak inspiratory pressure necessary to support a neonate through the pulmonary complications of PDA may result in damage from oxygen toxicity and barotrauma. The increased pulmonary blood flow that occurs may also contribute to pulmonary damage. A persistent, hemodynamically significant PDA is an added risk for the development of BPD, whereas the duration of a smaller, nonsignificant PDA is not a risk factor for BPD/CLD.[455]

Because of these findings, medical closure of the ductus with indomethacin, ibuprofen, or surgical ligation is advocated (see Chapter 24) but has not affected the incidence of BPD. However, surgical ligation decreases mortality in extremely preterm infants.[562] Later PDA ligation and prolonged PDA is associated with BPD/CLD and death.[455]

Nutrition. **Preterm infants who are SGA or intrauterine growth restricted (IUGR) are undernourished in utero and at twice the risk for the development of BPD/CLD and neonatal mortality.**[160,383,411] Because growth restriction compromises lung development and function, preterm infants who are SGA/IUGR also are at increased risk for developing pulmonary hypertension with their BPD.[125,411] **Provision of adequate nutrition in the first week of life—especially enteral nutrition—is critical in decreasing the risk of BPD/CLD.**[125,411] Postnatally, inadequate **nutrition caused by poor intake or increased nutritional requirements resulting in catabolism potentiates the effects of oxygen and barotrauma on the neonatal lung. In VLBW preterm infants, exclusive breastmilk intake resulted in slower weight gain but a reduced risk of BPD/CLD.**[463,487] Enteral supplementation of docosahexaenoic acid (DHA) does not decrease the risk of BPD.[100] Optimizing nutritional support of infants at risk of BPD/CLD is an area of active research (see Chapter 17).

Fluids. **BPD/CLD is common in preterms who have developed symptoms of fluid overload within the first few days of life.** Fluid balance in a VLBW infant is complicated by huge insensible water loss and often intolerance for enteral feedings. **Intake, output, and changes in weight must be closely monitored to calculate the fluid needs.** A retrospective chart review of preterm infants (<32 weeks' GA and <1500 g birth weight) found that those infants with a **higher fluid intake in the first 2 to 4 days of life were at an increased risk for the development of severe BPD/CLD.**[199]

Family History of Asthma. **Maternal asthma is associated with an increased risk of BPD/CLD in their preterm infants,** particularly if the mothers did not receive antenatal steroids.[175] The lungs of these infants may be less tolerant of the insults of pulmonary disease, oxygen, pressure, and fluids.

Prematurity. **Developmental immaturity is of principal importance in the etiologic picture of BPD/CLD.** Premature births alone may have a significant effect on pulmonary development, because **prematurity results in differences in the development of small airways.** As a result, premature infants are more susceptible to additional damage to the small airways from oxygen, ventilator pressure, fluids, and circulatory overload.

Oxygen and Antioxidants. Oxygen accepts free electrons generated by oxidative metabolism within the cell and produces free radicals, molecules that are toxic to living cells or tissues. Normally, antioxidants protect cells against free radicals, but this balance may be upset by increased free radical production or decreased antioxidant defense. **A preterm neonate is deficient in antioxidants and thus more susceptible to lung damage from free radicals and oxidative stress when subjected to hyperoxemia for even brief periods of time.**[125,546]

Inflammation/Infection. **Oxygen radicals, barotrauma, infection, and other factors initiate the inflammatory process,** resulting in the infiltration of leukocytes, with release of other inflammatory mediators, resulting in pulmonary damage (e.g., decrease in capillary endothelial integrity, albumin leakage in the alveoli resulting in pulmonary edema). **Neonates whose lungs are mechanically ventilated have increased pulmonary cytokine and phagocyte levels within 1 to 3 hours after the onset of mechanical ventilation.**[530] Blood cytokine levels differ among preterm infants with classic versus atypical BPD and those without lung disease.[114] Activated neutrophils release enzymes that directly destroy the elastin and collagen of the lung. **Lung inflammation and injury predispose the lung to increased susceptibility to volutrauma and oxidant-induced lung injury.**[125] This inflammatory cycle produces significant pulmonary injury during a critical period of rapid lung growth and development (24–40 weeks) (see Table 23.1). Two systematic reviews show that chorioamnionitis is not a risk factor for the development of BPD/

CLD, but postnatal infection, including nosocomial infection, is a risk factor for the development of BPD/CLD.[33,213,299,336] Variation in nosocomial infection rates may be a factor in the variation in inter-NICU BPD/CLD rates.

Prevention. Potentially better practices to reduce the BPD/CLD in VLBW infants are listed in Box 23.12. Widespread use of antenatal steroids and surfactant administration has not reduced the rate of BPD/CLD or the NICU disparities in BPD/CLD rates in extremely preterm infants.[500] **A single course of antenatal steroid therapy decreases the incidence and severity of BPD/CLD.**[372] Premature and full-term infants (with pneumonia or MAS) treated with surfactant replacement have a lower incidence of BPD/CLD because of (1) better ventilation and pressure distribution in the alveoli, (2) stabilization of the alveoli, (3) prevention of overdistention, and (4) decreased cytokines and inflammatory response.

Noninvasive respiratory support using NCPAP or mechanical ventilation using the nasal route reduces or eliminates the need for intubation and mechanical ventilation.[127,312,314,501] However, despite the increased use of noninvasive ventilation strategies, one prospective, longitudinal follow-up study of extremely preterm infants found an increase in oxygen dependence at 36 weeks and worse lung function at 8 years of age.[143] In an attempt to prevent reinjury and allow healing, **inspired oxygen tensions should be kept as low as is reasonable to provide adequate arterial oxygen tension. Pressures on the ventilator should be reduced when possible to prevent barotrauma.**

Use of iNO in care of preterms with RDS remains controversial. A systematic review of 17 RCTs of inhaled nitric oxide therapy in preterm infants found that iNO does not improve survival without BPD/CLD.[41] Although iNO reduces inflammatory markers in tracheal aspirate of preterm infants, there was no effect on survival without

BOX 23.12 POTENTIALLY BETTER PRACTICES TO REDUCE THE INCIDENCE OF CLD/BPD IN THE VERY-LOW-BIRTH-WEIGHT PRETERM INFANT

- Use NCPAP in delivery room and as initial respiratory support as an alternative to routine intubation and early/prophylactic use of surfactant*
- Early NCPAP as the initial respiratory support decreases the need for surfactant*
- Combine early NCPAP with selective noninvasive surfactant therapy in extremely preterm infants[14,412,513,590] (see Table 23.15)
- Avoid endotracheal intubation for surfactant administration[417;457,513] (see Table 23.15) and mechanical ventilation[171]
- Use noninvasive mechanical ventilation strategies such as NCPAP, NSIPPV, BiPAP: compared with mechanical ventilation, prophylactic noninvasive ventilation reduces the need for invasive (endotracheal intubation) mechanical ventilation and surfactant, the incidence of BPD/CLD and death or BPD/CLD in very preterm infants†
- Use of the antioxidant *vitamin A*[124,462,533]
- Optimal nutritional management (exclusively with human milk)[463,487] to promote adequate growth and pulmonary healing[125,411] and prevent postnatal growth restriction[160,383] (see Chapters 17 and 18)
- Use of permissive hypercapnia[75,442]
- Decrease the incidence of sentinel events such as air leaks and unplanned extubations
- Minimize exposure in the delivery room to supplemental oxygen by titrating FiO_2 and monitoring oxygen saturations with PO to maintain normoxia[452]
- Early closure of PDA, either medically or surgically
- Monitor and minimize tidal volumes on mechanically ventilated preterms
- Extubate from assisted ventilation as soon as possible[174,245,432]
- Use nasal bubble CPAP[174,258,339,363,444]
- Improve teamwork in the delivery room[452]
- Use Neopuff instead of hand ventilation to minimize overinflation of the preterm lung
- Provide consistent respiratory management and consistent ventilator weaning
- Provide blended FiO_2 in the delivery room and during transport to the NICU to minimize exposure to unnecessary levels of supplemental oxygen[452]
- Early use of steroids: low-dose hydrocortisone therapy,[46,47] inhaled budesonide,[44] or budesonide/surfactant intratracheal instillation[58,584,585]
- Early use of caffeine therapy‡
- Prevent and treat infections[160,300,595]

BPD/CLD.[302] Other studies show that early low-dose therapy with iNO did not decrease the overall risk of chronic lung disease and mortality or survival without neurodevelopmental impairment.[214,247] Long-term pulmonary outcomes of preterm infants treated with iNO remain inconclusive and study results inconsistent.[492]

In a multicenter trial, administration of vitamin A (e.g., 5000 international units IM three times a week for 4 weeks) to VLBW infants slightly reduced the risk for BPD/CLD.[533] Monitoring of serum levels (the desired range of plasma vitamin A concentrations is 30–60 mcg/dL; the desired plasma retinol-binding protein [RBP] concentration is >25 mg/dL)[462] and assessment for manifestations of toxicity (e.g., lesions on skin/mucous membranes, bone and joint abnormalities, jaundice, hepatomegaly, and increased intracranial pressure) should accompany vitamin A administration.[469] However, in another study, oral supplementation of vitamin A (e.g., 5000 international units/day for 28 days) in ELBW infants did not significantly alter the incidence of BPD/CLD.[557] A *Cochrane* review of 11 RCTs found that supplementing VLBW infants (<1000 g) with vitamin A is associated with a small benefit in the reduction in death, oxygen requirement at 1 month of age, and chronic lung disease (oxygen requirement at 36 weeks' PMA).[124] The *Cochrane* review concludes that use of repeated IM doses of vitamin A may be based on: (1) the local incidence of BPD/CLD, (2) the value of a "modest" reduction of BPD/CLD, (3) acceptability, and (4) the lack of evidence of either benefit or harm (neurodevelopmentally) from use of vitamin A.[124] Another systematic review of four studies concluded that vitamin A injections have benefit with minimal risk and supplementation is warranted.[462] The multicenter NeoVitaA Trial evaluating the efficacy of high-dose oral vitamin A supplementation for 28 days on the incidence of BPD or death in ELBW preterm infants is now in progress.[344]

Prevention of oxygen free radical injury to the pulmonary tree and CNS (e.g., CLD/BPD and IVH/PVL)[294] occurs with intratracheal injection of recombinant human CuZn superoxide dismutase (rhSOD). A significant decrease in markers of pulmonary inflammation occurred in rhSOD-treated preterm infants without short- or long-term abnormalities.[126]

Data Collection

History. A history of prematurity, moderate to severe RDS, intubation with oxygen and positive-pressure ventilation in the first week of life, inability to be weaned from the ventilator, and increasing oxygen requirement at the end of the first week of life are associated with BPD/CLD. Long-term features include tachypnea, rales, retractions, abnormal chest x-ray examination results, and the need for supplemental oxygen for more than 28 to 30 days of life or at 36 weeks' postmenstrual age.

Signs and Symptoms. Tachypnea, exercise intolerance (feeding and handling), oxygen dependence, and respiratory distress (retractions, nasal flaring, fine rales at the bases or throughout the lung fields) are associated with BPD/CLD.

Laboratory Data. X-ray findings (Fig. 23.3) correlate with the stage of disease, but the pathologic changes are often more severe than the chest x-ray findings indicate[380]:

- Stage I: Reticulogranular pattern and air bronchogram or RDS (first 3 days of life)
- Stage II: Coarse granular infiltrates that are dense enough to obscure the cardiac markings (first 3 to 10 days of life)
- Stage III: Multiple small cyst formation within the opaque lungs and visible cardiac borders (first 10 to 20 days of life)
- Stage IV: Irregular larger cyst formation that alternates with areas of increased density (after 28 days of life)

Mild hyperinflation as demonstrated on a chest x-ray film is a common finding in VLBW infants with BPD/CLD.

Cardiovascular changes include (1) right ventricular hypertrophy on ECG, (2) elevated right ventricular systolic time intervals or left ventricular and septal wall thickening on echocardiogram, or (3) elevated pulmonary vascular pressures and resistance at cardiac catheterization.

Treatment. The therapeutic goal is to reduce those factors that produce reinjury and to allow the lung to heal so that normal function can resume. This process may take weeks, months, or even years in severe lung injuries or in small infants under 1000 g.

Concurrent supportive therapies include (1) maintenance of adequate oxygenation and ventilation, (2) adequate nutrition and fluid restriction, (3) early PDA closure, and (4)

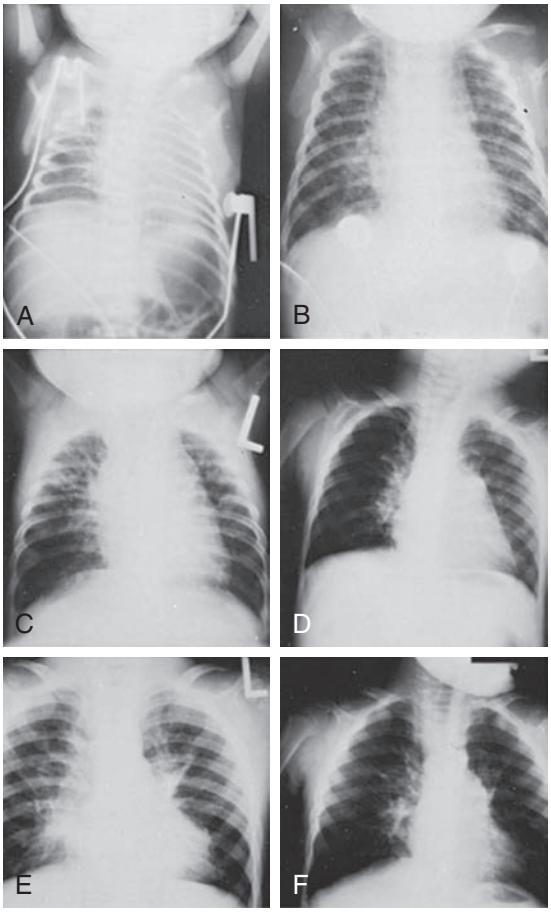

FIGURE 23.3 Serial chest x-ray films of premature infant with bronchopulmonary dysplasia over 2-year period. **A,** Newborn. **B,** Two months. **C,** Three months. **D,** One year. **E,** Two years. Infant's disease process was characterized by multiple hospitalizations for reactive airway disease and pulmonary hypertension. Note progressive lung disease characterized by hyperinflation and eventual clearing of infiltrate by 2 years of age **(F)**.

pharmacologic management. Sufficient PIP should be used to prevent atelectasis while maintaining the lowest FiO_2 (if possible, 0.5 or lower) to maintain adequate oxygenation (i.e., PaO_2 60–80 mm Hg; O_2 saturation 90%–95%). Weaning from mechanical ventilation is done slowly and may be facilitated by (1) use of SIMV that reduces the work of breathing, (2) use of methylxanthines before extubation, and (3) use of nasal CPAP after extubation.[127,128] **Usually in BPD/CLD, the infant's ability to maintain ventilation develops before the ability to maintain adequate oxygenation.** Often infants are discharged from the NICU on home oxygen therapy. **Infants with BPD/CLD who require oxygen at a rate of 20 mL/kg/min or less and those who can maintain oxygen saturations of 92% or above after 40 minutes of breathing room air are ready to begin successful weaning from supplemental oxygen.**[476]

Neonates with BPD/CLD have an increased resting metabolic expenditure as the major reason for growth failure, especially in the smallest, sickest infants.[290] **These infants may require 150 to 200 kcal/kg/day to support adequate growth** (i.e., 10–30 g/day weight gain). Without adequate protein or caloric intake, damaged pulmonary tissue cannot heal, and provision of appropriate nutrition to the neonate with BPD is essential (see Chapters 14 through 18).

Pharmacologic management of BPD/CLD includes the use of bronchodilators, steroids, and diuretics (see Table 23.12). Inhaled and systemic bronchodilators improve lung mechanics and gaseous exchange by relaxation of bronchial smooth muscle.[125] However, bronchodilators may fail to relieve airway obstruction because of relatively poor development of bronchial smooth muscle in preterm infants.

Methylxanthine therapy promotes weaning of infants with RDS from low rates of ventilatory support.[218] A meta-analysis of seven trials evaluating the prophylactic use of methylxanthine treatment for successful extubation observed a significant reduction in the incidence of failed extubation within the first week of life.[218]

Diuretics alone and diuretics combined with methylxanthines improve lung mechanics, clinical respiratory status, and ability to wean from mechanical ventilation (Table 23.13). Aerosolized diuretics (e.g., a single dose of furosemide at 1 mg/kg) transiently improve lung mechanics in preterms older than 3 weeks with BPD/CLD. RCTs are needed to evaluate the effects of aerosolized diuretics on oxygen dependence, mortality rates, duration of ventilator use, length of stay, and long-term outcomes.[66]

Steroids reduce lung inflammation and improve pulmonary function in severe RDS. Use of a single course of antenatal steroid (ANS) therapy is associated with (1) improved survival, (2) more rapid ventilator weaning and less need for mechanical ventilation because of decreased severity of RDS, (3) decreased need for supplemental oxygen (e.g., BPD/CLD), (4) lowered incidence of IVH, PDA, NEC, and (5) less systemic infection in the first 48 hours of life.[372,431] **ANS is most effective when**

TABLE 23.13 PHARMACOLOGIC AGENTS USED IN TREATMENT OF CHRONIC LUNG DISEASE/BRONCHOPULMONARY DYSPLASIA

DRUG	DOSAGE	COMMENTS
I. Bronchodilators A. Inhaled 1. Beta$_2$-agonists		During first month of life, longer duration of MV is associated with bronchodilator use. Among US CHs, use ranges from 0%–81%.[481] Response to bronchodilator therapy depends on the type of severe BPD with the best response, 74% in obstructive BPD, 63% in mixed types, and 25% in restrictive types.[470] Further clinical trials are needed to assess the role of bronchodilators in the treatment and prevention of CLD/BPD.[376]
a. Albuterol (Proventil; Ventolin)	0.1 mg/kg up to 5 mg in 2 mL of NS solution q 4–6 hr Max dose: 0.5 mL or 2.5 mg/ treatment; up to six treatments/24 hr Onset: 5–15 min Peak action: 30 min to 2 hr Duration: 3–4 hr	Drug of choice for bronchospasm—improves pulmonary resistance and lung compliance by bronchial smooth muscle relaxation; tachycardia, tremors, nausea and vomiting; can cause paradoxic bronchoconstriction, irritability. MDI dosage improves lung function and nebulization and is faster and more cost effective.
b. Terbutaline (Brethine)	0.03–0.3 mg/kg/day Onset: 5–30 min Duration: 3–4 hr	Same as for albuterol.
2. Histamine inhibitor (Cromolyn: 20 mg/2 mL solution for nebulizer)	10–20 mg TID	Prevents release of inflammatory mediators and reduces airway hypersensitivity; urticaria, rash, and throat irritation; dosage may need adjusting in patients with hepatic or renal dysfunction. A systematic review showed no significant evidence that cromolyn has a role in the treatment or prevention of CLD/BPD.[377]
B. Systemic 1. Methylxanthines		
a. Caffeine citrate	Loading: 20 mg/kg Maintenance: 5 mg/kg/day IV or PO Half-life: as long as 100 hr	Promotes weaning from low rates of ventilatory support by reduction of pulmonary resistance, improved lung compliance, and improved skeletal muscle and diaphragmatic contractility; has diuretic effect; excreted unchanged in urine; safer drug with fewer side effects than theophylline. Side effects are rare but include tachycardia, diuresis, dysrhythmias, glucosuria, seizures, ketonuria, vomiting, hyperglycemia, jitteriness, hemorrhagic gastritis.
b. Theophylline	PO: 4–6 mg of active theophylline, which should produce a serum level of 10–20 mcg/mL Maintenance: calculated by rate of plasma clearance, usually 3–7 mg/kg/day q 12 hr Half-life: 30–40 hr IV: Loading: 4.6 mg/kg over 30 min. Maintenance: From 0 to 24 days of age: 1 mg/kg IV q 12 hr > 24 days of age: 1.5mg/kg IV q 12 hr	Metabolized to caffeine in the liver and excreted in urine; multisystem effect; CNS stimulant; increases respiratory rate, inspiratory drive, and surfactant production; increases GFR; increases heart rate, contractility, and output; decreases GI motility and increases GI secretions; increases glucose levels, ketonuria, and glycosuria; increases muscle contractility; increases catecholamine and insulin levels. Side effects: same as for caffeine citrate.
2. Beta$_2$-agonists		
a. Terbutaline	5 mcg/kg subcutaneously q 4–6 hr	Improves pulmonary mechanics; side effects same as for albuterol; adjunct to methylxanthines.
b. Albuterol	0.15 mg/kg/dose PO q 8 hr	Reduces pulmonary resistance; adjunct to methylxanthines; side effects same as albuterol.

Continued

TABLE 23.13 PHARMACOLOGIC AGENTS USED IN TREATMENT OF CHRONIC LUNG DISEASE/BRONCHOPULMONARY DYSPLASIA—CONT'D

DRUG	DOSAGE	COMMENTS
III. Steroids		
A. Inhaled		
1. Corticosteroids (dexamethasone [Decadron])	100 mcg/inhalation from MDI	30%–60% systemic bioavailability versus 53%–78% from oral intake; majority removed from lung within 20 min after administration; anatomic, physiologic, and pathophysiologic variations in the neonate, coupled with the aerosol delivery system and its use, influence the amount of drug actually administered and the aerosol's efficacy. Side effects: oral candidiasis, bronchospasm, and pituitary-adrenal suppression, tongue hypertrophy. Increasing evidence that early administration of inhaled corticosteroids to VLBW neonates is effective in decreasing the incidence of death and chronic lung disease.[43–45]
2. Glucocorticoids		
a. Flunisolide (Aerobid)	250 mcg/inhalation	Unknown stability—do not mix with other drugs; bronchospasm may result from buffers and/or preservatives.
b. Beclomethasone (Beconase; Vancenase)	42 mcg/inhalation	Side effects: same as for dexamethasone.
c. Budesonide (Symbicort; Pulmicort)	1 neb every 12–24 hr 2 puffs/MDI (200 mcg/puff) q 12 hr for first 2 weeks of life; 1 puff q 12 hr from day 15 of life till 32 weeks' PMA or no longer needs supplemental oxygen or positive-pressure support[43,44] 2 puffs every 12 hours	Side effects: same as for dexamethasone.
B. Systemic (corticosteroids—dexamethasone [Decadron])	0.5 mg/kg/day IV or PO q 12 hr for 3 days; decrease to 0.3 mg/kg/day for 3 days Taper 10%–20% q 3 days	Hyperglycemia; hypothalamic-pituitary-adrenal axis suppression; renal calcification; protein depletion and/or tissue catabolism (increase BUN; failure to gain weight); gastric irritation, perforation, bleeding; restlessness and/or irritability; myocardial hypertrophy; hypertension; increased risk for infection (see Box 23.13).
	Initial dose: 0.1–0.2 mg/kg/day for 3 days[246]	Use for ventilator-dependent infant at 14–28 days of age who is developing CLD/BPD to accomplish extubation.
	If extubated, taper dose over 3–6 days (total treatment 6–9 days) If unable to extubate after initial 3 days of therapy, discontinue therapy[248]	Lower dose for shorter treatment period. Avoids hyperglycemia and hypertension seen in the higher doses of longer duration.[248]
III. Diuretics		The frequency, type, and therapeutic regimen of diuretics use at CHs in the US varies markedly. Safety and efficacy of long-term diuretic use needs to be researched to inform development of evidence-based recommendations.[480]

TABLE 23.13 PHARMACOLOGIC AGENTS USED IN TREATMENT OF CHRONIC LUNG DISEASE/BRONCHOPULMONARY DYSPLASIA—CONT'D

DRUG	DOSAGE	COMMENTS
a. Furosemide (Lasix)	Initial dose: 1 mg/kg IV, IM, PO May increase by 1 mg/kg no sooner than 2 hours after previous dose Maximum dose: Preterm: 1 mg/kg/day Full term: 6 mg/kg/dose Onset: 5 min IV; 1 hr PO Duration: 2–4 hr	Acute and chronic administration of furosemide in preterm infants >3 weeks of age with CLD/BPD improves lung compliance. Chronic administration of IV or PO furosemide also improves oxygenation. Routine or sustained use of systemic loop diuretics in infants with or developing CLD/BPD cannot be recommended based on current evidence.[498,499] Treatment of choice for fluid overload in CLD/BPD—decrease interstitial edema and PVR; daily or alternate-day administration improves pulmonary mechanics and facilitates weaning from ventilator. Side effects: metabolic acidosis, hypokalemia, hypocalcemia, hypochloremia, hyponatremia, renal calcifications, gallstones, ototoxicity, requires KCl supplementation. For preterms >3 weeks of age with CLD/BPD, administration of distal diuretics improves pulmonary compliance; chronic use improves oxygenation and lung compliance.[499] Acute and chronic administration of thiazides to preterms >3 weeks of age with BPD/CLD improves pulmonary mechanics and reduces the need for furosemide.[498]
B. Thiazide		
1. Chlorothiazide (Diuril)	5–20 mg/kg/dose IV or PO BID	Less potent than furosemide; promotes potassium and bicarbonate excretion with sodium and chloride; spares calcium given with spironolactone. Combination of thiazide and spironolactone results in improved lung mechanics and increased urine output. Side effects: electrolyte imbalance, hypercalcemia, hyperglycemia, decreased magnesium level, hypersensitivity, GI upset, glycosuria.
2. Hydrochlorothiazide (HydroDIURIL)	1–2 mg/kg/dose PO BID Onset: 1–2 hr Duration: 6–12 hr	Side effects: electrolyte imbalance, hypercalcemia, hyperglycemia, metabolic alkalosis, increased urinary losses of sodium, potassium, magnesium, chloride, phosphorus, and bicarbonate; spares calcium.
3. Spironolactone (Aldactone)	1.5 mg/kg/dose PO BID Onset: 2–3 days	Weak diuretic; causes increased sodium chloride and water loss; spares potassium. Side effects: irritability, lethargy, vomiting, diarrhea, rash.
4. Bumetanide (Bumex)	0.015 mg/kg/day up to 0.1 mg/kg/day PO	40 times the potency of furosemide; used in neonates and infants with CLD/BPD refractory to furosemide therapy. Side effects: same as for furosemide plus hypophosphatemia.

birth occurs within 7 days after a completed dose in preterms less than 33 weeks' gestation (especially in preterms of 24–29 weeks' gestation).[18] Use of antenatal steroids in 34 weeks' or later gestation reduces the risk of respiratory morbidities (i.e., RDS, TTN, mechanical ventilation and duration and amount of supplemental oxygen).[205,443] **Use of antenatal steroids should be considered for women between 34 and 36 weeks' gestation who are at risk of premature delivery within the next 7 days and who have not yet received antenatal steroids.**[18] However, caution in use of antenatal steroids in late-preterm pregnancies has been raised because of unanswered questions about the safety and efficacy in this population.[254]

Extremely preterm infants (22–27 weeks' gestation age) exposed to a complete course of ANS have lower mortality and better neurodevelopmental outcomes at 18 to 22 months compared with preterms exposed to an incomplete course or no ANS.[83] Use of antenatal steroids in extremely preterm multiple gestations is associated with lower mortality with no significant differences in the composite of neurodevelopmental impairment or death.[59] Although benefits of antenatal steroids occur in a dose-dependent manner, an incomplete course of antenatal steroids is beneficial (i.e., significant reduction in need for vasopressors and less mortality) when compared to no antenatal steroids.[379]

The NIH consensus statement[372] **discourages multiple courses of ANS** because of (1) impaired head/fetal growth, in a dose-dependent manner; (2) impaired brain development and behavior and psychomotor development; (3) increased incidence of IVH; (4) increased sepsis, mortality, and lung disease; (5) associated gastroesophageal reflux[90]; and (6) increased severity of ROP. **The American College of Obstetricians and Gynecologists (ACOG) recommends a repeat course of ANS if the fetus is less than 34 weeks' gestation and the previous ANS course was more than 14 days age.**[18] Long-term effects of multiple ANS therapy are associated with increased cortisol activity in response to stress,[5] a non-statistically significant difference in the incidence of CP (e.g., 2.9% in the repeated-doses group vs. 0.5% in the placebo group),[556] and a reduced risk of neurodevelopmental delay at 2 years of age due to a reduction in inflammation.[94] **An evaluation of the risk-benefit ratio of multiple courses of ANS found that administration at under 29 weeks' gestation has more benefits, but administration of multiple courses after 29 weeks has more risks than benefits.**[591]

Postnatal steroid use became widespread in the 1990s without properly conducted RCTs for safety and efficacy,[166] despite warnings from researchers in the 1970s about serious potential dangers. Steroid use has been enthusiastically accepted because of the dramatic short-term improvements in respiratory status (e.g., facilitates extubation, more rapid ventilator weaning, reduced risk for BPD/CLD and PDA).[140,145;170] Large RCTs of postnatal steroid use were halted because of serious short-term complications—intestinal perforation, growth restriction, PVL, hyperglycemia, hypertension, and infection.[490] **Adverse long-term outcomes are listed in** Box 23.13. **Adverse developmental outcomes are the result of the effects of steroids on the developing nervous system.** The most recent *Cochrane*

BOX 23.13 LONG-TERM ADVERSE EFFECTS OF STEROID USE

Slower Growth[490]

- Somatic and head/brain growth[393] (even into adolescence)[89]
- Arrested lung development caused by interference in pulmonary alveolarization and vascularization

"Neurotoxic" Substances[6,39]

- Further reduces size of cerebral and cerebellar[509] tissue/gray matter volume of premature brain[389] (effects lasting into adolescence)[89]
- Increased rate of cerebral palsy (CP)[142,575]
- Increased risk for CP significantly related to the total cumulative doses of dexamethasone[414]
- Reprogramming of the hypothalamus-pituitary-adrenal axis that alters the ability to adjust to the environment resulting in more social problems and anxious, depressed behaviors in adolescent girls between 14–17 years of age[515]
- Increased cognitive deficits at school age, children had lower scores on verbal or written language skills, math, perceptual organization, freedom from distractibility, and processing speed[575]
- Increased special education, poorer performance on neuropsychological tasks (i.e., alertness, visuomotor coordination, emotion recognition), poorer gross motor skills at 14 to 17 years of age[514]
- Increased severity of retinopathy of prematurity

Contributes to Long-Term

- Cardiovascular disease
- Immune system disorders/autoimmune diseases
- Renal calcifications
- Neurologic and behavioral deficits

review on the use of systemic postnatal steroids to prevent BPD cautions that recommendations about the optimal type of steroid, dosage, or timing of initiation to prevent BPD/CLD in preterm infants cannot be made based on the current level of evidence. Large, well-designed RCTs are needed.[389] Additionally, two *Cochrane* reviews caution that the short-term benefits of early (<7 days) and late (>7 days) **postnatal steroids may not outweigh the actual or potential adverse effects.**[140,141]

The administration of inhaled corticosteroids to prevent or treat BPD/CLD in ventilated VLBW infants without exposing them to systemic steroids is an attractive alternative. **Increasingly, there is evidence that early administration of inhaled steroids to VLBW neonates is effective in significantly decreasing the incidence of CLD at 36 weeks' PMA.**[465,473] An RCT of early inhaled budesonide in 23 to 27 weeks' GA preterm infants found a lower incidence of BPD/CLD, surgical closure of PDA, and need for reintubation.[44] The group who received the inhaled budesonide had a mortality rate of 16.9% compared to the placebo group with a mortality rate of 13.6%.[43] The rate of neurodevelopmental disability in this cohort of preterm infants does not differ from the group receiving placebo, but the mortality rate was higher in the early inhaled budesonide group.[45] One systematic review found less mortality,[465] whereas another found no impact on mortality, adverse events, or other morbidities.[473] However, the clinical relevance of these studies remains to be elucidated by studies of variations in delivery methods and dosing regimens, short- and long-term benefits, and adverse effects, especially growth, respiratory, and neurodevelopmental outcomes of VLBW preterms exposed to inhaled corticosteroids.[465,473] Late (≥7 days) administration of inhaled corticosteroids did not reduce the outcomes of death or death and BPD, did not decrease mechanical ventilation or oxygen supplementation, and is not currently recommended to reduce BPD.[389]

A pilot study and a larger RCT of intratracheal instillation of budesonide (using surfactant as a vehicle) in VLBW infants with severe RDS significantly decreased the incidence of BPD/CLD or death when compared to the group who received only surfactant.[58,584,585] No short-term adverse effects were noted, and follow-up at 2 years showed comparable neurodevelopmental outcomes.[288,585] However, appropriately powered studies to determine long-term neurodevelopmental outcomes and the safety of this regimen need to be conducted before this strategy is used in clinical practice.[58]

Historically, steroids have been used "routinely," with widely varying practices about type of medication (e.g., natural hormone [hydrocortisone] or synthetic hormones [dexamethasone, betamethasone]), dosage (e.g., standard or low dose), timing (e.g., early or late), and duration (e.g., weaning after 7 to 10 days or 42-day treatment).[166,248] Because it was considered routine practice, parents were rarely asked to give informed consent. **Parents (in addition to health care providers)**[38,490] **must be informed honestly about the experimental nature of steroid use and its short-term and long-term complications,** so that they are able to participate in giving or withholding their fully informed consent.[38,211] The DART Study of low-dose steroid use was halted because infants could not be recruited; fully informed parents concerned about risks to their infant refused permission to be part of the study.[142]

Based on the premise that very preterm infants have early adrenal insufficiency, early use of hydrocortisone therapy to decrease BPD/CLD has been studied in four RCTs.[60,397,558,559] **In all four studies the hydrocortisone-treated preterms were favored with a significant increase in survival without BPD/CLD.** The largest multicenter randomized trial to test early low-dose hydrocortisone therapy was halted because of an increase in spontaneous GI perforations in the treated preterms, especially those also receiving indomethacin.[558] Prophylaxis of early adrenal insufficiency decreased mortality rate and improved survival rate without BPD/CLD only in the chorioamnionitis-exposed preterms.[558] Another RCT of early administration (within the first 36 hours of life) of hydrocortisone to prevent BPD/CLD was terminated early because of the increased incidence of GI perforations and found lower rates of BPD/CLD.[397,398] The 18- to 22-month follow-up of the infants in both of these RCTs showed no difference in growth, no increase in CP, and indicators of improved neurodevelopmental outcome in those treated with early, low-dose hydrocortisone.[398,559] However, the follow-up at 5 to 7 years of age in one of the cohorts who received hydrocortisone found minor to severe neurologic dysfunction in 61% of the treated group compared to only 39% of the placebo group. More

of the treated children had lower IQs, and 22% required physical therapy compared to none of the placebo group.[399] **Comparison of preterm infants born at less than 27 weeks' GA in two centers found BPD/CLD rates significantly lower in the center using hydrocortisone after 14 days of ventilation without apparent effects on neurodevelopment at 2 years' corrected age.**[424]

The PREMILOC trial evaluated preterm infants (24–27⁄7 weeks' GA) receiving early low-dose hydrocortisone at 22 months corrected age and found no neurodevelopmental impairment and survival free of BPD/CLD in the treated group.[46,47] Early low-dose hydrocortisone benefits extremely preterm infants and especially those born after placental vascular disease.[223]

After reviewing the short-term and long-term effects of systemic and inhaled corticosteroid use for the prevention and treatment of CLD/BPD in the VLBW infant, both the AAP and the Canadian Paediatric Society have issued and reaffirmed position statements about use of postnatal steroids.[16,246] These policy statements on use of postnatal corticosteroids to prevent or treat BPD recommend the following[16,246]:

- High-dose dexamethasone (0.5 mg/kg/day) cannot be recommended until RCTs show improved short- and long-term outcomes.
- Low-dose dexamethasone (less than 0.2 mg/kg/day) cannot be recommended because of insufficient evidence.
- Early hydrocortisone therapy (low dose: 1 mg/kg/day in the first 2 weeks of life) may be beneficial in a specific population of preterms (i.e., prenatal inflammation). However, hydrocortisone therapy cannot be recommended for all infants at risk for BPD because of insufficient evidence.
- High-dose hydrocortisone (3 to 6 mg/kg/day; started after the first week of postnatal age) cannot be recommended because of insufficient data.

The dose and duration of use of late postnatal corticosteroids should be minimized and reserved for preterms who cannot wean from the ventilator and are still being mechanically ventilated at 7 to 14 days of life.[141,209,248] Table 23.13 gives a proposed (expert opinion rather than evidence-based) dosing regimen for low-dose, short-duration treatment with dexamethasone.[248]

Complications. ***Pulmonary hypertension*** **complicates approximately 25% of BPD/CLD cases and results in a 14% to 38% mortality rate.**[125] Early pulmonary vascular disease, as evidenced on echocardiogram at 7 days of age, is associated with development of BPD/CLD and late pulmonary hypertension.[358] Use of phosphodiesterase inhibitors, such as sildenafil, to treat the pulmonary hypertension and pulmonary artery pressure of BPD/CLD is being studied.[224] A retrospective review of 21 infants with BPD-associated pulmonary hypertension were treated with oral sildenafil to determine the effects of sildenafil on gas exchange.[382] Although sildenafil decreased pulmonary artery pressure, there was no corresponding improvement in gas exchange in the 48 hours after treatment. Chronic sildenafil therapy for BPD-associated pulmonary hypertension should be done cautiously, awaiting clinical studies and adequate evidence.[382] The most recent *Cochrane* review of sildenafil use to treat pulmonary hypertension found that it improved oxygenation and has the potential to decrease mortality, especially in resource-limited settings when iNO is not available but cautions that large RCTs are needed.[263]

Complications of CLD/BPD are most common in the smallest, sickest infants (Box 23.14). Surviving preterm infants with BPD/CLD have persistent pulmonary dysfunction and exercise intolerance and more frequently develop asthma and early onset emphysema.[101,125] Survival (75%–80%) of infants with severe BPD/CLD is improved with an interdisciplinary approach to care.[2,180]

Acute Respiratory Diseases

RESPIRATORY DISTRESS SYNDROME

Pathophysiology. RDS is a disease of immature lung anatomy and physiology. Anatomically, the preterm lung cannot support oxygenation and ventilation, because alveolar saccules are insufficiently developed, causing a deficient surface area for gas exchange. Also, the pulmonary capillary bed is deficient and the interstitial mesenchyme is present to a greater extent, increasing the distance between the alveolar and endothelial cell membranes.

Physiologically, the volume of surfactant is insufficient to prevent collapse of unstable alveoli. Because the alveoli collapse with each breath, normal FRC is not established. **Because of alveolar collapse, oxygenation and ventilation are**

BOX 23.14 COMPLICATIONS OF CHRONIC LUNG DISEASE/BRONCHOPULMONARY DYSPLASIA

Increased Mortality

Increased Morbidity

Pulmonary.

- *Acute:* pulmonary interstitial emphysema, air leaks, pulmonary hypertension, cyst formation
- *Chronic:* altered pulmonary function, pulmonary hypertension, respiratory infections, rehospitalizations, home oxygen/ventilator[2]

Cardiac.

- Cor pulmonale and right-sided heart failure
- Systemic hypertension[2]
- Feeding difficulties[2]
  - GERD

Growth Restriction.

- Somatic growth (weight)
- Head growth
- Orthopedic
  - Fractures, rickets

Neurodevelopmental Delay.

- Cognitive impairment/impaired intelligence/increased need for special education services
- Cerebral palsy/delays in gross motor skills
- Behavior/attention/school problems
- Cerebral ventriculomegaly

Sensory Deficits.

- Sensorineural hearing loss
- Increased severity (stage 3) retinopathy of prematurity

Gene Expression[406].

- Alteration of gene expression—nearly 10%

Long-Term Effects of Steroid Use

insufficient and each breath requires increased energy output.

Compliance is related to the volume achieved during a given application of pressure. **Compliance of the lung is equal to the ratio of the change in volume to the change in pressure. The lung in RDS has low compliance (i.e., little change in volume is achieved with a relatively great application of pressure), thereby contributing to increased work of breathing.** However, the chest wall of the neonate unfortunately is very compliant; a slight application of pressure results in a large change in volume. The infant may not be able to create enough inspiratory pressure to open the alveoli as the chest wall retracts and collapses about the relatively stiff lung. Thus in RDS, the diaphragm contracts, creating an inspiratory pressure that moves less volume into the lung than expected and simultaneously causes large sternal and intercostal retractions of the chest wall.

The increased effort of these opposing forces usually results in hypoxemia and acidemia, which cause constriction of the pulmonary vascular (arterial) musculature, severely limiting pulmonary capillary blood flow. The integrity of pulmonary capillary blood flow is critical for the integrity of the alveolar epithelial membrane and the production of surfactant. Without adequate pulmonary capillary blood flow, the type II pneumocytes become deficient in the precursor material necessary for production of surfactant. Lack of surfactant production compounds the deficiency and leads to low compliance. **These physiologic factors (surfactant deficiency and decreased lung compliance) promote increased work of breathing, fatigue, atelectasis, reduced FRC, and ventilation-perfusion (V/Q) mismatch.**

In the fetus, PVR is high, and pulmonary artery blood pressure is greater than systemic blood pressure, causing blood flow from the main pulmonary artery to travel through the open ductus arteriosus to the descending aorta. A second right-to-left shunt occurs across the foramen ovale in the fetus. The high PVR is "reactive" to the normal fetal "hypoxemia" because the PVR and the pulmonary artery blood pressure decrease as the PaO_2 of the neonate increases. At birth, the ductus arteriosus actively constricts in response to the increase in PaO_2 (PaO_2 >50 mm Hg), eliminating blood flow across the ductus and completing the transition to neonatal circulation.

The fetal circulatory pattern may persist from birth or be initiated by a transient hypoxemic episode. **In the instance of neonatal hypoxemia, the pulmonary vasculature "reacts" by vasoconstriction, raising PVR, and the ductus arteriosus "reacts" by relaxing, once again allowing blood flow from the pulmonary artery to the descending aorta, as normally occurs in the fetus.** PVR is increased with shunting through the ductus arteriosus. Fetal circulatory patterns are perpetuated by hypoxemia and acidemia and produce systemic hypoxemia that aggravates and perpetuates the condition.

Endothelial damage and alveolar necrosis aggravate the already existing surfactant deficiency. A cyclic deterioration is established, and hypoxia and acidosis persist unless treatment is initiated.

Microscopically, the events that occur in the lung include injury to and death of the alveolar epithelial cells and airway epithelial cells. This injury and death are followed by sloughing of the cells from the respiratory basement membrane—leaving the basement membrane denuded—followed by exudation of serum. Fibrin in the serum clots and hyaline membranes are formed, covering the denuded basement membranes in the airways and alveolar spaces. If there is sufficient hypoxic damage to the cells and basement membranes, frank hemorrhage may fill the alveolar spaces. These factors decrease the total surface area of the gas exchange membrane. The result is hypoxemia, acidemia, and increasing respiratory distress.

The entire sequence of events in RDS is related to the inability to maintain lung expansion and alveolar stability as a result of surfactant deficiency. **RDS evolves from two interrelated problems: atelectasis and persistence of pulmonary hypertension** (Figs. 23.4 and 23.5).

Etiology. RDS occurs in infants born prematurely (including the late-preterm infant of 34⁶⁄₇–36⁶⁄₇ weeks' gestation) and is a consequence of immature lung anatomy and physiology. In premature or stressed infants, atelectasis from the collapse of the terminal alveoli resulting from lack of surfactant appears after the first few hours of life. **In a premature infant, surfactant production is limited and stores are quickly depleted.** Surfactant production may be further diminished by other unfavorable conditions, such as high oxygen concentration, poor pulmonary drainage, excessive pulmonary hygiene, or effects of respirator management.

Data Collection

History. A history of prematurity, cesarean section, birth order (second-born twin),[65] or asphyxial episodes may be seen in infants with RDS. In one study, elective cesarean section at "term" (i.e., ≥34 weeks' gestation) resulted in infants of 37 to 38 weeks' gestation being 120 times more likely to have surfactant deficiency requiring ventilatory support than those born at 39 to 41 weeks. Recommendations include only using delivery by elective induction or elective cesarean section at

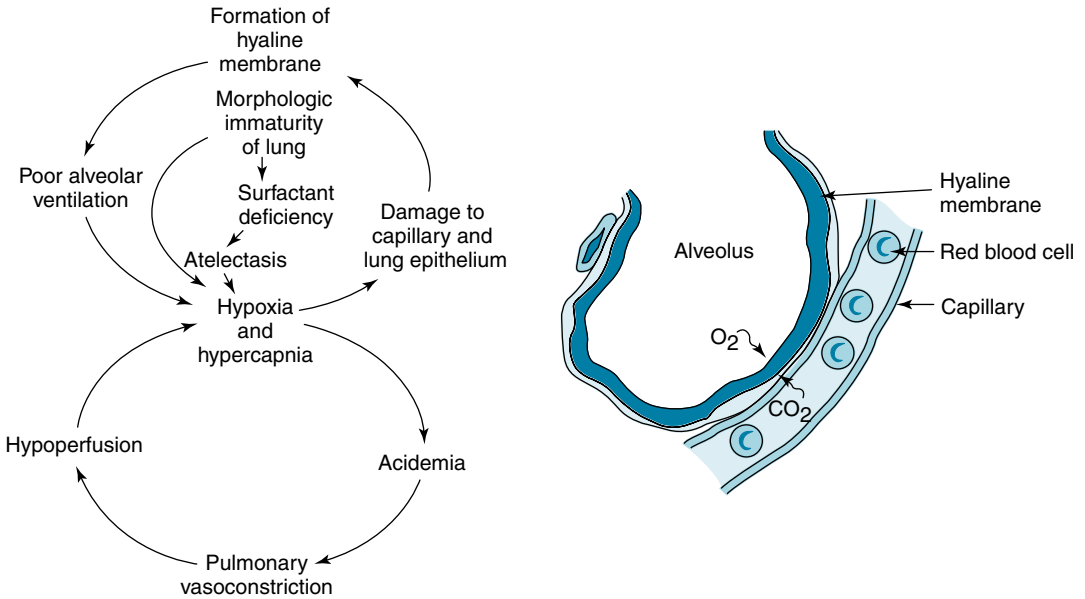

FIGURE 23.4 Interdependent relationship of factors involved in pathology of respiratory distress syndrome. (From Pierog SH, Ferrara A. *Medical Care of the Sick Newborn.* 2nd ed. St Louis, MO: Mosby; 1976.)

39 weeks' gestation (see Chapter 5). Moderately preterm, late-preterm, and term newborns who are monozygotic twins (especially the second-born twin), are of European descent, male sex, delivered by C-section, and with low 5-minute Apgars are at higher risk for developing RDS.[468]

Physical Examination. **Infants with RDS are often tachypneic and demonstrate grunting, nasal flaring, and chest retractions within the first few minutes to hours of life. Pallor or cyanosis also may be present.** The trachea is midline, and the apical pulse is normal. **Auscultation of the chest reveals decreased breath sounds and often rales. Many of these infants may be hypotensive with prolonged capillary refill.**

Laboratory Data. **Chest x-ray findings in RDS include (1) reduced lung volume, (2) air bronchograms, (3) reticulogranularity, and (4) lung opacification.** Surfactant deficiency results in diffuse atelectasis, a reduction in lung volume, and decreased lung expansion as demonstrated on x-ray examination. **Atelectasis increases lung density and results in visible outlines of air-filled bronchi (e.g., air bronchograms) against opaque lung tissue.** Chest x-ray examination also reveals a ground-glass appearance that represents areas of atelectatic respiratory alveoli adjacent to expanded or even hyperexpanded respiratory units. **This bilateral reticulogranular pattern is uniformly distributed throughout the lung fields and may also contain air bronchograms (Fig. 23.6).** Diffuse opacification caused by (1) nonexpanded alveoli with little or no terminal airway aeration, (2) pulmonary edema, or (3) pulmonary hemorrhage results in loss of visible heart borders, with a **"whiteout" appearance on chest x-ray films** (Fig. 23.7). Early radiologic evidence of severe RDS is predictive of nasal CPAP failure, especially ELBW premature infants (<26 weeks' gestation).[500] Lung ultrasound has been shown to have sensitivity (95.6%) and specificity (94.4%) in diagnosing both RDS and TTN.[548]

Arterial blood gases reveal hypoxemia and often acidemia that may be metabolic, respiratory, or a combination of both (see Chapter 8).

A noninvasive surfactant adsorption test (SAT) reliably identifies preterm infants who will fail

CPAP and may be developed into a screening test for surfactant replacement in preterm infants.[25]

Prevention. **A single course of antenatal steroids decreases the incidence and severity of RDS,** comorbid conditions (e.g., NEC, intracranial hemorrhage, CLD), and mortality in infants of less than 32 weeks' gestation. **Very premature infants, as young as 23 weeks' GA, benefit from antenatal steroids.**[529] Even a partial course appears to be beneficial.[372] **For women at risk for late-preterm delivery, antenatal steroids also reduce the risk of RDS.**[205] Between 1993 and 2012, the use of antenatal steroids for women at risk for delivering an extremely preterm infant increased from 24% to 87% in 26 academic centers in the United States.[500]

Before the routine use of NCPAP initially after birth, prophylactic use of surfactant was associated with lower mortality rate, less air leak, and less BPD/CLD than rescue use of surfactant. After routine use of NCPAP, the benefits of prophylactic surfactant were no longer demonstrated.[503]

Treatment

Surfactant Replacement Therapy. Because **surfactant deficiency is the primary abnormality of RDS,** the development of an effective clinical strategy for administering exogenous surface-active material to premature infants was the focus of research efforts for many years. **Administration of surfactant leads to**[118,546]**:**

- **Reduction in surface tension**
- **Dramatic and rapid improvement in gas exchange**
- **Decreased need for high levels of supplemental oxygen and ventilatory support**
- **Less barotrauma**
- **Reduction in air leaks**
- **Improved chest x-ray findings** because of improved lung compliance and lung volume
- **Improvement in perfusion index** after a short decline in first minute (that occurs earlier with beractant compared to poractant); transcutaneous carbon monoxide levels decrease and normalized earlier in poractant[516]
- **Improved survival**

The use of lower levels of ventilatory support decreases the mortality rate and the incidence of pneumothorax. However, surfactant administration does not fully correct lung abnormalities of

the VLBW infant with RDS,[257] nor does surfactant improve short-term outcomes in late-preterm infants with RDS.[118]

Optimal clinical strategies—the type of surfactant to use, the timing and method of administration, the number of doses, and the GA of the neonates—affect surfactant safety, efficacy, and outcomes.

Types of Surfactant. **Both animal-derived and synthetic surfactant are effective in preventing and treating RDS.**[22] A meta-analysis of 16 RCTs comparing animal-derived surfactants found that infants treated with bovine versus porcine surfactant extract had a higher risk of death prior to discharge, death or oxygen requirement at 36 weeks' PMA, PDA requiring treatment, and receiving more than one dose of surfactant.[477] Because these studies used a higher dose of porcine surfactant, it is not clear whether the difference in outcomes are due to the higher dose or the origin of the surfactant. There were no differences in clinical outcomes between the use of bovine lavage or bovine minced surfactant.[477]

Use of animal-derived surfactants entail the risks of infection, immunogenicity, proinflammatory mediators, and variability of concentration of active ingredients in different aliquots. Lucinactant, a synthetic surfactant, is as safe and effective as the natural surfactants without these potential risks (Table 23.14). This synthetic surfactant contains sinapultide, a peptide that mimics surfactant protein B (SP-B) and its effects on lung tissue.[520] Another synthetic surfactant (CHF5633) has been tested in vitro and in vivo and found to be as effective as poractant alfa.[427] The first human study of CHF5633 in 20 preterm infants with RDS receiving 100 mg/kg and 20 infants receiving 200 mg/kg showed tolerance and clinical efficacy; more ongoing RCTs are planned.[507]

Methods of Surfactant Administration. **Numerous methods and outcomes of surfactant administration are compared in** Table 23.15. Even though noninvasive surfactant administration does not use an ETT, the preterm infant must be laryngoscoped for instillation. **A recent study of the use of premedication (i.e., atropine and ketamine) for less-invasive surfactant administration found low pain scores,** stable hemodynamic parameters (i.e., transient increase in heart rate and blood pressure), and more frequent and prolonged oxygen desaturations or apnea requiring intubation.[63]

Even in low- and middle-income countries, surfactant replacement therapy has the potential to reduce air leaks and neonatal mortality in low-resource settings, although the cost effectiveness and incidence of BPD/CLD have not been well studied.[449] **When compared to early NCPAP and selective surfactant use, prophylactic surfactant and rapid extubation to NCPAP are associated with a higher risk of mortality, less BPD/CLD, and higher rates of intubation, surfactant use, and the need for multiple doses of surfactant.**[92,146,436] **When early NCPAP is used**[146,569] **as recommended in the AAP respiratory support and surfactant therapy guidelines,**[14,412] **there is no benefit of the INSURE method of surfactant administration.**

Bolus injection improves the homogenous distribution of surfactant in lungs when compared with slow injection or ultrasonic nebulization.

Aerosolized surfactant therapy may prevent the need for intubation. Pilot studies showing clinical efficacy despite low total administered dose, enhanced pulmonary distribution, and cost effectiveness need to be confirmed in RCTs.[1] In animal studies, intratracheal aerosolized surfactant is as safe as bolus surfactant with the added benefit of more stable cerebral hemodynamics and oxygen metabolism during administration when compared to bolus.[425]

Timing of Administration. **Timing of surfactant may be early (usually defined to be within 30–60 minutes of birth) or late (between 7 and 14 days of life).** Early surfactant administration is associated with less time being mechanically ventilated, longer duration of CPAP, and longer length of stay but is not significantly protective against the development of BPD/CLD or death among treated preterm infants.[415] Another study of early surfactant therapy and NIPPV as the initial respiratory therapy for preterm infants found significantly fewer NIPPV failures, resulting in less use of invasive MV when early surfactant was used.[144] The *Cochrane* review of early (within the first 2 hours of life) versus late selective treatment found benefit for early therapy.[31] **However, for those preterm infants initiated on NCPAP at birth, many do not ever need to be treated with surfactant.**[14,412,569]

The multisite Trial of Late Surfactant (TOLSURF) to assess the effect of late doses of surfactant on BPD in extremely preterm infants (≤28 weeks' GA) who required invasive mechanical ventilation between 7

TABLE 23.14 COMMERCIALLY AVAILABLE SURFACTANTS FOR REPLACEMENT THERAPY

DRUG/SOURCE	INDICATIONS	ADMINISTRATION AND DOSAGE	ADVERSE EVENTS
Beractant* (Survanta) Exogenous surfactant from bovine lung extract	Prophylaxis and treatment ("rescue") of RDS in preterm infants; significantly reduces the incidence of RDS, mortality, and air leak complications[486] Prophylaxis: In preterm infants <1250 g BW or with evidence of surfactant deficiency, give as soon as possible, preferably within 15 min of birth Rescue: To treat infants with RDS confirmed by x-ray examination and requiring mechanical ventilation, given within the first 12 hours after birth[412]	Administration: For intratracheal administration only; instillation through a 5-Fr end-hole catheter inserted into the infant's ETT and/or via a thin catheter during spontaneous breathing or on NCPAP[120,121] above the infant's carina; each dose is 100 mg of phospholipids/kg BW (4 mL/kg; 100 mg/kg); four doses can be administered in the first 48 hr of life; give doses no more frequently than every 12 hr (unless surfactant is being inactivated by blood, meconium, or an infectious process[412]); repeat doses are based on the infant's BW	The most commonly reported adverse experiences are associated with the dosage procedure: transient bradycardia, oxygen desaturation, alterations in BP, drug reflux.
Poractant alpha* (Curosurf) Modified porcine-derived minced lung extract	Prophylaxis and treatment ("rescue") of RDS in preterm infants	For *intratracheal* administration, see above Dosage: *Initial dose:* 2.5 mL/kg divided into aliquots *Subsequent dose:* Up to two doses of 1.25 mL/kg/dose given 12 hr apart, if needed Systematic analysis found higher mortality risk, death or oxygen requirement at 36 weeks' PMA; PDA requiring treatment and receiving more than 1 dose when beractant compared to poractant[477]	As for beractant
Calfactant* (Infasurf) Natural surfactant extracted from calf lung lavage	Prophylaxis and treatment ("rescue") of RDS in preterm infants	Administration: For *intratracheal* administration, see above Dosage: *Initial dose:* 3 mL/kg (105 mg/kg) divided into two aliquots *Subsequent dose:* Up to three doses of 3 mL/kg/dose given 12 hr apart, if needed	As for beractant
Lucinactant (Surfaxin) Synthetic surfactant containing sinapultide, a peptide that mimics surfactant protein B (SP-B)	Prophylaxis and treatment ("rescue") of RDS in preterm infants	For *intratracheal* administration, see procedure for beractant Dosage: *Initial dose:* 5.8 mL/kg (175 mg/kg) dosing q 6 hr based on clinical response Gels when stored at 4° C; requires up to 15 min of warming at 44° C in a heating block to liquefy; rapidly cools to body temperature when removed from heating block	As for beractant

*Use of bovine and porcine products may be objectionable to persons of Jewish, Islamic, and/or Hindu beliefs; informed consent from parents is essential.

TABLE 23.15 INVASIVE AND NONINVASIVE METHODS OF SURFACTANT ADMINISTRATION

METHOD	DEFINITION	RESEARCH EVIDENCE
Invasive:		
INSURE	**I**ntubation- **SUR**factant-**E**xtubation	Early INSURE and NCPAP after birth decreased the need for MV and decreased the incidence of air leak. No difference in death, BPD/CLD, or need for MV among preterm infants (27–34 weeks' GA) randomized to NCPAP or INSURE and NCPAP.[365]
IN-REC-SUR-E	**IN**tubate-**REC**ruit-**SUR**factant-**E**xtubate	Comparison of lung recruitment with HFOV prior to surfactant versus INSURE alone in spontaneously breathing preterm infants requiring NCPAP as initial respiratory support/reaching CPAP failure is being studied.[544]
Noninvasive LIST	**L**ess **I**nvasive **S**urfactant **T**herapy	

LISA	**L**ess **I**nvasive **S**urfactant **A**dministration (thin endotracheal catheter placed during spontaneous breathing and surfactant instilled.)	LISA/LIST vs INSURE:
		• Less intubation and MV[†]
		• Both increase MAP during administration. Transient change in cerebral autoregulation (oxygenation and BP) with surfactant administration[53,316]:
		  • Less than 5 minutes with LISA and 5–10 minutes with INSURE[316]
		  • Higher decrease in cerebral oxygenation with LISA accompanied by an increase in cerebral fractional oxygen extraction rate that suggests a compensatory mechanism.[53]
		• Shorter duration of MV[281,301*]
		• Shorter duration of NCPAP[281,301*]
		• Shorter duration of oxygen supplementation[301*]
		• Decreases the risk of death, of death or BPD/CLD,[‡] and of CPAP failure[429*]
		• Less incidence of pneumothorax[282]; no significant difference in incidence of pnemothorax[301*]
		• Less IVH[550] and less severe IVH[238*,282]
		• No difference in rate of MV in first 72 hours[35]
		• No difference in mean duration of oxygen requirement between groups[35]
		• No difference in death,[301*] BPD/ CLD, IVH, ROP, NEC, or duration of respiratory support[35,581*]
		• Lacks long-term follow-up[429*]
		LISA vs INTUBATION and MV[298]:
		• Significantly less MV, days with supplemental oxygen, and rates of BPD/CLD
		• Less use of analgesics and sedatives

MIST	Minimally Invasive Surfactant Therapy (orogastric tube used for tracheal catheterization to deliver surfactant)	Comparison of MIST and historical cohort of INSURE administration of surfactant: • No differences in intubation and MV, morbidity/mortality rates. Duration of MV and CPAP significantly shorter in MIST group.[524] • Rapid increase in end-expiratory volume in dependent, then independent pulmonary regions within 5 minutes and oxygenation improved within 1 hour of instillation[538] • Significant reduction in MV and pneumothoraces among moderate and late-preterm infants with RDS[385]
CALMEST	Catheter And Laryngeal Mask Endotracheal Surfactant Therapy	On mannequin and in vivo pilot trial that was quick, effective, and with less neonatal stress; alternative approach for staff with low expertise in laryngoscopy and intubation[541]

*Systematic review.

BOX 23.15 RECOMMENDATIONS FOR SURFACTANT REPLACEMENT THERAPY[412]

- Initiate NCPAP at birth as an alternative to routine intubation and early/prophylactic surfactant therapy.[14]
- Combine early NCPAP with selective surfactant therapy in extremely preterm infants.[14]
- Use less invasive surfactant administration (LISA) for preterm infants (<33 weeks' gestation) that lowers the risk of mortality, BPD, and severe intraventricular hemorrhage when compared to mechanical ventilation and a lower incidence of mortality, death, and air leaks when compared to NCPAP alone.[238]
- Preterm infants <30 weeks' gestation who require mechanical ventilation for severe RDS should be given surfactant after initial stabilization.
- Rescue surfactant may be considered when respiratory failure is due to secondary surfactant deficiency occurring with meconium aspiration syndrome, sepsis, pneumonia, or pulmonary hemorrhage.
- Nursery and transport professionals with experience in administering surfactant and managing multisystem illness should care for preterm and term neonates receiving surfactant.
- Providers inexperienced with surfactant administration and managing multisystem illness should wait for transport team to arrive.

BOX 23.16 TREATMENT FOR RESPIRATORY DISTRESS SYNDROME

1. Reducing hypoxemia (see General Treatment Strategies in this chapter and in Chapter 8)
   a. Maintain in thermoneutral environment (see Chapter 6)
   b. Maintain blood pressure and hematocrit (see Chapters 5 and 20)
   c. Decrease stimuli from the neonatal intensive care environment (see Chapter 13)
   d. Recognize and relieve pain or agitation (see Chapter 12)
2. Correcting acidemia (see Chapter 8)
3. Increasing the functional residual capacity (see General Treatment Strategies)
   a. Maintain appropriate temperature (see Chapter 6)
   b. Monitor vital signs and arterial blood gases (see Chapters 7 and 8)
   c. Provide appropriate fluid, electrolytes, glucose, and calories (see Unit Three)
   d. Observe for complications of disease and treatments (see General Complications)
4. Monitoring for complications (see Acute Complications and Chronic Complications under General Complications)
5. Caring for parents (see Chapters 29, 30, and 32)
6. Preparing for discharge and follow-up care (see Chapter 31)

and 14 days of age and were receiving iNO therapy found no difference in survival without BPD at 36 or 40 weeks' PMA when these neonates received as many as five doses of late surfactant.[34] A French study in 13 level III perinatal centers also found that late surfactant therapy did not alter the course of BPD/CLD but did result in less respiratory morbidity in the first year of life.[215] Two follow-up studies of the TOLSURF group found that rising mean airway pressure (MAP) is a marker for prolonged ventilation and need for tracheotomy and a lower incidence of the use of home respiratory equipment and better respiratory outcomes at 1 year corrected age.[262,553]

Methods of resuscitation, types of ventilators (NCPAP vs. CMV vs. HFOV), and ventilation style (e.g., **as few as six large tidal volume breaths in a surfactant-deficient lung causes lung injury)**[237] also contribute to lung injury resulting in BPD/CLD. **Use of noninvasive ventilation strategies benefits the preterm lung by optimizing pulmonary mechanics, improving gaseous exchange, and reducing metabolic demands.**[7] The first study of SNIPPV as the primary method of respiratory support for RDS compared the outcomes of 600 to 1250 g preterms who were randomized to CMV or SNIPPV after their initial dose of surfactant.[54] Only 20% of the preterms receiving SNIPPV versus 52% receiving CMV had the primary outcome of BPD/CLD/death, with no difference in the groups on mental/psychomotor indices.[54]

Recommendations for surfactant replacement therapy for RDS are outlined in Box 23.15. **Other treatment for RDS is directed toward the indications in** Box 23.16.

Inositol Therapy. Inositol, an essential nutrient, promotes maturation of several components of surfactant. A systematic review of inositol supplementation for RDS found significant reductions in (1) mortality, (2) ROP, and (3) >grade II IVH with no increase in sepsis or NEC but no significant reduction in BPD/CLD.[231] A large multicenter RCT of multiple dose myo-inositol given to preterm infants of 29 weeks' or earlier GA found that at 80 mg/kg/day

there were no adverse side effects, previously effective serum levels were obtained, and that a phase III trial is warrented.[405]

Inhaled Nitric Oxide Therapy. **Inhaled nitric oxide (iNO) therapy is not only a selective pulmonary vasodilator but also improves oxygenation by redirecting blood from poorly aerated (atelectatic) and diseased lung (with RDS) regions to better aerated distal air spaces.**[271] Early RCTs of iNO in late-preterm infants found improved oxygenation, decreased need for mechanical ventilation, improved survival without increase in IVH, and a trend toward a decrease in CLD/BPD.[373] Recent meta-analysis,[41] NIH Consensus panel,[99] and AAP clinical report[286] on use of iNO in preterm infants found no improvement in (1) survival of preterms with respiratory failure, (2) incidence of BPD/CLD, (3) severe IVH, (4) neurodevelopmental outcomes,[147] or (5) pulmonary outcomes.[286] **Therefore inhaled nitric oxide is not recommended for use in preterm infants** (see Table 23.21). However iNO continues to be used in an off-label fashion with a reported increase of 23% in 23 to 29 week preterm infants from 2009 to 2013 with an expenditure of $153 million for preterms under 34 weeks' GA in the United States.[156] This off-label use is not associated with a reduction in mortality among extremely premature neonates with RDS.[74]

PULMONARY INSUFFICIENCY OF THE NEWBORN

Pulmonary insufficiency continues to be a diagnosis used in term newborns demonstrating respiratory symptoms soon after delivery. This condition was first described as the insufficiency of gas exchange commonly caused by atelectasis of the lung, congenital abnormalities, and in infants with aspiration syndrome.[51]

Pathophysiology. This is a **condition of term infants and consists of the insufficiency of gas exchange secondary to atelectasis, congenital anomalies, or aspiration syndrome.**

Etiology. **These infants are often term or near term and born with adequate respiratory effort.** Within minutes to a few hours after delivery, they decline, requiring supplemental oxygen support.

Data Collection

History. **Late preterm or term infants who usually start with normal Apgar scores and then decline within minutes to a few hours after delivery.**

Physical Examination. Evidence for respiratory distress may be seen, including tachypnea, mild retractions, grunting, and flaring. Cyanosis in room air also may be present.

Laboratory Data. **Mild hypoxemia (requiring less than 40% oxygen) and mild acidemia are usually present.**

Treatment. In general, **support of the neonate with pulmonary insufficiency requires only the provision of sufficient supplemental oxygen to maintain an arterial oxygen tension of more than 70 to 80 mm Hg and maintenance of usual supportive neonatal care.** These infants are often discharged on low-flow oxygen until respiratory status improves.

TRANSIENT TACHYPNEA OF THE NEWBORN (RESPIRATORY DISTRESS SYNDROME TYPE 2)

Pathophysiology. **TTN is the result of delayed reabsorption of normal lung fluid, and thus an alternative name is *wet lung syndrome,* or *RDS type 2.*** Lung fluid accumulates in the peribronchiolar lymphatics and the bronchovascular spaces. **Thus TTN is an "obstructive" lung disease, whereas RDS is a "restrictive" lung disease.** Abnormalities in lung function of neonates with TTN include high total ventilation, high breathing frequency, low tidal volume, high dead space, prolonged nitrogen clearance, and low dynamic compliance. Reabsorption of lung fluid occurs by the following: (1) lung liquid production slows; (2) pulmonary epithelium changes from chloride-secreting to sodium-absorbing barrier; (3) air intake at birth shifts fluid from alveoli to interstitium and perivascular spaces; and (4) a higher protein content and osmotic pressure of blood/lymph facilitates flow of lung fluid.

Etiology. **TTN generally occurs in term or late-preterm infants with a history of cesarean section (especially elective section in the late-preterm infant**—see Chapter 5), low Apgar

scores, pulmonary artery hypertension, poor left ventricular function, lower umbilical artery pH (less than 7.25), vitamin D deficiency, higher/lower TSH levels depending on GA, and precipitous delivery.[32,135,259,387] **In these situations, there is a lack of the gradual compression of the chest that eliminates some fluid during a normal vaginal delivery.** Accumulation of interstitial fluid interferes with the forces that hold the bronchioli open, causing collapse and air trapping. In term infants with TTN, decreased surfactant function may also contribute to TTN, as well as a prolonged course.[329]

Prevention. Two recent RCTs of late-preterm and term neonates randomized to free flow oxygen or **20 minutes of facemask CPAP after C-section delivery showed a shorter duration and severity of TTN in the CPAP group.**[78,390] There also were fewer admissions to the NICU, less mechanical ventilation, and higher plasma B-type natriuretic peptide that correlated with the duration of tachypnea and the length of stay in the CPAP group.[78,390]

Data Collection

History. Term or late-preterm male infants with a history of cesarean section, precipitous delivery, prenatal exposure to methamphetamine, or other abnormalities of labor and transition are predisposed to TTN.[135] **Onset is usually 2 to 6 hours after birth. At initial presentation, TTN has a similar presentation as pneumonia.** However, the presence of perinatal infectious agents is more common in pneumonia and the course of pneumonia is for a longer period and with more support (i.e., oxygen and ventilation).[108]

Physical Examination. **Evidence for respiratory distress, including tachypnea, mild retractions, grunting, and flaring, may be seen. Cyanosis in room air also may be present.**

Laboratory Data. **Mild hypoxemia (requiring less than 40% oxygen) and mild acidemia are usually present.** A significant degree of hypoxemia or acidemia tends to constrict the pulmonary vasculature and aggravate the problem. Lower umbilical cord levels of cortisol, adrenocorticotropic hormone, and free triiodothyronine, as well as a higher epinephrine level, have been found in neonates developing TTN who were delivered by cesarean section.[24]

Chest x-ray examination reveals hyperexpansion with streaky infiltrates radiating from the hilum. These infiltrates are thought to represent interstitial fluid along the bronchovascular spaces. Air trapping causes the appearance of mild to moderate hyperaeration or inflation on the chest radiograph. Visible fluid in the pulmonary fissures and cardiomegaly also may be seen on chest radiograph.

Echocardiography may also be necessary because significantly more newborns with TTN have been found to also have structural cardiac lesions.[368]

Use of **lung ultrasonography** in infants with TTN shows pulmonary edema, alveolar-interstitial syndrome, "white lung," and the presence of comet-tail artifacts ("double lung point") in the inferior lung fields.[323] Lung ultrasound shows a high sensitivity (95.6%) and specificity (96.5%) in diagnosing TTN and RDS,[548] with no increased risk for pulmonary hemorrhage.[240] Fetal pulmonary artery Doppler acceleration to ejection time (PATET) is a noninvasive test to rule out the subsequent diagnosis of TTN.[69] A significantly lower fetal PATET ratio is indicative of TTN in the subsequently born neonate.

Treatment. In general, **support of the neonate with TTN requires only provision of sufficient supplemental oxygen to maintain an arterial oxygen tension of more than 70 to 80 mm Hg and maintenance of usual supportive neonatal care.** Usually little more than general support is necessary while the normal absorption of lung fluid through the lymphatics takes place. **As the lung fluid clears, both the x-ray abnormalities and clinical presentation resolve within 72 hours.** Use of the nasal route for CPAP or mechanical ventilation is well tolerated and effective.[132]

Although diuretic agents have been advocated, a recent *Cochrane* systematic review found no benefit and recommends against use of oral or intravenous diuretics, including furosemide for treatment of TTN.[255] Use of empiric antibiotics in infants with TTN who do not have risk factors for infection is not warranted.[130] In one study, fluid restriction for infants with TTN was safe and resulted in a shorter duration of respiratory support.[131] One small study of 40 neonates with TTN found a shorter duration of supplemental oxygen and use of empiric antibiotics with inhaled albuterol therapy, with no adverse effects.[270] Inhaled racemic

epinephrine,[354] salbutamol[353] and early inhaled corticosteroids in late-preterm and term newborns have no effect on the clinical course of TTN.[536]

Complications. TTN is independently and significantly associated with the development of childhood wheezing and asthma, especially in male infants.[188]

MECONIUM ASPIRATION SYNDROME

Pathophysiology. Before meconium aspiration can occur, meconium must find its way into the amniotic fluid. A hypoxic event before birth stimulates intestinal peristalsis and relaxation of the anal sphincter. **Colonic peristalsis ensues, resulting in the expelling of meconium into the amniotic fluid and, in severe cases, gasping in utero that leads to meconium aspiration. Respirations after birth draw meconium first into major airways and, subsequently, into the smaller airways, causing obstruction, atelectasis, air trapping, and pneumothorax. Meconium can also cause chemical pneumonitis and inactivation of surfactant,** further impairing gas exchange and potentiating barotrauma. **This condition occurs more often in term or postterm infants when a hypoxic episode is experienced in utero.**[543] These movements open the glottis so that meconium flows into the oropharynx and on into the lung. Thus the pathophysiology of lung disease in meconium aspiration syndrome (MAS) is related to the mechanisms causing fetal stress and the direct adverse effects of meconium in the lung. MAS is a common reason for lung disease in neonates.

Etiology. Meconium aspiration produces disease by several mechanisms: (1) meconium physically obstructs the glottis, trachea, or any number of smaller airways, resulting in atelectasis, air trapping, alveolar collapse, and ventilation-perfusion mismatching; (2) it promotes an inflammatory response known as *chemical pneumonitis;* (3) it contains increased levels of secreted phospholipase A_2 that promote inflammation[438]; (4) it inhibits surfactant function; and (5) it increases PVR, caused by asphyxial episodes, resulting in increased right-to-left shunting and the development of PPHN (Fig. 23.8).[177] While the incidence of being born through meconium-stained amniotic fluid varies from 7.93%[169] to 9.2%,[309] the incidence of developing MAS also varies from 0.067%[169] to 10.2 %.[309]

Prevention. Before an infant is born, meconium aspiration may be prevented by early recognition of the compromised fetus, elective induction for pregnancy at 41 weeks' gestation or later, aggressive management of abnormal fetal heart rate patterns, and fewer infants with low Apgar scores.[505] Amnioinfusion is associated with improvements in perinatal outcomes only in settings where facilities for surveillance are limited; in settings with standard perinatal surveillance, amnioinfusion is either ineffective or masked by other strategies to optimize perinatal outcomes.[228]

A large multicenter (12-hospital) RCT of intrapartum oropharyngeal or nasopharyngeal suctioning for term infants born through meconium-stained amniotic fluid showed **no significant difference in the incidence of MAS (e.g., 4% for both the suction and the no-suction group),** the need for mechanical ventilation, mortality rate, duration of oxygen use, days of ventilation, and length of stay.[535] The study's conclusion that routine suctioning does not prevent MAS (confirmed in more recent studies)[86,551,561] has resulted in revision of present recommendations for care of these infants (see Chapter 4). **Routine tracheal suction is no longer recommended for nonvigorous or depressed infants (e.g., nonvigorous infants with depressed tone and respirations and/or heart rate less than 100 beats/min).**[81,366,561] An interdisciplinary health care team for "rapid response" prepared and credentialed (e.g., NRP) for management of the neonate born through meconium-stained amniotic fluid, coupled with interdisciplinary postnatal assessment, observation, and prompt treatment, is recommended for prevention of MAS and its associated morbidity and mortality risks.

Use of orogastric suctioning and chest physiotherapy to prevent MAS is not supported by evidence from any studies.

Data Collection

History. A history of asphyxia, IUGR, postterm delivery, caesarean delivery, meconium-stained amniotic fluid, thick meconium, nonreassuring fetal heart tracing, fetal tachycardia, intrapartal maternal fever, low Apgar scores (≤3 at 1 minute;

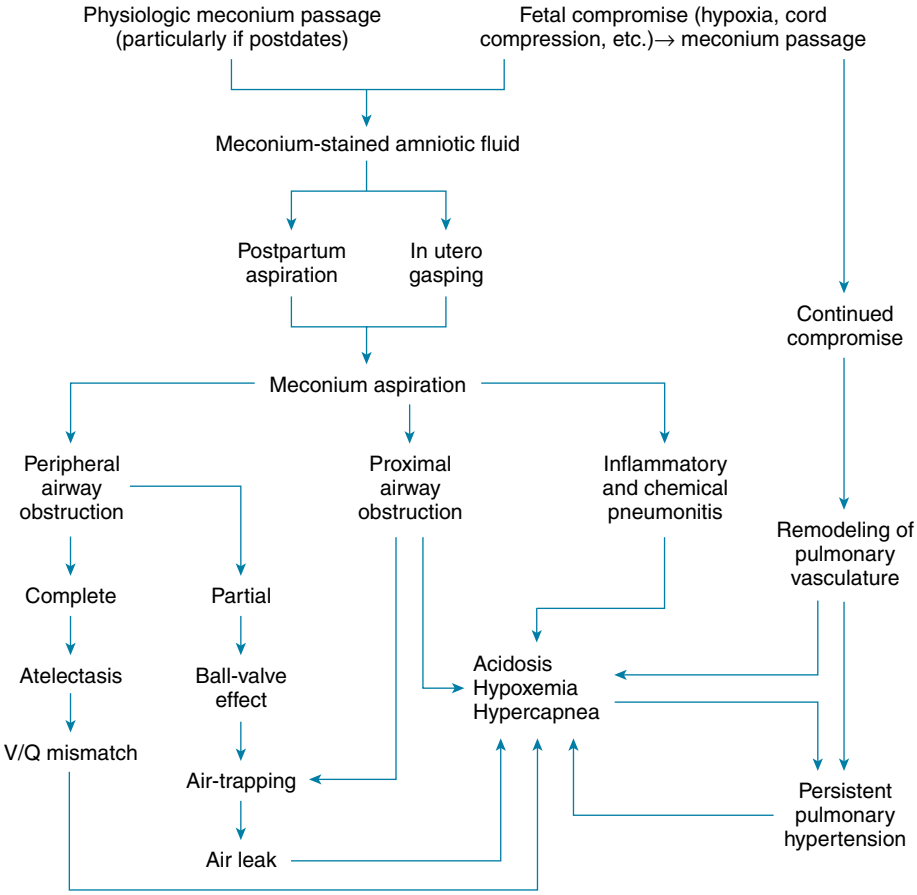

FIGURE 23.8 Pathophysiology of meconium passage and the meconium aspiration syndrome. *V/Q*, Ventilation-perfusion. (From Wiswell T, Bent R. Meconium staining and the meconium aspiration syndrome: unresolved issues. *Pediatr Clin North Am.* 1993;40[5]:957.)

<5 at 5 minutes), need for endotracheal intubation at birth, and African American race may be present.[144,169,384,479] **There is a positive association between chorioamnionitis, funisitis, or infection with the passage of meconium at term gestation and the severity of MAS.**[269,309] Maternal risk factors associated with placental insufficiency (e.g., hypertension, pregnancy-induced hypertension, chronic respiratory/cardiovascular disease, diabetes, IUGR, heavy cigarette smoking, drug use, and postterm pregnancy) may also lead to fetal asphyxia and meconium passage.[568]

Physical Examination. **Tachypnea, rales, and cyanosis are seen in mild cases.** Respiratory distress occurs in 33.4% of infants born through meconium-stained amniotic fluid, and 25.9% are MAS.[479] Respiratory distress occurs within 12 hours in 97.9% and is severe in 21.7% of cases.[479] **In moderately severe cases, grunting, retractions, and nasal flaring also may be seen. In severe cases, the infant is asphyxiated and severely depressed at birth. There is profound cyanosis and pallor, irregular gasping respirations, and an increased anteroposterior diameter of the chest (a barrel chest) as a result of gas trapping and alveolar overdistention.**

Laboratory Data. **The chest x-ray examination shows marked air trapping, hyperexpansion, and hyperinflation. There are bilateral, diffuse, coarse, patchy infiltrates** (Fig. 23.9). **Complete occlusion by debris results in atelectatic areas. Air leaks are frequently seen.** Pleural effusion may

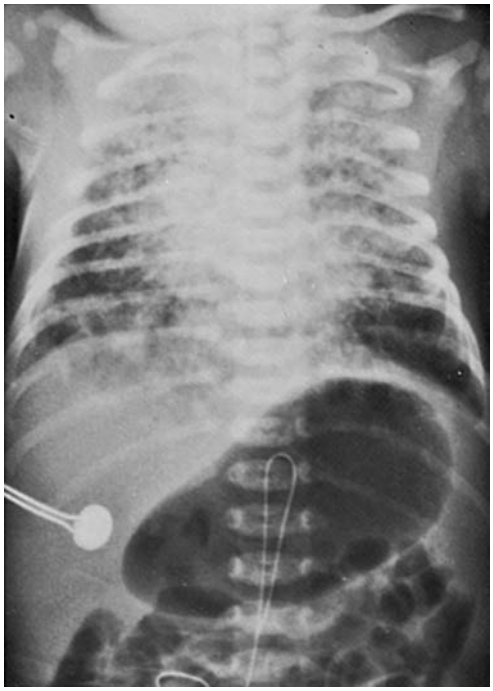

FIGURE 23.9 Chest x-ray film of infant with meconium aspiration. Note diffuse infiltrates.

occur as a result of the inflammatory process in the lung. Cardiomegaly may be present; this results from intrauterine asphyxia or cardiac hypoxia.

Severe hypoxemia and hypercapnia as a result of ventilation-perfusion mismatching and right-to-left shunting caused by pulmonary hypertension are present. Severe acidosis usually is combined respiratory and metabolic acidosis. A retrospective analysis of the inflammatory markers in 239 infants with MAS (without early onset sepsis) found a correlation between elevated C-reactive protein (CRP) levels and immature-to-total neutrophil ration (IT-ratio) with low white blood count (WBC) and absolute neutrophil count (ANC) and the severity of MAS.[226]

Lung ultrasonography findings in MAS include: (1) pulmonary consolidation with air bronchogram (100% of newborns), (2) alveolar-interstitial syndrome (100%), (3) pleural line anomalies and disappearance of A-line (100%), (4) severe massive atelectasis (16.2%), and (5) pleural effusion (13.7%).[322]

Treatment. **Hypoxemia is the major problem in meconium aspiration, and treatment should be directed at improving oxygenation.** Mildly affected infants will frequently require only warmed, humidified oxygen by hood. **Increasing severity of meconium aspiration will require increased levels of intervention. The need for surfactant therapy (see later) is a predictor of the severity of MAS.**[384] About 30% to 50% of infants with MAS require CPAP or mechanical ventilation.[120] **Some infants respond to CPAP (4 to 6 cm H_2O), but others require full ventilator support.** Use of bubble NCPAP as a primary respiratory therapy for MAS versus standard care was recently studied in an RCT of 67 neonates over 34 weeks' gestation. **Bubble NCPAP reduced the need for mechanical ventilation in the first 7 days of life in infants with MAS,** but there was no difference in the incidence of PPHN or length of stay between the two groups.[392]

Because these infants are usually term or postterm, they resist assisted ventilation and may require paralyzation (Table 23.16), sedation, and/or analgesia (see Chapter 12) to ventilate and oxygenate the lungs adequately. With paralysis, these infants may require rapid rates, high peak inspiratory pressure, and PEEP for adequate oxygenation and ventilation. Although the majority of MAS infants are able to be treated with CPAP and CMV, use of other treatment modalities (e.g., HFV, iNO, ECMO/ECLS) may become necessary with accompanying PPHN and severe respiratory failure.[120] **When using CMV to ventilate infants with MAS, a higher tidal volume (26% higher) and a higher minute ventilation (42% higher) are necessary to achieve similar alveolar ventilation.**[467] **Early use of HFOV with surfactant therapy results in significant reduction in the duration of oxygen supplementation and mechanical ventilation and reduced length of stay** when compared to CMV or HFOV alone.[88]

Meconium in the lung inhibits surfactant function in a dose-dependent manner. To decrease surfactant inactivation in MAS, the following is recommended: (1) aspirate meconium from the airway and lungs to decrease the amount that interacts with surfactant in the alveoli, (2) provide surfactant replacement at a sufficient dose to replace inactivated endogenous surfactant and repeat as necessary, and (3) combine surfactant replacement with antiinflammatory drugs to reduce meconium-induced inflammation.[350,351] Studies of

TABLE 23.16 DRUGS FOR PARALYZATION

DRUG	DOSAGE	COMMENTS
Pancuronium (Pavulon)	Give a test dose of 0.02 mg/kg IV to measure responsiveness 0.1 mg/kg IV push (0.04-0.15 mg/kg) q 1-2 hr based on duration of paralysis Onset: 1-2 min	*Indications:* paralysis for mechanical ventilation to improve oxygenation/ventilation; reduce barotrauma and alteration in cerebral blood flow Although paralyzed, neonate still feels pain—analgesia necessary for painful procedures and to accompany paralysis (see Chapter 12) *Adverse effects:* corneal drying (lubricate eyes); tachycardia; increased salivation; blood pressure changes (hypotension and hypertension) Reversed by: Neostigmine: 0.04-0.08 mg/kg IV Atropine: 0.02 mg/kg
Vecuronium	0.1 mg/kg IV push (0.03-0.15 mg/kg) q 1-2 hr based on duration of paralysis Onset: 1-2 min	*Indications:* same as above *Adverse effects:* corneal drying (lubricate eyes); decreases in heart rate and blood pressure when used with narcotics; special sensitivity in preterms (that diminishes with age); duration of effect prolonged in preterms *Reversed by:* same as above

surfactant replacement to infants with MAS suggest improvement in some neonates with severe respiratory failure and MAS. Improved oxygenation/ventilation, decreased severity of respiratory compromise, no increase in air leaks, and less use of ECMO have been observed in some studies.[158] Variable study results of surfactant use in MAS may result from timing, type, amount, and method of surfactant administration. Animal studies of surfactant replacement in MAS show that a combination of glucocorticoid and surfactant therapies improved gaseous exchange and lasted longer than surfactant alone.[346] A recent study of controlled hypothermia in 10 asphyxiated newborns with/without MAS found improved surfactant function after 48 to 72 hours of whole-body cooling that persisted for 6 hours after rewarming.[26]

Surfactant lavage has been shown to result in (1) improved oxygenation/ventilation and pulmonary function measurements (e.g., increased lung compliance and decrease in airway resistance), (2) earlier weaning from assisted ventilation, (3) need for less oxygen, (4) less mortality and use of ECMO, and (5) more rapid weaning of mean airway pressure.[122,279] Recovery of lung lavage fluid is associated with lower MAP at 24 hours and shorter duration of respiratory support and should be a priority in the lavage procedure.[123] **Complications of lung lavage include hypoxemia (transient or severe) and no alterations in heart rate and blood pressure or systemic hypotension.**[122] A systematic review of surfactant lung lavage and bolus surfactant found a shorter length of stay and duration of mechanical ventilation, and bolus surfactant reduced the need for ECMO, but there was no reduced risk of mortality.[371] **Surfactant lavage remains an experimental therapy.**

Mucosal irritation and increased mucosal secretion hamper respiratory and mucociliary clearance efforts. **Frequent pulmonary hygiene (every 2 to 3 hours)** may help alleviate this problem.

Antibiotic use in MAS shows no clinical benefits and no evidence of sepsis in neonates with MAS; the small number of studies and number of subjects necessitates more evidence about the efficacy and cost-effectiveness of antibiotics (and surfactant) to treat MAS.[371] The latest *Cochrane* review found **no difference in infection rates of infants who were born through meconium-stained amniotic fluid and those with MAS occurring in neonates with or without antibiotics.**[264]

As with any sick infant, close attention must be given to physiologic support and homeostasis. (See General Treatment Strategies earlier in this chapter; see also Chapters 6, 7, and 8 and Unit Three.)

Complications. Use of new treatments has decreased the mortality rate to less than 5%.[543] **Persistent pulmonary hypertension frequently complicates MAS, potentiates the difficulties in**

oxygenation, and contributes to a large portion of the mortality associated with MAS.[177] Air leaks are complications of both the disease (ball-valve obstruction causing air trapping) and the treatment. Infants with MAS are at increased risk for adverse neurologic outcomes (e.g., CP and global delays)[49] and long-term pulmonary problems (e.g., increased airway reactivity, abnormal pulmonary function).[589] A recent study found elevated aspartate aminotransferase levels in infants with MAS at birth who eventually have poor neurodevelopmental outcomes.[85] These researchers recommend early intervention to improve the neurodevelopmental outcomes of those MAS infants with high levels of aspartate aminotransferase at birth.[85]

NEONATAL PNEUMONIA

Neonatal pneumonia occurs perinatally or postnatally in about 1% of term neonates and 10% of preterm neonates and may be as high as 28% for ventilated ELBW infants in the NICU.[50] **Neonates requiring prolonged hospitalization in the NICU are at risk for developing pneumonia from nosocomially acquired organisms.** The organisms most often causing neonatal pneumonia are mainly group B streptococci and gram-negative organisms (e.g., *Escherichia coli, Klebsiella, Pseudomonas,* and *Serratia marcescens*) but also include *Staphylococcus aureus, Staphylococcus epidermidis, Streptococcus pneumoniae,* and *Candida*. Less commonly acquired viral infections include herpes, cytomegalovirus, varicella-zoster, and syphilis. Community-acquired viral infections also occur in the NICU setting and include respiratory syncytial virus, enterovirus, adenovirus, and parainfluenza virus infections (see Table 23.16).[50]

Pathophysiology. In bacterial pneumonia, alveoli are often more edematous and inflamed than in viral infections. Protein-rich fluid may partially or completely fill the alveoli. Reduced pulmonary compliance during neonatal pneumonia is due to an increase in surfactant proteins that resolves with the resolution of the pneumonia.[116] This is often followed by an influx of polymorphonuclear leukocytes and red blood cells. Macrophages enter the alveoli and remove intraalveolar debris, restoring normal lung functioning. *S. aureus* and *Klebsiella* organisms often cause severe damage to alveoli and destroy lung tissue by causing necrosis of the septum between the alveoli. In some cases, abscesses form.

Viruses and *Mycoplasma* organisms may also be acquired transplacentally, during the delivery, or postnatally. Viral and mycoplasmal pneumonias commonly involve the bronchi and peribronchial interstitium more often than the alveoli. Viral and mycoplasmal organisms cause loss of epithelial ciliary appendages and sloughing into the airways. This results in stasis of mucus and secretions and bronchial obstruction with atelectasis. A secondary inflammatory response is characterized by mononuclear infiltration into the submucosa and perivascular areas causing narrowing of the airway lumen. Another response to this inflammatory process is smooth muscle constriction, which leads to increased airway obstruction and bronchospasm. In severe cases of viral and mycoplasmal infection, the inflammatory process involves the alveoli.

Fungal infections, the most common being *Candida* infection, may be acquired in utero, during the birth process, or in the postnatal period. Congenitally acquired pneumonia can be diffuse, resulting from the inflammatory process at birth. *Candida* often invades the pharynx and larynx and may produce a thick layer of hyphae that lines the upper and lower respiratory tract. Ulceration of the pharynx, larynx, and the lower respiratory tract can occur.

Etiology. Predisposing factors that lead to the development of neonatal infections and pneumonia include the immaturity of the immune system, colonization of the mother's genital and vaginal tracts with pathogens, amnionitis, prolonged rupture of membranes, prematurity requiring intubation and assisted ventilation, and nosocomial infections acquired in the NICU.[50] Bacterial pneumonia can be secondary to the spread of pathogens from the mother to the baby in utero.[108] Pneumonia acquired in utero often leads to stillbirth and premature delivery.

Neonates who require NICU care are at particularly high risk for colonization of their upper respiratory tract with pathogenic organisms and the passage of pathogens from caregivers or contaminated equipment.[80] *Ventilator-associated pneumonia* (VAP), a nosocomial-acquired infection in a neonate who has been ventilated for longer than 48 hours, occurs from 1.4 to 7 episodes per 1000 ventilator days in developed countries to 16

to 89 episodes per 1000 ventilator days in developing countries.[80] **Risk factors for VAP include (1) prematurity, (2) LBW/VLBW/ELBW, (3) reintubation, (4) use of sedatives, (5) use of TPN, and (5) prolonged duration of mechanical ventilation resulting in an ETT biofilm.**[50,80,310,391,518] Most causative agents of VAP are gram-negative bacteria (i.e., *E. coli, Klebsiella,* and *Pseudomonas*), followed by gram-positive organisms (i.e., *S. aureus*) and fungi (i.e., candida).[391]

Prevention. Prevention **begins with identifying mothers at risk for infection** (e.g., group B *Streptococcus* [GBS], herpes, chlamydial infection, syphilis, gonorrhea); **early management of infections with antibiotic therapy; meticulous equipment disinfection and hand hygiene practices** (handwashing/alcohol-based hand sanitizers) by health care providers in the NICU[435]; and **restricting the entry of *anyone* with respiratory infections into the NICU** (see Chapter 22).

Rapid extubation and use of noninvasive ventilator strategies prevent and reduce the incidence of VAP.[80] **Prophylactic use of probiotics prevents sepsis in the NICU**[259] **and may also prevent neonatal VAP.**[80] An RCT of 60 intubated infants (half in supine position and the other half in side-lying) investigated whether positioning would decrease VAP. Despite no significant difference in the number of positive tracheal cultures after 2 days, **after 5 days cultures were positive in 87% of the supine versus 30% of the side-lying group.**[10] In developing countries, initiation of multidimensional infection control strategies has resulted in reduction of VAP rates.[439] **Adaptation of adult practices to prevent VAP into an evidence-based neonatal VAP bundle in one tertiary center reduced the incidence of VAP** over a 4-year period, including a zero incidence over a 20-month period.[560] Elements of the evidence-based bundle included: (1) hand hygiene, (2) intubation, (3) feeding, (4) suctioning, (5) positioning, (6) oral care, and (7) respiratory care equipment.[560]

Data Collection

History. The clinical presentation of neonatal pneumonia varies depending on the infecting organism and the incidence of acquisition. **Acute respiratory distress** is frequently seen in intrauterine and intrapartally acquired secondary infections. Neonates with pneumonia often have a history of low Apgar scores, temperature instability, and poor tone and activity. **The clinical signs and symptoms of pneumonia are similar to those of respiratory distress, TTN (RDS type II)/retained lung fluid, or sepsis.** Late-acquired pneumonia may have a gradual or abrupt onset, depending on the organism. Infants with chlamydial pneumonia frequently present with a characteristic staccato cough.

Physical Examination. The infant with pneumonia often presents with respiratory distress (e.g., tachypnea, low pulse oximetry readings, respiratory deterioration, apnea, temperature instability, hypoglycemia). **The signs and symptoms of pneumonia often are nonspecific and difficult to differentiate from other neonatal respiratory problems** without the aid of chest x-ray evaluation. Combined viral (usually RSV) and bacterial pneumonia is often associated with more serious clinical findings, including recurrent wheezing.[594] **VAP results in an increase in the volume and character of secretions** (i.e., purulent mucus) suctioned from the ETT.[80] Many NICU infants with viral respiratory tract infections are asymptomatic.[50]

Laboratory Data. The appearance of pneumonia varies depending on the duration of infection, cause of the pneumonia, and presence of underlying respiratory disease (e.g., RDS, BPD). **Serial x-ray films are more valuable than one isolated x-ray examination in making the diagnosis and following the course of the disease.** Infiltration patterns on chest x-ray films include lobar consolidation; patchy alveolar infiltrates; hilar and peribronchial infiltrates; reticulogranular, nodular, or miliary infiltrates; and hazy or opaque lungs (Table 23.17). **Lung ultrasound has been shown to be a reliable diagnostic tool in neonatal pneumonia.**[324]

Endotracheal aspirate examination/culture and blood culture also are useful tools in identifying the organisms of pneumonia, including VAP.[200] A **workup for sepsis** is often part of the diagnostic evaluation for these neonates (see Chapter 22).

Treatment. **Treatment of neonatal pneumonia includes supportive care** (e.g., thermoregulation, nutrition, oxygenation, ventilation if necessary, and parenteral support). If the **causative agent is bacterial, antibiotic therapy must be instituted after a sepsis workup; if viral, an antiviral agent is considered; if fungal, an antifungal agent is used** (see Chapter 22). Neonatal pneumonia may be accompanied by surfactant

TABLE 23.17 ETIOLOGIC FACTORS AND CHEST X-RAY FINDINGS IN NEONATAL PNEUMONIA

CAUSATIVE AGENT	CHEST X-RAY FINDINGS
Bacterial	
Group B beta-hemolytic streptococci (GBS)	Diffuse reticulogranular pattern, opacity ("whiteout"), patchy infiltrates, and pleural effusion
Streptococcus pneumoniae	Patchy infiltrates (lobar), pleural effusion
Staphylococcus aureus	Diffuse infiltrates; pneumatocele
Methicillin-resistant *Staphylococcus aureus* (MRSA)	Diffuse infiltrates; abscess formation
Staphylococcus epidermidis	Hazy lung fields; infiltrates
Listeria monocytogenes	Bilateral patchy infiltrates
Escherichia coli	Lobular consolidation; pneumatocele
Klebsiella	Bilateral consolidation; lung abscess, pneumatocele
Pseudomonas and *Serratia*	Parenchymal consolidation (patchy or basilar); pneumatocele
Haemophilus influenzae	Nonspecific; x-ray findings similar to those of GBS (above) or respiratory distress syndrome
Viral	
Herpes virus	Perihilar infiltrates; streaky, lobar consolidation; pleural effusion (late onset)
Cytomegalovirus	Nonspecific, perihilar streaking; hazy lung fields; infiltrates; opacification
Rubella virus	Interstitial infiltrates; hazy lung fields
Respiratory syncytial virus	Hyperexpansion; patchy consolidation
Adenovirus, enterovirus	Hyperexpansion; patchy consolidation
Fungal	
Candida albicans	Diffuse granularity; coarse infiltrates; opacification
Mycoplasma	
Ureaplasma urealyticum	Fine reticular pattern progressing to opacification and consolidation
Mycoplasma hominis	Diffuse reticular pattern, opacity, and pleural effusion
Other	
Treponema pallidum (syphilis)	Diffuse opacification; consolidation
Chlamydia trachomatis	Hyperinflation; streaky infiltrates
Pneumocystis jiroveci (formerly *carinii*)	Diffuse haziness; granularity; opacity

Modified from Carey B, Trotter C. Neonatal pneumonia. *Neonatal Netw.* 2000;19(4):46.

inactivation; **use of rescue surfactant for respiratory failure accompanying neonatal pneumonia is effective in improving oxygenation in late-preterm and term neonates requiring mechanical ventilation**[137] (see Box 23.15). Early use of surfactant in pneumonia is associated with lower risk of mortality and use of ECMO.[278]

Nebulized ambroxol (a mucolytic and secretolytic) improved lung function index and decreased inflammatory factors and inhibition of cell apoptosis when compared to a group receiving standard supportive care.[583] **Use of nebulized budesonide to treat VAP has been shown to decrease mortality and shorten mechanical ventilation and length**

of stay while improving pulmonary diffusion function.[315]

Complications. The mortality rate for perinatally acquired pneumonia is variable but has been estimated at 20%, with a higher mortality rate (50%) for postnatally acquired pneumonia. In a review of perinatally acquired neonatal infections, the overall mortality rate for pneumonia was 10%.[80] The decline in mortality rate is the result of perinatal antibiotic use. VAP in the NICU results in longer length of stay, higher cost, and higher mortality rate.[80,517]

PERSISTENT PULMONARY HYPERTENSION OF THE NEWBORN

PPHN manifests as severe pulmonary hypertension with pulmonary artery pressure elevation to levels equal to systemic pressure or higher and large right-to-left shunts through the foramen ovale and the ductus arteriosus. PPHN manifests early in life: 77% of cases are diagnosed in the first 24 hours of life, 93% in the first 48 hours, and 97% by 72 hours of age. The incidence of PPHN is 2 to 6 in 1000 live births and complicates one-third of infants with moderate to severe CLD/BPD.[289]

Pathophysiology. Once the placental blood source is severed, adequate oxygenation of the newborn depends on inflation of the lungs, closure of the fetal shunts, a decrease in PVR, and an increase in pulmonary blood flow (an eightfold to tenfold increase at the first breath). **Normally, PVR decreases with the first breath of life.** When it remains high, successful transition from fetal to neonatal circulation is impaired. **In an infant manifesting PPHN, high PVR and pulmonary hypertension impede pulmonary blood flow. Factors that increase and decrease PVR are listed in** Table 23.18.

Increased PVR leads to hypoxemia, acidemia, hypercarbia, and eventually lactic acidosis. The pulmonary arterioles respond to this process with further constriction, promoting an additional decrease in blood flow; thus a cyclic pattern is established.[289] **PVR also maintains higher right-sided pressures in the heart that equal or exceed systemic pressures, resulting in right-to-left shunting, which is characteristic of PPHN.** PPHN also produces direct and indirect effects on myocardial function. A combination of pressure alterations, hypoxia, and acidemia leads to a cyclic pattern of decreased cardiac output, decreased pulmonary blood flow, and further vasoconstriction (Fig. 23.10).

TABLE 23.18 FACTORS THAT ALTER PULMONARY VASCULAR RESISTANCE (PVR)

LOWERS PVR	INCREASES PVR
Endogenous mediators and mechanisms:	Endogenous mediators and mechanisms:
Oxygen	Hypoxia
Nitric oxide	Acidosis
PGI2, PGE2, PGD2	Endothelin-1
Adenosine, ATP, magnesium	Leukotrienes
Bradykinin	Thromboxanes
Atrial natriuretic factor	Platelet-activating factor
Alkalosis	Ca2+ channel activation
K+ channel activation	Alpha-adrenergic stimulation
Histamine	PGF2α
Acetylcholine	
Beta-adrenergic stimulation	
Mechanical factors:	Mechanical factors
Lung infection	Overinflation or underinflation
Vascular cell structural changes	Excessive muscularization, vascular remodeling
Interstitial fluid and pressure changes	Altered mechanical properties of smooth muscle
Shear stress	Pulmonary hypoplasia
	Alveolar capillary dysplasia
	Pulmonary thromboemboli
	Main pulmonary artery distention
	Ventricular dysfunction, venous hypertension

ATP, Adenosine triphosphate; *$PGF_2\alpha$*, prostaglandin $F_2\alpha$; *PGI_2*, *PGE_2*, *PGD_2*, prostaglandins I_2, E_2, and D_2; *PVR*, pulmonary vascular resistance.

From Kinsella J, Abman S. Recent developments in the pathophysiology and treatment of *PPHN*. *J Pediatr*. 1995;126(6):855.

Etiology. Pulmonary vascular resistance (PVR) remains high after birth because of underdevelopment, maldevelopment, or maladaptation of pulmonary vasculature (Table 23.19). In utero, development of increased vascular smooth muscle or perinatal factors that cause or contribute to vasospasm are thought to be prime mechanisms of PPHN. Independent predictors of pulmonary hypertension in the preterm infant

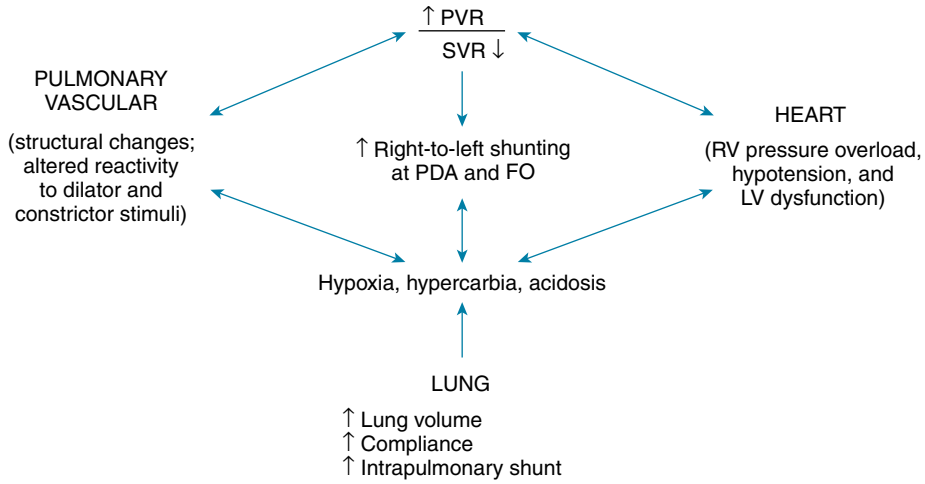

FIGURE 23.10 Cardiopulmonary interactions in persistent pulmonary hypertension of the newborn. *FO,* Foramen ovale; *LV,* left ventricle; *PDA,* patent ductus arteriosus; *PVR,* pulmonary vascular resistance; *RV,* right ventricle; *SVR,* systemic vascular resistance. (From Kinsella J, Abman S. Recent developments in the pathophysiology and treatment of PPHN. *J Pediatr.* 1995;126:855.)

include (1) low Apgar scores, (2) preterm premature rupture of membranes (PPROM), (3) oligohydramnios, (4) pulmonary hypoplasia, and (5) sepsis.[289]

Prevention. **Prevention of PPHN includes minimizing intrauterine and perinatal risk factors when possible, maintaining postnatal physiologic homeostasis, and detecting and correcting any underlying abnormality.**

Data Collection

History. In addition to the risk factors listed in Table 23.19, **maternal tobacco use, maternal obesity, premature rupture of membranes, maternal lack of private or use of public insurance, cesarean delivery, late-preterm or postterm birth, LGA infant, race (black, Asian), maternal diabetes, and maternal asthma are associated with an increased risk for PPHN.**[222]

There are two major considerations in the history of these infants: (1) the recognition of major disease processes or syndromes that are highly associated with pulmonary hypertension and (2) the timing of the onset of cyanosis and the deterioration of the infant.

Physical Examination. **The initial clinical presentation is usually a late-preterm (≥34 weeks' GA), term, or postterm infant with worsening cyanosis within the first 24 hours of life.** Tachypnea is a common finding and, when accompanied by retractions, is indicative of decreased pulmonary compliance. **Cyanosis may be either intense at birth or may progressively worsen in association with increased right-to-left shunting.**

Despite increasing FiO_2, the infant continues to have low PaO_2 (hypoxemia) as a result of right-to-left shunting. Milder cases of PPHN feature minimal tachypnea and cyanosis, frequently associated with stress from crying or feeding. **Severe cases are characterized by marked cyanosis, tachypnea, low systemic blood pressure, and decreased peripheral perfusion.**

Increased pulmonary artery pressure results in the following signs:

- Pulmonic systolic ejection clicks
- A second heart sound that is single, loud, or narrowly split with a loud pulmonary component
- A prominent right ventricular impulse that is visible or palpable at the lower left sternal border
- A soft systolic murmur in the pulmonary area

Laboratory Data. The laboratory evaluation of an infant with suspected PPHN should include a **complete blood count (CBC) with differential, platelet count, chest x-ray examination, and serum glucose, calcium, electrolytes, and arterial blood gas determinations.** The CBC is used to detect anemia, which could contribute to

TABLE 23.19 CRITICAL FINDINGS ETIOLOGIC FACTORS IN PERSISTENT PULMONARY HYPERTENSION OF THE NEWBORN

DEVELOPMENTAL PROCESS	PATHOPHYSIOLOGY	ASSOCIATED CONDITIONS
Underdevelopment, a decreased number of pulmonary vessels	Interruption in lung development, resulting in shunting of blood because of fewer pulmonary vessels and less area for gaseous exchange	Pulmonary hypoplasia (e.g., diaphragmatic hernia, premature rupture of membranes, oligohydramnios, Potter syndrome)
Maldevelopment, abnormally developed pulmonary vessels	Hypertrophy of musculature and extension into nonmuscularized arteries resulting in smaller lumen size, which increases PVR	Intrauterine asphyxia/hypoxia, MAS, and maternal smoking Intrauterine fetal ductus arteriosus closure increases pulmonary blood flow Congenital heart defects that result in abnormal pulmonary vessel formation (TAPVR, pulmonary vein stenosis)
Maladaptation (from intrauterine to extrauterine life) as a result of transient or persistent vasoconstriction	Results in remodeling and abnormal muscularization of small pulmonary arteries Results in pulmonary vasospasm and vascular remodeling	Hypoxia/acidosis/asphyxia Asphyxia may result in persistent vasospasm Pulmonary parenchymal disease (RDS, MAS, pneumonia, TTN, surfactant protein B deficiency)
	Pulmonary vasospasm and decreased cardiac output resulting from release of endotoxins and reaction to systemic inflammatory response	Bacterial sepsis Prenatal pulmonary hypertension (e.g., fetal systemic hypertension or premature closure of the ductus arteriosus) associated with maternal ingestion of NSAIDs (e.g., ibuprofen, naproxen, indomethacin), salicylates, phenytoin, lithium, prostaglandin inhibitors, or SSRIs (absolute risk <1%)[52]
	Prevents normal circulatory transition at delivery	Delayed or ineffective resuscitation, narcosis, other central nervous system depression, hypothermia, hypotension, severe congenital anemias[297]
	Potentiation of vasoconstriction	Hypothermia, hypoglycemia, hypocalcemia, acidosis, hypoxia, myocardial dysfunction, and ischemia
	Functional obstruction of pulmonary vascular bed	Polycythemia, hyperviscosity

MAS, Meconium aspiration syndrome; *NSAIDs,* nonsteroidal antiinflammatory drugs; *PVR,* pulmonary vascular resistance; *RDS,* respiratory distress syndrome; *SSRI,* selective serotonin reuptake inhibitors; *TAPVR,* total anomalous pulmonary venous return; *TTN,* transient tachypnea of the newborn.

Data from VanMarter L. Persistent pulmonary hypertension of the newborn. In: Cloherty J, Stark A, eds. *Manual of Neonatal Care.* 4th ed. Philadelphia, PA: Lippincott-Raven; 1998; Weardon M, Hansen T. Persistent pulmonary hypertension of the newborn. In: Hansen T, Cooper T, Weisman L, eds. *Contemporary Diagnosis and Management of Neonatal Respiratory Diseases.* 2nd ed. Newton, PA: Handbook of Health Care; 1998; Steinhorn RH. Diagnosis and treatment of pulmonary hypertension in infancy. *Early Hum Dev.* 2013;89(5):865.

systemic hypertension; detect polycythemia, which could lead to increased PVR; and detect an infectious process, such as group B streptococcal sepsis or pneumonia.

Arterial blood gases demonstrate acidosis, hypoxia, and increased $PaCO_2$. If blood gas specimens are obtained simultaneously in the right radial artery (preductal) and the descending aorta (postductal), the right-to-left shunt can be documented (preductal PaO_2 greater than postductal). Simultaneous preductal and postductal pulse oximetry or transcutaneous oxygen measurements may also be useful in the diagnosis. Other diagnostic tests are outlined in Table 23.20.

The most common **chest x-ray findings** associated with PPHN include:

- Prominent main pulmonary artery segment
- Mild to moderate cardiomegaly
- Variable pulmonary vasculature (increased, decreased, or normal)
- Signs of left ventricular dysfunction that include pulmonary venous congestion and cardiomegaly

The ECG is usually normal but may demonstrate right ventricular hypertrophy, evidence of

TABLE 23.20 DIAGNOSTIC TESTS FOR PERSISTENT PULMONARY HYPERTENSION OF THE NEWBORN (PPHN)

TEST	USE
Hyperoxia test	If P_{O_2} does not increase in 100% oxygen, a right-to-left shunt is demonstrated (may be secondary to either PPHN or congenital heart defect)
Comparison of preductal and postductal arterial PaO_2	Demonstrates ductal shunting; if negative, it does not rule out PPHN; most infants with congenital heart disease have no ductal shunting
Contrast echocardiography "bubble echo"	Demonstrates foramen ovale shunting but should be present in most cases of PPHN
Hyperoxia-hyperventilation	Most definite test; if P_{O_2} <50 mm Hg prehyperventilation and rises above 100 mm Hg is almost always PPHN

From Duara S, Gewitz MH, Fox WW. Use of mechanical ventilation for clinical management of persistent pulmonary hypertension of the newborn. *Clin Perinatol.* 1984;11(3):641.

pulmonary hypertension, and signs of myocardial ischemia. **Echocardiography is essential** in (1) evaluating cardiac structures, (2) ruling out cyanotic cardiac lesions, (3) diagnosing the right-to-left shunting at the foramen ovale and/or ductus arteriosus, (4) estimating pulmonary artery pressure, (5) determining therapy, and (6) evaluating response to therapy.[271]

Treatment. Historically, treatment of PPHN included hyperventilation, IV infusions (e.g., systemic vasodilators, sedatives, narcotics, paralysis, alkali, and inotropes), surfactant administration, high-frequency ventilation, and ultimately ECMO/ECLS as a last resort, and in limited neonatal centers. These treatments were widely used without RCTs to test safety and efficacy, and none of these treatments improved survival in infants with PPHN.

Treatment of PPHN focuses on preventing or intervening in the development of the cyclic pattern illustrated in Fig. 23.10. Goals of current therapy include (1) **treating associated pathology** (e.g., antibiotics for sepsis/pneumonia; partial exchange transfusion for polycythemia/hyperviscosity; volume expanders), (2) **providing adequate oxygenation,** (3) **reducing PVR** by pulmonary vasodilation that improves pulmonary blood flow, (4) **increasing and maintaining systemic vascular resistance (SVR)** (e.g., systemic blood pressure), and (5) **preventing right-to-left shunting** by decreasing PVR and increasing SVR. Pulmonary blood flow should increase if PVR is decreased or if SVR is increased.[292,492,493]

Adequate Oxygenation. Maintaining adequate oxygenation is a prime goal of care of infants with PPHN. Both hypoxemia and hyperoxemia should be avoided, so that paO_2 values should be maintained in the range of 60 to 80mm Hg and PO saturations between 90% and 97% in term and late-preterm infants.[295-297,537] **To maintain adequate oxygenation, alterations in "routine" care and handling are essential. Because handling a sick newborn for *any* reason causes a fall in PaO_2, the benefits of handling for routine care such as changing linens, weighing, suctioning, and taking vital signs must be balanced against the risk for iatrogenic hypoxia. PaO_2 variations in the newborn are as follows**[113,161]**:**

- **At rest: ±15 mm Hg variation**
- **While crying: decreased PaO_2 by as much as 50 mm Hg**
- **With routine care: decreased PaO_2 by as much as 30 mm Hg**

Maintaining organized, coordinated care and minimizing disturbances are therefore very important. Keeping the infant calm is important because severe hypoxia accompanies crying. Using pacifiers and decreasing noxious stimuli (e.g., invasive procedures) keep struggling and crying to a minimum. **Continuously monitoring vital signs, blood pressure, and pulse oximetry decreases the need for physical manipulation and disturbance. These large, vigorous infants require sedation and analgesia** (see Chapter 12) or paralysis (see Table 23.16) to promote effective oxygenation and ventilation and decrease air leaks.

Ventilation Therapy. Use of CMV to produce hypocarbia (↓$PaCO_2$) and respiratory alkalosis is no longer used due to the effects resulting from (1) adverse neurologic sequelae (e.g., CP and cystic PVL); (2) exposure of the lung to barotrauma/volutrauma, CLD/BPD, and air leaks; (3) the increased risk of sensorineural hearing loss; and (4) no improvement in the clinical outcomes of PPHN.[119,505]

HFV, both oscillator and jet, is used to treat PPHN. Use of HFOV optimizes lung inflation/

recruitment[293] and oxygenation, improves ventilation, and achieves respiratory alkalosis.[272] HFOV is an effective rescue treatment for some neonates meeting ECMO/ECLS criteria who were unresponsive to CMV.[79]

A *Cochrane* review of the use of rescue HFJV compared with CMV in preterms with severe pulmonary dysfunction found no significant difference in mortality rates or adverse events.[437] However, the reviewers concluded that the existing evidence does not support the use of HFJV as recue therapy for preterm infants. A single-center retrospective review of 34 premature infants with hypercapnic respiratory failure found that infants who responded well to HFJV had lower PMA, improved capillary pCO_2, lower pH at 1 hour after therapy began, and reduced FiO_2 requirements.[566]

Inhaled Nitric Oxide (iNO). Endogenous NO production dilates the fetal pulmonary vascular bed and is essential in decreasing PVR after birth.[102] **Because endogenous production of NO in the pulmonary vasculature of neonates with PPHN is reduced, treatment with iNO is beneficial because iNO is a selective pulmonary vasodilator (e.g., decreases pulmonary hypertension and increases oxygenation without reducing systemic blood pressure).[271]** Early clinical studies of iNO demonstrated brief exposure actually improved oxygenation and lowered pulmonary artery pressure. RCTs from multicenters have confirmed that prolonged iNO treatment for PPHN (1) results in sustained improvement of oxygenation,[373] (2) decreases the need for ECMO/ECLS treatment,[373] (3) is an adjunct to CMV,[373] and (4) combined therapy (e.g., iNO, HFOV) is more effective than either therapy alone.[286] The Neonatal Inhaled Nitric Oxide Study Group (NINOSG)[374] found that iNO had no effect on mortality rate, length of stay, number of days of ventilatory support, incidence of air leak, CLD/BPD, IVH/PVL, seizures, and pulmonary and GI hemorrhages. **Use of iNO for PPHN is associated with severe coagulopathies.[510]** The effectiveness of iNO depends on (1) the initial degree of pulmonary vasoconstriction and hypoxemia, (2) the severity of parenchymal lung disease, and (3) the recruitment of adequate lung volume/inflation that decreases intrapulmonary shunting and improves iNO delivery to the pulmonary system.[271] In the ECMO/ECLS population, iNO use has increased from 0% to 24%.

Inhaled NO is an effective treatment for PPHN but "should be considered a part of the overall clinical strategy that cautiously manages parenchymal lung disease, cardiac performance, and systemic hemodynamics."[271] **Inhaled NO has been approved by the U.S. Food and Drug Administration for treatment of near-term (>34 weeks' GA) and term neonates with PPHN. Recommendations for use of iNO are listed in** Table 23.21. Use of iNO in moderate PPHN improves oxygenation,[182] decreases the amount of ventilation needed, and prevents progression to severe PPHN. A retrospective study comparing the use of HFOV and HFJV with iNO found similar short-term effects of decreasing the need for ECMO and improving oxygenation and ventilation of infants with PPHN regardless of which type of ventilator was used.[98]

Severe pulmonary hypertension in preterm infants occurs in less than 2% of all preterm births.[273] **Use of iNO to treat severe pulmonary hypertension in these infants has been reported in numerous case studies and case series.[87,91,97,464,504]** Improved survival (from 67%[91] to 90%[464]) for premature infants with severe pulmonary hypertension is due to marked improvement in oxygenation after use of iNO, similar to the responses of term and late-preterm neonates with PPHN. The Pediatric Pulmonary Hypertension Network proposed a prospective registry of premature infants with severe pulmonary hypertension who were treated with iNO, other pulmonary vasodilators or no specific pulmonary hypertension therapy.[273] A six-year cohort study of 89 preterm infants (<35 weeks' GA) treated with iNO for acute pulmonary hypertension found improved survival rate without disability, lower mortality and disability with early use of iNO especially in neonates with higher GAs, and acute hypertension associated with preterm prolonged rupture of membranes.[29] **Recommendations for the role of iNO in premature infants are listed in** Table 23.21.

Noninvasive strategies for administration of iNO have been reported. A case report of iNO administration through an NC precluded the use of MV in a spontaneously breathing term infant,[364] and noninvasive iNO administered by bubble NCPAP improved oxygenation in preterm and term infants with hypoxic respiratory failure.[445]

TABLE 23.21 RECOMMENDATIONS FOR USE OF INHALED NITRIC OXIDE (iNO)

RECOMMENDATION	RESEARCH BASIS
Gestational Age	
≥34 weeks' gestation	Clinical trials,[97,373] Canadian Pediatric Society,[396] and FDA approval support use of iNO in late-preterm/term newborns.[271]
≤34 weeks' gestation	Clinical data does not support use of iNO for early routine, early rescue, or later rescue therapy in preterm infants[41,99,286] iNO should not be used to prevent BPD/CLD[41,99,289] Beneficial for severe hypoxemia primarily due to PPHN physiology, rather than parenchymal lung disease, particularly in the presence of oligohydramnios; lung hypoplasia; prolonged rupture of membranes and sepsis Preferred pulmonary vasodilator for premature infants based on safety profile from outcomes of multicenter RCTs for BPD/CLD prevention[273]
Postnatal Age	
Within the first week of life; postnatal age alone should not define the duration of therapy when prolonged therapy could be beneficial	Clinical trials support iNO use within the first week of life; may also be used as adjunct therapy after ECMO/ECLS treatment
Severity of Illness	
Oxygenation index (OI) = (MAP × FiO_2 × 100 ÷ PaO_2) >25 with echocardiographic evidence of extrapulmonary right-to-left shunting	Mean OI in multicenter trials was 40 Earlier use of iNO at lower OI (15-25) has not resulted in reduction of mortality, ECMO/ECLS use, or outcomes[280,493] Early use of iNO (at OI ≥15 and ≤20) is associated with shorter LOS and decreased cost[278] Delayed use (OI >40) increases length of supplemental oxygen use[189]
Dose	
Initial: 20 ppm in term and near-term newborns with PPHN who do not have diaphragmatic hernia[42] Brief exposure to 40-80 ppm is safe Sustained treatment with 80 ppm increases the risk for methemoglobinemia	Increasing dose to 40–80 ppm does not improve response to 20 ppm Initial treatment with low dose (1-2 ppm) does not compromise responses to higher doses (10-20 ppm); a majority of low doses require dose increases The lowest effective starting dose has not been determined
Duration	
Typically <5 days	Longer usage may be necessary in pulmonary hypoplasia For therapy >5 days, other causes of pulmonary hypertension should be investigated
Weaning and Discontinuation	
Differing approaches toward weaning have been studied with few differences in outcomes until iNO is discontinued: After 4 hours at 20 ppm, iNO reduced to 6 ppm without change in oxygenation iNO decreased by 20% increments in stepwise fashion to dose of 1 ppm before discontinuation	Withdrawal of iNO can be associated with life-threatening elevations in PVR, profound oxygen desaturation, and systemic hypotension because of decreased cardiac output Dose-response relationship between iNO given and a drop in PaO_2 A decrease in iNO to 1 ppm before discontinuation minimizes decrease in PaO_2, and compensatory changes in FiO_2 and ventilator parameters are unnecessary

Continued

TABLE 23.21 RECOMMENDATIONS FOR USE OF INHALED NITRIC OXIDE (iNO)—CONT'D

RECOMMENDATION	RESEARCH BASIS
Ventilator Management	
High-frequency oscillatory ventilation (HFOV)	Inadequate lung inflation results in less response to iNO therapy
With significant parenchymal lung disease	Combination of HFOV and iNO results in best improvement in oxygenation because of improved lung inflation during HFOV that augments response to iNO by reducing intrapulmonary shunting and improving iNO delivery to pulmonary circulation
Without significant parenchymal lung disease	Combination of HFOV and iNO and iNO alone are more effective than HFOV alone
Congenital Diaphragmatic Hernia	
Routine use in CDH not recommended	CDH infants are poor responders to iNO Limited to CDH infants with suprasystemic PVR (after establishing optimal lung inflation and echocardiography determination of adequate LV function)
Late pulmonary hypertension in CDH infants	Late pulmonary hypertension is clinically evident when PVR becomes suprasystemic with right-to-left venoarterial admixture across the FO and/or ductus arteriosus measured on echocardiography
Use in ECMO/ECLS Centers	
Use to stabilize before cannulation for ECMO Use of iNO has not adversely affected outcome by delaying ECMO	Lower mortality rate for iNO-treated group than for infants not treated with iNO[95] iNO treatment associated with improved short-term pulmonary outcomes,[97] and decreased ECMO use is not associated with increased late-term morbidity[95,374]
Use in Non-ECMO/ECLS Centers and Transport with iNO	
If progressive deterioration in oxygenation occurs in centers without ECMO/ECLS, transport to ECMO/ECLS center without interruption of iNO therapy must be accomplished	Withdrawal of iNO to transport to an ECMO/ECLS center may result in acute and life-threatening deterioration

Modified from Kinsella JP. Inhaled nitric oxide in the term neonate. *Early Hum Dev.* 2008;84(11):709; Kinsella JP, Steinhorn RH, Krishnan US, et al. Recommendations for the use of inhaled nitric oxide therapy in premature newborns with severe pulmonary hypertension. *J Pediatr.* 2016;170:312; Data from Kinsella JP. Inhaled nitric oxide in the term neonate. *Early Hum Dev.* 2008;84(11):709.

Use of HFOV and iNO to treat PPHN has decreased the number of neonates meeting ECMO/ECLS criteria who subsequently require ECMO/ECLS treatment, has shortened length of hospital stay, and has decreased costs. However, a recent national survey of neonatal nurse practitioners (NNP) found that late rather than early use of iNO, only 35% of respondents knew the oxygen index at which iNO should be initiated and fewer than 20% knew that early initiation prevents progression to use of ECMO/ECLS. The surveyors concluded that more education of NNPs was necessary, especially related to the hazards of oxidative stress on neonates.[261] A quality improvement project using a shared baseline protocol improved evidence-based iNO use.[233]

Pharmacologic Therapy. **Surfactant replacement therapy is used when significant parenchymal lung disease (e.g., MAS) is the cause of PPHN.** Secondary surfactant deficiency also may exist in PPHN. Surfactant replacement in the early phase of PPHN significantly decreases the need for ECMO/ECLS in term newborns without increasing the risk for complications.[286] **In term and late-preterm**

infants with hypoxic respiratory failure, early use of surfactant and iNO improves outcomes (less mortality and ECMO use).[279,293]

Use of inotropic support (e.g., vasopressors) (Table 23.22) increases SVR, which decreases right-to-left shunting through the foramen ovale and ductus arteriosus. Cardiac output, cardiac contractility, and systemic blood pressure are all increased. A small study of newborns (n = 18) treated with iNO for PPHN (but with symptoms of circulatory failure [despite adequate fluids]) showed that IV norepinephrine improved lung function by decreasing the ratio between pulmonary and systemic artery pressures and improving cardiac performance.[528]

Systemic vasodilators (e.g., tolazoline, sodium nitroprusside, prostaglandin E1) have been used to decrease PVR. These medications have resulted in variable and unpredictable results and are associated with systemic hypotension, the need for volume expansion and fluid resuscitation, and an inability to achieve and maintain pulmonary vasodilation. When vasodilators are infused in dosages sufficient to decrease pulmonary hypertension, there is increased venous admixture as a result of right-to-left shunting of venous blood and pulmonary ventilation-perfusion mismatch. **Because of these adverse effects, use of systemic vasodilators is no longer recommended.**

From 40% to 50% of neonates do not respond to iNO therapy,[518] **so alternatives and synergistic agents are used for pulmonary vasodilation.** The reason for nonresponse to iNO is unknown, but a recent retrospective review found that infants receiving iNO with blood group A were poorer responders than those with B or O blood groups.[155] In poor or partial response to iNO, the need for ECMO is able to be predicted after 72 hours of iNO therapy.[534]

Phosphodiesterase inhibitors are used as an alternative, as a supplement, or for weaning from iNO in PPHN (Table 23.23).[8,293,340,493,495] **In term and late-preterm neonates with PPHN who are nonresponders or have a suboptimal response to iNO, use of IV milrinone results in improved clinical and ECMO changes.**[340] Intravenous (IV) milrinone improves oxygenation without compromising systemic blood pressure.[340] Use of sildenafil (1) is as effective as iNO in improving pulmonary vasodilation, (2) assists weaning from iNO, (3) improves oxygenation, (4) may or may

TABLE 23.22 VASOPRESSOR RESPONSE IN THE NEONATE

DRUG DOSE	DISADVANTAGE
Dopamine	
<4 mcg/kg/min: renal vasodilation, mesenteric and cerebral vasodilation (effects unknown) plus increase in cardiac output	May decrease systemic arterial pressure
5-20 mcg/kg/min: increase in cardiac output depending on myocardial norepinephrine	Loss of renal and mesenteric perfusion
>20 mcg/kg/min: systemic arterial pressure increases more than pulmonary artery pressure	Cardiac output may decrease Myocardial oxygen consumption increases Marked increase in left ventricular afterload Dysrhythmias noted
Dobutamine	
10 mcg/kg/min: increases cardiac contractility directly; cardiac output increases depending on myocardial catecholamine stores	No selective renal or mesenteric vasodilation Tends to increase skeletal blood flow at the expense of viscera Increase in pulmonary artery pressure
Isoproterenol	
0.05-1 mcg/kg/min: lowers pulmonary vascular resistance in pulmonary hypotensive and vascular disease in child and adult; lowers hypoxemia-induced pulmonary vascular resistance in animal models	Dysrhythmias No specific vasodilation effects
Nitroprusside	
0.4-5 mcg/kg/min: cardiac output increases because of decreased left ventricular afterload; systemic vascular resistance (indicated by blood pressure) decreases because of decreased left ventricular afterload	Systemic vascular resistance remains constant if CO_2 increases

Modified from Drummond W. The use of cardiotonic therapy in the management of infants with PPHN. *Clin Perinatol.* 1984;11(3):715.

TABLE 23.23 PHOSPHODIESTERASE INHIBITOR THERAPY FOR PPHN

DRUG	DOSE	COMMENTS
Milrinone[340]	Loading dose: 50 mcg/kg IV over 60 min Maintenance dose: 0.33–0.99 mcg/kg/ min for 24–72 hr Half-life: 4.1 hr Duration: 24–42 hr Clearance reduced in neonates and increases with age[178]	Improves oxygenation (increased PaO_2) Reduces FiO_2 Decreases oxygen index, MAP, and iNO dose Lowers inotrope score Improves base deficit and plasma lactate levels Monitor: blood pressure for transient systolic hypotension; heart and respiratory rate and rhythm; assess COP; fluid/electrolytes and renal function; platelet counts for thrombocytopenia Used in suboptimal or nonresponders to iNO ECHO: Lowers PA pressure Better right-to-left ventricular function Less right-to-left shunting
Sildenafil* [263]	0.3–1 mg/kg/dose per OG tube every 6–12 hr Peak concentration: 30–120 min Bioavailability: 40% Loading dose: 0.4 mg/kg continuous IV over 3 hr[495] Maintenance dose: 1.5 mg/kg/day continuous IV infusion[495]	Pulmonary vasodilation as an alternate, supplement, or weaning agent from iNO Concentrated in the presence of erythromycin, cimetidine, amlodipine Adverse effects: systemic hypotension, blood pressure lability, worsening oxygenation (decreased Pao_2)

*FDA issued a warning against the use of sildenafil for the treatment of pediatric pulmonary hypertension because of the higher risk of death with higher (3–6 mg/kg/day) versus lower doses. (From US Food and Drug Administration. Revatio [sildenafil]: drug safety communication—recommendation against use in children. Silver Spring, MD: US Food and Drug Administration; 2012.) FDA issued a clarification of the 2012 warning stating that use of sildenafil in children may be warranted when the benefits outweigh the risks, when other treatment options are limited, and when use of sildenafil can be closely monitored. (From US Food and Drug Administration. Revatio (sildenafil): drug safety communication—FDA clarifies warning about pediatric use for pulmonary arterial hypertension. Silver Spring, MD: US Food and Drug Administration; 2014.)

ECHO, Echocardiogram; *FiO_2,* fraction of inspired oxygen concentration; *iNO,* inhaled nitric oxide; *MAP,* mean airway pressure; *OG,* orogastric; *PA,* pulmonary artery; *PPHN,* persistent pulmonary hypertension of the newborn.

not decrease systemic blood pressure, (5) improves cardiac output, (6) is more effective when used together with iNO than either used separately, (7) is useful in resource-limited areas where iNO is unavailable, and (8) is safe, effective, and well tolerated with chronic use.[8,263,492,495] **RCTs are needed to establish the safety, efficacy, side effects, and long-term outcomes of sildenafil and milrinone use in PPHN.[263,400] Other drugs used to treat PPHN are listed in** Table 23.24.

Complications. **Follow-up at 18 to 24 months of age of the neonates in the NINOSG trial found no increase in neurodevelopmental or behavioral abnormality;** the children in the control group experienced a higher incidence of seizures after discharge than did the iNO-treated group.[374] Two other studies also showed no increase in adverse neurodevelopmental or pulmonary outcomes as a result of treatment with iNO and avoidance of ECMO treatment.[95,319] Other studies found high rates of neurodevelopmental impairment at 18 months of age[280] and a lower incidence of respiratory morbidity (26%) compared with the respiratory morbidity after ECMO treatment (37%) or CMV (56%).[229]

A follow-up study of 85 children (at 5 to 11 years of age) who had been treated for PPHN compared with a matched reference group found (1) sensorineural hearing loss (11%), (2) increase in chronic health problems (42% vs. 17%), (3) use of bronchodilators (21% vs. 8%), and (4) increased use of remedial education (19% vs. 5%).[159] Survivors of PPHN may have significant pulmonary and neurodevelopmental impairment, whether treated with conventional methods or with ECMO/ECLS, and should have long-term follow-up.

TABLE 23.24 OTHER DRUGS USED TO TREAT PPHN

DRUG	DOSAGE	COMMENTS
PGI_2 (iloprost ; treprostinil): Synthetic prostacyclin analog	Inhaled iloprost: 0.5–2 mcg/kg/dose	Selective pulmonary vasodilator; effects similar to iNO[265] More effective than oral sildenafil as alternative therapy for PPHN Benefits VLBW preterm infants with severe pulmonary hypertension[153,187]
Bosentan: Endothelin receptor antagonist	1 mg/kg every 12 hr PO by gastric tube[330]	Single-center RCT: improves oxygenation in PPHN without iNO use[348] Multi-center RCT: no additive effect as adjuvant therapy to iNO in PPHN[494] Mild systemic hypotension after initiation of therapy[330]

BID, Twice daily; *iNO*, inhaled nitric oxide; *kg*, kilograms; *mcg*, micrograms; *mg*, milligrams; *PGI_2*, prostaglandin I_2; *PO*, per os (by mouth); *PPHN*, persistent pulmonary hypertension of the newborn; *RCT*, randomized controlled trial; *VLBW*, very low birth weight.

APNEA

Pathophysiology. **The two major control mechanisms that regulate pulmonary ventilation are the neural and chemical systems. The cerebral cortex and brainstem are the governing agents for the neural control system, which regulates respiratory rate and rhythm.** The peripheral components of this system are found in the upper airway and lung. **The chemical control center is found in the medulla and is sensitive to changes in $PaCO_2$.** The peripheral portion of the chemical system lies in the carotid and aortic vessels and is sensitive to changes in $PaCO_2$. **Alveolar ventilation is controlled by the chemical system, and this system is the principal defense against hypoxia.** Neonates have a unique response to hypoxemia and carbon dioxide retention. Unlike adults, who have sustained increase in ventilation to hypoxemia, infants have a brief period of increased ventilation followed by respiratory depression.

Carbon dioxide responsiveness is less developed in the preterm infant, which may be the result of decreased sensitivity in the chemical center or mechanical factors that prevent an increase in ventilation. **Apnea is the cessation of breathing for 20 seconds or longer or cessation of breathing for 15 seconds with cyanosis and/or bradycardia. Apnea of prematurity or primary apnea is not associated with other specific disease entities. The younger the GA, the greater is the incidence of apnea, so at least 85% of preterms less than 34 weeks' gestation have apnea of prematurity.**[458] In one observational study, the incidence of apnea of prematurity was 28.6% in a cohort of late-preterm infants with 10.9% receiving caffeine therapy.[386] Apnea and bradycardia episodes usually begin within the first week after birth and spontaneously resolve at 36 weeks' PMA.[407] In infants born at 27 weeks' gestation or earlier, 58% to 60% have persistent apnea at 36 weeks' postconceptual age.[150] Apnea may be associated with hypoxemia, neuronal immaturity, sleep, catecholamine deficiency, and respiratory muscle fatigue.

Etiology. **Causes of apnea in the premature are characterized as *central apnea* (absence of breathing effort), *obstructive apnea* (breathing efforts occur but the airway is blocked), or, most commonly, *mixed apnea* (an initial central apnea followed by obstruction of the airway).** Various conditions may cause apnea in the premature infant by producing hypoxia and/or altering the sensitivity of peripheral or central chemoreceptors (Table 23.25). Neuronal immaturity is a plausible cause for apnea because respiratory efforts are more unstable at younger GAs. The decreased response appears to be the result of a general lack of dendritic formation and limited synaptic connections, thereby decreasing the excitatory drive. Another hypothesis is that apneic episodes are manifestations of synaptic disorders that occur without a motor component. Such phenomena have been confirmed on EEG. Infants depend on alternating excitation and inhibition to establish rhythmic breathing; therefore imbalances (e.g., hypoxia, hypoglycemia, hypocalcemia) may cause respiratory arrest.

Apnea is more frequent during sleep and especially during rapid eye movement (REM) or active sleep in both term and preterm infants.[527]

TABLE 23.25 CAUSES OF APNEA IN THE PREMATURE INFANT

CAUSE	SPECIFICS
Infection	Pneumonia, sepsis, meningitis
Respiratory distress	Immaturity of respiratory development, RDS, airway obstruction, CPAP application, postextubation, congenital anomalies of the upper airways
Cardiovascular disorders	Patent ductus arteriosus, congestive heart failure
Gastrointestinal disorders	Vomiting, necrotizing enterocolitis, deglutition syncope
Central nervous system disorders	Depressant drugs, intraventricular hemorrhage, seizure, elevated bilirubin levels, bilirubin encephalopathy/kernicterus, infection, tumors/ischemia
Metabolic disorders	Hypoglycemia, hypocalcemia, hyponatremia/hypernatremia
Environmental	Rapid increase of environmental temperature, hypothermia, vigorous suctioning, feeding, stooling, stretching/movement; fatigue/stress, prenatal exposure to maternal cigarette smoking, position, sleep state (e.g., active vs. quiet) Pain* First immunization (DTP/IPV/Hib): increase in apnea, bradycardia, and desaturations within 72 hours of immunizations
Hematopoietic	Polycythemia, anemia

*Oral sucrose relieves pain but does not decrease apnea and bradycardia.
DTP, Diphtheria-tetanus-pertussis; *CPAP*, continuous positive airway pressure; *Hib*, *Haemophilus influenzae* type B; *IPV*, inactivated polio virus; *RDS*, respiratory distress syndrome.

Apnea associated with sleep becomes more significant in premature infants, particularly those of less than 32 weeks' gestation, who spend 80% of their time asleep. Equally significant is the time spent in REM sleep, the predominant sleep state of premature infants. Apnea is uncommon in non-REM sleep, but periodic breathing may be observed. The effects of REM sleep are inhibition of spinal motor neurons, increase in brain activity causing increasing eye movements and muscular twitching, and changes in brain temperature and cerebral blood flow and CNS arousal, shown by EEG changes.

A premature infant has a more compliant chest cage and less compliant lungs, resulting in greater respiratory workload. Respiratory muscle fatigue occurs easily in the absence of fatigue-resistant fibers.

Secondary apnea may be associated with a particular disease entity or in response to special procedures. Many disorders leading to secondary apnea may exert their influence through hypoxemia and subsequent respiratory center depression.

The majority of cases of secondary apnea arise from four conditions. In RDS, apnea is related to the degree of parenchymal disease and may result from muscle fatigue. With CNS hemorrhage and seizures, apnea arises from asphyxia with subsequent hypoxemia and respiratory center depression or actual brain injury. Apnea is related to central depression in sepsis. In addition, carbon dioxide retention and hypoxemia associated with the left-to-right shunting of a PDA may cause apnea.

Iatrogenic causes of apnea include increased environmental temperature, sudden increases in environmental temperature, vagal response to suctioning of the nasopharynx or to a gavage tube, vomiting, and obstruction of the airway. **Reflex apnea occurs when foreign material (milk or secretions) is present in the oropharynx.** This laryngeal chemoreflex is protective in that it prevents inhalation of the substance into the airway and has been documented in preterm and hospitalized infants. **Obstruction may occur from improper neck positioning or aspiration.**

Cerebral blood flow (CBF) velocity decreases with apnea and bradycardia[402] and is directly correlated with the severity of bradycardia,[421] and an increase in CBF may occur on recovery.[325] Decreased oxygen saturation also correlates with the duration of apnea, regardless of type. Obstructive apnea is associated with significantly greater maximum fall in cerebral blood volume than central or mixed apneic episodes. **Because alteration of CBF may cause or exacerbate IVH, obstruction of upper airways with resultant apneic episodes should be prevented.**

Prevention. All infants assessed as being at high risk for apneic spells should be carefully monitored for at least 10 to 12 days. Impedance apnea monitors do not distinguish normal respiratory efforts from gasping movements associated with obstruction. **Both heart and respiratory rates should be monitored.** Alarm systems should be used at all times. A qualified observer is essential.

Apneic episodes are frequently associated with alterations in heart rate and oxygen saturation—the degree of these changes is related to the duration of apnea. Apnea generally precedes a drop in heart rate and oxygen desaturation. Changes in oxygen saturation are distinct from heart rate changes, so the desaturation cannot be predicted from changes in heart rate patterns. Because episodes of apnea and bradycardia are associated with a decrease in CBF and because oxygen desaturation (as little as 5% to 10%) is associated with alteration of cerebral circulation,[325] **oxygen saturation monitoring should accompany cardiorespiratory monitoring** (both in-hospital and home monitoring).

Pulse oximetry monitors may detect hypoxemic conditions that may lead to apneic spells. In a premature infant younger than 32 weeks' gestation, this type of apnea is common. Care should be organized to decrease stressful hypoxic episodes.

Apneic episodes may be prevented or decreased by several means. **Reducing environmental stress by providing adequate rest** has resulted in a faster rate of decline in apneic episodes.[525] **Gentle tactile stimulation** alone has been shown to be effective in decreasing and preventing apneic spells in most premature infants. Noxious stimuli such as shaking or banging on the incubator should be avoided. If tactile stimulus is ineffective and **temporary bag-and-mask ventilation is necessary,** attention should be paid to preventing undue pressure on the lower chin and neck so that the airway remains open. Bagging that is too vigorous also may stimulate pulmonary stretch receptors and induce apnea; therefore it should be avoided. **Waterbed flotation** may decrease the frequency of apnea but generally does not completely eliminate it. Systematic reviews have concluded that (1) prophylactic use of kinesthetic stimulation (e.g., waterbed, oscillating mattress) to reduce apnea or bradycardia cannot be recommended,[219] (2) prophylactic use of methylxanthine for prevention of apnea is not supported by data,[220] and (3) prophylactic use of methylxanthines increases the chances of successful extubation of preterm infants within 1 week.[218]

Increased environmental temperature and sudden changes in temperature have resulted in apneic episodes; prevention includes maintaining the environmental temperature at the lower end of the normal spectrum, particularly if an apneic episode already has occurred. **Incubator temperature may require a 0.5° to 1.0° C (1° to 2° F) decrease to counter the problem.** The frequency of apnea during active sleep is influenced by temperature: more apnea occurs in a warmer environment, whereas apnea is less frequent in cooler conditions.[527] **Phototherapy may provide sufficient radiant energy to increase an infant's temperature** and contribute to the incidence of apnea. **Care should be taken to avoid sudden changes in temperature.** An infant should not be placed on a cold scale; he or she should be placed in a prewarmed incubator or bed. Oxygen should be warmed and humidified before administration.

Careful attention must be paid to prevent airway obstruction. Small neck rolls under the neck and shoulders have been used to decrease neck flexion and prevent airway obstruction when in the supine position. Prone positioning improves lung mechanics and oxygenation, but with increasing gestation age (>32 weeks), the sudden infant death syndrome precautions of supine position for sleep need to be followed (see Chapter 13). A study comparing supine with prone positioning of preterm infants ($n = 21$) found no clinically significant increase in acid gastroesophageal reflux (GER) or obstructive apnea episodes associated with GER in asymptomatic convalescent preterms.[55] **Close monitoring should be done during procedures such as lumbar puncture in which accidental airway obstruction may occur.**

An RCT using olfactory stimulation with vanillin compared with no intervention was conducted in 36 preterm infants less than 2500 g at 2 days of age.[148] Compared with no intervention, the preterms exposed to a saturated vanillin solution had a significantly lower (3.1-fold) incidence of apnea, as well as arterial oxygen saturation and heart rates, during the study. In addition to calling for more research, the study authors speculated that vanillin might also be used to treat apnea of prematurity.[148]

Data Collection. Evaluation of apnea should include studies to rule out treatable causes.

History. Evaluation of the prenatal and birth history may give a clue to the causes and provide a basis for further study.

Physical Examination. A thorough physical and neurologic examination rules out grossly apparent abnormalities. **Observation and documentation of apneic and bradycardic episodes and any relationship to precipitating factors help differentiate**

primary from secondary apnea. A continuous, computerized analysis system to document apnea, bradycardia, and desaturation is more reliable in accurately capturing episodes.[547]

Laboratory Data. **A CBC and CRP assay assess for infection and anemia as causes of apnea. Measurements of serum glucose, calcium, phosphate, magnesium, sodium, potassium, and chloride levels assess metabolic causes. Arterial blood gas measurements assess hypoxemia and metabolic and respiratory contributions to apnea. Blood, urine, and cerebrospinal fluid (CSF) cultures rule out sepsis as the cause of apnea.** The CSF culture is usually performed only when other signs and symptoms of infection are present. **Chest x-ray examinations** assess cardiac and respiratory causes. The examinations may also rule out aspiration of gastric contents caused by vomiting or gastroesophageal reflux. **Ultrasonographic examination of the head and an EEG may be used to rule out IVH or other neurologic causes of apnea.**

Treatment. Treatment of secondary apnea is aimed at the diagnosis and management of the specific causes. In the treatment of **primary apnea (apnea of prematurity), initial efforts should begin with the least invasive intervention possible. Gentle tactile stimulation** is frequently successful, especially with early recognition and intervention. When infants do not immediately respond to external stimuli, **bag-and-mask ventilation** must be initiated. **Generally, an FiO_2 approximating that used before the spell but not exceeding a 10% increase will alleviate hypoxemia and avoid marked elevations in the arterial PaO_2.** The use of pulse oximetry monitoring allows closer evaluation of PaO_2 fluctuation and helps prevent complications of oxygen toxicity. Elevation in ambient oxygen concentrations, although decreasing the frequency of apnea, causes prolongation of apnea spells.

Apnea responds to low-pressure (3–5 cm H_2O) nasal CPAP.[409] Mechanical ventilation may be necessary if the infant fails to respond to lesser measures and continues to have repeated and prolonged apneic episodes. It also may be necessary in extremely immature, unstable, or debilitated infants. **Mechanical ventilation for apnea may be administered with nasal prongs or nasotracheal tube to avoid intubation.** SNIPPV is more effective than NIPPV or NCPAP in reducing apnea, desaturations, and bradycardia.[183]

An RCT of 36 preterm infants (mean GA 30.5 weeks ±3 weeks; mean birth weight of 1409 g ±450 g) with apnea of prematurity, bradycardia, and oxygen desaturations used **vibration-based therapy.**[483] The stochastic resonance (vibrating) mattress successfully reduced: (1) the number of apneic episodes by 50%, (2) bradycardia intensity reduced by 20%, and (3) the number, duration and intensity of oxygen desaturation episodes by 20% to 35%.[483]

Methylxanthines (e.g., caffeine, theophylline, aminophylline) are used to treat apnea of prematurity (Table 23.26). They are used only in primary apnea (i.e., when pathologic causes have been eliminated). Methylxanthines are potent cardiac, respiratory, and CNS stimulants and smooth muscle relaxers. **The effect on decreasing the frequency of apnea is related to central stimulation rather than to changes in pulmonary function.** Caffeine citrate is considered the drug of choice because (1) administration is once a day; (2) there is an earlier onset of action; (3) it has a wide therapeutic range, requiring fewer serum blood level evaluations; (4) there is no alteration of CBF; and (5) there are fewer side effects than with theophylline.[221,321] **Methylxanthines reduce the frequency of apnea and are associated with a decrease in the use of mechanical ventilation.**[218,220,221] A large (n = 2006 preterm with birth weight of 500–1250 g) multisite, international RCT of caffeine use for apnea of prematurity found that caffeine (1) reduced the incidence of CLD/BPD (36% in the treated group vs. 47% in the placebo group), (2) reduced the use of positive airway pressure by 1 week, and (3) temporarily (in the first 2 weeks of the study) reduced weight gain.[456] A recent RCT determined the frequency of intermittent hypoxia after caffeine therapy was discontinued and whether extended use of caffeine (to 40 weeks' PMA) reduced intermittent hypoxia with apneic episodes.[426] Extended use of caffeine reduced intermittent hypoxia (PO <90%) by 47% for preterms of 35 to 39 weeks' PMA.[426]

Caffeine is safe and efficacious when used for prophylaxis and/or treatment of apnea of prematurity.[321] Benefits of early administration include: (1) within 2 hours of life: improved BP and systemic blood flow[256]; (2) within the first 2 days of life: reduced rates of death, BPD/CLD, and PDA[327]; and (3) within the first week of life: reduced risk of acute kidney injury[210] and better lung function

TABLE 23.26 METHYLXANTHINES USED TO TREAT APNEA OF PREMATURITY

DRUG	DOSAGE	THERAPEUTIC LEVELS	SIDE EFFECTS
Caffeine citrate	Route: PO Loading: 20-40 mg/kg Maintenance: 5-8 mg/kg/day administered 24 hr after the loading dose Route: IV Dose: Cafcit 20 mg/mL Administer IV over 15-30 min to avoid cardiac dysrhythmias Half-life: 3-4 days with a range of 40-230 hours; inversely related to gestational age and postconceptual age	Afterload: 8-14 mcg/mL Maintenance: 5-25 mcg/mL Toxic: >40-50 mcg/mL	Administer orally with feedings: Administer in morning so infant's sleep pattern is less disrupted than evening administration Tachycardia (withhold dose if >180/min), dysrhythmias, diuresis, glucosuria, ketonuria, hyperglycemia, jitteriness, seizures, vomiting, hemorrhagic gastritis, NEC
Theophylline	Route: PO Loading: 4-6 mg/kg Maintenance: 1.5 mg/kg q 8 hr to 3 mg/kg q 12 hr IV: Aminophylline 4-6 mg/kg over 30 min	5-15 mcg/mL, although levels of 3-4 mcg/mL have been shown to be effective in decreasing apnea	See above Tachycardia more prevalent with aminophylline than with caffeine citrate[474] IV theophylline delays gastric emptying in VLBW infants Aminophylline is effective in preventing apnea that is associated with prostaglandin E_1 (PGE_1) injection in infants with ductal-dependent lesions[317]

IV, Intravenous; *NEC,* necrotizing enterocolitis; *PO,* per os (by mouth); *VLBW,* very-low-birth-weight.
Data from Young T, Magnum B. *Neofax 2008*. Raleigh, NC: Acorn Publishing; 2008.

at 11 years of age.[143] In preterm infants under 29 weeks' gestation, caffeine levels over 14.5 mcg mL are associated with a reduction in BPD/CLD, duration of ventilation, oxygen at discharge, and length of stay.[11]

Several recent studies have investigated the use of high- versus low-dose caffeine for apnea of prematurity. In an RCT the use of high (40 mg/kg/day loading; maintenance of 20 mg/kg/day) versus low (20 mg/kg/day loading; maintenance of 10 mg/kg/day) dose caffeine was studied in the first 10 days of life in preterm infants 32 weeks' GA or under.[349] **Those preterms receiving the higher dose of caffeine had less apnea of prematurity and less extubation failure without significant side effects.** A pilot study of high loading dose (80 mg/kg/IV) versus low loading dose (20 mg/kg/IV) in the first 24 hours of life in 74 premature infants (≤30 weeks' GA) found a higher incidence of cerebellar hemorrhage, hypertonicity, and alteration in early motor performance in the group receiving the higher loading dose.[342] Another study using high (loading 20 mg/kg/day; maintenance 15 mg/kg/day) versus low (loading 20 mg/kg/day; maintenance 5 mg/kg/day) dosing in preterms less than 32 weeks GA found **significantly less apnea in the high-dose group, as well as fewer extubation failures, without a significant increase in side effects or clinical outcomes.**[592]

Theophylline has been shown to significantly decrease CBF velocity. A recent RCT comparing theophylline with inhalation of (0.8%) CO_2 to treat apnea of prematurity found equal efficacy in decreasing the number and duration of apneic episodes, with fewer side effects and no alteration of CBF with the inhalation therapy.[9]

A systematic review of doxapram for use as therapy in apnea of prematurity showed that there are limited studies and levels of evidence about its safety and efficacy.[552] The reviewers recommend a large multicenter RCT before routine use of doxapram can be recommended.

Although gastroesophageal reflux is frequent in preterm infants because of lower esophageal sphincter relaxation, recent studies do not find an association between predischarge apnea and reflux.[55,138] Reflux events are unrelated to apneic events; apneic events are not a frequent marker of reflux, and when there is a temporal association, there is no effect on apnea duration, desaturation, or bradycardia.[138] Another study measured cardiorespiratory and GER event rates during prefeeding and postfeeding intervals and found that the frequency, height, and pH of GER are significantly altered by feedings in preterms but that apnea, bradycardia, and desaturations were not more prevalent after feeding.[482] A more recent study found that the feeding method (bolus versus slow infusion) does not reduce the number or duration of apneic episodes in preterm infants.[375]

For premature infants, the AAP recommends that GER is normal, resolves with age, usually resolves without treatment, and preterm infants older than 32 weeks' PMA should be positioned supine using safe sleep practices.[152] **Prokinetic agents to improve gastric emptying (e.g., metoclopramide, domperidone, and erythromycin) do not reduce GER symptoms in preterm infants.**[107,152] Histamine-2 (H_2) receptor blockers (e.g., ranitidine, famotidine) have not been studied for their efficacy in relieving GER symptoms. **These medications are associated with increased incidence of NEC, late-onset infections, and death, possibly due to intestinal microbiome alteration.**[152,197,201] **Proton-pump inhibitors (e.g., omeprazole, lansoprazole) are ineffective in relieving clinical signs of GER in infants and may have similar potential side effects as H_2 blockers.**[152] The AAP recommends that the **use of medications should be in moderation, if at all, because their efficacy is not supported with evidence and harm is associated with their use.**[152]

Complications. Side effects of xanthines include gastric irritation, hyperactivity (restlessness, irritability, wakefulness), myocardial stimulation (tachycardia, hypotension), and increased urinary output.

The prognosis for apnea arising from an underlying cause depends on the outcome of the disease process itself. The prognosis for apnea is generally good in infants who are otherwise well and healthy and for whom the apnea is not prolonged. **Delayed resolution of apnea (>36 weeks' PMA) and prolonged episodes of hypoxemia (>1 minute in duration) are associated with an increased risk for neurodevelopmental disturbance** at 13 months' postconceptual age[407] and at 18 months of age.[410] Long-term follow-up of the preterms in the randomized multicenter trial of caffeine use for apnea of prematurity (CAP) study found improved rates of survival without neurodevelopmental disability, reduced incidence of CP, and reduced BPD/CLD at 18 to 21 months of age among the caffeine-treated group.[458] The 11-year follow-up study of preterm infants in the CAP trial found a reduced risk of motor impairment in VLBW preterm infants given caffeine for apnea of prematurity but no significant reduction of the combined rate of academic, motor, and behavioral impairments.[457] More research is needed on the effects of caffeine on the developing brain, especially at the cellular/molecular levels, with administration of various doses and durations and the impact on the structure and function of the developing brain.[23]

PARENT TEACHING

Parental attachment to an infant with respiratory disease is especially difficult. It is made more difficult if the infant is also premature. Normal interaction is curtailed by the infant's condition and appearance, the environment, and the parent's reaction to these factors. An infant who is in an oxygen hood or receiving ventilation therapy to the lungs may give inadequate cues to arouse parental attachment and instead may arouse feelings of grief and loss (see Unit Six).

The goal of discharge planning is the best possible outcome with the least family disruption. Evaluation of parental readiness to care for their infant is essential to effective teaching and learning (Box 23.17). **Physical surroundings and preparations for the infant are assessed when possible by a home visit. Parental concerns at bringing home an infant with special care needs must be assessed and discussed.** The parents learn to be comfortable in handling and caring for their infant gradually throughout hospitalization. A specially designated or decorated room is used for family visiting and caregiving. Before discharge, the mother and/or father spends the night caring for the infant. Positive reinforcement and praise from the professional staff should be freely given to parents who

BOX 23.17 PARENT/CAREGIVER TEACHING IMPORTANT ASPECTS FOR PARENTS OF INFANTS WITH RESPIRATORY DISEASE

- Individualize parent teaching and evaluate parental readiness to care for an infant with ongoing respiratory care needs (e.g., home oxygen, tracheostomy, or ventilator care).
- Involve and teach parents care of their infant throughout hospitalization.
- Provide parents with written instructions for home care (e.g., tracheostomy care, suction, gastrostomy tube [g-tube] care).
- Provide parents with written instructions about all medications (dose, route of administration, side effects).
- Teach parents how to feed their infant, and encourage frequent feeding opportunities; teach parents how to feed with alternative feeding methods such as gastrostomy tube.
- Teach parents and other care providers how to perform cardiopulmonary resuscitation.
- Instruct parents in use of apnea monitors and other equipment for home use.
- Instruct parents to notify emergency personnel about their infant, posting emergency phone numbers.
- Instruct parents about the importance of follow-up care.

attend classes and successfully master the tasks of caregiving for their infant.

Special equipment such as oxygen tanks, NCs, a ventilator, and suction equipment for home use must be acquired before discharge. Sources, mode of delivery, and use of equipment must all be taught to parents before discharge. Pulmonary hygiene for infants with prolonged difficulty in handling secretions also must be taught. **Written protocols and instructions should be provided to parents, whenever possible. Parents must be informed of dosage, route of administration, side effects, and planned duration of use of all medications.**

Fluid and nutritional status is very important to any infant with a chronic condition, and nutritional information for parents is necessary. **Infants with tachypnea (CLD/BPD) often have difficulty with coordinating suck and swallow. Often smaller, more frequent feedings are necessary with use of supplemental oxygen.** Alternative feeding methods such as gavage or gastrostomy feeding may be necessary to safely provide enough calories with a minimum of work.

Apnea is especially distressing to parents because of their fears of recurrence once the infant goes home. If apnea is related to an underlying disease, treatment of the cause should result in resolution of the apneic episodes. Parents can be assured reliably that recurrence is unlikely unless the disease recurs. **With apnea of prematurity, assurance can be offered that infants do grow into a regular ventilatory pattern as their respiratory center matures, generally by 43 weeks' PMA.**[151] The AAP does not recommend the use of routine home monitors for preterm infants with resolved apnea of prematurity. However, home monitoring may be indicated for some preterm infants who have had an "unusually prolonged course of recurrent, extreme apnea," [151] and is usually discontinued after 43 weeks' PMA.

Before an infant needing a home monitoring system is discharged from the hospital, the parents must be given adequate support and instruction. Classes on the use of the apnea monitors must include demonstration of the equipment and return demonstrations. Minor equipment checks and repairs should be mastered before discharge.

Support by the primary care providers after discharge is essential. Parents must have telephone numbers of the medical facility and personnel they can call 24 hours a day in case of problems or equipment failure.

Anticipatory support includes discussion of potential stress factors related to having an infant on a monitor and/or oxygen at home. An apnea monitor in the home may provoke anxiety despite discussion and instruction. **When infants are discharged with apnea monitors, there is a marked increase in maternal fatigue 1 month after discharge** compared with a similar group discharged without monitors.[573] Increased fatigue interferes with activities of daily living and ability to parent and increases caregiver stress.[573] Interventions to alleviate fatigue after discharge may include spousal support, household help, child care for siblings, and opportunities for increasing sleep.

The parents of every infant who has apneic episodes or serious respiratory disease must be taught CPR. This set of skills is learned over the course of time by reading written materials and seeing and returning the demonstration. **Learning CPR cannot be done on the day of discharge but, rather, must be a staged process of individual and class instruction.** Supplying instructional

pamphlets written just for parents' aids in initial learning and provides a quick reference. If other family members or babysitters will provide child care during work or evening hours, they too must be able to resuscitate the infant.

Other emergency actions for which parents must be prepared include clearing the infant's airway, calling for help (having emergency phone numbers easily accessible), planning for an alternative communication source (e.g., neighbor's phone), and notifying the community rescue squad of the infant's presence in the home.

Parents must be taught how to recognize signs of illness or significant deterioration in the condition of their infant. In addition to information about special care needs, parents need information about normal newborn care. Developing realistic expectations and positive parenting skills is as important to these parents as it is to all new parents.

For the parents of an infant with special respiratory problems, the importance of continuous follow-up care must be emphasized. Follow-up visits should coincide with developmental stages, the natural course of the disease, and expected complications of the disease.

The parents whose child has special respiratory needs must learn a myriad of involved technical information. The primary care provider (frequently the primary nurse) is responsible for organizing, teaching, coordinating, and documenting the information. This nurse is also responsible for ensuring that the parents have not only been taught but in fact understand these concepts.

24 CARDIOVASCULAR DISEASES AND SURGICAL INTERVENTIONS

TARA SWANSON AND LORI ERICKSON

Congenital heart disease (CHD) is the most common life-threatening birth defect encountered in the neonatal intensive care unit (NICU). Although the incidence of these conditions has remained constant at approximately 1% of all infants born in the United States, the methods of diagnosis and treatment have undergone tremendous change over the past several decades.[8,40,99] It is the responsibility of the practitioner to recognize the presence of CHD and to provide accurate diagnosis and treatment. This chapter reviews the anatomy and physiology of the fetal and neonatal circulations, the pathophysiology of CHD, and the most current evidence-based treatments.

CONGENITAL HEART DISEASE: OVERVIEW

History

In 1892, Dr. William Osler wrote that CHD was of "limited clinical interest as in a large proportion of cases the anomaly is not compatible with life, and in others, nothing can be done to remedy the defect or even relieve the symptoms."[19] Dr. Maude Abbott, along with Dr. Helen Taussig and Dr. Alfred Blalock, suggested surgery to help these "blue babies."[97] This opened up the field of surgical treatment for cyanotic malformations of the heart. In 1938 Dr. Robert Gross was the first to successfully ligate a patent ductus arteriosus in a 7-year-old girl at Boston's Children's Hospital. The first successful adult heart transplant in the United States was done at Stanford University by Dr. Norman Shumway in 1968.[15] The first single-ventricle Fontan surgery was reported by Francis Fontan in 1971.[29,33] Remarkable progress has been made in the assessment and treatment of CHD in the subsequent decades. This is the direct result of advances in pediatric and fetal cardiology, cardiac surgery, neonatology, and neonatal intensive care nursing.

Incidence

Each year, approximately 40,000 babies born in the United States are diagnosed with CHD.[3,8] Highly sensitive echocardiography has led to the detection of more trivial forms of CHD, such as tiny ventricular septal defects. This inclusion has led to the higher incidence figures in recent years. The incidence of structural CHDs in liveborn infants is 4 to 10 per 1000 live births.[8,19] **Of these infants, approximately 25% will have *critical congenital heart disease* (CCHD) that results in death or requires cardiac surgery or cardiac catheterizations during the first year of life.**[8,37,67] Advances in diagnostic imaging, cardiac surgery, and neonatal intensive care have led to significant decreases in mortality rates. Infants with cardiac lesions that were once considered fatal are now surviving into adulthood.

Embryology

The heart is one of the earliest differentiating and functioning organs. **In human embryos, the heart begins to beat at about 22 to 23 days of life**

BLUE type highlights content that is particularly applicable to clinical settings.

and begins to effectively pump blood in the fourth week of life. The heart develops from the cardiogenic mesoderm and begins as a primitive heart tube. During the first few weeks of life, this primitive heart tube receives blood from three different venous systems (cardinal, vitelline, and umbilical) and supplies blood to six paired aortic arches. These veins and aortic arches must each regress or mature, and the primitive heart tube must undergo a complex process of looping, shifting, and septating to result in a normal heart with normal venous and arterial communications. **Cardiac development is almost complete by week 6 of gestation, which may be before a pregnancy is even recognized.**

Alterations in normal cardiac embryology result in a nonviable circulation (which leads to spontaneous fetal demise) or the abnormal but viable CHDs we see postnatally. Some cardiac lesions are viable in the setting of fetal circulation with a patent foramen ovale (PFO) and patent ductus arteriosus (PDA) but are not viable if these fetal connections close. **These congenital heart lesions require lifesaving treatment soon after birth, so a diagnosis must be made prenatally or within hours after birth to prevent cardiovascular collapse and death.**

Physiology

The physiologic changes that occur during the transition from intrauterine to extrauterine life have been well documented. To develop a clear understanding of the various congenital heart defects, knowledge of the basic principles of fetal circulation must be established.

FETAL CIRCULATION

Fetal circulation relies on the placenta for gas exchange, whereas postnatal circulation uses the lungs for gas exchange (Fig. 24.1). Highly oxygenated blood from the mother enters the fetal circulation through the vein in the umbilical cord. This blood enters the inferior vena cava via the ductus venosus. Blood from the inferior vena cava enters the right atrium (RA). Most of this blood is directed through the *foramen ovale* (a special fetal opening between the left and right atria) and into the left atrium (LA). Blood then passes through the mitral valve into the left ventricle (LV) and then through the aortic valve into the aorta. From the aorta, blood is first sent to the coronary arteries and brachiocephalic vessels. This results in **perfusion of the brain, the upper extremities, and the heart with the most highly oxygenated fetal blood. Only a small percentage of this blood will travel further in the aorta to supply the rest of the body.** After oxygen has been removed by the organs of the upper body, the blood returns to the right atrium through the superior vena cava. Some of the blood entering the right atrium stays on the right side of the heart, traveling through the tricuspid valve, right ventricle (RV), and pulmonic valve to eventually flow into the pulmonary artery.

Fetal lungs are not used for breathing. The work of exchanging oxygen and carbon dioxide is performed by the placenta. Because of high pulmonary vascular resistance (PVR), fetal circulation shunts most of the blood away from the lungs. Blood is shunted from the pulmonary artery to the aorta through a connecting fetal blood vessel called the *ductus arteriosus.*[72] Blood traveling through the ductus arteriosus has low oxygen content. This blood supplies the lower portion of the fetal body before returning to the placenta through the two umbilical arteries. Blood then enters the placental circulation and is resaturated.

TRANSITION FROM PRENATAL TO POSTNATAL CIRCULATION

In utero, systemic vascular resistance (SVR) is low, primarily because of low resistance in the placenta. Conversely, the PVR is high, with the constricted and hypertrophied pulmonary arterioles being relatively resistant to blood flow.

Both the labor process and the first few breaths of life begin the termination of fetal circulation and the transition to newborn circulation. **At birth, the placenta is removed from the circulation, thereby greatly increasing the SVR. The first few breaths inflate the lungs for the first time and also increase the oxygen content in the neonatal blood. Both of these changes cause a decrease in PVR, which leads to increased pulmonary blood flow.**

The *patent ductus arteriosus* (PDA) is extremely sensitive to oxygen levels in the blood. As the neonatal Pa_{O_2} rises, this fetal connection between the aorta and the pulmonary artery (PDA) is no longer needed and begins to close. Constriction of the PDA leads to functional closure of this vessel within the first few days of life. Permanent, fibrotic closure of the PDA usually

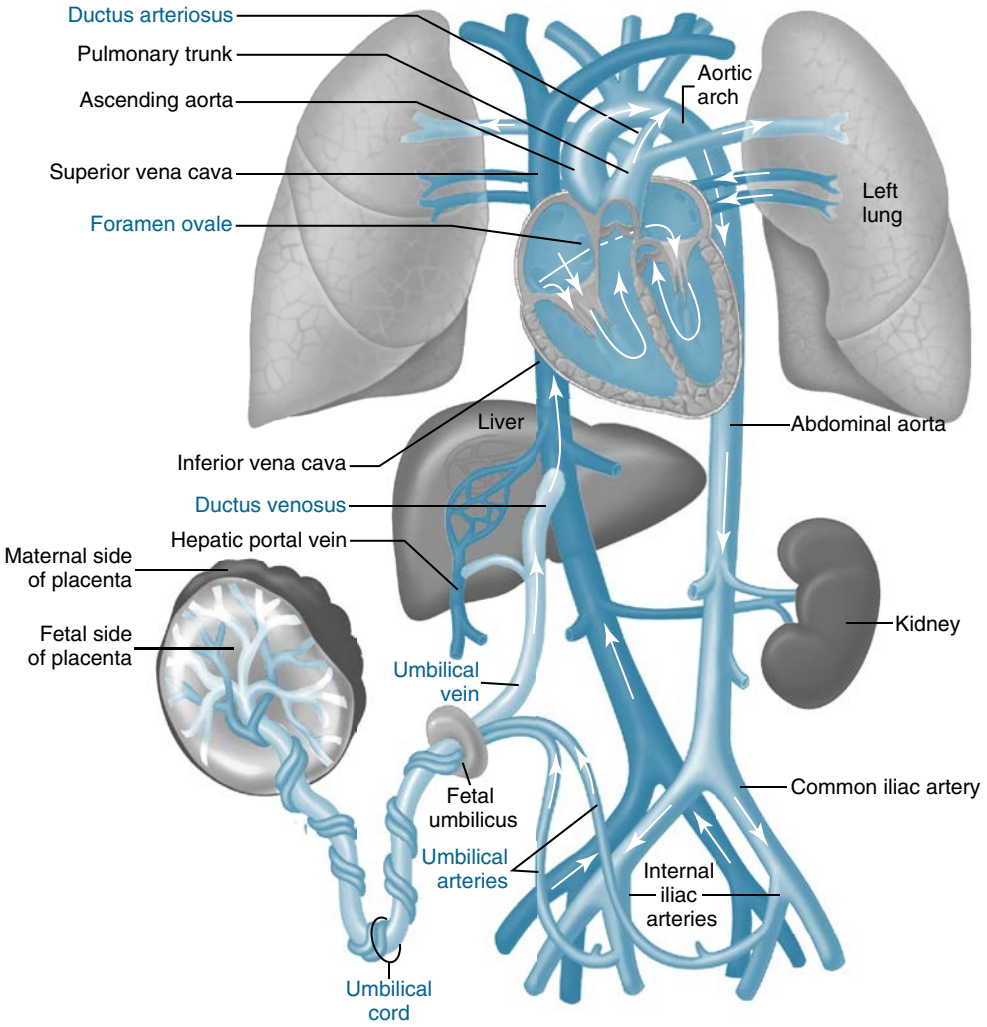

FIGURE 24.1 Fetal circulation. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. (Modified from Patton KT, Thibodeau GA. *Anatomy and Physiology*. 7th ed. St. Louis: Mosby; 2010.)

occurs weeks to months after birth. As the PVR drops and the PDA closes, circulation to the lungs increases, resulting in increased blood return to the left atrium. This increased pressure in the left atrium causes the foramen ovale to close. **Anatomic closure of the foramen ovale can take months to years.** Finally, with the clamping of the umbilical cord, umbilical venous flow ceases, and the ductus venosus begins to close, with anatomic closure taking approximately 1 to 2 weeks.[74]

Once these changes occur, the newborn's circulation resembles that of an adult (Fig. 24.2). Deoxygenated blood returns to the heart by the inferior and superior venae cavae and enters the RA, RV, pulmonary artery, and pulmonary circulation, where oxygen and carbon dioxide are exchanged. Oxygenated blood then returns to the heart through the pulmonary venous system and enters the LA, LV, and ultimately the aorta and systemic arterial system. **However, PVR and pressures in the right ventricle and pulmonary system remain elevated in the neonate because of hypertrophy of the pulmonary vessels.** This hypertrophy slowly resolves so that PVR and right

heart pressures decrease to lower levels between 1 and 2 months of age.

Etiology

In most cases, the cause of abnormal cardiac development is unknown. Traditionally, **the etiology of congenital heart defects is thought to be multifactorial, involving a complex interaction between genetic and environmental factors.** Some maternal factors contribute to the risk for CHD. For example, women with pregestational diabetes or women with excessive alcohol consumption are at increased risk of having an infant with a heart defect. Maternal phenylketonuria, maternal systemic lupus erythematosus, and maternal infections also increase the risk of CHD for offspring. The use of assisted reproductive technology also results in increased risk for a heart defect in fetuses conceived by these methods.*

However, **most CHD occurs in the absence of any identifiable maternal risk factors,** so most mothers should be reassured that they did not cause their child's malformation. Table 24.1 lists the most common maternal and familial risk factors for cardiac malformations.[96] Box 24.1 lists fetal risk factors associated with an increased incidence of cardiac defects that should be referred for evaluation by a fetal cardiologist.[23]

Recent studies suggest that the single greatest risk factor for CHDs is genetic. Table 24.2 shows the most common genetic abnormalities associated with CHDs. Children with chromosomal abnormalities such as trisomy 13, trisomy 18, and trisomy 21 often have significant CHD. At the level of the individual gene, there are well-established single-gene mutations that cause heart disease, such as mutations in *NOTCH-1* that cause aortic valve disease.[50] Smaller genetic abnormalities, such as deletions, duplications, and rearrangements, can also be closely associated with a high risk of structural heart disease. For example, 1p36 deletion syndrome is a microdeletion, with up to 71% of patients having a structural abnormality.[7] In familial CHD, there could be a 31% to 46% chance of identifying the genetic variant causing the defect in the known CHD genes.[10] With rapid advances in genetic testing capabilities, such as robust microarray testing and extremely rapid genome sequencing, new genetic causes of abnormal cardiac development are being identified daily.[93]

PRENATAL DIAGNOSIS

Because of the widespread use of antenatal ultrasound, it is increasingly common for the fetus to be diagnosed with CHD. Fetal echocardiography has proven to be a valid, reliable, and accurate tool in the prenatal diagnosis of CHD.[22] **The recommended timing for a fetal echocardiogram is between 18 and 20 weeks of gestation,** although detailed cardiac evaluation and accurate CHD diagnoses can be made as early as 12 weeks' gestation.[63]

Studies have shown that prenatal diagnosis of CHD can improve patient outcomes and survival after birth.[30,50] Being born at or near a hospital with pediatric cardiothoracic surgery services has also been shown to reduce neonatal morbidity and mortality rates.[64] **Some neonates with extremely critical CHD require cardiac intervention within the first minutes to hours of life;** these children have little chance of survival unless their heart disease is identified prenatally and their postnatal care providers are prepared for and capable of delivering emergency treatment in the delivery room.

An increased chance for survival of infants with CCHD is documented at greater than 38 weeks' gestation. A higher birth prevalence of

TABLE 24.1 MOST COMMON MATERNAL AND FAMILIAL RISK FACTORS ASSOCIATED WITH CHD

	ASSOCIATED RISK, % LIVE BIRTHS	TIMING FOR FETAL EVALUATION AND COMMENTS
Maternal Factors		
Pregestational DM or DM noted in the first trimester	3-5	18-22 weeks for fetal echocardiogram; DM can be associated with numerous cardiac defects and ventricular hypertrophy in the third trimester with poorly controlled DM
Phenylketonuria	12-14	18-22 weeks for fetal echocardiogram
Lupus or Sjögren's syndrome if SSA/SSB autoantibody positive	1-5	16 weeks initially then frequently if heart block identified Maternal hypothyroidism or vitamin D deficiency may also increase risk
Maternal infections	1-2	18-22 weeks for fetal echocardiogram. Maternal rubella has been associated with CHD; parvovirus, coxsackievirus, adenovirus, and cytomegalovirus have been associated with fetal myocarditis
Teratogens: medication exposures	1-2	
Anticonvulsants	1.8	18-22 weeks for fetal echocardiogram
Lithium	<2	18-22 weeks for fetal echocardiogram
ACE inhibitors	2.9	18-22 weeks for fetal echocardiogram
Retinoic acids	8-20	18-22 weeks for fetal echocardiogram
Vitamin A (>10,000 IU retinol/day)	1.8	18-22 weeks for fetal echocardiogram
SSRIs	1-2	18-22 weeks for fetal echocardiogram, reports of associated risk for RVOT lesions
NSAIDs	1%-2% structural defects 5%-50% for ductal constriction	18-22 weeks for fetal echocardiogram With daily use rule out ductal constriction after exposure
Maternal and Family History		
Use of assisted reproductive technology	1.1-3.3	18-22 weeks for fetal echocardiogram Both IVF and IVF with ICSI seem to carry risk for CHD
Maternal structural cardiac disease	3-7 (all) 10-14 (atrial ventricular septal defects) 13-18 (aortic stenosis) <3 (TOF, d-TGA)	18-22 weeks for fetal echocardiogram
Paternal structural cardiac disease	2-3	18-22 weeks for fetal echocardiogram
Sibling with structural disease	3 Up to 8% for hypoplastic left heart syndrome	18-22 weeks for fetal echocardiogram
Second- and third-degree relatives with CHD	1-2	18-22 weeks for fetal echocardiogram

CHD has been noted with very or extremely premature births compared with term births (7.4 per 1000 or premature births versus 1.5 per 1000 term births). Improved prenatal detection and referral to advanced maternal-fetal consultation is warranted to try to reduce the mortality and morbidity associated with a preterm infant with CHD.[18]

Unfortunately, less than half of children with CHD receive a prenatal diagnosis.[59] Even when routine prenatal ultrasound screening is performed during the pregnancy, one study showed that only 39% of CHD is detected.[71] Thus, access to medical care is not the only barrier to prenatal detection of heart lesions. Better screening methods are required, along with referral for a detailed fetal echocardiogram for any child at increased risk of having heart disease (see Box 24.1).[23] Even in the most experienced hands, fetal echocardiography is limited by technical and fetal factors that make some cardiac diagnoses impossible to detect before birth. **Box 24.2 lists CHDs that are often undetected by prenatal ultrasound evaluation.**

Extracardiac anomalies should prompt referral for intense cardiac evaluation because there is a high incidence of heart disease in children with even one other organ abnormality.[85] Conversely, children prenatally diagnosed with a congenital heart lesion should have a detailed evaluation of extracardiac structures to rule out associated anomalies.

BOX 24.1 FETAL RISK FACTORS FOR CONGENITAL HEART DISEASE THAT SHOULD BE REFERRED FOR FETAL ECHOCARDIOGRAM BY A FETAL/PEDIATRIC CARDIOLOGIST

Fetal Factors

- Suspected cardiac abnormality on obstetric ultrasound
- Rhythm abnormalities: tachycardia, bradycardia, complete heart block, irregular rhythm
- Identified noncardiac abnormality: central nervous, respiratory, gastrointestinal, genitourinary, musculoskeletal
- Known or suspected chromosomal abnormality
- Increased nuchal translucency on obstetric ultrasound
- Abnormality of umbilical cord, placenta, or intraabdominal venous anatomy
- Monochorionic twinning
- Hydrops fetalis

Data Collection

HISTORY

A detailed family history should be obtained because a parent or sibling with CHD increases the likelihood of CHD for a child.[23] Pregnancy details such as viral exposure during pregnancy (rubella, coxsackievirus B, and enteroviruses), maternal medications, and maternal ingestion of alcohol or illegal substances should be evaluated. Labor and delivery complications should be carefully examined for risk factors that could affect the cardiovascular system. For example, intrauterine hypoxia

TABLE 24.2 CHROMOSOMAL ABERRATIONS EVIDENT IN NEONATAL PERIOD THAT ARE ASSOCIATED WITH CONGENITAL HEART DISEASE

POPULATION	INCIDENCE OF CONGENITAL HEART DISEASE (%)	MOST COMMON LESIONS		
		1	2	3
Trisomy 21 syndrome	50	Ventricular septal defect, endocardial cushion defect	Atrial septal defect	Patent ductus arteriosus
Trisomy 18 syndrome	99+	Ventricular septal defect	Patent ductus arteriosus	Pulmonary stenosis
Trisomy 13 syndrome	90	Ventricular septal defect	Patent ductus arteriosus	Dextrocardia
Turner syndrome	35	Coarctation of the aorta	Aortic stenosis	Atrial septal defect
22q deletion syndrome (DiGeorge syndrome)	50	Interrupted aortic arch	Truncus arteriosus	Tetralogy of Fallot

and perinatal hypoxia are risk factors for the development of myocardial dysfunction or persistent pulmonary hypertension of the newborn (PPHN).

CLINICAL PRESENTATION OF INFANTS WITH SEVERE CARDIAC DISEASE

CHD is often not suspected until after birth when the newborn presents with one or more signs or symptoms (Box 24.3).[98] **The timing of presentation of signs or symptoms depends on the severity of the defect and alterations in cardiovascular physiology during transitional circulation (i.e., closure of the ductus arteriosus and the fall in PVR).** Despite the presence of many heterogeneous forms of heart disease, a limited number of signs and symptoms present in the neonate.

Murmurs. Heart murmurs are a common finding in neonates and can be normal. Closure of the PDA causes a murmur, so all neonates who go through the normal cardiac transition will have a murmur briefly as the ductus arteriosus closes. Although cardiac murmurs in the neonatal period do not necessarily indicate heart disease, they must be carefully evaluated. The absence of a murmur does not exclude severe, life-threatening cardiac anomalies.

Pathologic murmurs tend to appear at characteristic ages. Murmurs associated with semilunar valve stenosis and atrioventricular valve insufficiency tend to be noted very shortly after birth. In contrast, **murmurs caused by left-to-right shunt lesions (PDA, ventricular septal defect [VSD]) may not be heard until the second to fourth week of life.** The age of the neonate when the murmur is first noted gives an important clue about the nature of the cardiac defect. **The timing of the murmur during the cardiac cycle is important; diastolic murmurs are almost never innocent. The intensity (loudness), quality (harsh, vibratory), location, and radiation of the murmur in addition to other associated findings (click, rub, gallop) can all be used to help make a diagnosis.**

Cyanosis. Cyanosis (a bluish discoloration of the skin, nail beds, and mucous membranes) is one of the most common presenting signs of CHD in the neonate. Cyanosis occurs with CHD when deoxygenated venous blood abnormally shunts "right to left" within the heart and then enters the systemic arterial system again (without going through the lungs to pick up oxygen). **Depending on the underlying skin complexion, clinically apparent cyanosis is usually not visible until there is more than 3 g/dL of desaturated hemoglobin in the arterial system.**[28] Cyanosis depends on both the severity of hypoxemia (which determines the percentage of oxygen saturation) and the hemoglobin concentration. **True central cyanosis should be differentiated from acrocyanosis (blueness of the hands and feet only), which is a normal finding in the neonate.**

Cyanosis in the newborn must be differentiated between cardiac and noncardiac causes. Primary lung disease (see Chapter 23) is a common cause of labile cyanosis due to persistent pulmonary hypertension.[34] Central nervous system abnormalities can also cause hypoxia and result in cyanosis. Clinical cyanosis can occur without hypoxemia in a neonate with *methemoglobinemia* and *polycythemia*.

The *hyperoxia test* is beneficial in differentiating respiratory disease from cyanotic heart disease. This test is a sensitive and specific tool in the initial evaluation of the neonate with suspected CHD and is used

BOX 24.2 CARDIAC LESIONS OFTEN UNDETECTED BY FETAL ECHOCARDIOGRAPHY

- Small ventricular septal defect (VSD)
- Atrial septal defect (ASD)
- Persistent patent ductus arteriosus (PDA)
- Total or partial anomalous pulmonary venous return (TAPVR/PAPVR)
- Mild aortic or pulmonary stenosis
- Coarctation of the aorta

BOX 24.3 CRITICAL FINDINGS SEVERE CARDIAC DISEASE

- Cyanosis
- Respiratory distress
- Congestive heart failure
- Diminished cardiac output
- Abnormal cardiac rhythm
- Cardiac murmurs

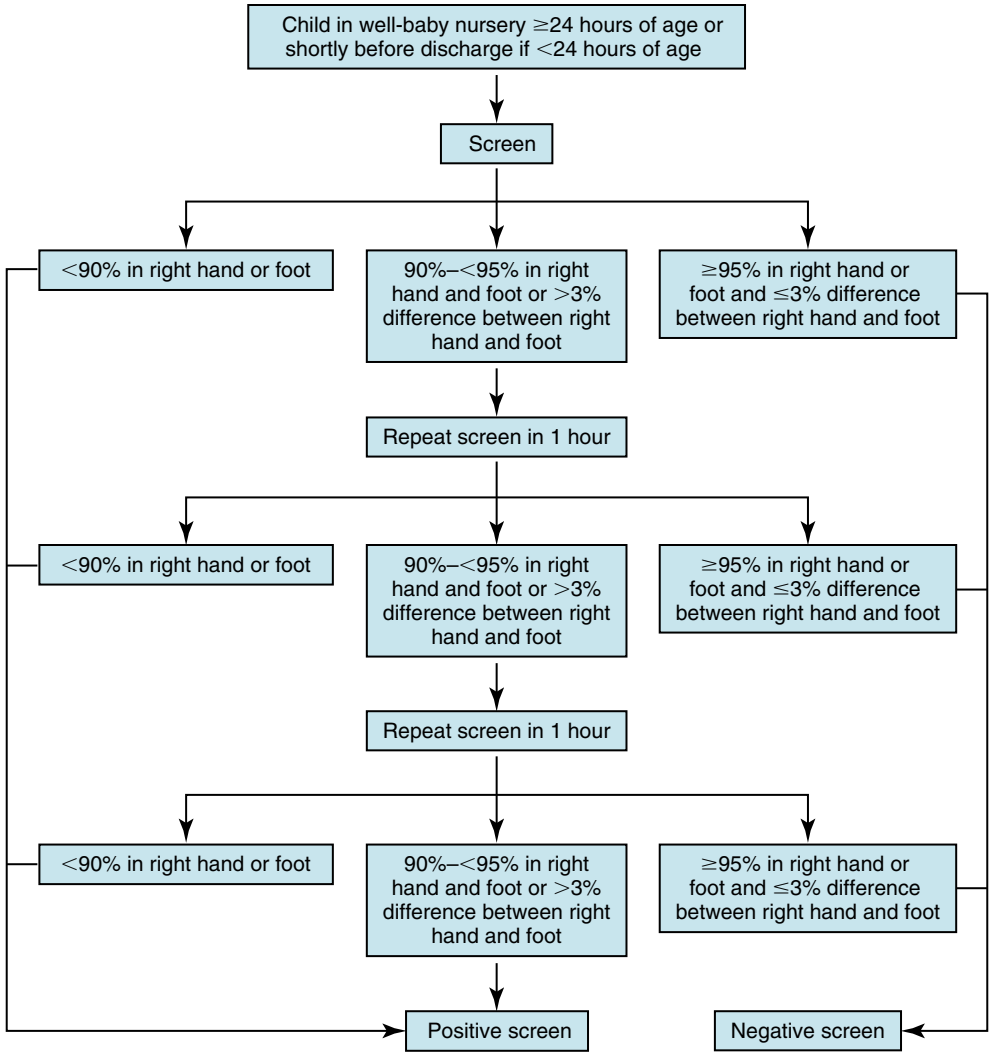

FIGURE 24.3 Screening for congenital heart disease. (From Kemper AR, Mahle WT, Martin GR, et al. Strategies for implementing screening for critical congenital heart disease. *Pediatrics.* 2011;128:e1–e8.)

to investigate the possibility of a fixed (intracardiac) right-to-left shunt. The hyperoxia test is performed by obtaining arterial blood gas measurements (preferably from the right radial artery) when the infant is in room air and then after the infant has been in 100% oxygen for 5 to 10 minutes. **If the Pa_{O_2} is greater than 150 mm Hg, the presence of a right-to-left shunt and CHD as the cause of cyanosis is unlikely.**[92]

Pulse oximetry screening is a simple and effective screening tool that has become mandated by many individual states in the United States to screen for CCHD. **Routine pulse oximetry is performed in asymptomatic newborns after 24 hours of life but before hospital discharge** (see Chapter 31).[57,58] **Utilization of routine pulse oximetry screening has found that infants with CCHD may have a low percentage of oxygen saturation before other clinical symptoms are noted** (Fig. 24.3).[49] Pulse oximetry completed after 24 hours of age has been shown to have a high sensitivity (76.5%) and specificity (99.9%) and a low false-positive rate (0.05%).[68] **An oxygen saturation (Spo2) of less than 92%**

and Spo2 differences of greater than 10% from preductal to postductal can be indicators of ductal-dependent cardiac disease.[34] Although all hypoxia found with pulse oximetry screening may not be caused by CHD (as noted with the false-positive results), infants with significant noncardiac hypoxia likely require NICU care.

Respiratory Distress. Most infants with cyanosis from CHD do not have respiratory distress (e.g., tachypnea, intercostal retractions, grunting, nasal flaring). Often the degree of cyanosis is not proportional to the degree of respiratory distress evaluated from the physical and chest x-ray examinations. If a cardiac lesion is present that allows a fixed right-to-left shunt, increasing inspired oxygen will have little effect on the arterial blood gases. However, if the cyanosis is caused by a diffusion defect in the lungs (pulmonary disorder), the degree of cyanosis often decreases with increasing inspired oxygen.

Respiratory distress most often occurs with CHD when the lungs become too "wet." This occurs when too much blood is pumped to the lungs (pulmonary overcirculation) or when the lung circulation cannot drain well due to pulmonary vein or left heart abnormalities. When there is too much blood in the lung circulation, fluid leaks into the lung tissues and causes pulmonary edema. This can affect the lungs' ability to exchange oxygen and carbon dioxide, and it is difficult for the lungs to expand when they are stiff due to excessive fluid. Signs and symptoms of respiratory distress include tachypnea, retractions, nasal flaring, head bobbing, and abdominal breathing. A chest x-ray identifies cardiomegaly and pulmonary edema, although it cannot determine whether the pulmonary edema is due to primary lung disease or a congenital heart lesion.

Congestive Heart Failure. CHF occurs when the heart cannot meet the metabolic demands of the tissues. Signs and symptoms of CHF reflect venous congestion and decreased tissue perfusion due to inadequate cardiac output. In the early stages, the neonate may be tachypneic and tachycardic with an increased respiratory effort, diaphoresis, hepatomegaly, and delayed capillary refill. If severe, CHF may present acutely with cardiorespiratory collapse and shock, particularly with obstructive defects. In less severe cases, CHF signs can be subtle such as feeding difficulties and growth failure. Edema caused by CHF is rarely seen in neonates. Birth asphyxia and anemia must also be considered as causes of CHF in neonates.

BOX 24.4 CRITICAL FINDINGS
CONGESTIVE HEART FAILURE

- Tachycardia
- Cardiac enlargement
- Tachypnea
- Gallop rhythm
- Decreased peripheral pulses and skin mottling in the extremities
- Decreased urine output and edema
- Diaphoresis
- Hepatomegaly
- Hypotension
- Decreased activity
- Failure to thrive and feeding problems
- Diminished cardiac output

The common symptoms associated with CHF (Box 24.4) can be understood using the physiologic principles previously outlined.

Tachycardia. The heart attempts to compensate for the decrease in cardiac output (CO) by increasing either the heart rate (HR) or the stroke volume (SV) (CO = HR × SV). The neonatal myocardium has fewer contractile elements and is poorly innervated by the sympathetic nervous system, thus limiting its capacity to increase stroke volume. Neonatal increases in cardiac output are achieved mainly by increasing the heart rate. In the sick neonate, a fast heart rate must be inspected closely to be certain it is a sinus tachycardia rather than an arrhythmia.

Cardiac Enlargement. Hypertrophy and dilation of the heart occur in response to a pressure or volume overload. This is referred to as *cardiomegaly.* This enlargement is evident on chest x-ray examination.

Gallop Rhythm. The gallop rhythm is an abnormal filling sound that can be present with CHF. It is heard as a triple rhythm on auscultation.

Decreased Peripheral Pulses/Poor Capillary Refill. Decreased cardiac output results in a compensatory redistribution of blood flow to vital tissues. Peripheral tissue

perfusion is decreased, which results in **decreased peripheral pulses and poor capillary refill.** A decrease in peripheral perfusion is often subtle, but it is an alarming sign of declining cardiac output and impending cardiovascular collapse. **Capillary refill and peripheral pulses are essential to monitor in the child at risk for decreased cardiac output.**

Decreased Urine Output and Edema. **Decreased renal perfusion results in decreased glomerular filtration. The body interprets this as a decrease in intravascular volume and begins to initiate compensatory mechanisms such as vasoconstriction and retention of fluid and sodium.** Neonates may manifest this as weight gain and periorbital edema. **Poor urine output can be a sign of poor central perfusion, and as such, urine output should be monitored closely.**

Diaphoresis. **CHF leads to an increase in metabolic rate and increased activity of the autonomic nervous system, resulting in diaphoresis.** This is representative of the increased workload of the heart in failure. In neonates, this is most concerning during feedings or other periods of increased metabolic demands.

Hepatomegaly. The right ventricle in CHF does not adequately empty. This leads to a backup of blood and elevated pressures in the RA central venous system, and hepatic system. ***Hepatomegaly* results from hepatic venous congestion and is an easily evaluated sign of systemic venous overload.**

Hypotension. **An infant with low cardiac output will exhibit systemic hypotension, which can be detected and monitored by invasive or noninvasive blood pressure measurements.** The causes of hypotension are complex and can stem from cardiac, respiratory, and endocrine abnormalities.[84] Short- and long-term complications are possible, including intraventricular hemorrhage, periventricular leukomalacia, poor long-term neurodevelopment, hepatic and renal injury, or death. These adverse events may be worse in preterm infants with hypotension.[14,43]

There are multiple causes of systemic hypotension, including pulmonary hypertension, arrhythmia, and structural heart disease. **Preload, contractility, and afterload all impact systemic blood pressure, and abnormalities can contribute to hypotension. Mean arterial pressure (MAP) should be followed, and normative values are impacted by gestational age.** Both systolic and diastolic hypotension can be a sign of impending cardiac failure.[43]

Decreased Activity and Exercise Intolerance. **The decreased perfusion to peripheral tissues and the increased energy needed by the heart in failure leave little energy for activities such as feeding and crying.** The infant in heart failure may sleep more than other infants.

Failure to Thrive/Feeding Difficulties. **The basal metabolic rate is increased in neonates with CHF,** and both the heart and lungs have a higher demand for energy due to their increased workloads and inefficiencies. However, tachypnea and easy fatigability compromise the infant's ability to feed. **Poor growth and failure to thrive occur from the mismatch between above-normal caloric needs and below-normal ability to eat.** Significant feeding support is often necessary. **Most infants require higher-calorie formula or expressed breastmilk supplemented with high-calorie additives.** Nasogastric (NG) or gastrostomy (G) feeding tubes may be required when caloric intake requirements cannot be met with oral feeding. **Supplemental feeding tubes also decrease the amount of work required to feed, so they can be beneficial to help augment the caloric intake and decrease the caloric needs of an infant.** Cardiac nutrition and dietary support are vital for infants with CHD and heart failure.

Dysrhythmias. Abnormalities of the cardiac rhythm and murmurs are discussed individually later in the chapter.

CARDIAC EXAMINATION

See Specific Conditions later in this chapter.

LABORATORY DATA

Blood Pressure/Four-Extremity Blood Pressure. Adequate blood pressure is vital to deliver enough blood to the body. **Hypotension is an alarming sign that may suggest worsening cardiac function and poor cardiac output.** An ill neonate may first show signs of peripheral vasoconstriction and poor perfusion, mechanisms that will maintain normal central blood pressure at the expense of peripheral tissue perfusion. **Neonates at risk for decreased cardiac output should have blood pressure evaluated frequently, as well as frequent monitoring of capillary refill and peripheral pulses.**

The measurement of blood pressure should be taken in both arms and both legs. A systolic pressure that is more than 10 mm Hg higher in

the right upper extremity compared with the lower body is abnormal and suggests coarctation of the aorta, aortic arch hypoplasia, or interrupted aortic arch. However, this is a highly specific test with low sensitivity; the lack of a systolic blood pressure gradient does not conclusively rule out aortic arch abnormalities. **After an aortic arch anomaly has been ruled out, routine blood pressure monitoring may be performed in a single extremity.**

Chest X-Ray Examination. Frontal and lateral views (if possible) of the chest should be obtained. In neonates, the size of the heart may be difficult to determine because of the overlying thymus. **Chest x-ray examination may be normal even in the presence of life-threatening CHD. However, the degree of pulmonary vascularity helps define the type of CHD present and is characterized as being increased, normal, or decreased. Pulmonary edema can also be assessed and can suggest pulmonary overcirculation or pulmonary venous congestion.** The heart size should be evaluated, and the cardiac silhouette can suggest which cardiac chamber may be enlarged.

Near-Infrared Spectroscopy. Near-infrared spectroscopy (NIRS) is a helpful, noninvasive tool to monitor cerebral and splanchnic oxygen saturations and can be used to infer details about regional hemodynamics in the critically ill newborn. **Downtrends in values may be an early indicator of low cardiac output before other clinical signs are noted.** NIRS monitoring is especially helpful for left-sided obstructive lesions, such as hypoplastic left heart syndrome and coarctation of the aorta, to monitor for early clinical indicators of low cardiac output.[39]

Arterial Blood Gases. The $Paco_2$ in cardiac disease is often normal unless primary pulmonary disease is also present. **In CHF and low cardiac output, metabolic acidosis may be present.** Frequent monitoring of blood gases may be necessary with CCHD that is ductal dependent to assess cardiac output and peripheral tissue perfusion. In general, **the acid-base balance should be monitored closely in neonates with critical CHD.**

Venous Blood Gases. Venous, capillary, and arterial blood gases can be used to assess acid-base status and guide ventilator and respiratory support. Mixed central venous saturations can provide important information about cardiac output and tissue oxygenation.[91]

Lactic Acid. Lactic acid production increases when there is poor tissue perfusion. An increased lactic acid level can indicate low cardiac output or insufficient systemic perfusion.

Basal Metabolic Panel. Electrolyte and renal function evaluation should be normal. **With low cardiac output, poor renal perfusion may lead to decreased renal function.** Renal function should be closely monitored, including blood urea nitrogen (BUN) and creatinine levels.

Hypoglycemia is not a primary effect of CHD, but it can result from poor feeding, genetic abnormalities associated with CHD, or medications used to treat the infant. **The glucose level should be closely monitored, and neonates should be maintained in a normal glycemic state.**

The use of diuretics for CHF can lead to electrolyte imbalances. Neonates taking diuretics may require electrolyte monitoring and supplementation to maintain normal balance. Sodium, potassium, and chloride depletions are most commonly noted with prolonged diuretic use.

Complete Blood Count. Significant anemia decreases the blood's oxygen-carrying capacity, increases the cardiac workload, and worsens hypoxemia in neonates with CHD. The desired hemoglobin level may be altered based on the infant's age and hypoxia because polycythemia is an expected and potentially helpful response to chronic cyanosis. Elevation of the white blood cell count is not expected with CHD and, if present, should prompt assessment for possible infection. Platelet levels should be normal in neonates with CHD.

Brain-Natriuretic Peptide. Although levels may vary in individual cardiac defects, following trends for **brain-natriuretic peptide (BNP) or N-terminal (NT)-Pro BNP levels may help to predict clinical outcomes and the degree of cardiac stress. These values are not reliable in the first few days of life as an indicator of CHD alone but can be used in the preoperative and postoperative management of simple and complex CHD.**[27]

Electrocardiogram. **A neonatal electrocardiogram (ECG) is most useful for evaluating cardiac dysrhythmias and less useful for evaluating structural heart disease.** An abnormal ECG can help define the type of structural heart disease, but **a newborn ECG is frequently "normal for age" despite significant structural defects** (e.g., transposition of the great arteries). Some structural heart defects are associated with abnormal development of the conduction system. **An ECG is essential to evaluate conduction system abnormalities, including sinus node dysfunction, heart block, or accessory pathways.**

Echocardiogram. **The echocardiogram is indispensable in the diagnosis of CHD.** Two-dimensional echocardiography can define cardiac anatomy and can assess cardiac physiology by estimating pressures and gradients and evaluating cardiac function.[17] **Supplemented with Doppler and color Doppler, the echocardiogram has become the primary diagnostic tool in pediatric cardiology.** During the procedure, close monitoring is recommended, with attention to vital signs, respiratory status, and temperature.

A noninvasive transthoracic echocardiogram is the most commonly used approach. Three-dimensional echocardiograms that offer real-time three-dimensional imaging have improved significantly and are becoming more clinically useful, especially for evaluating valve anatomy and function. Transesophageal echocardiography (TEE) is almost never used for infants outside of the operating room, but this imaging modality is routinely used for cardiac evaluation in the operating room immediately before and after surgical repair.

Computed Tomography. Sixty-four-slice multidimensional computed tomography (64-MDCT) can image some thoracic regions beyond the scope of an echocardiogram and can help define the spatial relationship and distance between thoracic structures when planning surgery. **Computed tomography (CT) currently requires significantly shorter scan times compared with cardiac magnetic resonance imaging,[86] so sedation is not usually required.** This benefit can be substantial when evaluating a sick, unstable neonate. **CT exposes the infant to radiation, but newer technologies and protocols are now applied to keep the radiation dosage as low as possible.[20]**

Magnetic Resonance Imaging. Like CT, magnetic resonance imaging (MRI) offers three-dimensional reconstruction and high-resolution images of the heart and great vessels. MRI is of particular use in evaluating extracardiac vascular abnormalities, such as arch anomalies, vascular rings, and pulmonary arteriovenous anomalies. **MRI provides high spatial resolution, excellent soft-tissue definition, and a large field of view, and it does not expose the patient to radiation. However, an hour or two may be required to perform the test, so sedation is often required and this may be contraindicated for an unstable patient.** In addition, MRI is expensive.[35]

General Treatment Strategy

Optimal management of infants with heart disease requires specialized expertise. **Infants require close monitoring for hypoxia, hypoglycemia, acidosis, CHF, and poor peripheral perfusion.**

The infant must be kept in an incubator or radiant heat warmer in which body temperature is maintained while color changes (pallor and increased cyanosis) may be observed. **A cardiorespiratory monitor is necessary for continuous cardiac monitoring to detect bradycardia, tachycardia, and dysrhythmias. Monitoring of oxygen saturations is mandatory** to determine the adequacy of pulmonary blood flow and/or increased need for supplemental oxygen. Pre- and post-ductal oxygen saturations may both be required, depending on the child's cardiac disease. **Respiratory effort should be frequently assessed** for tachypnea, shallow breathing, apnea, retractions, grunting, abdominal breathing, head bobbing, and nasal flaring. **Urine output, peripheral pulses, blood pressures, NIRS, and capillary refill should be monitored closely. Other signs of CHF should be documented, such as diaphoresis, hepatomegaly, decreased activity level, and poor feeding behavior.**

MANAGEMENT OF CONGESTIVE HEART FAILURE

The medical management of CHF attempts to reverse the outlined process and helps the heart compensate with increased cardiac output. **Maintaining the balance of pulmonary blood flow and systemic blood flow is the primary concept that is used to treat CHF in neonates.**

If CHF is due to a ductal-dependent cardiac lesion, prostaglandin infusion should be used after consultation with pediatric cardiology. If signs of low cardiac output are present, small-volume fluid boluses may be needed to increase preload to improve systemic blood flow. Continuous inotrope or vasoactive infusion may be needed with significant CHF and CCHD.

Digoxin acts primarily as a positive inotropic (improves contractility) agent (Box 24.5). This drug should be used with caution if acidosis, myocarditis, or obstructive lesions (e.g., tetralogy of Fallot, subvalvular pulmonary stenosis, asymmetric septal hypertrophy) are present. Diuretics such as furosemide (Table 24.3) decrease total body water (which is increased as a result of CHF), and they effectively decrease pulmonary edema, which helps to decrease the work of breathing. Medications that reduce afterload, such as captopril, enalapril, and milrinone, may be used to reduce the systemic blood pressure and encourage systemic perfusion. Chronic fluid restriction and low-salt diets are not commonly used in newborns or infants with CHF.

Hypotension is a late sign of CHF, but frontline volume resuscitation (5 to 10 mL/kg) can be used with caution. A decision to escalate treatment with inotropic support with intravenous (IV) agents such as dopamine, dobutamine, epinephrine, norepinephrine, and vasopressin should be made in conjunction with cardiology consultation. Evaluation of end-organ function and utilization of near-infrared spectroscopy may help to determine if advance support is necessary with the risk of possible side effects and the cause for CHF in each infant.[43]

Corticosteroids, such as hydrocortisone stress dosing, may be helpful for hypotension, especially in preterm infants.[14] Some studies on cortisol levels did not find a correlation between cortisol levels and gestational age or after treatment, so they may be used cautiously as a deciding factor for treatment in refractory hypotension.[84] **Hydrocortisone should be used cautiously over 2 to 3 days and weaned judiciously, with monitoring of blood pressures and stress-dosing intervals of every 6 to 12 hours, depending on gestational age.**[41]

Infants with CHF often have difficulty feeding. They may have trouble sucking, swallowing, and breathing simultaneously. They may have to rest frequently during a feeding, thus prolonging feeding times, and they may fall asleep exhausted before adequate caloric intake is achieved. **Caloric requirements are higher in infants with CHD; thus, the use of higher-caloric formulas may be necessary.** Adequate nutrition must be ensured by the following:

- **Observing the infant's ability to nipple feed.** A soft, free-flowing nipple offers the least resistance to sucking and helps the infant conserve energy. If necessary, alternative feeding methods such as gavage or continuous nasogastric drip may be required if the infant is sucking poorly.
- **Providing adequate calories for growth,** including higher-calorie formula or expressed breastmilk supplemented with a high-calorie additive
- **Anticipating the infant's hunger and offering feedings before the infant uses energy by crying**
- **Positioning the infant in a semierect position for feeding**

BOX 24.5 DIGOXIN DOSAGES AND COMMON SIDE EFFECTS

Digitalizing Schedule

Preterm Infant PO route: 20-30 mcg/kg total dose* **Term Infant** PO route: 25-35 mcg/kg total dose*	Total dose is usually divided into three doses giving one-half, then one-fourth, then one-fourth of the total dose q 8 hr. Check electrocardiogram rhythm strip for rate, PR interval, and dysrhythmias before each dose. Doses based on lean body weight and normal renal function for age.

Maintenance Schedule

Preterm Infant PO route: 5-7.5 mcg/kg/day* **Term Infant** PO route: 6-10 mcg/kg/day	Total dose should be divided BID. Allow 12-24 hr between last digitalizing and first maintenance doses. It takes about 6 days to "digitalize" a patient with maintenance doses alone. The sign of digitalis effect is usually prolongation of the PR interval. The first sign of digitalis toxicity is usually vomiting, dysrhythmia, or bradycardia. Drugs such as quinidine, amiodarone, and diuretics predispose to digoxin toxicity. The clearance of digoxin is directly related to renal function. Dosage must be reduced in patients with impaired renal function.

*Intravenous (IV) dose is 75% of oral (PO) dose.
BID, Twice daily; *PO,* per os, by mouth.
Data from Lexicomp Online. Digoxin. Accessed June 1, 2018.

TABLE 24.3 CARDIAC DRUGS

DRUG	ROUTE	DOSE	ONSET OF ACTION	COMMENTS
Adenosine	IV	0.05-0.1 mg/kg, increase by 0.05-0.1 mg/kg for nonresponsive SVT	Seconds	Slows the spontaneous heart rate and prolongs the PR interval; may cause transient complete heart block and hypotension; half-life is only 9.3 seconds, so its effects quickly dissipate
Amiodarone	IV PO	10-15 mg/kg/day in 1-2 divided doses 2.5-10 mg/kg/day daily maintenance dose	Hours 2-3 days	Should only be used with a pediatric cardiologist and electrophysiology consultation Hypotension, abnormal liver function, and abnormal thyroid function can occur
Atropine	IV	0.01-0.03 mg/kg/dose PRN (max 0.4 mg)	Seconds	May cause tachycardia, urinary retention, or hyperthermia
	ETT	Give 2-3 times the IV dose followed by NS flush	Minutes	May cause tachycardia
Calcium chloride (10% solution)	IV	10-20 mg/kg/ dose q 4-6 min PRN for hypocalcemia	Minutes	Slow infusion; must be IV; potentiates digoxin, bradycardia
Calcium gluconate (10% solution)	IV	200-800 mg/kg/day divided in 4 doses for hypocalcemia	Minutes	Slow infusion (over 10-30 min); must be IV; potentiates digoxin, bradycardia/dysrhythmias
Captopril (Capoten)	PO	Preterm and postnatal age <7 days: Initial dose: 0.01 mg/kg/dose q 8-12 hr Titrate: up to max 0.5 mg/kg/dose Term neonates >7 days: Initial dose: 0.05-0.1 mg/kg/day Titrate: up to 0.5 mg/kg/dose in 1-4 divided doses	15 min +	Hypotension, tachycardia, increased BUN and serum creatinine, hypercalcemia Monitor BP for 2 hours after first dose
Chlorothiazide (Diuril)	IV PO	5-10 mg/kg/day in 2 doses 20-40 mg/kg/day in 2 divided doses	15 min 2 hours	Hypotension, electrolyte disturbances
Dobutamine (Dobutrex)	IV	2-15 mcg/kg/min	Minutes	Do not use if IHSS or tetralogy of Fallot, may cause ventricular ectopy, tachycardia, or hypertension Incompatible with alkaline solutions
Dopamine (Intropin)	IV	1-15 mcg/kg/min	Minutes	Tachydysrhythmia, vasoconstriction, gangrene of extremities, anginal pain, and palpitations can occur; inactivated in alkaline solution
Enalapril	PO	0.1 mg/kg/day in 1-2 divided doses, increase to max of 0.5 mg/kg/day	Hours	Monitor for hypotension with initiation and dosage changes
Epinephrine (1:10,000)	IV/ETT	0.1-0.3 ml/kg/dose (max 5 ml/dose) q 3-5 min PRN	Seconds	May cause tachycardia, dysrhythmias, or hypertension; not effective if acidosis is present

Continued

TABLE 24.3 CARDIAC DRUGS—CONT'D

DRUG	ROUTE	DOSE	ONSET OF ACTION	COMMENTS
Esmolol (Brevibloc)	IV	*Initial dose:* 50-75 mcg/kg/min Continuous infusion: titrate 50-200 mcg/kg/min	Minutes	May cause bradycardia, hypotension, bronchoconstriction
Flecainide	PO	1-3 mg/kg/day in 3 divided doses	Hours	May cause ECG changes and hypotension
Furosemide (Lasix)	IV	1-2 mg/kg/dose	5-15 min	May cause metabolic alkalosis and hypokalemia; monitor electrolytes—may need KCl supplementation; renal calcification
	PO	1-4 mg/kg/dose	30-60 min	
Ibuprofen lysine (NeoProfen)	IV	10 mg/kg first dose; then 5 mg/kg second and third dose (q 24 hr)	Most effective in first 3 days of life	Monitor urine output and creatinine levels; discontinue drug if dramatic decrease in urine output Significantly fewer adverse effects (compared with indomethacin) on renal and mesenteric blood flow; less oliguria and increase in serum creatinine levels
Indomethacin (Indocin)	IV	0.1-0.2 mg/kg/dose; may be repeated q 8 hr for a total of 3 doses		Less effective if administered after 7 days of age; probably will have no effect after 14 days Monitor urine output and creatinine levels; discontinue drug if dramatic decrease in urine output Contraindications: severe renal impairment, active bleeding in the CNS or GI tract, and NEC
Isoproterenol (Isuprel)	IV	0.05-2 mcg/kg/min	30-60 seconds	May cause tachycardia/ventricular tachydysrhythmia; may also cause subendocardial ischemia
Lidocaine (Xylocaine)	IV	*IV bolus:* 1-2 mg/kg *IV drip:* 20-50 mcg/kg/min		May cause dysrhythmia, CNS agitation or depression
Milrinone (Primacor)	IV	*Loading:* 50 mcg/kg over 15 min *Maint.*: 0.25-1 mcg/kg/min	5-15 minutes	May cause ventricular dysrhythmias, ventricular fibrillation, or hypotension
Nitroprusside (Nipride)	IV	0.2-4 mcg/kg/min (protect from light; change solution q 4 hr)	Within 2 minutes	May cause hypotension and reflex tachycardia; may cause thiocyanate toxicity, especially if decreased renal function is present
Procainamide (Pronestyl)	IV	*Loading:* 7-10 mg/kg/dose over 5 min (max 100 mg) *Maint.*: IV 20-80 mcg/kg/min	1-5 min	May cause hypotension or lupus-like syndrome

TABLE 24.3 CARDIAC DRUGS—CONT'D

DRUG	ROUTE	DOSE	ONSET OF ACTION	COMMENTS
Propranolol (Inderal)	PO	Dysrhythmias: 0.25 mg/kg/dose TID-QID (max daily dose 5 mg/kg/day)	30-60 min	May severely decrease cardiac output
Prostaglandin E_1 (Prostin VR)	IV	*Initial dose:* 0.02-0.1 mcg/kg/min cont. IV infusion *Maint.:* 0.01-0.05 mcg/kg/min cont. IV infusion	30 min	May cause apnea, fever, or hypotension
Sotalol	PO	*Initial dose:* 1 mg/kg/dose q 12 hr Increase gradually as needed every 3-5 days until stable rhythm is maintained *Maximum dose:* 4 mg/kg/dose q 12 hr		Antiarrhythmic used to treat refractory ventricular and supraventricular tachyarrhythmias Proarrhythmia effects in first days of treatment; cardiorespiratory monitoring essential
Spironolactone (Aldactone)	PO	1-2 mg/kg/day	3-5 days	Hyperkalemia, drowsiness, GI upset

Standard Concentrations: Each institution's concentration may vary; NOT to exceed maximum concentration per pharmacy reference manuals. Neonatal Drug Guidelines. Updated May 7, 2002.

BID, Twice daily; *BP,* blood pressure; *BUN,* blood urea nitrogen; *CNS,* central nervous system; *ETT,* endotracheal tube; *GI,* gastrointestinal; *IHSS,* idiopathic hypertrophic subaortic stenosis; *IV,* intravenous; *IM,* intramuscular; *KCl,* potassium chloride; *maint.,* maintenance; *max,* maximum; *mcg,* micrograms; *mg,* milligrams; *min,* minutes; *NEC,* necrotizing enterocolitis; *NS,* normal saline; *PO,* per os, by mouth; *PRN,* as needed; *q,* every; *QID,* four times a day; *SVT,* supraventricular tachycardia; *TID,* three times a day.

Data from Lexicomp Online. Medication reference. Accessed June 1, 2018.

- **Maintaining oral feedings at 15 to 20 minutes** to minimize overexertion for the neonate
- **Burping the infant after every half ounce** consumed to help minimize vomiting
- **Medical treatment of gastroesophageal reflux**
- **Weighing the infant daily** to check for appropriate weight gain

Before discharge from the nursery, the infant should be feeding well and gaining weight appropriately.

Many infants gain weight very slowly because of their cardiac defects. **Poor nutrition has been associated with increased respiratory support, increased hospital stay, and mortality risk after cardiac surgery.**[62] However, adequate growth can be achieved with the use of fortified formula or breastmilk and an NG tube, and possibly G-tube, to supplement basic oral feedings. **Frequent monitoring of weight gain is necessary.** Cardiac nutrition experts and cardiology providers can work together to promote nutrition with standardized feeding guidelines in the high-risk cardiac population.[4]

The family of an infant in CHF needs support and teaching. **Explanation of the term *congestive heart failure* should be given early because it is a frightening term for parents.** The phrase "heart failure" is often interpreted as "heart attack" or "cardiac arrest." Parents must understand that saying an infant is in heart failure does not imply that the infant's heart will stop beating. **Describing heart failure as a condition in which the heart struggles to pump enough blood to meet all the needs of the body can help decrease anxiety for the family.**

SPECIFIC CONDITIONS

Patent Ductus Arteriosus

PHYSIOLOGY

The ductus arteriosus is a normal pathway in the fetal circulatory system and allows blood from the right ventricle and pulmonary arterial system to

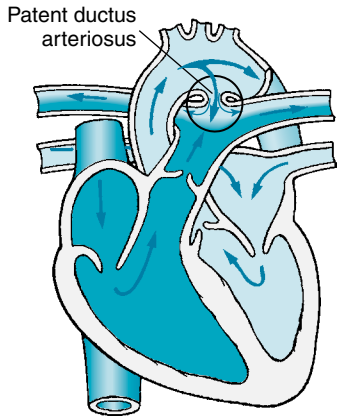

FIGURE 24.4 Patent ductus arteriosus. (Modified from Hockenberry MJ, Wilson D. *Wong's Essentials of Pediatric Nursing*. 8th ed. St Louis: Mosby; 2009.)

flow into the descending aorta for ultimate delivery to the placenta (Fig. 24.4). After birth, as a result of a decrease in the pressure of the pulmonary circulation and an increase in the pressure of the aorta, the blood flow through a PDA is predominantly from the aorta to the pulmonary artery (left-to-right shunt). **Functionally, the *patent ductus arteriosus* (PDA) closes within a few hours to several days after birth, but this closure is often delayed in premature infants.** The hemodynamic changes and the resultant clinical manifestations of a PDA depend on the magnitude of the pulmonary vascular resistance and the size of the ductal lumen.

DATA COLLECTION

History. Preterm birth, respiratory distress, inability to wean from a ventilator, labile blood pressures, feeding difficulties, necrotizing enterocolitis (NEC), intracranial hemorrhage, and increased oxygen (Fio_2) demand can all accompany a PDA.

Physical Findings. Increased flow to the pulmonary circulation often results in increased pulmonary edema and work of breathing.

Cyanosis. Generally, cyanosis is not present in an isolated PDA because the predominant shunt is from left to right. Oxygen saturation monitoring should have normal values.

Heart Sounds. Infants with a PDA may have an audible murmur as a result of the left-to-right shunting through the ductus arteriosus during systole. **The classic murmur from a PDA is a grade I to III/VI systolic murmur best heard at the upper left sternal border with radiation to the left axilla and faintly to the back.** Although this murmur occasionally may spill into diastole, the classical continuous machinery-like murmur is an unusual occurrence in the newborn period. It is often helpful to briefly disconnect the newborn from the ventilator before auscultation. **When a large PDA is present, there may be no audible murmur.**

Pulses. With a rapid upstroke and wide pulse pressure, the peripheral pulses are bounding. **Assessment of the pulses should include palpation of brachial, plantar, and femoral pulses. The presence of an easily palpated, hyperdynamic pulse in these areas suggests the presence of an aortic run-off lesion, which is most commonly a PDA.**

Congestive Heart Failure. With a volume overload of the left ventricle, the infant may show signs of CHF and pulmonary edema (see Congestive Heart Failure earlier in this chapter).

Laboratory Data

Arterial Blood Gases. Arterial blood gas values are usually normal. **A large PDA in a premature neonate may prevent adequate systemic blood flow and acidosis may result.**

Basic Metabolic Panel. **Electrolyte abnormalities may occur with the use of diuretics to manage pulmonary congestion.** Close monitoring to maintain normal electrolytes should be used. **Renal function should be monitored during medical treatment for the closure of a PDA.**

Chest X-Ray Examination. **Chest x-ray examination is normal in small shunts. Cardiomegaly is present with increased pulmonary vascularity in large shunts.** Pulmonary edema is present with CHF.

Near-Infrared Spectroscopy. Systemic NIRS monitoring may not be helpful in the preterm infant with hemodynamically significant PDA. Retrograde diastolic blood flow has not affected cerebral and renal NIRS measurements for infants <28 weeks of age.[90]

Brain Natriuretic Peptide. BNP values may be helpful to trend for each neonate and aid in deciding whether further intervention is recommended. BNP value cutoffs are difficult to generalize, especially in preterm infants. Medical treatment has been suggested for BNPs ranging from 250 to 800 pg/mL and surgery at levels higher than 2000 pg/

mL. Surgical intervention of preterm infants with hemodynamically significant PDA may be recommended if the NT-BNP value is >40,000 pg/mL.[52] NT-BNP should be used with caution if it is drawn less than 7 days before the physiologic decline.

Electrocardiogram. The ECG may be normal, demonstrate left ventricular hypertrophy, or demonstrate combined ventricular hypertrophy.

Echocardiogram. Echocardiographic imaging is the preferred method both to diagnose patency and to determine the significance of the ductus arteriosus. **An echocardiogram should be performed before medical or surgical closure of the PDA to rule out a ductal-dependent lesion or other associated anomalies.** Color-flow Doppler mapping allows visualization of the PDA and aids in determining the size and direction of the shunt across the PDA (i.e., left to right, right to left, bidirectional).

Cardiac Catheterization. Cardiac catheterization is usually not necessary for diagnosis. However, coil or device closure of a PDA by cardiac catheterization is highly successful later in infancy or childhood. **In a clinically symptomatic preterm infant with a moderate to large PDA, medical or surgical closure is preferred.**

TREATMENT

Medical Management. Asymptomatic infants with PDAs generally do not require medical management or surgical ligation. These infants should be monitored for evidence of CHF, failure to thrive, increasing oxygen requirement, or other complications. In extremely low-birth-weight (ELBW) infants less than 24 hours of age, prophylaxis for PDA closure with IV indomethacin should be considered with a high likelihood of severe intraventricular hemorrhage or pulmonary hemorrhage.[82]

Fluid restriction, watchful waiting, and ventilator support are frequently used as management strategies. However, severely symptomatic infants require ductal closure by either pharmacologic management or surgical ductal ligation. Indomethacin was first reported in the 1970s and became first-line therapy for the treatment of persistent PDAs. Ibuprofen lysine has also been shown to be effective.[67] Recently, **oral acetaminophen has been reported as a second-line treatment after indomethacin failure, with a 50% reduction in the need for surgical PDA ligation in preterm infants.**[95] Table 24.3 provides indomethacin and ibuprofen lysine doses, contraindications, and side effects. **Urine output and creatinine levels should be closely monitored with both medications. If urine output decreases dramatically, the drug should be discontinued.**

Surgical Treatment. Although surgical ligation of the ductus arteriosus through a lateral thoracotomy incision is a low-risk procedure when performed by an experienced surgical team, this should be reserved for those infants who cannot tolerate or have failed pharmacologic intervention. Questions have been raised about the long-term effects of surgical PDA closure in ELBW infants and the relationship between ligation and bronchopulmonary dysplasia (BPD), severe retinopathy of prematurity (ROP), and neurosensory impairment.[42,94]

COMPLICATIONS AND RESIDUAL EFFECTS

Complications and residual effects, although rare, include recanalization, recurrent laryngeal or phrenic nerve palsies, and false aneurysms. The surgical mortality rate in the neonatal period is generally less than 1%.

PROGNOSIS AND FOLLOW-UP

Asymptomatic infants have an excellent prognosis, although follow-up is necessary. If the ductus arteriosus remains patent beyond infancy, closure by interventional cardiac catheterization may be recommended.

Patent Foramen Ovale

A patent foramen ovale (PFO) is a communication in the atrial septum between the left and right atrium. Unlike an atrial septal defect, this is a flap-like opening with no deficiency of tissue. A PFO is needed before birth to allow blood to flow from the right atrium to the left atrium. After birth, increased pulmonary blood flow causes left atrial pressure to exceed right atrial pressure, and the flap opening shuts. A trivial left-to-right shunt often persists until permanent anatomic closure is completed. Approximately 20% of adults have a persistent PFO, but this rarely has clinical consequences.[36]

A PFO is considered a normal finding and requires no treatment or cardiology follow-up.

Atrial Septal Defect

PHYSIOLOGY

An atrial septal defect (ASD) may occur as an isolated anomaly or as part of a more complex cardiac disease. Only isolated ASDs are discussed in this section.

ASDs are common congenital heart lesions that are challenging to diagnose (Fig. 24.5). Prenatal diagnosis of an ASD rarely occurs because a natural atrial septal communication (patent foramen ovale) is always present before birth. **Neonates with ASDs are generally asymptomatic, so diagnosis often does not occur until later in life.**

Three types of ASDs exist, classified by location. A *secundum atrial septal defect* is most common and is located in the central portion of the atrial septum. A *primum atrial septal defect* is located close to the mitral and tricuspid valves and is often associated with a cleft mitral valve or atrioventricular septal defect. A *sinus venosus defect* is not a defect in the atrial septum, but it is often classified as an ASD due to its similar effects on the heart; this defect can be associated with partial anomalous pulmonary venous return. **Secundum ASDs can spontaneously close in the first few years of life, but primum ASDs and sinus venosus defects always require surgical closure.**

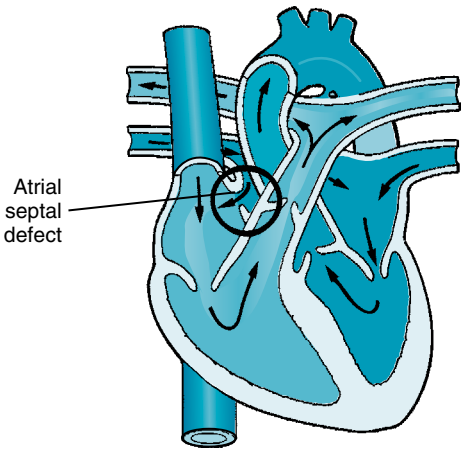

FIGURE 24.5 Atrial septal defect. (Modified from Hockenberry MJ, Wilson D. *Wong's Essentials of Pediatric Nursing.* 8th ed. St Louis: Mosby; 2009.)

DATA COLLECTION

Physical Findings

Cyanosis. An isolated ASD does not cause cyanosis because the predominant shunt is from the left atrium to the right atrium. Oxygen saturation monitoring is normal.

Heart Sounds. **Abnormal heart sounds are not usually appreciated during infancy.** In older children, fixed splitting of S_2 can be appreciated due to delayed closure of the pulmonary valve. S_1 is normal. **Flow across the ASD does not create a murmur.** However, when left-to-right atrial-level shunting is large, excessive flow across the pulmonary valve can create a systolic, ejection-type murmur that is indistinguishable from the murmur of mild pulmonary stenosis. Less commonly, excessive flow across the tricuspid valve can cause a low-pitched "diastolic rumble."

Congestive Heart Failure. CHF does not occur, even in the presence of a large ASD.

Laboratory Data

Arterial Blood Gases. Arterial blood gas values are normal.

Venous Blood Gases. Venous blood gas values are normal.

Basic Metabolic Panel. No major electrolyte abnormalities or renal dysfunction should be present related to an ASD.

Chest X-Ray Examination. A chest x-ray examination is normal. Later in life, right-sided heart dilation and cardiomegaly may be present.

Electrocardiogram. **The ECG in an infant with an ASD is usually normal.** As right-sided heart dilation occurs over the first few years of life, right atrial enlargement and right ventricular enlargement may be detected by ECG.

Echocardiogram. **A two-dimensional echocardiogram is diagnostic and can demonstrate the number, size, and location of atrial septal defects.** Right-sided heart enlargement may also be appreciated in older infants and children.

Cardiac Catheterization. A diagnostic cardiac catheterization is not necessary. (See Treatment section for discussion of interventional cardiac catheterization.)

TREATMENT

Medical Management. Medical management is not necessary because ASDs do not cause significant symptoms during childhood.

Cardiac Catheterization (Device Closure). **Device closure of a secundum ASD by interventional cardiac catheterization is often possible. This**

involves placing a device across the defect to plug the hole. Device closure is contraindicated if there are insufficient rims around the defect; the device must sandwich the atrial septum around the entire defect to avoid embolization of the device. Less commonly, device closure cannot be performed because the child's atria are too small to accommodate the appropriately sized device or the ASD is larger than commercially available devices. **This procedure is rarely performed in infants or toddlers.** Procedural risks are very low, but embolization of the device and erosion of the device through the heart are rare adverse events that can be life-threatening.

Surgical Treatment. Surgical treatment of an ASD is necessary for primum ASDs, sinus venosus defects, or secundum ASDs that cannot be closed by cardiac catheterization intervention. Surgery for isolated defects is rarely performed during infancy or the toddler years. Either primary suture closure or patch closure of the defect is performed through a median sternotomy incision.

COMPLICATIONS AND RESIDUAL EFFECTS

Complications or residual effects rarely occur but may include a persistent shunt (residual ASD) or rhythm abnormalities.

PROGNOSIS AND FOLLOW-UP

Eighty percent of neonatal secundum ASDs measuring 8 mm or less will close spontaneously within the first 2 years of life.[72] If spontaneous closure occurs, cardiology follow-up is not required. After surgical or device closure of an ASD, long-term cardiology follow-up is recommended.

Ventricular Septal Defect

PHYSIOLOGY

A VSD may occur as an isolated anomaly or as part of a more complex cardiac lesion. Only isolated VSDs are discussed in this section. **VSDs are the most common congenital heart defect.** VSDs can be located in various portions of the ventricular septum and are classified according to their anatomic position (Fig. 24.6). VSD types each have clinically important differences, such as the likelihood of spontaneous closure, possibility of affecting neighboring valve function, or complications that can develop with or without surgical repair.

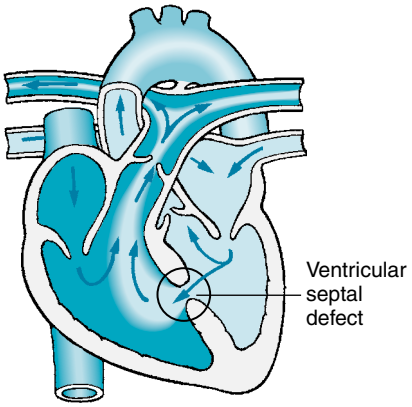

FIGURE 24.6 Ventricular septal defect. (Modified from Hockenberry MJ, Wilson D. *Wong's Essentials of Pediatric Nursing.* 8th ed. St Louis: Mosby; 2009.)

In addition to VSD type, the size of the defect also has an important role in clinical symptoms and treatment. A small VSD allows only a small amount of blood to shunt from the high-pressure LV to the lower-pressure RV. This small amount of left-to-right shunting is not enough to be clinically important or cause symptoms. Conversely, a large VSD allows a large amount of left-to-right shunting. Highly oxygenated blood returning from the lungs is shunted across the defect and back out to the lungs again. This pulmonary overcirculation results in CHF, pulmonary edema, respiratory distress, and failure to thrive.

Although the size of the VSD is of critical importance, the PVR also plays a role in how much blood shunts left to right across the ventricular septum. PVR is nearly systemic immediately after birth, so minimal blood travels across even a large defect. With minimal shunting, there are minimal symptoms and a minimal murmur. PVR usually rapidly falls in the first several days of life, then continues to fall more gradually over the next few months. **As PVR declines, more blood is shunted across the VSD, and symptoms gradually increase. Premature infants tend to have lower pulmonary vascular resistance at birth, allowing greater left-to-right shunting, and therefore may be symptomatic earlier.** Infants with severe lung disease (e.g., RDS, BPD, pneumonia) may have elevated PVR and therefore minimal left-to-right shunting and minimal symptoms.

DATA COLLECTION

Physical Findings

Cyanosis. Infants with isolated VSDs are rarely cyanotic because the predominant shunt is from the left ventricle to the right ventricle. Oxygen saturation values should be normal.

Heart Sounds. **Most infants with VSDs have a heart murmur. The time when this murmur is first audible depends on the PVR and the size of the defect.** The murmur is typically a grade II to III/VI harsh systolic murmur heard best at the lower left sternal border. A diastolic flow rumble at the apex indicates a large left-to-right shunt.

Congestive Heart Failure. A child with a moderate to large VSD will have increasing symptoms of CHF over the first few months of life as the PVR drops (see Congestive Heart Failure earlier in this chapter). CHF is unusual if the VSD is small and singular.

Laboratory Data

Arterial Blood Gases. Arterial blood gas values are normal.

Basic Metabolic Panel. Electrolytes are normal. If diuretics are used to treat CHF symptoms, electrolytes should be monitored, and electrolyte supplementation may be required.

Chest X-Ray Examination. A chest x-ray examination shows a normal to increased heart size with increased pulmonary blood flow.

Electrocardiogram. The ECG in an infant with a VSD is usually normal but may demonstrate left or biventricular hypertrophy.

Echocardiogram. **A two-dimensional echocardiogram can accurately diagnose even the smallest VSDs noninvasively.** The use of color-flow technology is particularly advantageous in identifying the presence of multiple VSDs and the direction of blood flow across a VSD.

Cardiac Catheterization. Cardiac catheterization is not necessary for diagnosis. Cardiac catheterization for intervention and device closure may be possible in older children and adults, depending on the type of VSD and associated cardiac issues.

TREATMENT

Medical Management. **Medical management of CHF associated with VSDs includes digoxin, diuretics, afterload reducers, and caloric supplementation** (see Congestive Heart Failure earlier in this chapter). Medical management may only be required temporarily as the child grows and the VSD becomes smaller. Spontaneous closure of the VSD later in life may also occur.

Surgical Treatment. **Failure to thrive despite maximum medical treatment is an indication for surgical repair of the defect.** Even if the defect is small, a VSD may require surgical repair due to the location of the defect (i.e., proximity to the aortic valve).

Surgical treatment of a VSD consists of either suture closure or patching (most commonly using a synthetic material such as Dacron). The surgical approach is through a median sternotomy incision. The defect is approached through the right atrium and tricuspid valve, thereby avoiding a right ventriculotomy.

If the infant is small (less than 2 kg) or if multiple muscular VSDs are present, it may be necessary to perform a palliative procedure called *pulmonary artery banding* to decrease pulmonary blood flow until the infant is older and can undergo debanding and closure of the VSDs. With improvements in surgical technique and technology, VSD closure can be performed safely and effectively in the younger pediatric population.[51]

COMPLICATIONS AND RESIDUAL EFFECTS

Complications or residual effects from surgery may include (1) a persistent shunt (residual VSD), (2) conduction abnormalities (right bundle-branch block and third-degree heart block), and (3) aortic or tricuspid insufficiency (less than 1%). The mortality rate from surgical repair of an isolated VSD is less than 1%,[32] although surgical correction in the neonatal period is rare and associated with a higher mortality rate.

PROGNOSIS AND FOLLOW-UP

Depending on the anatomic type, **small VSDs may close spontaneously in the first months of life, with reports of up to 84% closure with muscular VSDs.**[100] After spontaneous closure, complications have rarely been reported, and routine outpatient cardiology follow-up is generally not necessary.

If surgical repair is performed, long-term cardiology follow-up is recommended. If surgical repair is not performed and a large left-to-right shunt is persistent after 12 to 24 months of age, the child is susceptible to the development of

irreversible and life-limiting pulmonary vascular disease (Eisenmenger syndrome).

Coarctation of the Aorta

PHYSIOLOGY

Coarctation of the aorta is a localized constriction of the aorta that usually occurs at the junction of the transverse aortic arch and the descending aorta in the vicinity of the ductus arteriosus (Fig. 24.7). However, **coarctation can occur anywhere in the aorta. The precise location of the coarctation and the presence or absence of associated anomalies affect the clinical presentation.** Associated anomalies include PDA, VSD, and bicuspid aortic valve. **Coarctation is one of the more common CHDs, accounting for approximately 7% of cardiac lesions.**[25] Coarctation is observed in approximately 10% of infants with Turner syndrome.[24]

Coarctation of the aorta may only develop postnatally when the ductus arteriosus closes and causes constriction of the aortic periductal tissue. As such, coarctation of the aorta may not be able to be diagnosed before birth. **Neonates who had a fetal echocardiogram concerning for coarctation development may require a "coarctation watch" for the first few days after birth. This involves very close bedside monitoring of lower-extremity pulses, four-extremity blood pressures, urine output, and other measures of fetal well-being until postnatal echocardiogram confirms that the ductus arteriosus is completely closed.**

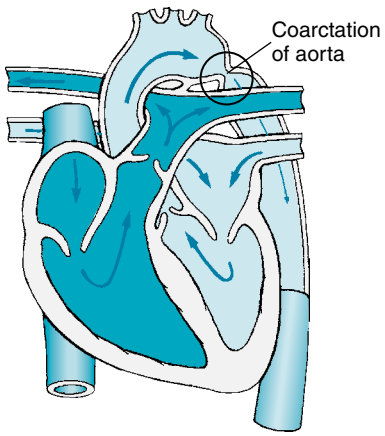

FIGURE 24.7 Coarctation of the aorta. (Modified from Hockenberry MJ, Wilson D. *Wong's Essentials of Pediatric Nursing.* 8th ed. St Louis: Mosby; 2009.)

DATA COLLECTION

Physical Findings. In utero, the majority of systemic blood flow to the lower body is via the ductus arteriosus. When ductal closure occurs after birth, the neonate with coarctation becomes critically ill because the left ventricle cannot pump the entire cardiac output past a significant point of obstruction. Newborns with critical coarctation of the aorta will have signs and symptoms of CHF and low cardiac output. **Severe coarctation of the aorta is a medical and surgical emergency. Untreated infants with severe coarctation often have a rapidly deteriorating clinical course that can progress to death unless prostaglandin infusion is started.**

Cyanosis. Generally, cyanosis is not present in the newborn with isolated coarctation of the aorta, but **an oxygen saturation difference may be found between the upper and lower extremities. Goal saturations should be greater than 92% unless another heart defect is noted.**

Heart Sounds. A **murmur heard only in the back is strongly suggestive of coarctation.** However, **a cardiac murmur may not be heard in isolated, severe coarctation of the aorta.** If other cardiac defects are present, murmurs from those anomalies will be heard. A gallop rhythm sometimes is present and is associated with CHF.

Pulses and Blood Pressure. **The blood pressure proximal to the area of obstruction is higher than the blood pressure distal to the area of obstruction. The most consistent physical finding in infants with critical coarctation of the aorta is a higher systolic blood pressure (greater than 10 mm Hg) in the right upper extremity than in the lower extremities.** This blood pressure must be measured with the appropriate-size cuff. **In addition, pulses are easily palpable in one or both upper extremities but are difficult to palpate or are absent in the lower extremities.** Pulses should be carefully evaluated in all extremities and blood pressures obtained in both arms and both legs.

Congestive Heart Failure. CHF is a common finding in infants with severe coarctation and is the result of pressure overload on the left ventricle (see Congestive Heart Failure earlier in this chapter).

Laboratory Data

Arterial Blood Gases. **Arterial blood gas values are normal until PDA closure causes severely decreased lower body perfusion. Metabolic**

acidosis due to peripheral tissue hypoxia then occurs.

Lactic Acid. An increased lactic acid level can be a sign of low cardiac output and should be monitored frequently.

Chest X-Ray Examination. Cardiomegaly may be seen on the radiograph. Pulmonary vascularity is normal unless associated anomalies are present.

Near-Infrared Spectroscopy. Systemic NIRS monitoring can help monitor for signs of low cardiac output.

Electrocardiogram. Right ventricular hypertrophy is frequently present. Left ventricular hypertrophy or combined ventricular hypertrophy is rarely seen in the newborn period. The ECG may be normal.

Echocardiogram. An echocardiogram is diagnostic; the area of coarctation can be visualized using two-dimensional techniques and color-flow mapping. However, interpretation of the findings may be difficult if a PDA is present.

Cardiac Catheterization. Cardiac catheterization is rarely necessary. Cardiac catheterization for balloon angioplasty of the coarctation is rarely performed because the results are usually only temporary for neonates.

TREATMENT

Medical Management. Medical management is used only for stabilization prior to surgery. **Medical management consists of continuous IV infusion of prostaglandin E1 (PGE1) to keep the ductus arteriosus open; dopamine and/or dobutamine for inotropic support; and correction of metabolic acidosis, hypoglycemia, and anemia.** CHF should be treated immediately and aggressively for stabilization before surgery. **Intractable CHF, acidosis, oliguria, and hypertension are indications for urgent corrective surgery.** (See General Treatment Strategy under Congenital Heart Disease earlier in this chapter.) Since the introduction of PGE1, emergency surgical repair is rarely necessary.

Surgical Treatment. The most common surgical procedure is resection of the coarctation with end-to-end anastomosis.[53] The area of the coarctation is resected, and the ends of the aorta reanastomosed. Coarctation repair is usually performed through a lateral thoracotomy incision and is highly successful in relieving coarctation and providing for the future growth of the aorta.

COMPLICATIONS AND RESIDUAL EFFECTS

Before surgery, significant lower-body ischemia puts neonates affected with this CHD at risk for NEC. After surgery, complications and residual effects include residual coarctation, persistent hypertension, chylothorax, phrenic nerve injury, and diaphragm paralysis. The overall operative mortality rate is low at less than 1%, but a higher mortality rate may apply if the neonate is medically unstable before surgery, weighs less than 2.5 kg,[25] or there are significant associated cardiac lesions.[88]

PROGNOSIS AND FOLLOW-UP

Infants with mild coarctation require minimal care initially. If these patients are medically managed, close follow-up is mandatory, and repair at a later date is likely. **Infants with severe coarctation require prompt medical and surgical treatment.** If this therapy is instituted early, the prognosis generally is favorable.

After surgical repair, frequent follow-up is necessary to ensure adequate coarctation repair. Cardiac catheterization may be necessary several months to years after the surgical procedure is completed if re-coarctation occurs. Balloon dilation and stent placement can be performed for re-coarctation. In adulthood, patients must continue to be monitored by a cardiologist for complications such as systemic hypertension and aneurysm formation at the coarctation site.

Critical Aortic Stenosis

PHYSIOLOGY

Obstruction of the left ventricular outlet may occur below the aortic valve, at the aortic valve, or above the aortic valve (subvalvular, valvular, or supravalvular aortic stenosis) (Fig. 24.8). **Valvular aortic stenosis is the most common type** and is discussed here. **Critical aortic stenosis is present if adequate blood supply to the body cannot get through the severely stenotic valve. In critical aortic stenosis, right-to-left shunting through the PDA helps supply blood to the body; with PDA closure, low cardiac output occurs and can be fatal.**

DATA COLLECTION

Physical Findings. Although most infants with aortic stenosis are asymptomatic in the neonatal period, **a neonate with critical or severe aortic**

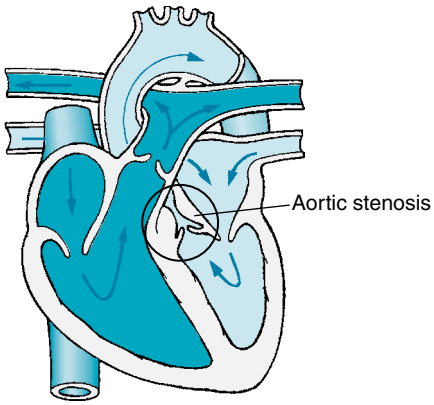

FIGURE 24.8 Aortic stenosis. (Modified from Hockenberry MJ, Wilson D. *Wong's Essentials of Pediatric Nursing*. 8th ed. St Louis: Mosby; 2009.)

stenosis needs emergent treatment. As the PDA closes, the infant with critical aortic stenosis will have signs and symptoms of CHF and low cardiac output.

Cyanosis. Cyanosis is generally not present in isolated valvular aortic stenosis. Oxygen saturation should be normal if the aortic stenosis defect is isolated.

Heart Sounds. A grade II to IV/VI harsh systolic murmur is typically heard at the upper right sternal border, radiating to the upper left sternal border and faintly to the neck. An ejection click may be heard at the apex. A suprasternal notch thrill is sometimes palpable.

Congestive Heart Failure. **Infants with critical aortic stenosis may have CHF caused by a pressure overload of the left ventricle** (see Congestive Heart Failure earlier in this chapter).

Laboratory Data

Arterial Blood Gases. Arterial blood gas values are generally normal unless PDA closure causes severely decreased cardiac output and body perfusion. Metabolic acidosis due to peripheral tissue hypoxia then occurs. Mixed venous gas values may be helpful in ensuring adequate cardiac output is being met.

Lactic Acid. An increased lactic acid level can be a sign of low cardiac output and should be monitored frequently.

Chest X-Ray Examination. A chest x-ray examination shows cardiomegaly with normal pulmonary vascularity.

Electrocardiogram. The ECG may be normal or demonstrate left ventricular hypertrophy. There is poor correlation between an electrocardiographic abnormality and the degree of aortic stenosis.

Echocardiogram. **A transthoracic echocardiogram is diagnostic.** The aortic valve is usually thickened and appears to open abnormally. Doppler interrogation can accurately estimate the systolic pressure gradient from the left ventricle to the ascending aorta and identify the level or levels of obstruction.

Near-Infrared Spectrometry. Systemic NIRS monitoring can be helpful for monitoring for signs of downtrends possibly indicating low cardiac output.

Cardiac Catheterization. Cardiac catheterization is not required for diagnosis but is the primary method of treatment.

TREATMENT

Medical Management. **Medical management consists of continuous IV infusion of PGE1 to keep the ductus arteriosus open; dopamine and/or dobutamine for inotropic support; and correction of metabolic acidosis, hypoglycemia, and anemia.** CHF should be treated immediately and aggressively for stabilization before cardiac catheterization intervention. **Intractable CHF, acidosis, and oliguria are indications for cardiac catheterization as soon as possible for critical aortic stenosis in the newborn** (see General Treatment Strategy earlier in this chapter).

Cardiac Catheterization. **Cardiac catheterization is performed to balloon dilate the aortic valve and improve aortic valve opening.** Dilation of the aortic valve often results in damage to the valve leaflets, resulting in valve regurgitation. Care must be taken to balance the desired improvement in aortic valve opening with the detrimental effect on aortic valve closing. Subsequent cardiac catheterizations for balloon valvuloplasty are often required during infancy and early childhood.

Surgical Treatment. Initial treatment with surgical aortic valvotomy is rarely required because balloon dilation of the valve in the cardiac catheterization laboratory is highly successful. However, repeated balloon valvuloplasties often result in significant aortic regurgitation, which can only be treated with surgical valve repair or valve replacement. **Newborns with critical or severe**

aortic stenosis often require surgical valve repair or replacement later in life.

COMPLICATIONS AND RESIDUAL EFFECTS

Complications and residual effects include aortic insufficiency and residual aortic stenosis. The mortality rate from aortic balloon valvuloplasty is low, and the procedure can be done safely even in premature infants weighing less than 2 kg. The newborn with critical obstruction has the highest risk.

PROGNOSIS AND FOLLOW-UP

All patients with critical aortic stenosis require lifelong follow-up. Further surgical or catheter intervention is almost always necessary.

Critical Pulmonary Stenosis

PHYSIOLOGY

In critical pulmonary stenosis, the flow to the pulmonary artery from the right ventricle is obstructed. The obstruction may occur below the valve in the infundibular area, at the valve, or above the valve (subvalvular, valvular, or supravalvular). In valvular stenosis, the orifice of the pulmonary valve is markedly narrowed (Fig. 24.9). The pulmonary artery distal to this area of stenosis may be dilated. The right ventricle is subjected to a marked increase in pressure and becomes hypertrophied. **Critical pulmonary stenosis is present if adequate blood supply to the lungs cannot get through the severely stenotic valve. In critical pulmonary stenosis, left-to-right shunting through the PDA helps supply blood to the lungs; with PDA closure, low cardiac output occurs and can be fatal.**

DATA COLLECTION

Physical Findings

Cyanosis. Cyanosis is generally not present in an isolated lesion but may occur in the presence of a right-to-left atrial shunt. Goal oxygen saturations are often greater than 85%.

Heart Sounds. A harsh grade II to III/VI systolic murmur is heard in the upper left sternal border, radiating to both axillae and faintly to the back. A murmur of tricuspid insufficiency (soft, systolic murmur at the lower left sternal border) may be heard. An ejection click also may be heard at the left sternal border.

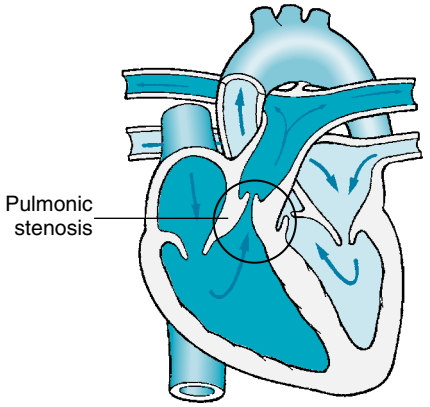

FIGURE 24.9 Pulmonic stenosis. (Modified from Hockenberry MJ, Wilson D. *Wong's Essentials of Pediatric Nursing*. 8th ed. St Louis: Mosby; 2009.)

Congestive Heart Failure. The infant with critical pulmonary stenosis typically has signs and symptoms of right-sided CHF resulting from excessive pressure overload (see Congestive Heart Failure earlier in this chapter).

Laboratory Data

Arterial Blood Gases. Arterial blood gas values generally are normal unless there is an atrial right-to-left shunt.

Venous Blood Gases. Venous blood gas values generally are normal.

Chest X-Ray Examination. The chest x-ray examination may be normal but usually demonstrates cardiomegaly with normal or decreased pulmonary vascularity.

Electrocardiogram. The ECG may be normal or demonstrate right ventricular hypertrophy.

Echocardiogram. A two-dimensional echocardiogram is diagnostic. Doppler interrogation and color-flow mapping can accurately estimate the systolic pressure gradient from the right ventricle to the pulmonary artery and identify the level or levels of obstruction.

Cardiac Catheterization. Cardiac catheterization is not required for diagnosis but is the primary method of treatment.

TREATMENT

Medical Management. PGE1 may be required to maintain the patency of the ductus arteriosus, thereby allowing adequate pulmonary blood flow until balloon dilation is performed. Oxygen saturations should be monitored as a sign

of adequate pulmonary blood flow before the cardiac catheterization procedure. CHF management including inotropic support is not usually required.

Cardiac Catheterization. **Catheter balloon valvuloplasty is the treatment of choice for this defect.** Successful balloon valvuloplasty is associated with excellent clinical results, although subsequent balloon dilation procedures may be necessary later in life. Pulmonary regurgitation often results from balloon valvuloplasty, but this rarely requires surgical pulmonary valve repair or replacement later in life.

Surgical Treatment. Surgical pulmonary valvotomy is rarely required because balloon dilation of the valve via a cardiac catheterization procedure is highly successful.

COMPLICATIONS AND RESIDUAL EFFECTS

Complications and residual effects include pulmonary insufficiency and residual pulmonary stenosis. The mortality rate for pulmonary balloon valvuloplasty is low, even in premature infants weighing less than 2 kg.

PROGNOSIS AND FOLLOW-UP

All patients with pulmonary stenosis require lifelong follow-up. Repeated catheterization procedures may be performed during infancy and childhood to treat residual or recurrent obstruction. The long-term prognosis is good.

Atrioventricular Septal Defect, Endocardial Cushion Defect (Atrioventricular Canal)

PHYSIOLOGY

An atrioventricular canal defect occurs when the endocardial cushions that form the central crux of the heart do not form normally. This results in an atrial septal defect, a ventricular septal defect, and one common atrioventricular valve (which should have separated into the tricuspid and mitral valves) (Fig. 24.10). **Nearly 70% of infants with a complete balanced atrioventricular canal had trisomy 21 (Down syndrome) in a single-site review conducted over 10 years.**[2]

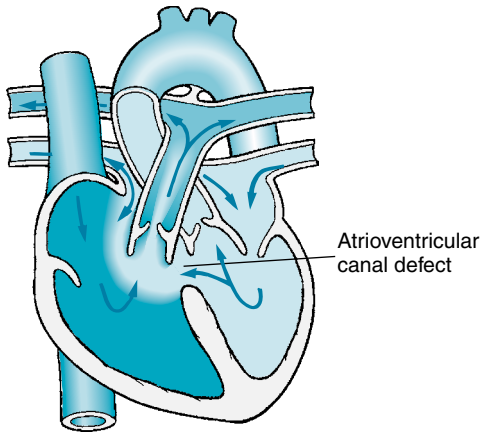

FIGURE 24.10 Atrioventricular (endocardial cushion) defect. (Modified from Hockenberry MJ, Wilson D. *Wong's Essentials of Pediatric Nursing.* 8th ed. St Louis: Mosby; 2009.)

These infants usually have a left-to-right shunt at both the atrial and ventricular levels. AV valve insufficiency also may be present. The symptomatology depends on the degree of shunting between the left and right sides and the amount of AV valve insufficiency present.

DATA COLLECTION

Physical Findings

Cyanosis. **There may be mild cyanosis, particularly in the immediate neonatal period before the pulmonary vascular resistance has fallen.** Goal oxygen saturations should be greater than 75% on room air.

Heart Sounds. **Often there is no murmur in the neonatal period.** If AV valve insufficiency is present, a blowing, holosystolic murmur best heard at the apex with radiation to the left axilla may be appreciated.

Congestive Heart Failure. **During the first few weeks of life, there are usually minimal cardiac symptoms due to elevated PVR. As the PVR falls, increasing left-to-right shunting causes infants to have increasing CHF symptoms.** AV valve insufficiency may also contribute to ventricular volume overload and may exacerbate the CHF (see Congestive Heart Failure earlier in this chapter). A minority of patients with trisomy 21 have persistent pulmonary hypertension and do not develop CHF symptoms. Oxygen saturations greater than 75% should be accepted because oxygen supplementation

can be detrimental and cause CHF through pulmonary overcirculation.

Laboratory Data

Arterial Blood Gases. The $Paco_2$ may be elevated if there is severe AV valve insufficiency and pulmonary edema. The pH and Pao_2 are usually normal.

Basic Metabolic Panel. Electrolytes are normal. With diuretic use for CHF symptoms, electrolytes should be monitored and replaced as necessary.

Complete Blood Count. Anemia may cause increased cyanosis and should be monitored in this cardiac defect. Inversely, chronic cyanosis may cause polycythemia.

Chest X-Ray Examination. The heart size may be normal or increased. The pulmonary vascularity is generally increased.

Electrocardiogram. An ECG with a left axis deviation, counterclockwise loop in the frontal plane, and superior axis suggests AV septal defect.

Echocardiogram. **A two-dimensional echocardiogram with Doppler and color-flow mapping is diagnostic** and demonstrates the ASD, VSD, common AV valve, and degree of AV valve insufficiency.

Cardiac Catheterization. Cardiac catheterization is generally not required.

TREATMENT

Medical Management. Medical management of CHF includes diuretics, digoxin, afterload reducers, and caloric supplementation. **Failure to thrive despite maximum medical treatment is an indication for surgical repair of the defect** (see Congestive Heart Failure earlier in this chapter).

Surgical Treatment. **Surgical repair is necessary. However, most centers do not perform surgery during the neonatal period.** Waiting until a few months of age has benefits, such as allowing the PVR to drop and allowing the child to grow bigger and stronger. The surgical procedure is performed through a median sternotomy incision and involves patch closure of the ASD and VSD and separation of the common atrioventricular valve into a mitral and tricuspid valve.

COMPLICATIONS AND RESIDUAL EFFECTS

Complications and residual effects include (1) persistent shunt (residual ASD or VSD), (2) mitral regurgitation, (3) tricuspid regurgitation, (4) left ventricular outflow tract obstruction, (5) conduction abnormalities (including third-degree heart block), and (6) dysrhythmias.

PROGNOSIS AND FOLLOW-UP

The prognosis after surgical repair is generally good, and future surgeries or cardiac interventions are rarely required. The prognosis is less favorable if early surgical repair was required, pulmonary hypertension persists after surgery, or surgical complications occur. Significant residual defects (shunt or AV valve regurgitation) may require subsequent surgical repair.

Ebstein Anomaly

PHYSIOLOGY

Ebstein anomaly is an uncommon heart defect with an abnormal tricuspid valve that is displaced down into the body of the right ventricle. The resultant right ventricular cavity is smaller than normal, and there is a varying degree of tricuspid regurgitation that affects the severity of symptoms.[69]

Right ventricular output is usually decreased and is dependent on the size of the RV cavity as well as the severity of tricuspid valve regurgitation. **Children with minimal tricuspid regurgitation generally have minimal symptoms and clinically do well.** However, **when severe tricuspid regurgitation is present, the right ventricle can only eject a trivial amount of antegrade flow into the pulmonary arteries. These neonates rely on the PDA to supply pulmonary blood flow and thus require prostaglandins to survive.** Infants with severe tricuspid regurgitation have significant shunting of deoxygenated blood from the right atrium into the left atrium through the foramen ovale, causing cyanosis. **Low right ventricular output in the neonate can improve with time as the PVR drops.**

DATA COLLECTION

Physical Findings

Cyanosis. **Varying degrees of cyanosis are present,** depending on the amount of right-to-left shunting at the foramen ovale and the amount of blood that enters the pulmonary circulation by the right ventricle. **In severe cases, the amount of**

pulmonary blood flow is markedly decreased, and these infants may be deeply cyanotic. Goal oxygen saturations should be greater than 75% and should be continuously monitored to ensure adequate pulmonary blood flow.

Heart Sounds. The second heart sound, S_2, is normal in the mildly affected infant, but the pulmonary component of S_2 may be diminished or inaudible in severely affected patients. The holosystolic murmur of tricuspid regurgitation is usually present at the cardiac apex and varies from a grade I/VI to a grade V/VI. Diastolic murmurs and triple or quadruple rhythms can also be heard.

Congestive Heart Failure. **Newborns with significant tricuspid regurgitation have CHF resulting from volume overload** (see Congestive Heart Failure earlier in this chapter).

Laboratory Data

Arterial Blood Gases. The Pao_2 may be normal to very low, depending on the amount of shunting at the atrial level. **Pao_2 values in the low 20s are not uncommon.**

Lactic Acid. Lactic acid levels should be normal. Elevated lactic acid levels can suggest a state of low cardiac output.

Chest X-Ray Examination. The chest x-ray examination shows cardiomegaly with decreased pulmonary vascularity. Massive cardiomegaly generally indicates severe tricuspid insufficiency.

Near-Infrared Spectrometry. NIRS monitoring is helpful to assess cerebral and splanchnic blood flow. Depression in NIRS can be a red flag for worsening cardiac output.

Electrocardiogram. An ECG shows abnormal P waves and can demonstrate various degrees of heart block. The QRS complex generally has a right bundle-branch block pattern. *Wolff-Parkinson-White* (WPW) (preexcitation) syndrome is frequently present, and dysrhythmias such as supraventricular tachycardia are common.

Echocardiogram. **A two-dimensional echocardiogram is diagnostic.** Doppler interrogation and color-flow mapping are very useful in evaluating the degree of tricuspid insufficiency, the amount of antegrade blood flow through the pulmonary valve, and shunting at the atrial level.

Cardiac Catheterization. Cardiac catheterization is not generally performed unless a question about the differential diagnosis exists (to rule out pulmonary atresia).

TREATMENT

Medical Management. Medical management is aimed at **supporting the neonate through the initial period of transitional circulation.** Because of elevated PVR, pulmonary blood flow may be severely limited, with profound hypoxemia and acidosis. **PGE1 may be required to maintain a patent ductus arteriosus. Providing a high level of supplemental oxygen, providing inhaled nitric oxide, and maintaining a mild respiratory alkalosis may help decrease PVR and promote antegrade pulmonary blood flow.** Sildenafil may also be helpful to reduce right ventricular afterload and improve forward flow of blood across the pulmonary valve.[1]

Ebstein anomaly is often associated with WPW syndrome and supraventricular tachycardia. Arrhythmia medications may be necessary to control rhythm abnormalities.

Surgical Treatment. Surgical treatment for Ebstein's anomaly is generally reserved for the severely symptomatic patient. The procedure, performed through a median sternotomy incision, involves repositioning the tricuspid valve and an annuloplasty to improve the competency of the valve. In addition, plication of the atrialized ventricle is often performed. Replacing the tricuspid valve may be necessary. In severe cases, a *Blalock-Taussig shunt* (BT shunt) is placed to provide pulmonary blood flow if prostaglandin infusion cannot be removed without causing severe cyanosis. This may lead a patient fully or partially down the single-ventricle pathway, with subsequent bidirectional *Glenn* and *Fontan* surgeries.

COMPLICATIONS AND RESIDUAL EFFECTS

Ebstein anomaly can be associated with pulmonary hypoplasia because the massively enlarged right heart in utero can prevent normal pulmonary development. Other complications include tricuspid insufficiency and dysrhythmias.

PROGNOSIS AND FOLLOW-UP

The prognosis usually depends on the severity of the tricuspid regurgitation (TR). The severity of the TR may improve in the early neonatal period as the PVR decreases and right ventricular output increases. The prognosis for mild Ebstein anomaly is favorable. Although surgery has been used successfully in the more severe forms of Ebstein anomaly, the prognosis is less favorable in

patients requiring surgical intervention. **The prognosis for neonates presenting with profound cyanosis caused by Ebstein anomaly is grave.** Long-term cardiology follow-up is necessary, and visits may be more frequent if arrhythmias are persistent.

Persistent Pulmonary Hypertension in the Newborn

PHYSIOLOGY

Infants with abnormally elevated PVR have persistent pulmonary hypertension of the newborn (PPHN) or persistent fetal circulation. These infants are generally hypoxic and acidotic but usually do not have severe pulmonary parenchymal disease or underlying cardiac disease. **These infants have a right-to-left shunt at the ductal and atrial levels.**

DATA COLLECTION

History. PPHN is usually associated with severe antepartum or peripartum conditions that involve hypoxia reflected by low Apgar scores (see Chapter 23). **These infants are generally term or late preterm and are symptomatic within the first hours after birth.** Associated findings may include polycythemia, hypoglycemia, or an anatomic abnormality such as a congenital diaphragmatic hernia.

Physical Findings

Cyanosis. The milder cases of PPHN have **minimal transient tachypnea and cyanosis associated with stress (crying or feeding). Severe cases demonstrate marked cyanosis, tachypnea, acidosis, and decreased peripheral perfusion.**

Heart Sounds. A loud pulmonary component of S_2 and occasionally the systolic ejection murmur of tricuspid regurgitation is heard.

Congestive Heart Failure. Infants with PPHN may have CHF because of pressure overload of the right ventricle (see Congestive Heart Failure earlier in this chapter).

Laboratory Data

Arterial Blood Gases. Arterial blood gas values demonstrate acidosis, hypoxia, and increased $Paco_2$. **If a blood gas measurement is obtained simultaneously from the right radial artery (preductal) and from the descending aorta with an umbilical artery catheter (postductal), the right-to-left shunt at the ductal level can be documented.** If blood gas measurements are repeated after intubation and pharmacologic intervention (see Treatment earlier in this chapter), the degree of hypoxia is often reduced.

Pulse Oximetry. Simultaneous preductal and postductal transcutaneous oxygen measurements may also be helpful to monitor.

Chest X-Ray Examination. The chest x-ray examination may demonstrate mild cardiomegaly with normal pulmonary vascular markings. The lung fields may be clear.

Electrocardiogram. The ECG frequently is normal but may demonstrate right ventricular hypertrophy.

Echocardiogram. An echocardiogram is helpful to rule out a cyanotic cardiac lesion. Evaluating the right ventricular and pulmonary artery pressures by Doppler interrogation and the degree of right-to-left shunting at the atrial and ductal levels is also helpful.

Cardiac Catheterization. Cardiac catheterization usually is not performed.

TREATMENT

Medical Management. See Chapter 23.

D-Transposition of the Great Arteries

PHYSIOLOGY

D-transposition of the great arteries (Fig. 24.11) is one of the most common forms of serious heart disease. **The aorta arises from the right ventricle, receives unoxygenated systemic venous blood, and returns this blood to the systemic arterial circulation. The pulmonary artery arises from the left ventricle, receives oxygenated pulmonary venous blood, and returns this blood to the pulmonary circulation. This creates a situation of "parallel circulations," which requires shunting of blood between the parallel circulations for survival. The only mixing of oxygenated and unoxygenated blood occurs in the presence of associated lesions** (e.g., patent foramen ovale, ASD, PDA, or VSD). The extent of the mixing depends on the number, size, and position of the anatomic communications; the pressure differential between the two systems; and changes in the systemic and pulmonary vascular resistance. A small percentage of patients with transposition have an associated VSD, which helps with preoperative mixing between the two circulations but adds complexity to the surgical

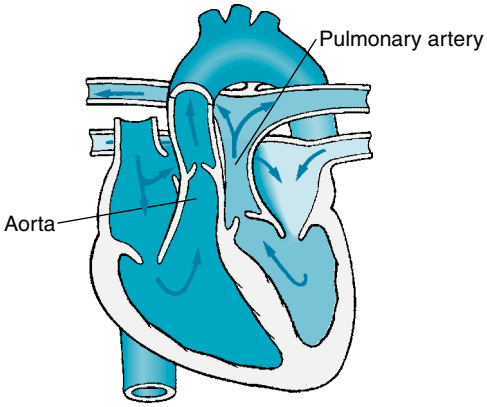

FIGURE 24.11 D-transposition of the great arteries. (Modified from Hockenberry MJ, Wilson D. *Wong's Essentials of Pediatric Nursing.* 8th ed. St Louis: Mosby; 2009.)

repair. The d-transposition anomaly can occur by itself or can be associated with other cardiac defects (e.g., pulmonary stenosis).

DATA COLLECTION

History. Transposition of the great arteries is more prevalent in males and is typically found in infants who are full term. The etiology of this congenital heart lesion is not well understood. Genetic defects are rarely associated, extracardiac anomalies are rarely present, and the pathogenesis is thought to be different from other conotruncal abnormalities.[89]

Physical Findings

Cyanosis. These infants are usually **cyanotic within the first hours of life, leading to their early diagnosis. Cyanosis is present in varying degrees, depending on the amount of intracardiac mixing present. Cyanosis may be mild if the mixing occurs through a significant VSD or PDA. Cyanosis is profound with an intact ventricular septum or a closing PDA.** Only a certain amount of oxygenated blood can reach the systemic circulation, and administration of additional oxygen does not improve this situation.

Cyanosis is exacerbated by neonatal stressors (crying, feeding, or exposure to cold temperatures). If the Pa_{O_2}, measured at rest in room air, is not greater than 35 mm Hg or if persistent metabolic acidosis is present, inadequate intracardiac mixing should be suspected. Initiation of PGE1 is mandatory. In addition, an emergency cardiac catheterization procedure to enlarge the interatrial communication may be lifesaving. Enlargement of the atrial communication is done by balloon septostomy (Rashkind procedure) and is performed to improve mixing between the two parallel circulations.

Oxygenation monitoring by pulse oximetry should reveal saturations greater than 75% due to a complete mixing lesion. Oxygen and ventilation support should be given to maintain this level of saturation.

Heart Sounds. The aorta arises from the anterior (right) ventricle, and the closure of the aortic valve is easily heard. The S_2 is single with an increased intensity. Murmurs, if present, are usually those of associated lesions.

Congestive Heart Failure. Congestive heart failure is usually not present.

Laboratory Data

Arterial Blood Gases. In neonates with transposition of the great arteries and an intact ventricular septum, **a very low Pa_{O_2} (15 to 20 mm Hg) with normal Paco2 and mild metabolic acidosis are often seen.**

Lactic Acid. Lactic acid levels should be normal if adequate intracardiac mixing is present preoperatively.

Basic Metabolic Panel. Electrolytes should be normal. Following renal function to ensure adequate preload and hydration can be important for ensuring hemodynamic stability with this mixing lesion.

Complete Blood Count. Anemia can worsen hypoxemia with mixing cardiac lesions. Intermittent evaluation of hemoglobin and hematocrit should be performed, and aiming for a higher baseline is clinically helpful.

Chest X-Ray Examination. The chest x-ray examination may be normal or demonstrate either decreased or increased pulmonary vascularity. The classically described "egg on a string" cardiac silhouette may be present; however, this finding is not diagnostic.

Electrocardiogram. The ECG may be normal or demonstrate right ventricular hypertrophy.

Echocardiogram. The echocardiogram is diagnostic. Special attention is directed to the size of the ASD, the size of the PDA, associated lesions, and the coronary arteries.

Near-Infrared Spectrometry. NIRS monitoring is used to assess cardiac output and is especially helpful in the setting of a critical mixing lesion.

Cardiac Catheterization. Cardiac catheterization may be necessary to perform a balloon atrial septostomy to improve intra-atrial mixing. A catheterization to delineate the coronary artery anatomy is not usually required because this can be accurately evaluated by transthoracic echocardiogram.

TREATMENT

Medical Management. **Serial venous and arterial pH measurements should be obtained to rule out the presence of a persistent metabolic acidosis that would suggest inadequate intracardiac mixing. PGE1 infusion is used to maintain ductal patency.**

Surgical Treatment. The *arterial switch procedure* is the treatment for d-transposition of the great arteries. This procedure, performed through a median sternotomy incision, involves transection of the main pulmonary artery and the aorta above the respective valves.[65] The pulmonary artery is anastomosed to the right ventricle, and the aorta is anastomosed to the left ventricle (the aortic valve becomes a functional pulmonary valve, and the pulmonary valve becomes a functional aortic valve). The coronary arteries are resected with a button of surrounding tissue and reanastomosed to the supravalvular area of the ascending aorta.[70] Additional defects are also repaired, including closure of atrial or ventricular defects and ligation of the PDA. **Surgery is usually performed in the first week of life.**

COMPLICATIONS AND RESIDUAL EFFECTS

Complications and residual effects of the arterial switch procedure include (1) dysrhythmias, (2) myocardial ischemia and infarction, and (3) aortic or pulmonary supravalvular stenosis.

PROGNOSIS AND FOLLOW-UP

After successful arterial switch operation, the long-term prognosis is good. Lifetime cardiology follow-up is mandatory to monitor for common longer-term problems, such as progressive valvar regurgitation.

Tetralogy of Fallot

PHYSIOLOGY

Tetralogy of Fallot is the most common cyanotic CHD (Fig. 24.12). The four components of tetralogy of Fallot are a VSD, an overriding of the ascending aorta, obstruction of the right ventricular outflow tract, and right ventricular hypertrophy. Although these patients have a large VSD, they traditionally do not have symptoms of CHF because their pulmonary circulation is protected from overcirculation by the right ventricular outflow tract obstruction.

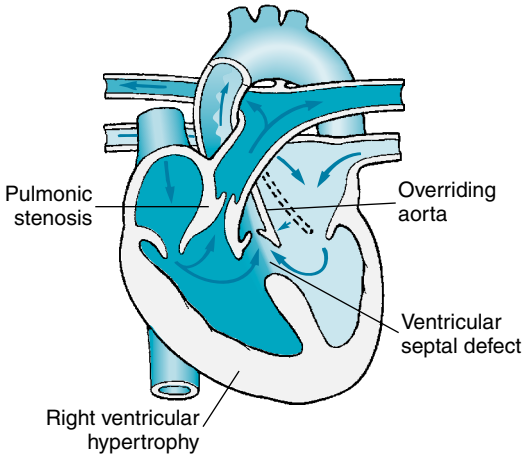

FIGURE 24.12 Tetralogy of Fallot. (Modified from Hockenberry MJ, Wilson D. *Wong's Essentials of Pediatric Nursing*. 8th ed. St Louis: Mosby; 2009.)

The degree of right ventricular outflow tract obstruction can vary significantly. A minority of children have too much pulmonary blood flow due to minimal right ventricular outflow tract obstruction. CHF will develop over time, much like a child with a simple large VSD (see Ventricular Septal Defect earlier in this chapter). **A child with minimal right ventricular outflow tract obstruction is sometimes called a "pink tet" and will not be cyanotic. On the other end of the spectrum, a child with severe right ventricular outflow tract obstruction may have too little pulmonary blood flow. In this case the ductus arteriosus may be vital to augment blood flow to the lungs, and the child may need prostaglandins and neonatal surgery.** Most children fall somewhere in the middle of the spectrum and have sufficient pulmonary blood flow but no CHF symptoms.

DATA COLLECTION

Physical Findings. Symptomatology in these infants relates to the degree of right ventricular outflow tract obstruction. **Newborns who are symptomatic usually have severe right ventricular outflow tract obstruction.**

Cyanosis. **The predominant intracardiac shunt is usually right to left; therefore, most infants with tetralogy of Fallot are cyanotic.** Varying degrees of cyanosis are present, depending on the amount of right-to-left intracardiac shunting and the amount of blood that enters the pulmonary circulation by the right ventricle. In severe cases, pulmonary blood flow is markedly decreased, and these infants are deeply cyanotic. However, if the right ventricular outflow obstruction is only mild or moderate, the intracardiac shunt can be left to right, and the infant will not be cyanotic.

Infants with tetralogy of Fallot are at risk for hypercyanotic (or "tet") spells. These spells consist of severe and intractable cyanosis, irritability, pallor, tachypnea, flaccidity, and possibly loss of consciousness. These spells are thought to be secondary to a transient increase in the obstruction of the right ventricular outflow tract, resulting in minimal or no pulmonary blood flow. See Medical Management later in the chapter for information on treatment. **True hypercyanotic spells rarely occur, but one significant spell should prompt early surgery because such spells can be life-threatening.**

Baseline oxygen saturations should be obtained before discharge from the neonatal intensive care unit. Oxygenation monitoring at home may be used if a BT shunt is placed before discharge.

Heart Sounds. A grade II to IV/VI harsh systolic murmur at the mid- to upper left sternal border is usually present but is diminished or absent during a hypercyanotic spell. The S_2 is usually loud and single (representing aortic closure).

Congestive Heart Failure. CHF is uncommon in tetralogy of Fallot. In rare "pink tet" cases, as described earlier, clinical symptoms will resemble a simple large VSD, and CHF will develop over time.

Laboratory Data

Arterial Blood Gases. The $Paco_2$ and pH are normal. The Pao_2 is normal if the pulmonary stenosis is mild and there is little right-to-left shunting at the ventricular level. If the pulmonary stenosis is more severe, the amount of right-to-left shunting is substantial, and the Pao_2 will be low.

Complete Blood Count. **Anemia can worsen hypoxemia with mixing cardiac lesions. Intermittent evaluation of hemoglobin and hematocrit should be performed, and aiming for a higher baseline is clinically helpful.**

Chest X-Ray Examination. The classic chest x-ray examination suggesting tetralogy of Fallot is a "boot-shaped heart" without cardiomegaly. However, this classic chest x-ray pattern described is not common in the newborn. Pulmonary vascularity is usually either normal or decreased.

Electrocardiogram. The ECG demonstrates right ventricular hypertrophy.

Echocardiogram. **An echocardiogram is diagnostic.** Doppler interrogation helps define the degree and level of pulmonary stenosis. Color-flow mapping can help delineate the size of the VSD and the direction of blood flow across the atrial and ventricular septa.

Cardiac Catheterization. Cardiac catheterization is not generally required.

TREATMENT

Medical Management. Immediate medical management is not generally required. Most infants with tetralogy of Fallot are stable and require no interventions or medications. **Neonates with severe right ventricular outflow tract obstruction may require PGE1 infusion to keep the ductus arteriosus open.**

Medical management of hypercyanotic (or "tet") spells includes **knee-chest positioning, oxygen, morphine, and fluid boluses.** If at home, parents should be instructed to calm the infant quickly and bring the infant's knees to his or her chest. A beta blocker (propranolol) and systemic vasopressor may also be tried. Rarely, emergent surgery is needed when medical management is insufficient.

Surgical Treatment. Total correction of tetralogy of Fallot involves intracardiac repair with patch closure of the large VSD and relief of the right ventricular outflow obstruction performed through a median sternotomy incision. A patch across the pulmonary valve annulus is often necessary. Contraindications include small size of the infant, anomalous left anterior descending coronary artery, and hypoplastic pulmonary arteries.

Total surgical repair of tetralogy of Fallot is not usually carried out in the neonatal period. Surgery is usually performed electively within the first year of life.[46,47] If surgical intervention in infancy is warranted (i.e., the infant is severely hypoxic because of inadequate pulmonary blood flow), a systemic-to-pulmonary

shunt (Blalock-Taussig (BT) shunt) is performed to provide adequate pulmonary blood flow until complete surgical repair at a later date.

COMPLICATIONS AND RESIDUAL EFFECTS

Surgical repair of tetralogy of Fallot often requires a patch across the pulmonary valve annulus. This makes the pulmonary valve dysfunctional and leaves the child with no functional valve in the pulmonary position. "Free" pulmonary regurgitation can be tolerated for decades with minimal symptoms, but right ventricular dilation gradually occurs, and right ventricular function can eventually be affected.[47] Pulmonary valve replacement is being performed earlier in life (teenage years), and advancements are moving toward performing pulmonary valve replacements by a cardiac catheterization procedure and tissue bioengineered valves that may one day grow with the patient.

PROGNOSIS AND FOLLOW-UP

The prognosis after surgical repair is good, although most children are left without a pulmonary valve. Severe pulmonary regurgitation can cause functional limitations in activities of daily living for some patients, and the right ventricular dilation secondary to severe pulmonary regurgitation can lead to ventricular arrhythmias and sudden death. Long-term follow-up after corrective surgery is necessary, and most children require a future surgery or intervention for pulmonary valve replacement.[77]

Pulmonary Atresia With Intact Ventricular Septum

PHYSIOLOGY

Pulmonary atresia is characterized by complete agenesis of the pulmonary valve. This lesion produces severe signs or symptoms soon after birth and is not compatible with life unless there is an associated interatrial communication and an additional pathway of entry for blood into the pulmonary circulation (through a PDA or collateral blood flow). **Because flow to the lungs usually depends on a PDA, death occurs when this structure closes.** The right ventricle is usually hypoplastic but may be normal or dilated, depending on the degree of tricuspid insufficiency present. The presence of sinusoidal connections between the right ventricle and the coronary arteries is associated with poorer long-term survival.[19]

DATA COLLECTION

Physical Findings

Cyanosis. **Cyanosis is always present due to reduced pulmonary blood flow and atrial right-to-left shunting.** Acceptable oxygen saturations are greater than 75% on room air when on PGE1 infusion.

Heart Sounds. The S_2 is single, and a soft systolic murmur may be heard as a result of either the PDA or tricuspid insufficiency.

Congestive Heart Failure. CHF is not present unless there is significant tricuspid insufficiency (see Congestive Heart Failure earlier in this chapter).

Laboratory Data

Arterial Blood Gases. The pH and $PaCO_2$ are usually within the normal range. **The PaO_2 is usually very low (20 to 30 mm Hg) unless there is a large shunt at the ductal or bronchial collateral level.** In some cases, the amount of pulmonary blood flow is insufficient, causing a low pH due to metabolic acidosis.

Complete Blood Count. **Anemia can worsen hypoxemia with mixing cardiac lesions.** Intermittent evaluation of hemoglobin and hematocrit should be performed, and aiming for a higher baseline is clinically helpful.

Chest X-Ray Examination. Heart size is normal unless tricuspid insufficiency causes cardiomegaly. Pulmonary vascularity is either decreased or normal, depending on the amount of shunting through the PDA or collateral blood flow.

Near-Infrared Spectrometry. NIRS can be helpful for monitoring in the immediate stabilization period, especially if the defect was not prenatally diagnosed.

Electrocardiogram. The ECG is usually normal but may demonstrate left ventricular hypertrophy.

Echocardiogram. A two-dimensional echocardiogram is diagnostic. Color-flow mapping can suggest the presence of coronary artery sinusoids.

Cardiac Catheterization. Cardiac catheterization may be performed if intervention to open the pulmonary valve is possible. Catheter intervention on the pulmonary valve is not possible if right-ventricle–dependent coronary sinusoids are present or if the

pulmonary valve annulus is extremely small. Balloon atrial septostomy may be performed at the time of catheterization but is rarely needed.

TREATMENT

Medical Management. **PGE1 is used to maintain the patency of the ductus arteriosus until surgical intervention** (see General Treatment Strategy earlier in this chapter).

Surgical Treatment. When the right heart structures are adequately sized, cardiac catheterization to balloon dilate the pulmonary valve may be the only intervention required in the neonatal period. However, if the pulmonary valve dilation is not possible or if it does not create enough pulmonary blood flow, a systemic-to-pulmonary shunt such as the Blalock-Taussig operation is performed. In cases where the right ventricle and tricuspid valve are not severely hypoplastic and coronary artery sinusoids are not present, a pulmonary valvotomy or right ventricular outflow tract reconstruction may also be performed in addition to a shunt. This establishes an open pathway through the pulmonary valve area and establishes blood flow through the right ventricle and pulmonary artery to promote the growth of the right heart. The pulmonary valvotomy and pulmonary outflow patch procedures are performed through a median sternotomy incision.

COMPLICATIONS AND RESIDUAL EFFECTS

Complications and residual effects of the Blalock-Taussig operation include CHF from a large shunt, inadequate pulmonary blood flow due to a too small shunt, shunt stenosis, and sudden death due to sudden shunt obstruction. The mortality rate in infants is 25% or higher as children go through long-term surgical and medical follow-up.[5,83]

PROGNOSIS AND FOLLOW-UP

Pulmonary atresia is fatal without surgical intervention. The size and function of the right ventricle and tricuspid valve determine if a child can eventually have a two-ventricle repair (where the right side of the heart functions independently and performs its normal job) or end up with single-ventricle physiology (where the right side of the heart is functionless and the left side of the heart does all the work) or something in the middle. The long-term prognosis depends on the original anatomy and the surgeries performed.[1] Multiple surgeries and long-term cardiac follow-up are always necessary.

Total Anomalous Pulmonary Venous Return

PHYSIOLOGY

Total anomalous pulmonary venous return (TAPVR) occurs when all the pulmonary veins do not drain normally into the left atrium. Instead, the pulmonary veins drain into an abnormal vein (or veins) connecting to the systemic venous system (superior vena cava [SVC], inferior vena cava [IVC], or coronary sinus). The systemic veins drain to the right atrium, so the oxygenated pulmonary venous blood ends up on the right side of the heart. The four main varieties of TAPVR are as follows:

- Supracardiac (most common) (Fig. 24.13), in which the four veins join behind the heart, travel superiorly, and the drainage is to the SVC
- Infracardiac, in which the four veins join behind the heart, pass inferiorly through the diaphragm, and connect to the portal venous system or IVC
- Intracardiac, in which the pulmonary veins drain into the coronary sinus or directly into the RA
- Mixed, in which at least two of the previous types of anomalous pulmonary drainage occur in the same child (e.g., right pulmonary veins return to the SVC, and left pulmonary veins drain to the coronary sinus)

Each of the various types of anomalous drainage can occur with or without obstruction along the pulmonary venous pathway. The presence or absence of obstruction profoundly affects the clinical course. **Because all pulmonary venous return (oxygenated blood) ultimately enters the RA (as opposed to the LA), a right-to-left shunt at the atrial level is necessary to sustain life.**

DATA COLLECTION

Physical Findings

Cyanosis. **Infants with TAPVR are frequently cyanotic, with saturations lower than 80% if obstructed venous return is present.** Obstructed TAPVR causes pulmonary venous congestion,

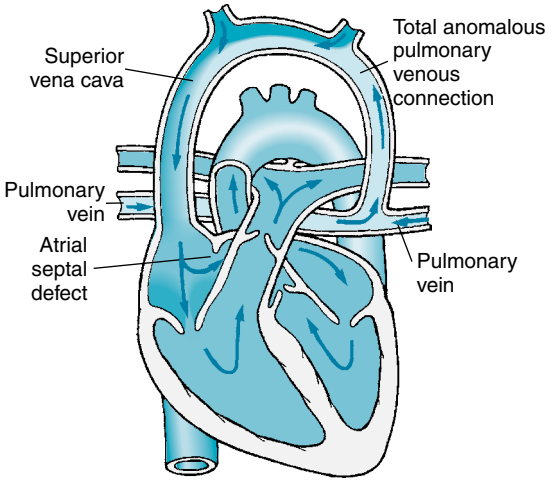

FIGURE 24.13 Total anomalous pulmonary venous return. (Modified from Hockenberry MJ, Wilson D. *Wong's Essentials of Pediatric Nursing.* 8th ed. St Louis: Mosby; 2009.)

which leads to reduced pulmonary blood flow and pulmonary edema, both of which also contribute to cyanosis.

Heart Sounds. **Murmurs are rarely heard in infants with TAPVR.**

Congestive Heart Failure. Infants with **unobstructed TAPVR usually show signs of CHF** (see Congestive Heart Failure earlier in this chapter). Infants with obstructed TAPVR have pulmonary venous congestion that can be life-threatening.

Laboratory Data

Arterial Blood Gases. The pH and $PaCO_2$ are usually normal. The PaO_2 is usually low but may be within the normal range if there is a large amount of pulmonary blood flow (always associated with severe congestive heart failure). If pulmonary venous obstruction is present, pulmonary blood flow is reduced, and the PaO_2 is low.

Chest X-Ray Examination. If the TAPVR is obstructed, the chest x-ray examination will demonstrate pulmonary venous congestion without cardiomegaly. If the TAPVR is unobstructed, the chest x-ray examination will demonstrate a marked increase in pulmonary vascularity and cardiomegaly.

Electrocardiogram. An ECG may demonstrate right axis deviation, RV hypertrophy, and RA enlargement.

Echocardiogram. **TAPVR is easily diagnosed by echocardiogram.** In two-dimensional imaging, an extravascular structure is seen behind the small left atrium. Color-flow mapping is helpful to trace the abnormal pulmonary venous connection to the SVC, coronary sinus, IVC, or mixed locations. The right-to-left shunting across the atrial septum can also be demonstrated.

Cardiac Catheterization. Cardiac catheterization is not usually required.

TREATMENT

Medical Management. **Obstructed TAPVR is a surgical emergency.** Nonobstructed TAPVR is usually stable enough to await elective surgery and rarely requires medical management.

Surgical Treatment. Surgical correction of TAPVR depends on the variety. The supracardiac and infracardiac varieties require surgical reimplantation of the common vein into the LA. Intracardiac TAPVR can usually be surgically repaired by realigning the atrial septum during closure of the ASD and directing the anomalous veins to the left atrial side.[37] All repairs are performed through a median sternotomy incision.

COMPLICATIONS AND RESIDUAL EFFECTS

Complications and residual effects include pulmonary venous obstruction and dysrhythmias. The mortality rate varies from 10% to 25% in infancy.[45]

PROGNOSIS AND FOLLOW-UP

Infants with nonobstructed TAPVR generally do well if the lesion is recognized early and early corrective surgery is performed. The prognosis for obstructed TAPVR is less favorable despite early surgical intervention. Pulmonary vein stenosis is a rare but frequently a progressive and lethal development that can also occur over time.

Tricuspid Atresia

PHYSIOLOGY

In tricuspid atresia, there is complete agenesis of the tricuspid valve, with no direct communication between the right atrium and right ventricle. Systemic venous blood entering the

right atrium is shunted through a patent foramen ovale or ASD into the left atrium. If a large VSD is present, the RV and pulmonary arteries may be normal in size. If the ventricular septum is intact but a large PDA is present, the right ventricular cavity is usually hypoplastic, but the pulmonary arteries may be slightly decreased or normal in size (Fig. 24.14). About 30% to 50% of these infants will have other associated anomalies, such as transposed great arteries and coarctation of the aorta.[87]

DATA COLLECTION

Physical Findings

Cyanosis. **Cyanosis is always present, although the degree of cyanosis varies. Newborns will have marked cyanosis if the pulmonary blood flow is compromised.** Oxygen saturations should be greater than 75% due to complete mixing of the oxygenated and deoxygenated blood within the heart.

Heart Sounds. Murmurs of associated shunts or lesions (VSD, PDA, pulmonary stenosis, etc.) may be present.

Congestive Heart Failure. CHF may be present with a large shunt (PDA or VSD) (see Congestive Heart Failure earlier in this chapter).

Laboratory Data

Arterial Blood Gases. The pH and $Paco_2$ usually are normal. The Pao_2 may vary from near normal if there is a large VSD or PDA to extremely low if there is limited shunting into the pulmonary system.

Complete Blood Count. Anemia can worsen hypoxemia with mixing cardiac lesions. Intermittent evaluation of hemoglobin and hematocrit should be performed, and aiming for a higher baseline is clinically helpful.

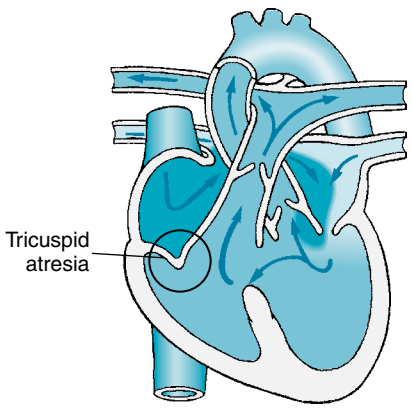

FIGURE 24.14 Tricuspid atresia. (Modified from Hockenberry MJ, Wilson D. *Wong's Essentials of Pediatric Nursing.* 8th ed. St Louis: Mosby; 2009.)

Chest X-Ray Examination. A chest x-ray examination may show a normal heart size or cardiomegaly. Pulmonary vascularity may be normal, decreased, or increased, depending on the amount of pulmonary blood flow.

Electrocardiogram. An ECG usually demonstrates left axis deviation with a counterclockwise loop, a superior axis in the frontal plane, and LV electrical dominance.

Echocardiogram. **Two-dimensional echocardiography is the gold standard for diagnosing tricuspid valve atresia,** as well as any associated anomalies. Color-flow mapping can identify the right-to-left shunt at the atrial level and the presence of a VSD, PDA, or valve stenosis.

Cardiac Catheterization. Cardiac catheterization is rarely required unless balloon atrial septostomy is necessary to improve intra-atrial mixing.

TREATMENT

Medical Management. **Immediate medical management is aimed primarily at maintaining adequate pulmonary blood flow.** In the usual case of severely limited pulmonary blood flow, **PGE1 infusion maintains pulmonary perfusion via the ductus arteriosus.**

Surgical Treatment. Complete repair of this heart defect is not possible because the mitral and tricuspid valves are necessary to achieve a two-ventricle circulation. Instead, **the single-ventricle palliative surgeries are necessary to allow the single left ventricle to perform all the work of the heart.** This palliative route may start with a systemic-to-pulmonary shunt (such as the Blalock-Taussig operation) if there is insufficient pulmonary blood flow, a pulmonary artery band placement if there is excessive pulmonary blood flow, or no surgery if there is a balanced circulation. Two subsequent staged surgeries are required, the *bidirectional Glenn* and *Fontan* procedures. Any associated defects are also repaired.

COMPLICATIONS AND RESIDUAL EFFECTS

If a BT shunt is required for pulmonary blood flow, interstage complications can include shunt occlusion and possible sudden death. Long-term

single-ventricle complications and residual effects include heart failure, chronic pleural effusions, renal or liver failure, persistent shunts, conduit obstruction, dysrhythmia, plastic bronchitis, and protein-losing enteropathy.[80] Survival through all three palliative surgeries depends on institutional experience and the specifics of each individual case, but the survival rate is generally up to 85% with a single-left-ventricle anatomy.[21]

PROGNOSIS AND FOLLOW-UP

The short-term prognosis for tricuspid atresia is guarded. Longer term, it is not known how long children can live with only a single ventricle performing all the work of the heart. Heart transplantation may eventually be performed. Long-term cardiology follow-up is a necessity.

Truncus Arteriosus

PHYSIOLOGY

Truncus arteriosus is characterized by one great artery arising from the left and right ventricles and, usually, an overriding VSD. This common artery has one valve and gives rise to (in order) the coronary arteries, the pulmonary arteries, and the brachiocephalic arteries. A second semilunar valve is not present. A coexisting VSD is present in more than 98% of cases. Truncus arteriosus is classified into three types, depending on the origins of the pulmonary arteries:

1. Type I—a short, main pulmonary artery arises from the common trunk that bifurcates into the right and left pulmonary arteries.
2. Type II—the right and left pulmonary arteries arise directly from the posterior surface of the common trunk.
3. Type III—the right and left pulmonary arteries arise directly from the lateral walls of the common trunk (Fig. 24.15).

In truncus arteriosus, the common trunk receives a mixture of unoxygenated blood from the RV and oxygenated blood from the left ventricle. Blood flow to the lungs varies with the type of truncus but is usually increased and at systemic-level pressure.

The ductus arteriosus is usually absent. A right aortic arch may be present. Extracardiac anomalies are present in 20% to 40% of cases, and 35% to 40% of neonates with truncus arteriosus have 22q11 deletion syndrome.[23]

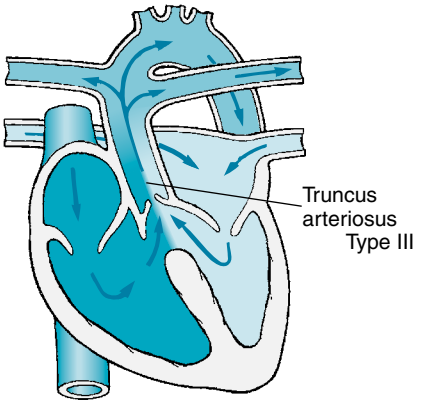

FIGURE 24.15 Truncus arteriosus type III. (Modified from Hockenberry MJ, Wilson D. *Wong's Essentials of Pediatric Nursing.* 8th ed. St Louis: Mosby; 2009.)

DATA COLLECTION

Physical Findings

Cyanosis. **Cyanosis may be present at birth but varies in intensity according to the amount of pulmonary blood flow.** Minimal cyanosis indicates adequate pulmonary blood flow.

Heart Sounds. The first heart sound, S_1, is normal, but the S_2 is single and loud because of the single valve of the common trunk. A loud systolic ejection click is frequently heard.

A loud pansystolic murmur maximal at the lower left sternal border that radiates to the entire precordium is commonly heard. A mid-diastolic rumble may be present. If the truncal valve is insufficient, a blowing diastolic murmur may be heard. A wide pulse pressure is often present.

Congestive Heart Failure. The presence of CHF depends on the amount of pulmonary blood flow. **Persistently high pulmonary arteriolar resistance in the first few weeks of life limits excessive pulmonary blood flow, and CHF may not be present until the PVR drops.** However, if the truncal valve has significant stenosis or regurgitation, CHF develops earlier due to pressure or volume overload (see Congestive Heart Failure earlier in this chapter).

Laboratory Data

Arterial Blood Gases. The pH and $Paco_2$ are usually normal. Pao_2 may be near normal if there is

adequate pulmonary blood flow (usually associated with severe CHF).

Complete Blood Count. Anemia can worsen hypoxemia with mixing cardiac lesions. Intermittent evaluation of hemoglobin and hematocrit should be performed, and aiming for a higher baseline is clinically helpful.

Chest X-Ray Examination. Cardiomegaly, displaced pulmonary arteries, and increased vascular markings are typical findings on the chest x-ray examination.

Electrocardiogram. Combined ventricular hypertrophy is most often seen on an ECG. Left atrial enlargement is also commonly found.

Echocardiogram. **A two-dimensional echocardiogram is diagnostic.** Particular attention is paid to the number of truncal valve leaflets, the presence of truncal valve insufficiency or stenosis, and the location of the bilateral branch pulmonary arteries.

Cardiac Catheterization. A cardiac catheterization is rarely necessary.

TREATMENT

Medical Management. **Medical management of these infants consists of stabilizing and treating CHF when present.** Calcium should be closely monitored because of the possibility of 22q11 deletion syndrome.

Surgical Treatment. Repair of truncus arteriosus consists of separating the pulmonary arteries from the common trunk, closing the VSD with a patch that dedicates the common trunk to the LV, and inserting an RV–to–pulmonary artery valve conduit. The use of homograft conduits for the repair of truncus arteriosus is common. Total repair of truncus arteriosus is performed through a median sternotomy incision.

COMPLICATIONS AND RESIDUAL EFFECTS

Complications and side effects include pulmonary vascular disease, residual shunts, truncal valve insufficiency or stenosis, and RV-PA conduit obstruction. The mortality rate is 10% to 20% and is dependent on the anatomy and severity of truncal valve abnormality.[61,73]

PROGNOSIS AND FOLLOW-UP

The longer-term outcome depends on the competency of the truncal valve. Severe truncal valve regurgitation or stenosis after truncus arteriosus repair is not well tolerated and may require reintervention.[16,81] Associated extracardiac anomalies or genetic abnormalities also significantly affect prognosis. Lifelong follow-up is always required.

Hypoplastic Left Heart Syndrome

PHYSIOLOGY

Hypoplastic left heart syndrome (HLHS) represents a clinical spectrum that includes severe coarctation of the aorta, severe aortic valve stenosis or atresia, LV hypoplasia, and severe mitral valve stenosis or atresia (Fig. 24.16). **Blood flow to the body is dependent on right-to-left shunting through the PDA. Ductal closure results in poor systemic perfusion and death. An atrial septal communication is also required to allow oxygenated pulmonary venous blood to shunt from the LA into the RA; a restrictive atrial septal defect can be life-threatening and require emergent cardiac catheterization intervention.**

DATA COLLECTION

Physical Findings

Cyanosis. **These infants are cyanotic, with a goal oxygen saturation in the range of 75% to 85%.** Blood flow to the lungs and systemically is in a delicate balance, so too much blood flow to the lungs results in poor systemic perfusion. This results in high oxygen saturations but marked poor perfusion, vasoconstriction, poor urine output, and CHF. **Too little blood flow to the lungs through the PDA can cause pulmonary undercirculation and low oxygen saturations.**

Heart Sounds. A nonspecific systolic murmur is heard in some infants with HLHS. A single S_1 and S_2 may be appreciated.

Congestive Heart Failure. CHF is present as a result of RV volume and pressure overload (see Congestive Heart Failure earlier in this chapter).

Laboratory Data

Arterial Blood Gases. **The arterial blood gas may represent the single best indicator of hemodynamic stability. Low arterial saturation (75% to 80%) with normal pH indicates an acceptable balance of systemic and pulmonary blood flow with adequate peripheral perfusion. Elevated**

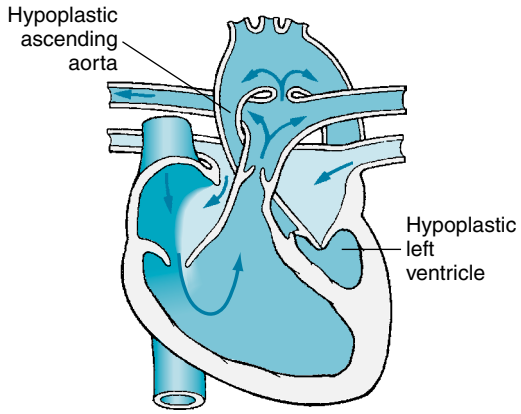

FIGURE 24.16 Hypoplastic left heart syndrome. (Modified from Hockenberry MJ, Wilson D. *Wong's Essentials of Pediatric Nursing.* 8th ed. St Louis: Mosby; 2009.)

oxygen saturation (greater than 90%) with acidosis represents significantly increased pulmonary and decreased systemic flow.

Complete Blood Count. Anemia can worsen hypoxemia with mixing cardiac lesions. Intermittent evaluation of hemoglobin and hematocrit should be performed, and aiming for a higher baseline is clinically helpful.

Brain-Natriuretic Peptide. BNP values may be helpful to differentiate respiratory or cardiac instability in neonates with HLHS. Values should be followed for trends rather than individual markers.

Chest X-Ray Examination. Cardiomegaly with increased pulmonary vascularity and pulmonary edema is seen on the x-ray examination.

Electrocardiogram. An ECG frequently demonstrates right axis deviation and right ventricular hypertrophy. However, the ECG may be normal.

Echocardiogram. An echocardiogram is diagnostic with a small left ventricular cavity and ascending aorta, mitral and aortic valve atresia or hypoplasia, and a dilated right ventricle. **Adequate atrial septal defect, patent ductus arteriosus, myocardial function, and degree of tricuspid regurgitation are essential parts of the echocardiogram.**

Near-Infrared Spectrometry Monitoring. NIRS monitoring is recommended to evaluate cerebral and systemic perfusion and monitor for low cardiac output.

Cardiac Catheterization. Cardiac catheterization carries a high risk in infants with hypoplastic left heart syndrome and is usually not necessary unless the atrial septal defect is not adequate for intra-atrial mixing. A balloon atrial septostomy and atrial septal stent placement can be performed if necessary.

TREATMENT

Medical Management. Pharmacologic maintenance of ductal patency with PGE1 with continuous infusion is required. Institutional practices vary, but the goal is a balanced pulmonary and systemic circulation by the use of volume expansion, inotropic support, and intubation. Maneuvers such as hypoventilation to increase PVR and redirect cardiac output to the body have been used. This may be a sign that cardiac surgery is necessary in an urgent manner due to an inability to balance the systemic and pulmonary circulation.

Surgical Treatment. Palliative cardiac surgeries are required for survival and occur over the first few years of life.[26] The *Norwood procedure* is performed in the neonatal period, consisting of enlargement of the atrial septal defect, ligation of the PDA, Damus-Kaye-Stansel (DKS) anastomosis of the pulmonary artery to the ascending aorta, aortic arch reconstruction, and creation of an aortopulmonary shunt (BT shunt) to provide pulmonary blood flow. Some centers use a hybrid approach with a PDA stent and bilateral pulmonary artery bands as a stage I palliation.[12,31] In the second stage, a *bidirectional Glenn* (anastomosis between the superior vena cava and the pulmonary arteries) is performed, and the aortopulmonary shunt is removed; this is usually performed at 5 to 9 months of age. The final stage is the *Fontan procedure,* which connects the inferior vena cava to the pulmonary arteries; this is generally done at 3 to 5 years of age.[26] Cardiac transplantation is an alternative surgical option, although infant donor hearts are rarely available. In some centers, the Norwood procedure is performed as a bridge to transplantation, allowing the infant to survive until a donor heart is available.

PROGNOSIS AND FOLLOW-UP

The longer-term outcome is variable and depends on associated factors such as a restrictive atrial septum, lung disease, genetic syndromes, and extracardiac anomalies. Turner syndrome, trisomy 13, trisomy 18, Holt-Oram, Smith-Lemli-Opitz, partial

trisomy 9, Jacobsen syndrome, and many others have been associated with HLHS. Since 2008 there has been an increased focus on improving interstage mortality after discharge from stage I Norwood (BT shunt) to stage II (Glenn), but this is still a high-risk time for infants with HLHS. There are advances with mobile technology (mHealth) during the interstage period, with reduced mortality and morbidity when compared with traditional interstage monitoring.[9] Current expectations are that up to 65% to 70% of newborns born today will survive all three palliative surgical procedures, but longer-term survival is not easily achieved.[21] Recently there have been case reports of HLHS patients having regenerative cellular strategies with autologous umbilical cord blood–derived cells at the second stage (Glenn surgery).[13] Although this research is in early phases without large clinical trials, the results are promising in feasibility trials. The results are encouraging for longer-term right ventricular function after cell-based therapy.

Heart Transplantation in Infants

For infants born with cardiomyopathy or uncorrectable CHD, heart transplantation may offer the only chance of long-term survival. Heart transplantation in infancy is severely limited by donor availability. There is a scarcity of donor hearts in this age and size group, so many infants on transplant lists die while waiting for donors. It is also important that families understand that heart transplantation requires lifelong medications, cardiac biopsies, hospitalizations for rejection of the organ or suspected infection (in the setting of the immunosuppression required after transplantation), and likely re-transplantation in the future.

Dysrhythmias

When evaluating an infant with a dysrhythmia, it is essential to assess simultaneously the electrophysiology and hemodynamic status. A neonate with poor perfusion and hypotension should first be treated for shock. A 12-lead ECG can then be done for definitive diagnosis of the type of dysrhythmia. When analyzing the ECG for the mechanism of dysrhythmia, a notation should be made in three main areas: (1) atrial and ventricular rates, (2) rhythm, and (3) QRS morphology.

PHYSIOLOGY

The development of the cardiac conduction system continues after birth, with a steady increase in the sympathetic innervation of the heart. This accounts for the observed heart-rate variability and the high frequency of benign dysrhythmias in the newborn. Premature ventricular beats (Fig. 24.17), premature atrial beats, brief episodes of ectopic atrial rhythms, wandering atrial pacemakers (Fig. 24.18), and even brief episodes of sinus arrest are all frequently seen in the newborn period. **The majority of these dysrhythmias do not require immediate treatment;** however, if they persist, the presence of CHD, sepsis, drug toxicity, persistent hypoxia, adrenal insufficiency, disorders of electrolyte and acid-base balance, hypoglycemia, and hypocalcemia should be considered.

All cardiac tissue is capable of generating a spontaneous depolarization. However, the sinoatrial (SA) node, atrioventricular (AV) node, and His-Purkinje system consist of specialized conductive tissue with rapid spontaneous depolarization. The SA node, located in the RA, is the normal pacemaker of the

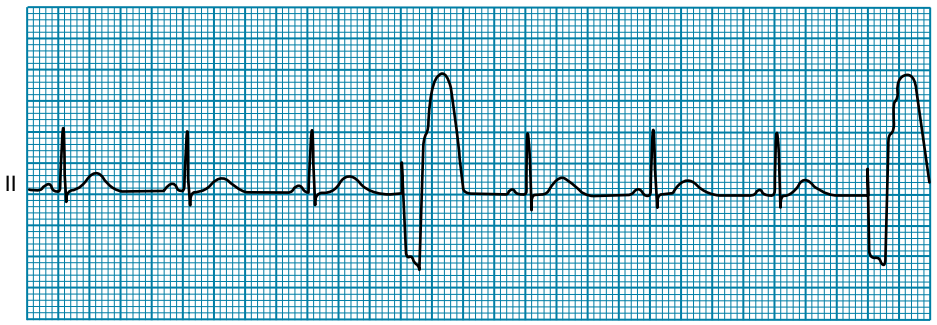

FIGURE 24.17 Premature ventricular beats.

heart because it has the fastest rate of spontaneous depolarization. If, however, the spontaneous depolarization of the SA node is delayed or slower than normal, an escape rhythm is generated by either the AV node or His-Purkinje system. These rhythms are called *nodal escape* or *ventricular escape,* respectively, and the heart rate set by these secondary pacing systems is slower than that of the SA node. Dysrhythmias also can originate from an automatic "ectopic" pacemaker located anywhere in the heart. These **ectopic pacemakers become more active in the presence of hypoxia, acidosis, digoxin toxicity, abnormal sympathetic nervous system stimulation, increased wall tension (CHF), or altered electrolyte balance.**

Drug therapy for dysrhythmias is based on the ability of certain medications to alter the electrophysiologic properties of cardiac tissue. One class of antidysrhythmic drugs directly increases the automaticity of certain cardiac fibers. Examples of such drugs are procainamide and lidocaine (see Table 24.3). Other drugs directly or indirectly affect the activity of the autonomic nervous system. Propranolol is a beta-adrenergic blocker and works in this fashion.

BENIGN DYSRHYTHMIAS: SINUS BRADYCARDIA, SINUS TACHYCARDIA, AND SINUS DYSRHYTHMIA

Of normal premature infants, up to 40% have brief episodes of sinus bradycardia (Fig. 24.19), sinus tachycardia, or sinus dysrhythmia (Fig. 24.20) that are benign and require no treatment. Healthy premature and term infants may have heart rates that range from 90 to 200 beats/min. Sustained heart rates (longer than 15 seconds) above or below this range should be evaluated with a 12-lead ECG and rhythm strip. The bedside monitor display is often contaminated with artifact that makes the accurate interpretation of dysrhythmias impossible. A 12-lead ECG provides necessary information that cannot be obtained from the bedside monitor alone.

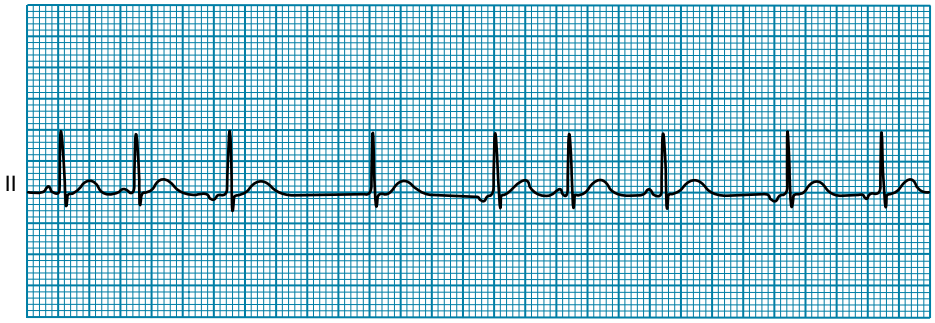

FIGURE 24.18 Wandering atrial pacemaker with junctional escape (fourth complex).

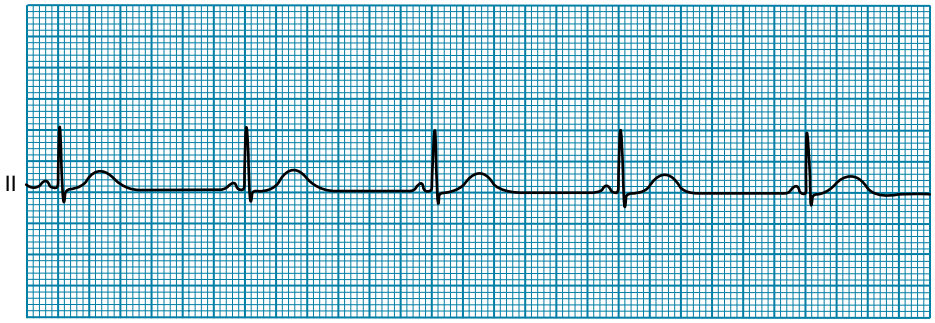

FIGURE 24.19 Sinus bradycardia.

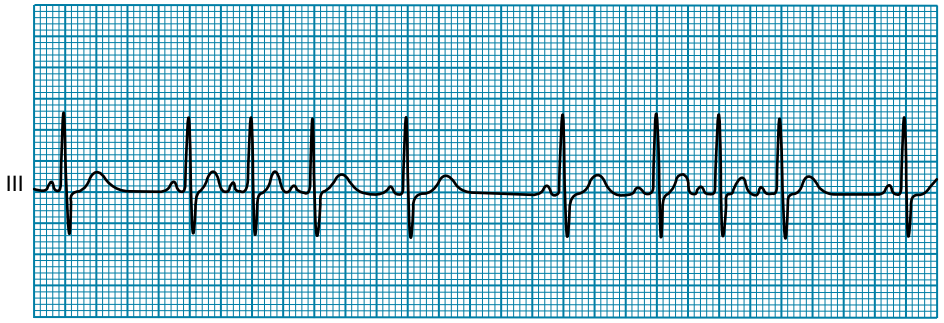

FIGURE 24.20 Sinus dysrhythmia.

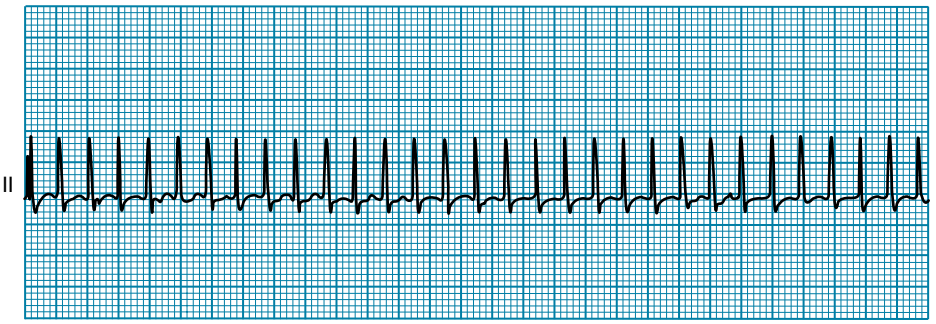

FIGURE 24.21 Supraventricular tachycardia.

SUPRAVENTRICULAR TACHYCARDIA

Supraventricular tachycardia (SVT) (Fig. 24.21) is the most common tachydysrhythmia in the newborn period. SVT can result from dual AV nodal pathways, rapid conduction through an accessory bundle (WPW syndrome), or the existence of an ectopic atrial pacemaker. SVT is occasionally associated with specific heart diseases, such as Ebstein anomaly of the tricuspid valve, cardiomyopathy, or myocarditis. These lesions are present in up to 25% of infants with SVT and should be excluded by evaluation with an echocardiogram.

Criteria for SVT include (1) persistent ventricular rate over 200 to 220 beats/min, (2) a fixed and regular R-R interval, and (3) little variability in heart rate with various activities (e.g., crying, feeding, apnea). The QRS complexes are most often narrow-complex, and P waves may be absent. **Newborns with SVT often have a history of restlessness, tachypnea, irritability, and poor feeding.** These symptoms may start abruptly with SVT initiation or may develop after 12 to 24 hours of SVT as ventricular function worsens. Prolonged tachycardia can be associated with CHF symptoms. **Without treatment, prolonged SVT can result in cardiovascular collapse, shock, and death.**[38]

Treatment. Various maneuvers may be used to attempt to convert the infant to normal sinus rhythm (NSR). Vagal maneuvers such as carotid occlusion and ocular compression should *never* be used. However, **stimulation of the diving reflex using an ice bag applied to the infant's face may be attempted and is the first line of treatment in the hemodynamically stable neonate with SVT.** Caution must be used with this procedure to ensure adequate ventilation for the infant. **Adenosine, a purinergic agonist, is an especially effective antidysrhythmic drug for the treatment of SVT** (see Table 24.3). Adenosine slows the sinus rate and produces a transient AV block, which can interrupt some types of SVT. Adenosine must be administered as a rapid bolus through an IV line to be effective, so venous access must be available to use this medication. Overdrive atrial pacing has been successful in converting SVT to NSR. However,

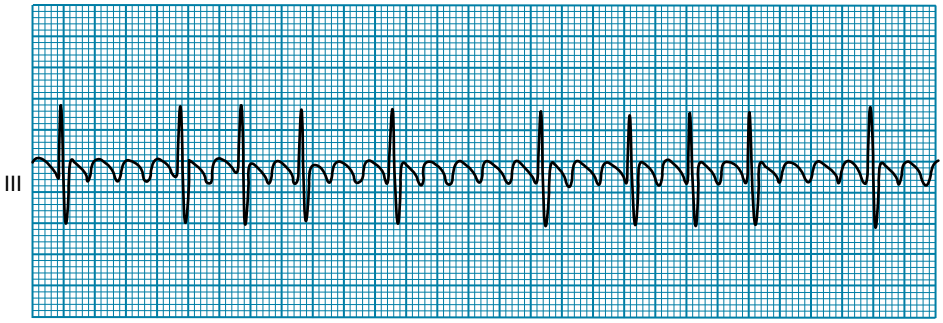

FIGURE 24.22 Atrial flutter.

direct-current (DC) cardioversion (1 to 2 watt-seconds/kg) is the most effective and rapid therapy and is the treatment of choice for a hemodynamically unstable neonate with SVT. The defibrillator must always be in the synchronous mode. If cardioversion is successful, maintenance drug therapy should be initiated with the consultation of pediatric cardiology.

For infants without WPW syndrome, digoxin or propranolol is often used for initial maintenance therapy. Digoxin should not be used in WPW syndrome, so this disorder should be ruled out before digoxin is used. Propranolol can be used for infants with SVT caused by WPW syndrome in the absence of CHF. Beta-blocking agents may inhibit circulating catecholamines, which are needed for the maintenance of adequate cardiac output in the face of CHF. In premature infants, propranolol may cause apnea and hypoglycemia. Esmolol is another beta-blocking agent that can be administered intravenously for SVT (see Table 24.3).

If the SVT fails to convert using the methods outlined previously, other drugs such as amiodarone, flecainide, or procainamide may be necessary. After conversion to NSR, maintenance drug therapy should be continued for 6 to 12 months or longer based on pediatric electrophysiology recommendations. **Relapses during the first 48 hours are common (70%) and should be anticipated.**

Fetal SVT is uncommon but, when present, can be associated with severe CHF and hydrops fetalis. Fetal SVT requires aggressive management, including conversion with maternally administered digoxin, flecainide, sotalol, or other antiarrhythmic medication. A favorable outcome usually can be expected for fetal SVT. Failure to control the fetal SVT in the presence of fetal hydrops is an indication for delivery if the fetus is of viable gestational age. The likelihood of SVT becoming a persistent problem after birth and cardioversion depends on the type and etiology of the fetal SVT.

ATRIAL FLUTTER AND FIBRILLATION

The presence of atrial flutter (Fig. 24.22) is often suggestive of a serious organic heart disease (endocardial fibroelastosis, Ebstein anomaly of the tricuspid valve, or complex heart defect). Atrial flutter is diagnosed when (1) the atrial rate is greater than 220 beats/min; (2) the P waves are very regular; and (3) there is a characteristic saw-tooth pattern, indicating a flutter wave. The ventricular rate will vary depending on the degree of AV block present. **Atrial fibrillation is extremely rare and almost always indicates a serious organic heart disease.** The prognosis for atrial flutter and fibrillation tends to be less favorable than those for SVTs caused by an accessory pathway or ectopic atrial pacemaker. However, **some cases of atrial flutter have been found in infants receiving broad-spectrum antimicrobials or those with an intracardiac catheter causing mechanical irritation of the right atrium.**[66] Atrial flutter is more difficult to treat in utero, more likely to be associated with structural heart defects, and more likely to develop hydrops fetalis.

Treatment. The treatment of atrial flutter or fibrillation is DC cardioversion or overdrive atrial pacing with pediatric electrophysiology consultation. In many cases, the neonate with atrial flutter will require a single cardioversion and then not require medication therapy to

prevent further episodes. However, maintenance therapy with an antidysrhythmic medication may be indicated and initiated by an electrophysiology specialist.

VENTRICULAR TACHYCARDIA

Ventricular tachycardia is relatively rare and is usually seen with severe medical illnesses such as hypoxemia, shock, electrolyte disturbances, and digoxin toxicity. Ventricular tachycardia is recognized by its characteristic wide QRS complexes, although it can be difficult to differentiate ventricular tachycardia from a supraventricular tachycardia with aberrant ventricular conduction. **A wide-complex tachycardia should always be assumed to be ventricular tachycardia until proven otherwise.** The presence of ventricular tachycardia is always alarming because the etiology is rarely benign, it can abruptly start and cause rapid hemodynamic instability and clinical deterioration, and it can be challenging to treat.

Treatment. Ventricular tachycardia is best treated with immediate DC cardioversion. Lidocaine may be used as a bolus (1 to 2 mg/kg intravenously) or as a continuous IV infusion of 20 to 30 mcg/kg/min. After conversion, maintenance therapy should be initiated using propranolol, lidocaine, procainamide, or amiodarone (see Table 24.3).

COMPLETE ATRIOVENTRICULAR BLOCK

In complete heart block, the SA node functions normally and sends out a depolarization impulse to the atria, but the AV node is dysfunctional and does not transmit this signal to the ventricles. As the ventricles receive no signal to depolarize from the atria, they depolarize on their own but at a much slower rate than the atrial rate. **The result is that atrial and ventricular depolarizations are completely independent of each other.** The ECG demonstrates P waves at a normal heart rate for age, but QRS complexes that occur at a much slower rate and are completely dissociated from the P waves.

Complete heart block can be seen in infants with specific structural cardiac defects, myocarditis, or endocardial fibroelastosis. **There is a strong association between congenital heart block and maternal collagen diseases such as systemic lupus erythematosus.** Often these mothers have no signs or symptoms of lupus, but laboratory confirmation is often possible.

Treatment. No treatment is immediately required unless the neonate is hemodynamically unstable due to significant ventricular bradycardia. Cardiac output is directly dependent on the ventricular rate; isoproterenol may be used temporarily to increase the ventricular rate until a pacemaker is placed. **If the ventricular rate is consistently below 55 beats/min, signs or symptoms of low cardiac output, or an associated congenital heart defect, pacemaker placement is indicated.** In most cases, the pacemaker will be set to listen to the child's normal SA node activity and will transmit these depolarization signals to the ventricles (the normal role of an AV node).

SICK SINUS SYNDROME

Sick sinus syndrome (SSS) is a broad term used to describe dysrhythmias resulting from abnormal sinus node function and includes a wide array of bradydysrhythmias, including sinus bradycardia, sinus pause/arrest, sinoatrial exit block, and slow escape rhythms, including junctional bradycardia. Although **most commonly acquired during surgical repair for CHD** (because of the proximity to the sinus node), **SSS may also be found congenitally in the neonatal period.** Mutations in the cardiac sodium channel gene *SCN5A* can result in congenital SSS.[99] **Treatment of SSS requires pacemaker placement,** but treatment is not always indicated.

PARENT TEACHING

The diagnosis of CHD in their child—whether given prenatally or postnatally—is a frightening experience and causes much distress to parents. Parents may grieve over the loss of the healthy newborn they had anticipated and experience shock, denial, guilt, anger, despair, or confusion.[28] **Comprehensive teaching, reassurance, and support are essential for the well-being of both the infant and the family** (Box 24.6).

If the diagnosis of CHD is made prenatally by fetal echocardiography, parent education

BOX 24.6 PARENT/CAREGIVER TEACHING

Key Points for Parents of Newborns with Heart Disease

- Refer to a pediatric facility experienced with infants with heart disease.
- Reassure and support the family for understanding that "this is not their fault."
- Explain all tubes, monitors, and equipment to decrease anxiety.
- Help parents accept and understand their infant's diagnosis.
- Encourage parental bonding with their infant and participation in care.
- Detail home care, including medications, signs and symptoms, and when to call the physician.
- Encourage normal activity.
- Explain the necessity of subacute bacterial endocarditis protection.
- Supply parents with resource information—booklets, brochures, Internet resources.

begins before the birth of the infant. Expectant parents should be referred to a pediatric facility experienced in providing complex medical and surgical care for infants with CHD. Arrangements should be made for parents to meet with key members of the medical and surgical team and tour the intensive care units. A multidisciplinary approach with providers and support staff from cardiology, cardiac surgery, the intensive care team, social work, chaplaincy, genetic counseling, and the palliative care team should be used.

Understanding the heart defect aids in decreasing anxiety, as well as allowing parents to provide good care for their child. Explain the infant's heart defect to the parents. Draw or show a picture of the heart defect, explaining the normal circulation of the heart in simple terms and how their infant's heart differs from normal. This explanation should be repeated often for parental understanding and retention. Careful explanation of all tubes, monitors, equipment, and procedures in the nursery also helps decrease parental anxiety.

Heart defects are not visible lesions. Infants with CHD can appear quite normal and healthy. It may be difficult for some parents to accept that their infant has a cardiac defect. In addition, parents are under great emotional and sometimes physical stress (from labor and delivery), which decreases their ability to hear new information and retain details. Patience and repetition of information are important.

Some parents may initially be unable to respond to their newborn with a heart defect. **Health care providers should facilitate bonding by encouraging interaction with the infant and enabling parents to participate in their infant's care.** Parental participation enables opportunities for parents to practice under the guidance of professionals and enables professional assessment of parental competencies. Parents should be encouraged to assist with diaper changes, positioning, and oral care and provide comfort measures even during the critical phase of illness. **During the postoperative and convalescent phase of hospitalization, parents should assume more of the infant's care, such as feeding, care of the incision, and medication administration.** Before discharge, parents should be encouraged to room with and completely care for their infant, with nursing assistance available as needed. Parents must feel comfortable caring for their infant and must demonstrate their ability to do so before discharge from the hospital.

Teaching home care of the infant before discharge should be detailed and include medications, signs to observe, and guidelines for care. It is critical that these be written instructions that can be referred to often. All medications should be explained in detail, including their purpose, action, and administration. Parents should be made aware of the potential adverse effects (side effects) of all of their infant's medications. **Parents should be observed giving medications in the nursery before the infant is discharged.** Parents should be instructed to telephone their physician if the infant demonstrates red flags such as (1) any behavior or bodily change that worries parents; (2) fevers; (3) poor weight gain; (4) increased work of breathing or stopping to breathe during feeds; (4) feeding difficulty, increased sweating during feeds, or excessive spitting up; (5) new or changed vomiting or diarrhea for a 12- to 24-hour period; (6) decreased activity level or irritability; (7) low oxygen saturations if home monitoring was prescribed; or (8) low number of wet diapers in a day.[66] Provide information about the infant's prognosis and follow-up care

and anticipatory guidance about special growth and development considerations.

Cyanotic heart disease is particularly disturbing to parents because their infant's skin color is "blue." Parents should be cautioned that their infant will appear blue, especially around the mouth, mucous membranes, hands, and feet, and that the blueness will increase with activity such as crying, feeding, and bowel movements. **Single-ventricle anatomy after the first stage of surgery requires that the discharged infant be followed closely with oxygen saturation checks twice a day or more, and parents should understand their child's expected oxygen saturation and how to contact their primary cardiac team for changes and concerns.** The neonates with the highest-risk cardiac anatomies will have a specialized follow-up in cardiology clinic for cardiology, nutrition, and family support.[9]

Normal Newborn Care and Maintenance

Many parents will develop a narrow, disease-oriented focus. **Emphasize to parents that their infant should be treated as normally as possible. It is often difficult for first-time parents to differentiate "normal baby problems" from cardiac-related problems.** It is important to have open communication among the family, primary care provider, and cardiologist. Parents should be encouraged to call medical personnel as needed for support, answers to questions, and reassurance. Support groups can also provide information, empathy, and practical tips to parents caring for children with CHD.

The trip home should occur in an **appropriate car seat, and a car seat screen is recommended to ensure oxygen saturations are maintained while restrained. Infection prevention strategies,** such as handwashing before handling the infant, avoiding ill contacts, and avoiding large crowds, are especially important to teach parents. Discharge planning should include normal newborn procedures if possible, including standard pediatric immunizations, hearing screen, and circumcision if permitted by the cardiac team. If there is a medical reason to delay these procedures, this should be discussed with parents, and future plans for these procedures should be made.

Infectious Endocarditis Protection

Infants with CHD are at increased risk for developing adverse outcomes associated with infectious endocarditis (IE), also known as bacterial endocarditis (BE). The American Heart Association's Endocarditis Committee extensively reviewed published studies and found no conclusive evidence to link gastrointestinal or genitourinary tract procedures with the development of IE in most patients with congenital heart defects.[11] **Antibiotic prophylaxis with dental procedures is recommended only for patients with cardiac conditions (e.g., prosthetic valves, previous endocarditis, cardiac transplant) associated with the highest risk for adverse outcomes from endocarditis. Antibiotic prophylaxis is also recommended for the following categories of CHD: (1) unrepaired cyanotic CHD, (2) completely repaired CHD with prosthetic material for the first 6 months after the procedure, (3) repaired CHD with residual defects adjacent to prosthetic material, (4) prosthetic cardiac valves, and (5) cardiac transplant recipients with valve regurgitation.**[11] Parents are encouraged to speak with their pediatric cardiologist regarding any questions related to IE antibiotic prophylaxis.

Activity

Normal newborn activity is encouraged after discharge. **There are no activity restrictions for infants with heart disease because infants "self-limit" according to their capacity. However, special precautions may be indicated for handling the infant.** Parents should avoid picking the infant up under the arms until the sternal wound and underlying structures are healed. If discharge occurs soon after surgery, there may also be special instructions for bathing the infant.

Supporting Ongoing Development

Infants with CHD are at risk for neurodevelopmental disorders, disability, or developmental delay for a number of reasons, including that the incidence of brain abnormalities is higher in children with CHD than in the general population. **Inform parents about their infant's increased risk for developmental delay, review normal developmental milestones, and provide pragmatic strategies**

to maximize infant development. These may include simple interventions such as prone placement ("tummy time") after the sternotomy has healed and continued oral stimulation if a G-tube is required. Referral to early intervention programs and cardiac neurodevelopmental clinics for developmental surveillance, screening, and evaluation throughout childhood may allow for later academic, behavioral, psychosocial, and adaptive functioning to maximize the child's potential development.[60]

Parenting an infant with CHD requires coping, adaptation, and evolution—from diagnosis to discharge from the hospital and through caretaking and parenting at home. Parents have reported feelings of posttraumatic stress associated with caring for infants with the most complex single-ventricle anatomies.[76] Consultation with a mental health professional may enable the family to recognize and build on strengths that will help them cope with this enormous challenge.

FUTURE RESEARCH

Improvements in the diagnosis, understanding, and treatment of CHD have drastically reduced the morbidity and mortality rates associated with these defects. Children with critical CHD that was once considered fatal are now living into adulthood, thanks to innovations in cardiac surgery, cardiology, anesthesia, intensive care, and nursing practices. However, we still have much to discover. The etiology of CHD is still poorly understood or completely unknown. Cardiac genetic research is focusing on similar cardiac anatomy and how genetic involvement may play into the development of CHD, but without an understanding of true CHD etiology, the prevention of CHD is almost impossible. Future developments are needed to promote earlier and widespread prenatal detection of CHD, as well as improvements in current fetal catheter and surgical interventions to intervene in defective cardiac development during fetal life. **Advanced screening methods are also necessary to promote early postnatal detection of CHD and avoid the morbidity and mortality risks that can occur at home from undiagnosed CHD.**

Medical, catheter-based, and surgical treatments for CHD continue to exponentially advance. Clinical practice guidelines are increasingly being used to standardize care and evaluate best practices.[65] Valve replacement without surgery is a rapidly developing reality, and the development of a tissue-engineered valve that will grow with a child is expected in the near future. Although we have much left to learn, the future is exciting and will bring improved care and health for children with CHD.

25 NEONATAL NEPHROLOGY

MELISSA A. CADNAPAPHORNCHAI, DANIELLE E. SORANNO, TERRI J. BISIO, ROSANNE WOLOSCHUK, AND MEGAN KIRKLEY

In utero, the fetal kidney is not necessary for toxin removal or fluid and electrolyte homeostasis; rather, the placenta performs these functions. By contributing to amniotic fluid, the fetal kidney instead has an essential role in the normal development of the fetus. **After birth, as the infant adapts to the external milieu, the kidney gradually assumes its role as regulator of fluid and electrolyte homeostasis.** At birth, renal function changes dramatically, complicating clinical assessment. Assessment of renal function is an even greater challenge in the premature infant. The more complicated an organ is in its development, the more subject it is to maldevelopment. In this aspect, the kidney outranks most other organs. **Abnormalities of the genitourinary system constitute up to 30% of all anomalies diagnosed prenatally.**[146,188] Some anomalies may be readily apparent in the neonatal period, whereas others remain undiagnosed until later life.

Although renal disease can clearly affect the health of the newborn, it may also contribute to lifelong renal pathology. **Congenital renal dysplasia, renal obstructive disorders, and cystic diseases account for a substantial percentage of patients with end-stage renal failure.** Furthermore, a growing body of **data supports a link between prenatal and neonatal events and later hypertension and renal insufficiency in adolescents and adults.**[22,115,116]

NORMAL DEVELOPMENT OF THE KIDNEY

The mammalian embryo progressively develops three sets of excretory organs, all of which might be termed the "embryonic kidney."[188] The pronephros and mesonephros regress in the human but induce the metanephros, which is the direct precursor of the adult kidney (Fig. 25.1). The pronephros, a solid mass of cells along the nephrogenic cord, is located at the cervical level at approximately 3 weeks' gestation. Degeneration of the pronephros begins soon after its formation, and regression has completely occurred by week 5. The pronephros has no excretory function but plays an important role in the formation of the mesonephros. The primitive ureter of the pronephros forms the *Wolffian, or mesonephric, duct* via fusion of the pronephric tubular buds. The mesonephric duct then induces the formation of the second kidney, *the mesonephros,* at approximately 4 weeks' gestation. The mesonephros develops from the nephrogenic cord and forms 40 pairs of thin-walled tubules and glomeruli with excretory function. Portions of the mesonephric duct system are retained in the male fetus and form the *ducts of the epididymis, the ductus deferens, and the ejaculatory duct*. The remainder of the mesonephric duct system in the male infant has degenerated by the fourth month of gestation as the metanephric kidney develops. In the female, near-complete degeneration has occurred by the third month of gestation.

The *metanephros* appears at 4½ to 5 weeks' gestation. The metanephric kidney is the product of a series of inductive interactions between the metanephric mesenchyme and epithelial ureteric bud. Initially, the ureteric bud grows from the mesonephric duct into the mesenchymal portion of the urogenital ridge; concomitantly, the metanephric mesenchyme changes, becoming histologically distinct from the surrounding tissue. When the metanephric mesenchyme and ureteric bud make contact, a condensation of cells begins along the

BLUE type highlights content that is particularly applicable to clinical settings.

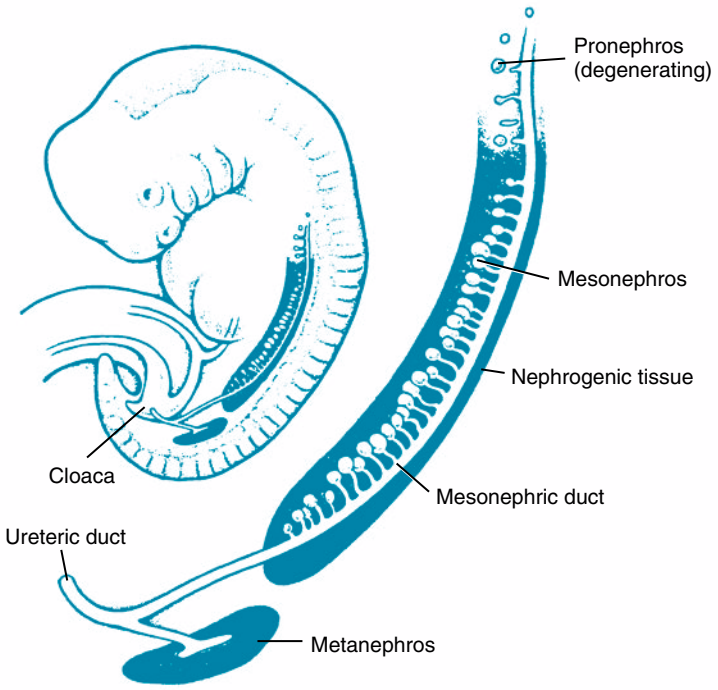

FIGURE 25.1 Schematic representation of overlapping stages in embryogenesis of human kidney. See text for detailed description. (From Holliday MA. Developmental abnormalities of the kidney in children. *Hosp Pract.* 1978;13(6):101. http://www.informahealthcare.com.)

surface of the bud. These cells are the beginnings of pretubular aggregates that undergo mesenchymal-to-epithelial transformation to become the segmented nephron. The condensed mesenchyme is also thought to produce a number of stem cells, which remain undifferentiated and proliferative. These cells serve to maintain a supply of precursor cells until the completion of nephron development. Thus, the epithelial portion of the adult kidney is derived from both the metanephric mesenchyme, via the stem cells ultimately responsible for individual nephron formation, and the ureteric bud, whose migration and division determine the pattern of formation of the urinary collecting system via its pretubular aggregates. **The ureteric bud migrates to the most caudal end of the nephrogenic cord and finally to the lumbar region by week 8 of gestation. The ureteric bud also rotates 90 degrees medially along the longitudinal axis. Abnormalities in ascent or rotation can lead to pelvic kidneys, horseshoe kidneys, or crossed fused ectopia.** Because of the complex interaction of metanephric mesenchyme and ureteric bud, anomalies of the kidney often accompany anomalies of the collecting system. **Congenital anomalies of the kidney and urinary tract (CAKUT) are a family of diseases with a diverse anatomic spectrum of kidney anomalies (agenesis, hypo/dysplasia, multicystic kidney dysplasia) and other urinary tract anomalies (duplex collecting system, megaureter, vesicoureteral reflux, posterior urethral valves).**[154,184] CAKUT is mostly considered polygenic at the current time, but recent studies have identified several causative single-gene mutations, including hepatocyte nuclear factor 1 beta (HNF1β) mutations, which account for up to 30% of CAKUT.[94,187] **CAKUT commonly cause progressive chronic kidney disease and constitute the most frequent cause of end-stage kidney disease and renal replacement therapy in childhood.**

Vascular system development occurs in concert with nephron formation. The surrounding major vessels and neural ganglia grow into the metanephros to complete the remaining cell types, and vessel architecture is similar to the newborn kidney

by 15 weeks of gestation. **The process of forming the adult complement of approximately 600,000 (range 250,000 to 2,000,000) nephrons in each kidney is complete by 34 to 36 weeks of gestational age (GA). In general, nephron development continues after birth in premature infants but at a slower rate than during gestation; thus, preterm infants are at higher risk for decreased nephron number compared with term infants.**

Physiologic Development of the Kidney

Although newborn kidneys are usually described as "immature," they are perfectly suited to their usual responsibilities.[37,138] During the latter part of gestation, their primary role is the maintenance of amniotic fluid volume. This requires a large volume of urine with a relatively high concentration of sodium. **Thus, fetal urine output is on the order of 10 mL/kg/hr of sodium-rich urine.** Fetal fractional excretion of sodium (FENa; i.e., the fraction of sodium in glomerular filtrate that appears in urine) is especially high, approximately 15%. This compares to less than 1% in a growing infant born after a full-term pregnancy.

The next major responsibility of the newborn kidney occurs during the first week of life. **Fetuses have a large amount of extracellular fluid (ECF) compared with older children and adults.** ECF as a percentage of body weight progressively diminishes throughout gestation, at approximately 65% of body weight at 26 weeks of gestation, 40% at full term, and 25% by 1 year of age. **Most of the postnatal reduction occurs in the first week of life and is the primary reason that body weight may decrease by up to 10% in breastfed term infants and even more in premature infants.** The healthy newborn kidney can handle this challenge without difficulty. Finally, in subsequent weeks, the kidney must retain the electrolytes needed for growth and the production of dilute urine to accommodate the large water load presented by breast milk. Growth itself is a powerful homeostatic ally. A substantial portion of carbohydrates, electrolytes, and nitrogenous wastes from protein absorbed from breast milk are never presented to the kidney for excretion but are instead incorporated into the growing body.

Only when the otherwise healthy neonatal kidney has to cope with unexpected derangements of water, electrolyte, or acid-base status secondary to premature birth or illness does its relative lack of ability to concentrate urine, excrete sodium and potassium loads, conserve sodium (in preterm infants), and regulate acid-base status become problematic. In older children and adults, normal kidneys can correct for substantial errors in clinical judgment in water and electrolyte administration or creation and/or correction of acid-base abnormalities. This is not so with neonatal kidneys, especially in smaller preterm infants. With that in mind, it is helpful to review specific aspects of neonatal renal function.

Glomerular Filtration Rate

The *glomerular filtration rate* (GFR) is the rate at which filtrate of renal plasma appears in proximal renal tubules.[1,15,175] For the fetus, the placenta serves to maintain fluid and electrolyte composition and clearance of metabolic wastes. Thus, renal arterial blood flow is approximately 5% of fetal cardiac output, compared with 25% in later life. This rapid increase in blood flow correlates with an increase in GFR from approximately 20 to 80 mL/min/1.73 m^2 by 6 months of age. GFR continues to improve over the first 2 years of life, typically reaching adult norms (when corrected for body surface area) by about 19 months of age. Table 25.1 shows glomerular filtration rates in healthy infants as measured by inulin clearance.

Tubular Function

Urine flow depends on both GFR and tubular reabsorption.[56,85,147] **Oliguria is ordinarily defined as urine output of less than 1 mL/kg/hr. However, urine output may transiently decrease immediately after birth to less than 1 mL/kg/hr because tubular reabsorption of water increases due to an increase in fetal antidiuretic hormone (ADH) during labor.** Nevertheless, **50% of full-term infants void by 12 hours, 92% by 24 hours, and 99% by 48 hours of life.** Causes for prolonged failure to void include true or perceived decreased effective circulating volume, primary renal dysfunction, and obstruction to urine flow. After transient oliguria/anuria, the urine flow rate increases as the newborn excretes the physiologically expanded fetal extracellular fluid volume as described earlier.

The **newborn has a limited capacity to concentrate urine.** Several factors account for this

TABLE 25.1 GLOMERULAR FILTRATION RATES* IN HEALTHY INFANTS AS MEASURED BY INULIN CLEARANCE

AGE	MEAN GFR (SD)
Preterm	
1-3 days	14.0 (5.0)
1-7 days	18.7 (5.5)
8-14 days	35.4 (13.4)
1.5-4 months	67.4 (16.6)
Term	
1-3 days	20.8 (5.0)
3-4 days	39.0 (15.1)
6-14 days	54.6 (7.6)
1-3 months	85.3 (35.1)
4-6 months	87.4 (22.3)
7-12 months	96.2 (12.2)

*Glomerular filtration rate (mL/min/1.73m^2).
GFR, Glomerular filtration rate; *SD,* standard deviation.

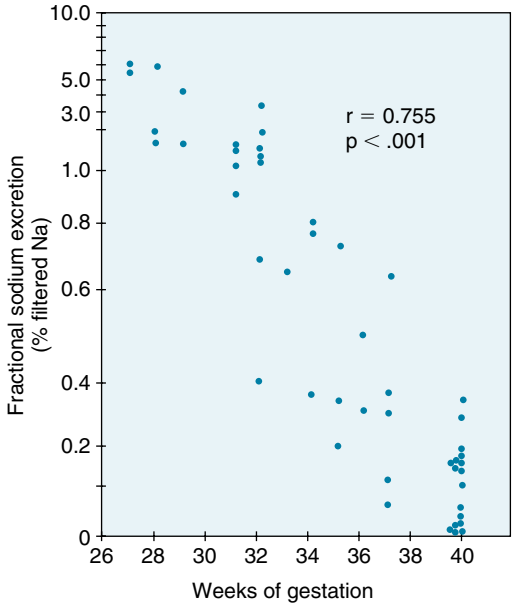

FIGURE 25.2 A decrease in fractional excretion of sodium occurs with increasing postconceptual age. *Na,* Sodium. (From Siegel S, Oh W. Renal function as a marker of human fetal maturation. *Acta Paediatr Scand.* 1976;65(4):481.)

observation. The concentration of osmotically active solutes in the urine is low during the first few weeks of life in association with high water and low protein content of breast milk and infant formulas, and ingested protein is preferentially used for growth rather than urea synthesis, leading to impairment of the countercurrent concentrating mechanism. Neonates also demonstrate resistance to ADH with decreased expression of collecting duct aquaporin-2 water channels, which normally enhance tubular water reabsorption. **These factors result in an increased risk of intravascular volume depletion when fluid intake is limited.** High-protein diets or urea supplementation can increase urinary urea excretion in newborn infants, thus enhancing urinary concentrating ability.

Proximal Tubular Function

The proximal tubule is responsible for reabsorbing glucose; amino acids; and most of the bicarbonate, sodium chloride, uric acid, and water in glomerular filtrate.[20,47,73,167] In smaller preterm infants, tubular transport mechanisms are insufficient to prevent spillage of each of these in varying degrees.

SODIUM

Physiologic diuresis in the first week of life is accompanied by physiologic natriuresis. The kidney is then responsible for conserving sufficient dietary sodium for growth.[91] **This is a challenge for preterm infants (Fig. 25.2), who often require extra sodium intake to compensate for obligatory sodium wasting.** Conversely, in the presence of a sodium load (e.g., from administration of large amounts of sodium), the neonatal kidney cannot compensate with a rapid increase in fractional excretion of sodium. The result is edema and possibly circulatory overload.

POTASSIUM

The kidney is an important site for regulation of potassium balance.[83,158] In the adult, it is responsible for maintaining zero balance. In contrast, **to sustain the neonate, the kidney must maintain positive**

potassium balance. In this context, it is less surprising that mechanisms for potassium excretion are underdeveloped at birth. **Serum potassium concentrations tend to be high in neonates (5.5 to 6 mEq/L) relative to older children and adults.** The levels are not of pathologic significance and perhaps play a role in supporting growth.

ACID-BASE BALANCE

By adult standards, serum bicarbonate concentrations are low in full-term newborns (19 to 21 mEq/L) and even lower in premature infants (16 to 20 mEq/L).[147,151] **Lower serum bicarbonate concentrations reflect limited ability to cope with the acid load from high protein intake and the acid generated by the formation of new bone.** The capacity of the neonatal **proximal tubule to reabsorb filtered bicarbonate is one third that of an adult.** Proximal tubular bicarbonate reabsorption is further compromised if ECF is overexpanded with crystalloid solutions; because proximal tubular sodium and bicarbonate reabsorption are closely linked, bicarbonate is wasted as sodium reabsorption decreases to rid the body of excess sodium chloride. **The capacities of ammoniagenesis and of the collecting duct to secrete hydrogen ions are also limited.** The net result is a limited capacity to correct metabolic acidosis. **This limitation is particularly evident in the setting of pathologic metabolic acidosis as may be seen in acute kidney injury.** However, the ability to achieve minimal urine pH values is usually intact. That is, **if serum bicarbonate is low enough (e.g., 14 to 15 mEq/L), the kidney can completely reabsorb the smaller amount of filtered bicarbonate and achieve a urine pH of 5.** Serum bicarbonate concentrations increase to adult levels of 24 to 26 mEq/L by the end of the first year.

URIC ACID

Serum uric acid concentrations are elevated in the newborn because production from nucleotide breakdown is increased just after birth, especially in premature infants.[170,177] This is accompanied by increased uric acid excretion. **High urinary uric acid concentrations may leave pink or red uric acid crystals in the diaper, which are often mistaken for blood (i.e., "brick-dust urine"). A microscopic urinalysis is helpful to exclude true hematuria in this setting.**

CLINICAL ASSESSMENT OF RENAL DISEASE IN THE NEONATE

History

A complete family history of renal disease or syndromes that involve the kidneys is important to obtain. Prenatal exposures to maternal infection, drugs, toxins, or medications are risk factors for neonatal renal disease. Paternal smoking and advanced age may also be associated with an increased risk for urinary tract anomalies.

The quantity of amniotic fluid is an indicator of fetal renal function because fetal urination is responsible for most of the amniotic fluid volume beginning in the second trimester of pregnancy. Normally, amniotic fluid volume increases during gestation, peaking at 34 weeks' gestation. **Any fetal renal condition associated with significant impairment in function with markedly diminished urine output can be associated with oligohydramnios.** With worsening oligo-/anhydramnios, a *Potter* sequence can be observed, in which the fetus develops pulmonary hypoplasia, a flattened nose, a recessed chin, low-set ears, and limb compression.[144,145] Serial amnioinfusion during pregnancy has been utilized to support lung development in this setting, although such intervention does not improve kidney function. Severe urinary concentrating defects (e.g., diabetes insipidus and Bartter syndrome) may be associated with polyhydramnios.

A review of the perinatal history should identify risk factors for renal ischemia. Special attention to the composition of administered parenteral fluids can help to identify iatrogenic contributions to fluid/electrolyte derangements. **Several potentially nephrotoxic medications are commonly used in the neonatal period, including diuretics, aminoglycosides, and nonsteroidal anti-inflammatory drugs (NSAIDs).**

Signs and Symptoms

Physical findings that are indicators of genitourinary tract abnormalities are outlined in Table 25.2. Although lower urinary tract and renal anomalies are seldom the presenting features of chromosomal disorders, they frequently form part of a multisystem malformation syndrome

TABLE 25.2 PERINATAL INDICATORS SUGGESTIVE OF ABNORMALITIES OF THE GENITOURINARY TRACT

FINDING	SUSPECTED ABNORMALITY
Oligohydramnios	Any congenital renal lesion associated with significant impairment in function
Polyhydramnios	Diabetes insipidus, Bartter syndrome
Enlarged placenta (>25% of infant birth weight) or >10-fold increase in maternal serum AFP	Congenital nephrotic syndrome—Finnish type
Velamentous insertion of umbilical cord	Increased congenital anomalies
Asphyxia neonatorum	Acute tubular or cortical necrosis
Physical Examination	
Hypertension	See text
Skin	
Hemangioma	Hemangioma of kidney or bladder
Edema	Congenital nephrotic syndrome
Head	
Encephalocele	Meckel-Gruber syndrome (polycystic kidneys)
Cleft lip and palate	Urinary tract anomalies
Macroglossia	Beckwith-Wiedemann syndrome (nephromegaly, cysts, structural urinary tract anomalies, nephrocalcinosis); Johanson-Blizzard syndrome (hydronephrosis, dysplasia); orofacial-digital syndrome (renal cystic disease)
Eyes	
Phakoma	Tuberous sclerosis
Retinitis pigmentosa	Nephronophthisis/renal ciliopathy
Cataracts	Lowe syndrome, WAGR, congenital rubella
Aniridia	WAGR
Ears	
Low-set or malformed	Increased risk for renal abnormalities, Potter syndrome/sequence
Ear tags	Branchio-oto-renal (BOR) syndrome
Preauricular pits	Structural renal disease
Skeleton	
Hemihypertrophy	Wilms tumor
Spina bifida	Neurogenic bladder
Arthrogryposis	Potter syndrome/sequence
Dysplastic nails	Nail patella syndrome
Vertebral anomalies	VATER/VACTERL syndrome
Polydactyly	Meckel-Gruber; renal ciliopathies
Limb anomalies	VACTERL syndrome

TABLE 25.2 PERINATAL INDICATORS SUGGESTIVE OF ABNORMALITIES OF THE GENITOURINARY TRACT—CONT'D

FINDING	SUSPECTED ABNORMALITY
Cardiac	
Congenital heart disease	Increased risk for renal abnormalities in association with multiple syndromes
Abdomen	
Absence of abdominal musculature	Prune-belly syndrome
Single umbilical artery	Increased congenital anomalies of the urinary tract
Umbilical discharge	Patent urachus
Abdominal mass	See Table 25.6
Hepatomegaly	Storage diseases, Beckwith-Wiedemann, Zellweger syndrome
Pulmonary	
Spontaneous pneumothorax	Oligohydramnios, Potter sequence
Pulmonary hypoplasia	Oligohydramnios, Potter sequence
Genitourinary—Male	
Undescended testes	Prune-belly syndrome, Noonan syndrome, Lawrence-Moon-Biedl syndrome, Denys-Drash syndrome
Congenital absence of vas deferens	Renal agenesis or ectopia
Hypospadias	Increase in renal anomalies
Abnormal urinary stream	Bladder dysfunction or urethral outlet obstruction
Genitourinary—Female	
Enlarged clitoris	Adrenogenital syndrome
Cystic mass in urethral region	Ectopic ureterocele, paraurethral cyst
Abnormal urinary stream or dribbling	Bladder dysfunction, urethral obstruction, urethral vaginal fistula
Common cloaca	Urinary tract abnormalities, obstructive uropathy
Urinalysis	
	See text
Rectal	
Abnormal anal sphincter tone	Neurogenic bladder dysfunction
Dilated prostatic urethra	Posterior urethral valves, prune-belly syndrome
Masses	Tumor, polycystic kidney disease, hydronephrosis, multicystic kidney disease
Anal atresia	VATER/VACTERL syndrome

AFP, Alpha-fetoprotein; *VATER/VACTERL,* vertebral defects, imperforate anus, cardiac disease, tracheoesophageal fistula, and limb anomalies; *WAGR,* Wilms tumor, aniridia, genitourinary anomalies, retardation.

Modified from Retik AB. Genitourinary problems in children. *Hosp Pract.* 1976;11(10):133.

caused by chromosomal anomalies. Renal disorders seen with chromosomal disturbance can include fused kidneys, duplication defects, renal agenesis or hypoplasia, hydronephrosis and hydroureter, renal dysplasia or cystic disease, hypospadias, micropenis, and cryptorchidism. The overall pattern of malformation with individual chromosomal disorders is usually sufficient for diagnosis; however, variation can be seen from one individual to another, even for patients with aneuploidy. Although **certain renal anomalies are characteristic of certain chromosomal disorders, no one renal malformation is unique to any particular chromosomal disorder.** A detailed description of chromosomal disorders associated with renal anomalies can be found elsewhere.[97]

Laboratory Data

SERUM CREATININE CONCENTRATION

Serum creatinine concentration is generally used to monitor renal function in the newborn. Cystatin C has been proposed as an alternative marker of renal function, but values can vary widely in the neonate.[1,8] **Serum creatinine is elevated at birth, reflecting maternal renal function, but rapidly declines to a stable level of around 0.4 mg/dL by 1 to 2 weeks of age in the term infant.** In the otherwise normal, very premature infant, there is a transient increase in serum creatinine (due to tubular reabsorption of creatinine in the setting of total body fluid loss and intravascular volume contraction) with a peak around day 4 of life, followed by a progressive decrease to normal neonatal values within 3 to 8 weeks of birth. **In general, the more premature the infant, the higher the serum creatinine and the longer it takes to normalize.**

Under ideal steady-state conditions (which are not always met by the ill neonate), **serum creatinine concentrations should provide an accurate indirect indication of GFR (see Table 25.1),** thus eliminating the need for timed urine collection or nuclear GFR scans. Creatinine is produced at a relatively constant rate. In a steady state, creatinine excretion in urine is equal to creatinine production and likewise constant. **As a general guideline, rising or stable serial serum creatinine concentrations, or an isolated value exceeding 0.5 mg/dL in a term infant, after 1 week of age indicate renal dysfunction.**

URINALYSIS

Specific Gravity. Urine specific gravity is a measure of the concentration of solutes in the urine, specifically the ratio of urine density compared with water density. Specific gravity in term infants ranges from <1.005 to 1.020. Specific gravity has been shown to have a good correlation with urine osmolality in neonates, although the relationship of these variables is somewhat different than in adults, likely due to decreased neonatal renal tubular reabsorption of low-molecular-weight proteins and other small molecules.[111] **It is, however, useful as an indicator of the ability of the kidney to concentrate and dilute.** It can be altered by the presence of glucose, protein, and urinary contrast agents. In such cases, osmolality must be measured directly.

Glucosuria. Trace quantities of glucose may be found occasionally in the urine of term infants and more frequently in premature infants. Even minor elevations of plasma glucose concentrations may cause glucosuria. Large glucose loads may cause osmotic diuresis.

Urinary pH. Urinary pH is typically around 6, although most neonates can achieve a urine pH of 5. Urine pH is frequently 7 or greater with distal tubular acidification defects.

Hematuria. A positive dipstick test for blood can be seen with hematuria, hemoglobinuria from hemolysis, or myoglobinuria from muscle breakdown, usually from perinatal asphyxia. Thus, a microscopic urinalysis is necessary to confirm the **presence of true hematuria, which is defined as >5 red blood cells (RBCs)/high-power field (hpf). Hematuria may occur if the kidneys are traumatized during delivery,** especially with an enlarged kidney (e.g., polycystic kidney disease or large hydronephrotic kidney). **Hematuria is also common in perinatal asphyxia.** Other conditions associated with hematuria include renal vein or artery thrombosis, urinary tract infection, trauma from catheterization, renal artery emboli (especially from umbilical artery catheters), renal cortical necrosis, hypercalciuria, and rarely coagulopathies. Factitious hematuria may occur as a result of blood from circumcision, perineal

irritation, uterine bleeding caused by withdrawal from maternal hormones, and uric acid crystals. **If hematuria is persistent, it should be evaluated with microscopic examination, consideration of urine culture, evaluation of urine protein and calcium excretion, assessment of GFR, and an anatomic evaluation of the kidneys.**

Pyuria. **Pyuria is common in newborns, especially females. Pyuria may indicate infection, and a urine culture should be obtained if clinically indicated.** However, pyuria also may indicate noninfectious renal injury. Interstitial nephritis is distinctly uncommon in the neonatal period.

Proteinuria. **A positive dipstick test for protein indicates the amino groups of proteins.** Although convenient, dipstick testing is subject to limitations. Because albumin and low-molecular-weight proteins give positive results, **dipstick testing cannot fully distinguish between glomerular and tubular proteinuria.** An alkaline urine (pH of ~8) may give a false-positive result, as can prolonged immersion of the strip and the presence of detergents in the urine. **The dipstick provides a qualitative assessment of proteinuria, which must be further confirmed by quantification of protein.** Because 24-hour urine collection is cumbersome in neonates, a random urine protein creatinine ratio (normal <0.5 mg/mg) may be helpful clinically.

IMAGING STUDIES

Fetal ultrasound can provide (1) estimation of amniotic fluid volume; (2) information on the appearance, size, and echogenicity of the kidneys; and (3) evidence of collecting system dilation. **Prenatal ultrasonography can define anatomy but does not accurately predict function.** Mild dilation does not necessarily denote obstruction, whereas more severe dilation and reduced amniotic fluid volume are more likely to signify obstruction and compromised renal function. The more severe the dilation (>7 mm after 32 weeks of gestation), the more likely the infant has urinary tract pathology. **The later in pregnancy that dilation is found, the more likely hydronephrosis will be confirmed postnatally. Although fetal ultrasound is helpful to detect renal anomalies, a confirmatory postnatal ultrasound is imperative.**

Nuclear renal scans (Tc99m-MAG3 [mercaptoacetyltriglycine] or Tc99m-DTPA [diethylene triamine pentaacetic acid]) are most useful to examine differential renal flow and function but are of limited value when GFR is low, due to limited filtration of tracer. **A *voiding cystourethrogram* (VCUG) can exclude vesicoureteral reflux and detect posterior urethral valves, bladder diverticula, and urinary tract fistulae. *Computed tomography (CT)* or *magnetic resonance imaging (MRI)* may be indicated in select cases when further anatomic definition is needed,** but this is rare in the neonate outside of tumor evaluation.

ACUTE KIDNEY INJURY

Introduction

***Acute kidney injury* (AKI) is a common and significant problem in the neonate.** A recent multicenter observational study demonstrated that AKI occurred in 30% of neonatal intensive care unit (NICU) admissions and was an independent risk factor for mortality among NICU patients.[95] **AKI is characterized by an abrupt decline in renal function, which manifests as a decrease in GFR, increase in serum creatinine, accumulation of nitrogenous waste products, and deranged fluid and electrolyte homeostasis. Timely detection of and intervention in AKI is important; evidence increasingly supports a relationship between AKI in the neonatal period and renal impairment in later childhood and adulthood.**[45]

Etiology and Pathophysiology

There are many causes of AKI in the newborn (Box 25.1). It is helpful to classify these etiologies as prerenal, intrinsic renal, and postrenal (obstructive).

Prerenal injury accounts for most AKI in the newborn. In prerenal AKI, renal function is diminished due to decreased renal perfusion, and the kidney is intrinsically normal. **Renal hypoperfusion can result from a true decrease in intravascular volume (e.g., hemorrhage, dehydration) or from decreased effective circulating volume (e.g., congestive heart failure, cardiac tamponade, third space losses).** Timely correction of the underlying disturbance and restoration of normal

BOX 25.1 ETIOLOGY OF ACUTE KIDNEY INJURY IN NEWBORNS

Prerenal Failure

Decreased Intravascular Volume

- Dehydration/intravascular volume depletion
- Gastrointestinal losses
- Hemorrhage
- Salt-wasting renal or adrenal disease
- Diabetes insipidus

Decreased Effective Circulating Volume

- Congestive heart failure
- Pericarditis
- Cardiac tamponade
- Third-space losses (sepsis, traumatized tissue, liver failure, nephrotic syndrome)

Intrinsic Renal Disease/Acute Tubular Necrosis

- Ischemic/hypoxic insult
- Drug induced
  - Aminoglycosides
  - Intravascular contrast
  - Nonsteroidal anti-inflammatory drugs
  - Amphotericin
- Pigment nephropathy
- Rhabdomyolysis/myoglobinuria
- Hemoglobinuria
- Vascular lesions
  - Renal artery thrombosis
  - Renal venous thrombosis
- Infectious causes
  - Pyelonephritis in a solitary kidney

Postrenal (Obstructive) Renal Failure

- Obstruction in a solitary kidney
- Bilateral ureteral obstruction
- Urethral obstruction

Adapted from Andreoli SP. Acute renal failure in the newborn. *Sem Perinatol.* 2004;28(2):112.

perfusion will return renal function to normal. Alternatively, **profound and prolonged hypoperfusion can lead to acute tubular necrosis (ATN) and even cortical necrosis.**[49] However, the evolution of prerenal failure to intrinsic renal failure is not sudden, and a number of compensatory mechanisms work together to maintain renal perfusion when it is otherwise compromised.[10]

Intrinsic renal injury is often considered synonymous with *acute tubular necrosis* and includes both tubular and vascular lesions. Glomerulonephritis and interstitial nephritis are exceedingly uncommon in the neonate. A number of intrinsic renal parenchymal diseases cause renal failure in the newborn period; these are more appropriately considered chronic in nature and are thus considered later in this chapter. **Perinatal asphyxia is associated with intrinsic renal failure in approximately 40% of affected term neonates and can manifest as either oliguric or nonoliguric renal failure.**[162] **The presence of AKI in these infants is associated with longer hospitalization and increased risk of abnormal brain MRI findings.**[157,162] **Sepsis is also a significant risk factor for AKI in term and preterm neonates.** Although distributive shock and hypovolemia do lead to prerenal AKI in the septic newborn, **sepsis also has direct microvascular effects that can lead to intrinsic renal failure, even when blood pressure and renal blood flow are maintained.**[29] Patients with congenital heart disease appear to be especially vulnerable to tubular necrosis after cardiac catheterization and cardiac surgery.[6,30]

Nephrotoxic drugs (including aminoglycoside antibiotics, diuretics, NSAIDs, intravascular contrast media, acyclovir, and amphotericin B) are commonly used in neonates and increase the risk of intrinsic renal injury. The nephrotoxicity induced by **aminoglycosides such as gentamicin typically manifests as nonoliguric renal failure, with a slow rise in serum creatinine and a hypo-osmolar urine developing after several days of treatment.** Progressive injury leads to tubular wasting of potassium, magnesium, calcium, bicarbonate, and glucose.[84]

Premature infants with symptomatic patent ductus arteriosus (PDA) may receive treatment with indomethacin or **ibuprofen**, two NSAIDs that lead to the closure of the ductus arteriosus via cyclooxygenase (COX) inhibition and a decrease in circulating prostaglandin. AKI reliably occurs in approximately 25% of neonates receiving indomethacin/ibuprofen for PDA closure.[4] **Although the vasoconstrictive effect of these medications inherently contributes to prerenal AKI, podocytes (terminally differentiated glomerular cells that do not regenerate) are found in the urine of preterm neonates receiving indomethacin, suggesting a component of tubular injury**

as well.[101] The administration of NSAIDs to preterm infants should be performed with care and frequent monitoring of renal function, even though these changes often are reversible. When a change or decline in GFR is noted (e.g., oliguria or plasma creatinine increase), the administration of NSAIDs should be halted. Patients at higher risk for significant AKI include those with persistent patent ductus arteriosus, preexisting intravascular volume depletion, and simultaneous administration of other nephrotoxic drugs. **Coadministration of furosemide and indomethacin does not improve outcome.[61]** Of note, NSAID use during the fetal period is contraindicated because it may induce renal dysplasia/dysgenesis, leading to oligohydramnios as well as in utero closure of the ductus arteriosus.[11] **Diuretics can contribute to acute tubular necrosis when given in the setting of intravascular volume depletion, and chronic use of loop diuretics can lead to nephrocalcinosis.[161]**

Vascular lesions leading to intrinsic AKI include renal artery and renal vein thrombosis. Risk factors include umbilical arterial catheters, birth asphyxia, maternal diabetes, significant **intravascular volume depletion, and coagulation abnormalities. Symptoms may include flank mass, microscopic or gross hematuria, oliguria, hypertension, and thrombocytopenia.[127]** AKI is most likely to develop when thrombosis is bilateral, or unilateral in a solitary kidney. Pigment nephropathy due to hemoglobinuria or myoglobinuria is rare in the newborn but can occur, particularly in association with hemolysis due to extracorporeal membrane oxygenation.

A variety of obstructive lesions can be associated with *postrenal AKI* in the newborn. Renal insufficiency is observed when there is functional or anatomic obstruction of both kidneys (e.g., bilateral ureteropelvic or ureterovesical junction obstruction, bladder outlet obstruction) or obstruction of a solitary kidney.

Diagnosis

Diagnosing AKI in the neonate is difficult because of the physiologic differences in neonatal renal function that complicate the interpretation of serum creatinine and urine output. Serum creatinine reflects maternal creatinine for the first 48 to 72 hours of life (longer in preterm infants), and thereafter its concentration is dependent on lean body mass, which is low in the neonate. Elevation in serum creatinine may not be noted until over 50% of GFR is lost.[130] Oliguria is likewise an unreliable and insensitive finding. Neonates enter a state of physiologic diuresis in the first 2 to 5 days of life, as fetal lung fluid is mobilized and total body water decreases.

Several definitions for AKI exist in the literature. **The modified neonatal Kidney Disease Improving Global Outcomes (KDIGO) criteria (Table 25.3) provide the current most accepted definition for AKI in neonates.[45]** This definition takes into account both absolute and relative

TABLE 25.3 NEONATAL ACUTE KIDNEY INJURY BASED ON KDIGO CLASSIFICATION

STAGE	SERUM CREATININE	URINE OUTPUT
0	No change in sCr *or* rise <0.3 mg/dL (<26.5 μmol/L)	≥0.5 mL/kg/hr
1	sCr rise ≥0.3 mg/dL (≥26.5 μmol/L) within 48 hr *or* sCr rise ≥1.5-1.9 times the reference SCr[a] within 7 days	<0.5 mL/kg/hr for 6-12 hours
2	sCr rise ≥2-2.9 times the reference sCr[a]	<0.5 mL/kg/hr for ≥12 hours
3	sCr rise ≥3 times the reference SCr[a] *or* sCr ≥2.5 mg/dL (≥221 μmol/L)[b] or receipt of dialysis	<0.3 mL/kg/hr for ≥24 hours or anuria for ≥12 hours

Differences between the proposed neonatal acute kidney injury (AKI) definition and KDIGO include:
[a]Reference sCr is defined as the lowest previous sCr value.
[b]An sCr value of 2.5 mg/dL (221 μmol/L) represents less than 10 mL/min/1.73 m^2.
KDIGO, Kidney Disease: Improving Global Outcomes; sCr, serum creatinine.
From Charlton JR, Guillet R. Neonatal acute kidney injury: diagnosis, exposures, and long-term outcomes. *NeoReviews.* 2018;19(6).

increase in serum creatinine and decrease in urine output. Despite the consensus acceptance of this definition, it has limitations for the reasons outlined previously. **Serum creatinine values that fail to decline at least 50% from birth, creatinine consistently above the 99th percentile, prolonged oliguria, or failure to achieve a diuresis all may be clinically relevant indicators of AKI.**

Urine osmolality (UOsm), urine sodium concentration (UNa), and fractional excretion of sodium (FENa) have been proposed as tools to help differentiate prerenal injury from ATN. This differentiation is based on the premise that the tubules are working appropriately in prerenal injury and therefore can conserve salt and water, whereas in ATN, the injured tubules cannot conserve sodium appropriately. However, and of importance, because the renal tubules in newborns and premature infants are relatively immature, the distinction between prerenal injury and intrinsic renal injury/ATN is not as clear as in older children. **In the newborn, values suggestive of prerenal failure include UOsm greater than 350 mOsm/L, UNa less than 20 to 30 mEq/L, and FENa less than 3%. Values suggestive of ATN are UOsm less than 350 mOsm/L, UNa greater than 30 to 40 mEq/L, and FENa greater than 4%.**[48,99] Note that these values vary according to gestational age and maturity, and there is increased overlap of values with increasing prematurity. Therefore, it is important to recognize the limitations of these indices in the assessment of renal failure in the newborn period.

A renal ultrasound examination should be considered in all neonates with AKI to assess for possible urinary tract obstruction, renal vascular thrombosis, and congenital renal abnormalities causing chronic renal disease.

Prevention

The prevention of AKI in the preterm and term infant is complicated. Nonetheless, the following are some general recommendations:

- **Avoidance and early recognition of perinatal asphyxia**
- **Avoidance of maternal and infant angiotensin-converting enzyme (ACE) inhibitor use**
- **Aggressive management of hypoxemia, hypovolemia, hypotension, acidosis, and hypothermia**
- **Early detection and treatment of infection**
- **Judicious use of agents with vasoactive or nephrotoxic properties that can exacerbate renal injury (e.g., diuretics, aminoglycosides, NSAIDs)**

Principles of Management

Once the diagnosis of AKI has been established, management of metabolic derangements needs to be initiated promptly, including consideration of fluid balance, electrolyte status, acid-base balance, and nutrition, as well as initiation of renal replacement therapy when appropriate.

The timeline for and degree of recovery of renal function in AKI depends on the nature and duration of exposure to the underlying events that precipitated the injury. Return of renal function may be accompanied by a polyuric phase characterized by excessive urine output. During this phase, close attention to fluid and electrolyte balance is important. Adequate fluid support promotes recovery and prevents additional prerenal damage or ATN from intravascular volume depletion.

Maintenance of Intravascular Volume

The mainstay of therapy for prerenal injury is improving perfusion of the kidney by restoring intravascular volume, optimizing cardiac output, and normalizing blood pressure. **In the setting of appropriate cardiac function, fluid challenge of 10 mL/kg of body weight of crystalloid for small preterm infants and up to 20 mL/kg of body weight for term infants should be attempted.** In selected cases, **colloid may be preferred, and inotropic support may be necessary. Accurate measurement of central venous pressure (CVP) may help target euvolemia.**

If restoration of intravascular volume to the euvolemic state does not improve urine output, diuretic therapy may be helpful, but the risks and benefits must be considered. The conversion of oliguric to nonoliguric AKI has not been shown to alter the course of the AKI, nor reduce mortality.[32] However, **increasing urine output can allow for increased fluid intake of vital medications and nutrition and can also facilitate mechanical ventilation in neonates by reducing pulmonary edema.**[89] **Excessive diuresis can induce**

intravascular volume depletion and exacerbate ATN. Loop diuretics are the primary agents used. Most need to be filtered before reaching their therapeutic target in the tubular lumen. Therefore, in the setting of diminished GFR, higher doses of loop diuretics (e.g., furosemide 3 to 5 mg/kg intravenously) may be required to achieve appropriate tubular fluid concentrations. Chronic loop diuretic use in neonates leads to compensatory hypertrophy of distal tubular cells, causing loop diuretic "tolerance" as sodium resorption increases at the distal tubule. This can generally be overcome with a small dose of thiazide diuretic administered 30 to 60 minutes prior to the loop diuretic.[27] Mannitol should be avoided in neonates, especially premature infants, because of its hyperosmolarity and increased risk for intraventricular hemorrhage.

Low-dose dopamine increases urine output in oliguric, normotensive neonates by improving renal perfusion.[50] However, there is no evidence that low-dose (2 to 5 μg/kg/min) dopamine prevents AKI, decreases the need for dialysis, or improves survival in neonates.[71] Fenoldopam, a selective D1-receptor agonist that also increases renal blood flow and urine output in adults, does not increase urine output or improve renal outcomes in neonates.[155,191]

MANAGEMENT OF ELECTROLYTE AND ACID-BASE DISTURBANCES

Mild hyponatremia is common in AKI and is usually the result of fluid overload leading to dilutional hyponatremia. Mild hypervolemic hyponatremia responds well to fluid restriction or free water removal by dialytic therapy. In severe cases (serum sodium <120 mEq/L), there is a greater risk for seizures. Prompt but steady correction to a sodium level of approximately 125 mEq/L with hypertonic saline should be considered.

Hyperkalemia is a common and potentially life-threatening complication of acute kidney injury. The risk for cardiac rhythm disturbances increases with the presence of acidosis and hypocalcemia.

Heel-stick capillary blood sampling is commonly performed in neonates to minimize phlebotomy losses, but hemolysis of the sample is common and can artificially inflate serum potassium measurements. Once an elevated potassium value (>6.0 mEq/L) is confirmed by venipuncture or arterial sampling, potassium-containing intravenous (IV) fluids should be stopped. Severe hyperkalemia requires prompt therapy with sodium bicarbonate, nebulized albuterol, IV glucose and insulin, and IV calcium gluconate.[139] It is important to remember, however, that maneuvers to decrease total body potassium content, such as loop diuretics, are ultimately essential because other available measures simply provide cardiac protection (calcium) or shift potassium intracellularly (albuterol, insulin, bicarbonate) without removing potassium from the body. Cation exchange resins (Kayexalate) are a mainstay of hyperkalemia treatment in older children and adults but have been associated with hypernatremia, necrotizing enterocolitis, and intestinal obstruction in neonates.[156,190] Refractory hyperkalemia is an indication for dialysis.

Hypocalcemia and metabolic acidosis are common in AKI. Severe metabolic acidosis can be treated with IV or oral sodium bicarbonate, oral sodium citrate solutions, and/or dialysis therapy. When treating acidosis, it is important to consider the serum ionized calcium level. Overly rapid correction of acidosis will decrease the ionized calcium concentration and may precipitate tetany and/or seizures. Finally, hyperphosphatemia is a common electrolyte abnormality noted during AKI. Hyperphosphatemia should be treated with dietary phosphorus restriction and with oral phosphorus binders such as calcium carbonate[130] or sevelamer. Pretreatment of certain formulas or breast milk with sevelamer has been shown to reduce dietary phosphorus content.[149,174] The goal serum phosphorus concentration is less than 6.5 to 7 mg/dL. Hyperphosphatemia alone is rarely an indication for dialysis.

In many instances, AKI is associated with marked catabolism, as evidenced by elevated blood urea nitrogen. Malnutrition can develop rapidly, leading to delayed recovery from AKI. Proper nutrition and accurate measurement of daily weight are essential in the management of the newborn with AKI.

Outcome and Prognosis

Recovery from acute kidney injury in the newborn and long-term renal prognosis are

highly dependent on the underlying etiology of the AKI. A single episode of prerenal AKI in the neonatal period, if it is managed appropriately and resolves, is unlikely to be associated with significant long-term renal injury. **However, survivors of a lengthy NICU stay may be exposed to multiple episodes of AKI. AKI from any cause is associated with increased mortality and hospital length of stay in neonates.**[95] **Other factors associated with increased mortality among infants with AKI include multi-organ failure, hypotension, need for vasopressors, hemodynamic instability, and need for mechanical ventilation and dialysis.**[10]

In general, **newborns who require more than 1 month of renal replacement therapy for AKI are considered to have end-stage renal disease (ESRD).** Newborns who recover from AKI but have suffered substantial loss of nephrons, as may occur in cortical necrosis, hypoxic-ischemic injury, and nephrotoxic injury, are at significant risk for late development of progressive chronic kidney disease long after the initial insult.[14,116] Those who required dialysis for renal failure, particularly if a prolonged course, are of particular concern.

Preterm infants are also a particular risk group for chronic kidney disease. Approximately 60% of nephrogenesis occurs in the third trimester, with an exponential increase in both renal mass and number of nephrons. Minimal nephrogenesis occurs after birth. **Preterm neonates have consistently lower nephron number and renal mass at term-corrected age.**[41,46] A smaller starting complement of nephrons, exposed to a barrage of stressors in the NICU as previously described, is hypothesized to place premature infants at even greater risk for nephron damage and chronic renal failure.[41,116]

Low birth weight and prematurity are associated with significantly increased odds of chronic kidney disease (CKD).[113] Therefore, **newborns with AKI and preterm or low-birth-weight infants should have lifelong monitoring of their renal function, blood pressure, growth, and urinalysis. Growth faltering is an early and ominous sign of CKD in infants.**[76] **Typically, the late development of chronic kidney disease will first become apparent with the development of hypertension or proteinuria and eventually an elevated blood urea nitrogen (BUN) and creatinine.** The lack of renal reserve in NICU survivors may not be apparent until puberty or later.[113]

RENAL REPLACEMENT THERAPY

Renal replacement therapy (dialysis) is indicated for fluid overload, metabolic acidosis, hyperkalemia, and hypocalcemia that are refractory to medical management; symptomatic uremia, which is unusual in the neonate; hyperammonemia refractory to medical management; and drug or toxin overdose. **Options for dialysis therapy in neonates include hemodialysis (HD), continuous renal replacement therapy (CRRT), or peritoneal dialysis (PD).** All dialytic therapies rely on the principles of diffusion (movement of solute from higher to lower concentration) and convection/ultrafiltration (bulk movement of solute in association with fluid removal). The optimal modality for any given neonate will be determined by the goals of therapy, hemodynamic stability, comorbid conditions, anticoagulation risk, and institutional preferences, as outlined next.

Hemodialysis. In hemodialysis, blood is removed from the neonate via a central hemodialysis catheter and flows across an appropriately sized artificial filter (dialyzer) while dialysate of the preferred composition travels countercurrent (in the opposite direction to blood) across the filter. In this manner, **solutes diffuse from higher to lower concentration, such that urea, creatinine, potassium, ammonia, dialyzable drugs, and toxins, amongst other substances, are removed from the patient while bicarbonate diffuses into the patient's blood.** The countercurrent flow of dialysate optimizes the diffusion gradient for solute removal. A transmembrane pressure is applied to the filter to induce fluid removal at the targeted rate. The fluid that is removed contains solutes. The blood is then returned to the neonate. **A typical hemodialysis session lasts 2 to 4 hours** but may be more prolonged if needed (e.g., for toxin or ammonia removal). An anticoagulant, most commonly heparin, is administered to prevent circuit clotting, particularly given the low rates of blood flow used for neonates, with care taken to avoid excessive anticoagulation. **The advantage of hemodialysis is that solute and fluid abnormalities can be rapidly corrected. Disadvantages include the need for vascular access** (usually a 7-Fr double-lumen venous hemodialysis catheter); **continuous skilled nursing support during the procedure; systemic anticoagulation,** which

increases the risk of bleeding complications, including intraventricular hemorrhage in premature infants; **and limited equipment targeted to the body size of neonates**. With respect to the latter, most neonates will also require a blood prime of the circuit because of the relatively large extracorporeal circuit volume.

Continuous Renal Replacement Therapy (CRRT). **CRRT has become increasingly popular in the treatment of AKI** (Fig. 25.3). The therapy consists of several variations of diffusion and convection, all of which result in net solute clearance and fluid removal from the blood. The procedure itself is similar to hemodialysis, but the therapy is provided on a continuous basis (e.g., 24 hours/day) and often for several days at a time. **Thus, CRRT allows for an overall slower rate of solute and fluid removal, which may be better tolerated in hemodynamically unstable patients**. Ongoing dialytic support may also be valuable in toxin/drug overdose in which prolonged clearance is needed or the toxin/drug is associated with a rebound of plasma levels, as the support can be aggressive initially and then decreased but maintained over time. **Disadvantages of CRRT include the need for continuous vascular access and anticoagulation and limited equipment targeted to the body size of neonates.** Anticoagulation can be systemic (e.g., heparin) or regional (e.g., citrate, which anticoagulates the blood as it leaves the patient and enters the circuit, with calcium provided as blood reenters the patient to reverse the anticoagulation). In recent years, improvements in the technologies of CRRT have made it more suitable for use in neonates, and **most centers in North America can provide CRRT routinely for acute neonatal dialysis.** However, filter sets (dialyzer and tubing) specific to the size of the neonate are not yet available for most CRRT systems in the United States, leading to the current need for a blood

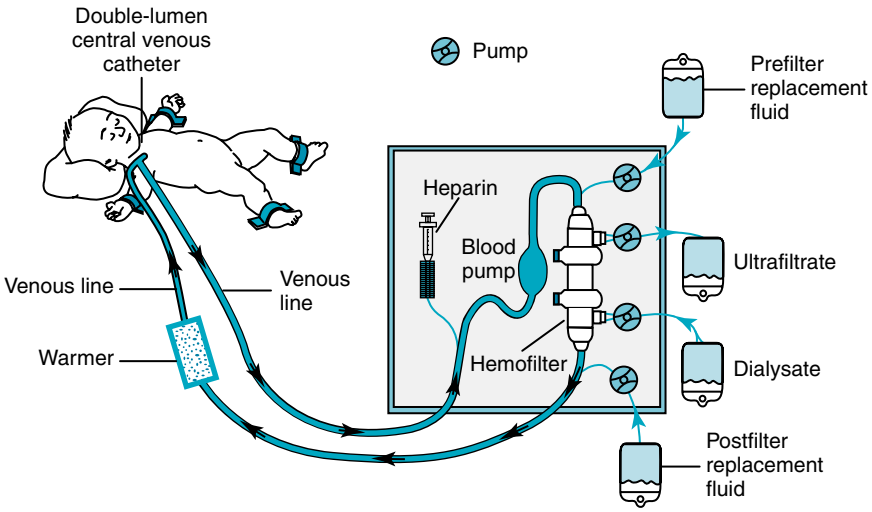

FIGURE 25.3 Continuous renal replacement therapy (CRRT) in the newborn. A typical setup is shown in the figure. Blood is pumped from the patient through a central line across a hemofilter (artificial kidney) at a rate of 5 to 10 mL/kg/min (minimum 30 mL/min). A constant anticoagulant infusion (shown here as heparin) is maintained to prevent circuit clotting. Dialysate can be administered countercurrent (in the direction opposite to blood flow) across the hemofilter (continuous venovenous hemodialysis [CVVHD]), replacement fluid can be administered pre- or post-hemofilter (continuous venovenous hemofiltration [CVVH]), or both dialysate and replacement fluid can be used (continuous venovenous hemodiafiltration [CVVHDF]). The amount of ultrafiltrate (fluid removed) is regulated according to individualized need and tolerance. The discarded ultrafiltrate contains fluid and solutes/toxins; thus, these are removed from the patient's circulation. Before the blood is returned to the patient, it is passed through a blood warmer to prevent hypothermia. With most commercially available CRRT systems, the total volume of the circuit exceeds 10% of the neonate's blood volume, so a blood prime of the circuit is required. Individual therapy goals and institutional preference affect the choice of vascular access, modality (CVVHD vs. CVVH vs. CVVHDF), anticoagulant, and flow rates.

prime of each new circuit. Some centers have experience performing CRRT via an Aquadex machine, which allows for smaller blood volumes; however, this is not yet the standard of care.[13]

Peritoneal Dialysis. Acute *peritoneal dialysis* (PD) **is a major modality of dialysis therapy for acute and chronic kidney failure in the neonate, particularly when vascular access is difficult to maintain.** PD works by the processes of diffusion and ultrafiltration using the peritoneal membrane as a filter. For this therapy, **an acute or chronic peritoneal dialysis catheter is placed into the peritoneum.** The best results are usually obtained with a well-secured "permanent" peritoneal dialysis catheter that is surgically placed by an experienced pediatric surgeon. The preferred catheter is a curled silastic Tenckhoff catheter with one or two cuffs that adhere locally to immobilize the interior portion of the catheter. **Dialysis fluid (dialysate) is infused into the peritoneal space, either via a machine or manually, and allowed to "dwell" for a designated time. During the dwell phase, particles move from high concentration to low concentration (diffusion).** The composition of the dialysate, which contains electrolytes and dextrose, is altered via this exchange of solutes between the dialysate and the peritoneal capillaries that perfuse the peritoneal lining. For example, high concentrations of urea and creatinine are filtered from the blood into the dialysate, which contains no urea or creatinine. Alternatively, the high concentration of bicarbonate diffuses from the dialysate into the blood, thus helping to counter metabolic acidosis. The concentration of dextrose in the dialysate, which is markedly higher than the serum glucose concentration, creates an osmotic gradient that stimulates the movement of fluid from the blood into the dialysate (ultrafiltration). The dialysate is then drained and discarded, and the cycle repeats. **Advantages of PD include that it is relatively easy to perform, does not require anticoagulation, and is well tolerated in hemodynamically unstable neonates.** However, a peritoneal dialysis catheter cannot be placed in children with major intraabdominal disease (postsurgical, gastroschisis, necrotizing enterocolitis, etc.). Because of the nature of the procedure, the correction of solute and fluid abnormalities occurs at a slower rate than by HD or CRRT, and fluid removal cannot be precisely controlled due to variation in individual peritoneal membrane transport characteristics. **The initial fill volume is generally 10 to 20 mL/kg progressing to 40 mL/kg for chronic dialysis; occasionally, even this small initial volume is poorly tolerated in the setting of severe respiratory failure. There is also the potential for peritonitis.**

INTRINSIC RENAL PARENCHYMAL ABNORMALITIES

Several congenital renal abnormalities can be classified by the amount of tissue, differentiation of tissue, and position of the kidneys.

Renal Agenesis

***Congenital absence or agenesis* of renal tissue can occur unilaterally or bilaterally.** Unilateral renal agenesis is seen more frequently (~1:3000 live births)[141] and may manifest as a solitary kidney with eventual enlargement caused by compensatory hypertrophy. The condition appears to be more common in males and infants of African American or diabetic mothers.[141] **Unilateral agenesis has also been associated with Turner, Poland, and VATER syndromes.** In unilateral agenesis, patients are often asymptomatic and are diagnosed inadvertently on imaging or based on the significant association with malformations of the lower genitourinary tract. **In newborns with a known solitary kidney, a VCUG should be considered to exclude vesicoureteral reflux.**[185] Renal dysplasia may rarely occur in the remaining kidney; thus, compensatory hypertrophy of the remaining kidney is an encouraging sign. Restriction from participation in contact sports based on the solitary kidney does not appear to be warranted.[77,78]

Bilateral renal agenesis, also known as *Potter disease,*[144] is seen rarely, with an incidence of 1 per 4000 births. **In bilateral renal agenesis, the majority of affected infants are male and small for gestational age with a history of maternal oligo-/anhydramnios.** The characteristic facial features accompanying Potter syndrome include wide-set eyes; infraorbital creases; a flattened nose; a receding chin; and large, low-set ears with little cartilage.

Other associated malformations can include pulmonary hypoplasia, hydrocephalus, meningocele, multiple skeletal anomalies, and imperforate anus. In the absence of fetal intervention, the fetus is typically stillborn or dies within hours of birth due to pulmonary hypoplasia. Although not the standard of care, some centers have attempted to improve pulmonary outcomes by providing serial amnioinfusion during pregnancy. Renal outcomes remain unchanged by this therapy.

Renal Hypoplasia

***Renal hypoplasia* is a deficiency in the amount of renal tissue and is expressed as an abnormally small kidney.** Histologically, the kidney structure is otherwise normal. However, the decreased nephron mass is often insufficient to maintain normal GFR throughout the child's life. The condition is apparent by ultrasound with variably echogenic kidneys, which are small for body size and do not grow at the expected rate with serial ultrasound.

Renal Dysplasia

Abnormalities in renal tissue differentiation are most commonly expressed as dysplastic kidneys. Renal dysplasia is a failure of the metanephric tissue to mature appropriately. Monogenic causes include mutations in individual genes, such as HNF1β, PAX2, and uroplakins, but there are also recent reports of children with compound heterozygote mutations in several renal/urinary tract developmental genes.[154,186] The result is a persistence of immature structures and a decrease in normal functioning renal tissue. Renal dysplasia may be seen in one or both kidneys and can involve the entire kidney, segments of the kidney, or microscopic foci of a kidney. Dysplasia is often expressed as cyst formation. **The extent of dysplasia will determine the risk of CKD and need for eventual renal replacement therapy.**

MULTICYSTIC DYSPLASTIC KIDNEY

Multicystic dysplastic kidneys (MCDKs) are nonfunctional, and therefore bilateral disease is associated with anhydramnios late in pregnancy. **Unilateral MCDK is both the most common cystic lesion of the neonatal kidney and one of the most frequently palpated abdominal masses in the newborn.** MCDK is usually sporadic, but some familial and syndromic cases have been reported. MCDK is slightly more common in males and on the left side.[9,160] Usually the ureter is absent, atretic, or stenotic. No orifice is found in the bladder. Such kidneys are enlarged and diffusely cystic. with histopathology showing nests of cartilage and mesenchymal mantles surrounding primitive tubules. A nuclear renal scan shows no flow or function of the MCDK. **Renal function and structure may be normal in the remaining kidney of infants with unilateral MCDK; however, approximately one third of patients can be shown to have abnormalities of the contralateral kidney, most commonly vesicoureteral reflux, ureteropelvic junction (UPJ) obstruction, or dysplasia.**[160] Therefore, a VCUG should be performed on every patient, with consideration of a nuclear renal scan to exclude obstruction in the setting of hydronephrosis with a normal VCUG. There is an increased risk of chronic hypertension, proteinuria, and CKD in patients with contralateral abnormalities.[121] Multicystic dysplastic kidneys generally involute with time, so a conservative approach is recommended.[57] The risk of malignancy in the MCDK has been shown to be negligible.[57] Rarely, the MCDK impacts nutrition because of its large size in the small preterm infant.

POLYCYSTIC KIDNEY DISEASE

***Polycystic kidney disease* (PKD) may present as one of two types in the infant: (1) autosomal-recessive polycystic kidney disease (ARPKD) or (2) autosomal-dominant polycystic kidney disease (ADPKD).**

Autosomal-Recessive Polycystic Kidney Disease. ARPKD manifests with varied severity, but it is always bilateral. The kidneys are enlarged, with a proliferation of renal tubules and dilated collecting tubules. These are not true "cysts" but ectatic dilations of the collecting tubules, and the kidney has a reniform shape. **Various combinations of cystic renal disease and hepatic disease occur in ARPKD,** with liver disease including congenital hepatic fibrosis due to ductal plate malformation with eventual hepatosplenomegaly and complications of portal hypertension, or nonobstructive dilation of intrahepatic bile ducts *(Caroli disease)* with a high risk of recurrent cholangitis. **Prenatal ultrasound frequently shows bilaterally enlarged echogenic**

kidneys, often associated with oligohydramnios. Significant hypertension, nephromegaly, pulmonary hypoplasia, hyponatremia, and renal insufficiency may be evident in the affected neonate.[79] However, a subset of patients manifest primarily with liver disease and may not be diagnosed until adulthood.[81] Nonetheless, ARPKD will eventually progress to ESRD at a rate of 14% by 5 years of age, 29% by 10 years of age, and 58% by 20 years of age.[52] The condition is transmitted in an autosomal-recessive manner, so there may be a history in siblings of ARPKD or a family history of miscarriage or early infant death. **Evaluation includes assessment of renal function and blood pressure.** The postnatal abdominal ultrasound typically shows enlarged bilateral kidneys with decreased corticomedullary differentiation. Liver abnormalities may be evident in the neonatal period but more commonly become apparent over time. Current treatment consists of supportive management, including control of hypertension and complications of chronic kidney disease. ACE inhibitors are frequently the preferred antihypertensive agent, although there is no evidence to support the superiority of this class of medications, and their use should be limited when GFR is less than 30 mL/min/1.73 m^2 and in preterm infants before completion of nephrogenesis. Renal replacement therapy, including kidney transplantation with or without liver transplantation, is typically required in later life. **The vast majority of children presenting with significant clinical manifestations in the neonatal period will reach ESRD in early to mid-childhood.**

Autosomal-Dominant Polycystic Kidney Disease. ADPKD involves cyst formation in any portion of the nephron and Bowman space. The condition is associated with the progressive development of renal macrocysts leading to compression of normal renal parenchyma and progression to ESRD at an average age of 60 years. Cysts also develop in other visceral organs, including the liver, pancreas, and spleen, with increasing age. There is an association between ADPKD and cerebral artery aneurysms, but the latter do not generally cause difficulty until adulthood.[25,26] ADPKD may be evident on prenatal ultrasound with enlarged echogenic and/or cystic kidneys, only rarely accompanied by oligohydramnios. In contrast to ARPKD, increased corticomedullary differentiation has been observed. However, it can be difficult to distinguish ADPKD from ARPKD by prenatal or early infancy ultrasound. The family history and sonographic evaluation of both parents can be helpful in this regard, although the **spontaneous mutation rate for ADPKD approaches 15%.** Many children who are diagnosed by prenatal ultrasound demonstrate improvement in sonographic findings over the first 1 to 2 years of life and likely would not have otherwise been diagnosed on clinical grounds for several years. However, a small subset of children with "very early onset" of ADPKD present within 18 months of birth with hypertension, gross hematuria, abnormal renal function, or other symptoms.[64,165] This group appears to show early progression of renal insufficiency. Management includes routine monitoring of blood pressure, with consideration of ACE inhibitor treatment when blood pressure exceeds the 75th percentile for age, sex, and height. ACE inhibitors in this setting may help to prevent the decline in renal function and the increase in left ventricular mass index associated with ADPKD. Recently pravastatin has been shown to slow progression of structural kidney disease in affected children and young adults ages 8 to 22 years;[37] however, this has not been studied in younger children.

RENAL VEIN THROMBOSIS

Renal vein thrombosis (RVT) can be an acute, life-threatening condition or insidious in onset.[33,58,110] **RVT is associated with conditions that cause intravascular volume depletion and decreased oxygenation within the kidney.** Perinatal associations with neonatal RVT include maternal diabetes, toxemia, maternal thiazide therapy, polycythemia, placental insufficiency, birth asphyxia, prematurity, respiratory distress syndrome (RDS), and sepsis. Angiography has also been associated with RVT. **Thrombosis most often occurs in the smaller renal veins rather than in the main renal vein. The involved kidney may enlarge secondary to obstruction to blood flow and form a palpable flank mass.** Other clinical signs and symptoms may include gross or microscopic hematuria, decreased urine output, anemia, and thrombocytopenia (<75,000). Family history

of thrombophilia should be reviewed, and evaluation pursued in appropriate settings. **Management includes treatment of the underlying illness, maintenance of appropriate intravascular volume, and consideration of anticoagulation. Administration of anticoagulants remains controversial for RVT.** Research on the effects of heparin-based anticoagulation and thrombolytic therapy on the long-term renal function of affected patients has yielded conflicting results.[33] Surgical excision of the thrombus is not usually necessary. Renal tubular dysfunction is often observed after recovery from RVT. Long-term follow-up may be needed to assess renal growth and function.

HYDRONEPHROSIS

Etiology and Associated Findings

The collecting system of the kidney is composed of the ureter, pelvis, and calyces, all of which function as a system for removing urine from the kidney. **Hydronephrosis, one of the most common causes of abdominal mass in the newborn, involves dilation of the pelvis and calyces, most often as a result of congenital obstruction.**[23,124] The impaired drainage of urine from severe or chronic obstruction during renal development may induce dysplastic and cystic changes that further impair kidney development and function.

The most common ureteral site of obstruction is at the ureteropelvic junction (UPJ). The ultrasound demonstrates ballooning of the renal pelvis with a normal appearance of the ureter and bladder. Obstruction at the ureterovesical junction (UVJ), also known as *primary megaureter,* occurs more often in the male infant. UVJ obstruction more frequently affects the left ureter. The ultrasound demonstrates hydroureteronephrosis with a normal-appearing bladder. **Affected patients with UPJ or UVJ obstruction are usually asymptomatic unless the obstruction is bilateral.** Rarely, recurrent vomiting, particularly after fluid intake, or abdominal discomfort may be evident. **A nuclear renal scan is helpful to diagnosis both UPJ and UVJ obstruction.** Definitive surgical repair can be undertaken in both conditions. In the case of UVJ obstruction, the stenotic segment can be removed and the ureter reimplanted into the bladder.

Posterior urethral valves (PUVs) are the major cause of urethral obstruction in males.[131] **Affected males show renal insufficiency and diminished urine output due to bladder outlet obstruction.** Complications include poor growth and urinary tract infection. In some cases, the enlarged bladder or hydronephrotic kidney(s) can be palpated. The ultrasound typically shows an enlarged thick-walled bladder with varying degrees of hydroureteronephrosis and renal dysplasia. **A VCUG is the definitive diagnostic study**, highlighting the trabeculated bladder and a dilated posterior urethra. In some cases, the valve leaflets are evident as lucencies; if leaflets are not apparent, prominence of the posterior urethra distally over the bulbar urethra may be noted. The anterior urethra is typically underfilled, and voiding is incomplete. **Associated vesicoureteral reflux is also often evident by VCUG. Bladder decompression is indicated until surgical repair of PUV is undertaken, and any secondary features of chronic kidney disease should be addressed.** Post-obstructive diuresis may occur with decompression, so careful attention to volume status is required. Tubular dysfunction with renal tubular acidosis or pseudohypoaldosteronism is frequent. Definitive surgical repair includes transurethral fulguration of the valves. **In preterm infants who are too small for a transurethral approach, an indwelling urethral catheter or suprapubic tube may be left in place, or a vesicostomy created, awaiting somatic growth.** Many affected males have chronic bladder dysfunction, and recent studies suggest a guarded long-term prognosis for renal function in later life, even in those who appear to do well clinically in childhood.[38,87]

Prune-belly syndrome, also known as *Eagle-Barrett syndrome,* is a less common cause of functional obstruction and dilation of the pelvis and calyces, with an incidence approaching 1:50,000. There is a strong male predominance. This triad of anomalies includes (1) absence or hypoplasia of the abdominal wall muscles, (2) bilateral cryptorchidism, and (3) urinary tract abnormality. **The loose, shriveled abdomen is responsible for the "prune-belly" appearance, which diminishes with age and rarely requires surgical correction. Renal dysplasia is usually seen in prune-belly syndrome and may range from mild to severe involvement.** The enlarged bladder may be seen in conjunction with a patent urachus draining urine. A VCUG demonstrates a hypoplastic prostatic

urethra, no evidence of PUV, and variable degrees of vesicoureteral reflux. Management includes ensuring appropriate drainage of urine, addressing any complications of chronic kidney disease, and eventual orchiopexy.

Vesicoureteral reflux is further discussed in the section on urinary tract infection.

Treatment

Mild to moderate unilateral obstruction does not require immediate treatment, assuming the other kidney is normal. Close follow-up is indicated for monitoring of kidney growth, and significant obstruction should be addressed with surgical intervention when feasible. Fetal intervention can be offered for significant bilateral disease with decreased amniotic fluid, depending on the gestational age of the fetus and severity of hydronephrosis. However, surgical intervention in utero is controversial and center-dependent, and the morbidity of this therapy is high. Although there is selection bias, in many fetal intervention cases, ESRD is reached in early childhood.

HYPERTENSION

Systemic hypertension is an important clinical problem in neonates. Although the reported incidence in all neonates is low, ranging from 0.2% to 3%,[67,168,182] **hypertension is more commonly observed in premature and other newborns cared for in the NICU, particularly those with chronic lung disease and/or a history of umbilical artery catheterization.**[21,68,164] **Hypertension in the neonate is often asymptomatic,** although rarely, marked hypertension is present and can be associated with severe sequelae such as congestive heart failure or intracranial hemorrhage.

Diagnosis

The gold standard for assessment of blood pressure (BP) in neonates is direct measurement by intra-arterial analysis of the pulse pressure waveform.[53] There is a good correlation between umbilical artery and peripheral artery catheter BPs in neonates.[35] Indirect measurement of BP by palpation or auscultation is not recommended for routine assessment in the NICU setting, and sonographic Doppler assessment has largely been replaced by oscillometric measurement.[114,134] It is important to note, however, that the latter procedure is based on detection of pressure oscillations within the artery; therefore, this method determines the mean arterial pressure and then uses an algorithm specific to each manufacturer to establish systolic and diastolic BP values. **There is generally a good correlation between oscillometric and umbilical or radial artery BP in neonates and young children.**[142] However, there are important limitations to this methodology. Few studies have compared specific oscillometric BP monitors to direct arterial measurements in neonates, and these have shown variable accuracy depending on the size of the infant,[51] with increased frequency of oscillometric methods to overread BP compared with direct measurement.[137]

It is also critical to consider the state of the infant at the time of BP assessment. Significant BP variations are observed with the neonate's level of activity, position, and particularly during feeding.[82] **A standardized protocol for conditions of BP assessment in neonates has been proposed,**[136] **including measurement of the right upper arm BP by an oscillometric device with the infant in a prone or supine position, 1.5 hours after feeding or medical intervention, using an appropriate size cuff with width to arm circumference ratio in the range of 0.45 to 0.55.** The BP is to be obtained on three successive readings at 2-minute intervals after a 15-minute period of rest after cuff placement with the infant in an asleep or quiet-awake state. This protocol has yet to be widely adopted.

Normal values for BP have been developed by body weight and postnatal age[60] **(Fig. 25.4). Studies in term and preterm infants show that BP increases with both gestational and postconceptional age as well as birth weight.**[102,103,193] **Systolic and diastolic BP have been shown to increase about 2 mm Hg/day over the first 5 days of life.** The rate of increase then slows to 0.25 mm Hg/day for systolic and 0.15 mm Hg/day for diastolic BP over the next 3 months.[193] **Preterm infants born at 28 to 31 weeks' gestation have been shown to have a more rapid rise in BP over the first 2 to 3 weeks compared with infants born at later gestational age.**[103] BP reaches a steady value for the first year of life by 2 to 3 months of age. Age-specific percentiles for normal

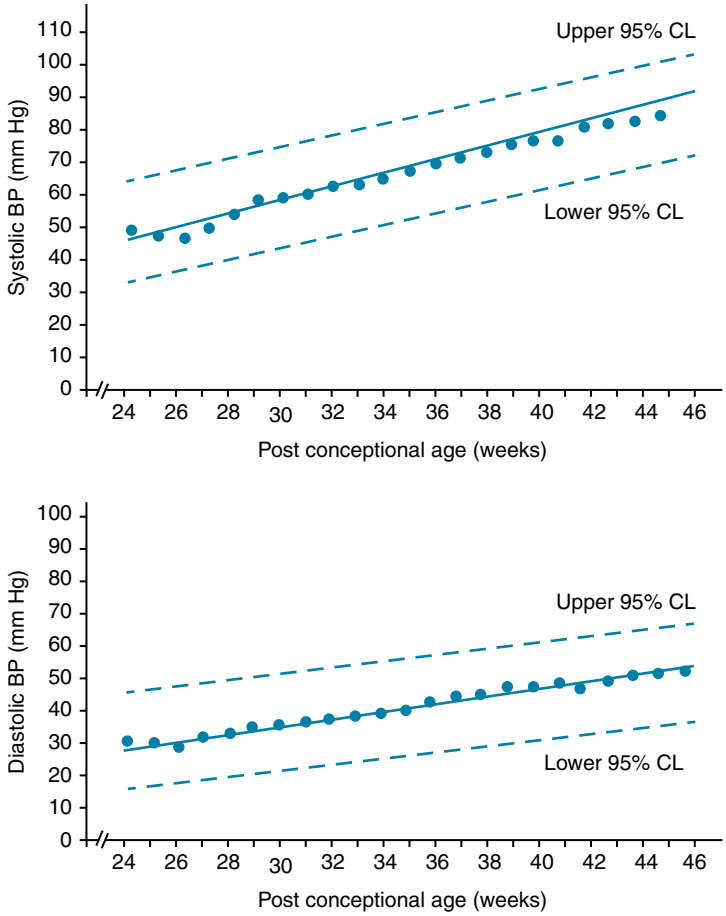

FIGURE 25.4 Linear regression of mean systolic **(upper panel)** and diastolic **(lower panel)** blood pressure (BP) by postconceptional age in weeks, with 95% confidence limits (CL, upper and lower dashed lines). Determinants of blood pressure in infants admitted to neonatal intensive care units: a prospective multicenter study. *J Perinatol.* 1995;15(6):470.)

BP for boys and girls from birth to 12 months have been published.[133] **Normal values for BPs in neonates after 2 weeks of age are shown in** Table 25.4 **and during infancy are shown in** Fig. 25.5.

Etiology

The causes of hypertension are listed in Box 25.2. All infants with hypertension require appropriate evaluation looking for a specific etiology. **The most common etiologies of systemic hypertension in neonates include renovascular and renal parenchymal diseases.** Up to 9% of neonates with umbilical artery catheters (UAC) develop hypertension. UAC-associated thromboembolism affecting the aorta and/or the renal arteries was initially described in the 1970s[135] and can occur even in the absence of demonstrable thrombi. Not surprisingly, **longer duration of UAC placement is associated with a higher risk of thrombus formation.**[32] Although high UAC placement is associated with fewer ischemic events such as necrotizing enterocolitis, the frequency of hypertension does not differ between high and low placement.[16] Thus, it has been proposed that **UAC-related hypertension is related to thrombus formation associated with endothelial disruption at the time of catheter placement.** Renal vein thrombosis is discussed

earlier in this chapter and can be associated with severe and prolonged hypertension. Fibromuscular dysplasia can be seen in infancy and is typically associated with branch vessel disease rather than main renal artery disease.[178] Mechanical compression of one or both renal arteries by tumor, abdominal mass, or a hydronephrotic kidney can induce renovascular hypertension.

Polycystic kidney disease, both autosomal recessive and less commonly autosomal dominant, can be associated with neonatal hypertension. Urinary tract obstruction can also be associated with hypertension in the absence of renal artery compression. **Hypertension is commonly seen in acute tubular or cortical necrosis** due to fluid overload or hyperreninemia. Hypertension may be more prominent in the recovery phase of ATN.

Abman et al. first **described hypertension associated with bronchopulmonary dysplasia (BPD)** in the mid-1980s[3] with **an incidence of hypertension upon discharge of 43% in infants with BPD compared with 4.5% without BPD. Importantly, more than half of the infants with BPD who developed hypertension did not demonstrate elevated BP until after hospital discharge, emphasizing the importance of routine BP assessment in the follow-up of NICU graduates.** The mechanism underlying BPD-associated hypertension is not known, although chronic hypoxemia and hypercarbia are known to induce diminished nitric oxide production and increased endothelial inflammation and vascular dysfunction in older children with obstructive sleep apnea.[134] **BPD-associated hypertension is correlated with a greater need for diuretic and bronchodilator**

BOX 25.2 ETIOLOGY OF HYPERTENSION IN THE NEONATE

Vascular
- Thromboembolism
- Renal artery stenosis
- Coarctation of the aorta
- Hypoplastic abdominal aorta (midaortic coarctation)
- Renal vein thrombosis
- Renal artery compression
- Congenital rubella infection
- Idiopathic arterial calcification

Renal Parenchymal Disease
- Congenital
  - Polycystic kidney disease (autosomal dominant or recessive)
  - Multicystic dysplastic kidney (rare)
  - Renal hypo-/dysplasia (rare)
  - Tuberous sclerosis
  - Urinary tract obstruction
- Acquired
  - Acute tubular necrosis
  - Renal cortical necrosis
  - Hemolytic-uremic syndrome (rare)
  - Urinary tract obstruction
  - Reflux nephropathy

Neoplasia
- Wilms tumor
- Neuroblastoma

Respiratory
- Bronchopulmonary dysplasia

Endocrine
- Adrenogenital syndrome
- Cushing disease
- Hyperaldosteronism
- Thyrotoxicosis
- Pseudohypoaldosteronism type II (Gordon syndrome)

Other
- Closure of abdominal wall defects (compartment syndrome)
- Fluid overload
- Hypercalcemia
- Increased intracranial pressure
- Medications
  - Phenylephrine
  - Corticosteroids
  - Theophylline/caffeine
  - Deoxycorticosterone
  - Vitamin D intoxication (hypercalcemia)
  - ACTH
  - Maternal cocaine or heroin use
- Adrenal hemorrhage
- Extracorporeal membrane oxygenation

From Dionne JM, Abitbol CL, Flynn JT. Hypertension in infancy: diagnosis, management and outcome. *ACTH,* Adrenocorticotropic hormone. *Pediatr Nephrol.* 2012;27(1):17.

use,[2] consistent with the concept that the risk is higher with more severe chronic lung disease. Aortic coarctation can be associated with hypertension both before and after repair, even in the absence of recurrent stenosis. Monogenic hypertension is rare in the neonate. Numerous medications can induce systemic hypertension in the neonate. **Maternal cocaine or heroin use may affect the developing kidney, resulting in an increased risk of hypertension.**[55,93] Tumors are rarely seen in the neonatal period but can cause direct compression of one or both renal arteries, urinary tract obstruction, or production of hormones that elevate blood pressure. Hypertension is commonly seen in neonates requiring extracorporeal membrane oxygenation. The underlying mechanisms are not clear.[31]

Data Collection

HISTORY

A detailed history of prematurity and associated comorbidities, including chronic lung disease or intracranial hemorrhage, is indicated. A history of UAC placement is important. It is important to review the medication history for specific contributors. The family history should be reviewed for early-onset hypertension, although monogenic hypertension is rare and often not evident within the first days of life.

SIGNS AND SYMPTOMS

Most neonates with systemic hypertension are asymptomatic. Congestive heart failure, renal

dysfunction, or hypertensive retinopathy can occasionally be seen with severe hypertension. **Nonspecific symptoms may be evident, including feeding difficulty, lethargy, irritability, failure to thrive, or seizures.** The general appearance of the infant, including any dysmorphic features, should be assessed. A careful abdominal examination may demonstrate a mass suggestive of either a hydronephrotic or polycystic kidney or tumor. Abnormal genitalia suggests congenital adrenal hyperplasia. **Femoral pulses should be assessed and BP measurements taken in all extremities to exclude coarctation of the aorta.**

LABORATORY DATA

Laboratory evaluation should include a review of electrolytes (e.g., hypokalemic metabolic alkalosis in monogenic hypertension/mineralocorticoid excess), renal function, serum calcium, and urinalysis. If proteinuria is present, it can be quantified. Assessment of serum cortisol, thyroid function tests, or serum aldosterone may rarely be appropriate in select cases. Plasma renin activity is not recommended as a routine test in the evaluation of neonatal hypertension but may be helpful in the setting of specific electrolyte abnormalities.[68] Levels are typically elevated in infancy, particularly in premature infants,[12] and peripheral plasma renin does not necessarily correlate with intrarenal pathology. Plasma renin can also be affected by medications such as caffeine and other methylxanthines as well as diuretics and ACE inhibitors.

All neonates with hypertension should have a Doppler renal ultrasound. Such imaging is valuable to evaluate renal anatomy, exclude renal vein or artery thrombosis, and look for aortic and renal artery thrombi. Color-flow Doppler can be used to exclude renal artery stenosis, although sensitivity and specificity are limited in this age group and vary with the experience of the ultrasonographer. **Magnetic resonance angiography (MRA) or CT with contrast add information about the anatomy of larger vessels,** but neither is typically sufficient to diagnose intrarenal branch stenosis. In such cases, classic contrast angiography may be helpful. However, the neonate's size and the potential for intervention should be considered before ordering these examinations. Even when intrarenal pathology is evident, definitive intervention may need to be delayed awaiting somatic growth. **Echocardiogram or VCUG** may be appropriate in select cases.

Treatment

Initial steps in management should include correction of any iatrogenic causes, treatment of hypoxemia in chronic lung disease, and hormone replacement as appropriate in endocrine disorders. **Any underlying disorders should be appropriately treated (e.g., urinary tract obstruction should be relieved). Surgical intervention may be appropriate in selected cases, such as ureteropelvic junction obstruction, tumor, and aortic coarctation.** There is general agreement that **neonatal hypertension should be treated with medications if BP exceeds the 99th percentile.**[53,68,69]

There are few controlled trials of antihypertensive medications in neonates. Therefore, treatment relies on case-series data, older clinical trials, expert opinion, and personal experience. **Drugs and dosages commonly used in the neonate are shown in** Table 25.5. In infants with **acute severe hypertension, especially with systemic symptoms, continuous IV infusion of antihypertensive medication is indicated to provide sustained control without rapid fluctuations in BP, which can contribute to cerebral ischemia or hemorrhage, particularly in premature infants.** Continuous infusions of several antihypertensive medications have been successfully used in neonates, including nicardipine, esmolol, sodium nitroprusside, and labetalol.[53,122,125] **In such situations, continuous monitoring via an indwelling arterial catheter is most appropriate.** Intermittent IV therapy with hydralazine or labetalol may be useful in neonates who cannot take oral antihypertensives. Of note, IV enalapril is not recommended in neonates because of the wide published range for appropriate dosing and risk of prolonged severe hypotension and AKI.[53] Oral antihypertensive medications commonly used in neonates include longer-acting dihydropyridine calcium channel blockers, vasodilators such as hydralazine, or beta blockers. Short-acting nifedipine has fallen out of favor for the management of hypertension because of the potential for rapid change in BP. Beta blockers should be avoided in chronic lung disease. **Diuretics may have a role in the control of BP, particularly in children with underlying chronic lung disease, who may have pulmonary benefit from the control of fluid balance.** The ACE inhibitor captopril is one of the few medications that has been studied in neonatal hypertension. However, caution is indicated

TABLE 25.5 RECOMMENDED DOSES FOR SELECTED ANTIHYPERTENSIVE AGENTS FOR TREATMENT OF HYPERTENSIVE NEONATES

CLASS	DRUG	ROUTE	DOSE	INTERVAL	COMMENTS
ACE inhibitors	Captopril	Oral	0.01-0.05 mg/kg/dose, max 2 mg/kg/day	TID	First dose can cause rapid drop in BP, especially if receiving diuretics
	Enalapril	Oral	0.08-0.6 mg/kg/day	QD-BID	
	Lisinopril	Oral	0.07-0.6 mg/kg/day	QD	
α- and β-Antagonists	Labetalol	Oral	0.5-1 mg/kg/dose; max 10 mg/kg/day	BID-TID	BPD relative contraindication
		IV	0.2-1 mg/kg/dose; 0.25-3 mg/kg/hr	Q4-6 hr; infusion	
	Carvedilol	Oral	0.1-0.5 mg/kg/dose	BID	
β-Antagonists	Esmolol	IV	100-500 mcg/kg/min	Infusion	Ultra short acting; monitor heart rate; avoid in BPD
	Propranolol	Oral	0.5-1 mg/kg/dose; max 8-10 mg/kg/day	TID	Monitor heart rate; avoid in BPD
Calcium channel blockers	Amlodipine	Oral	0.05-0.3 mg/kg/dose; max 0.6 mg/kg/day	QD	All may cause reflex tachycardia
	Isradipine	Oral	0.05-0.15 mg/kg/dose; max 0.8 mg/kg/day	QID	
	Nicardipine	IV	1-4 mcg/kg/min	Infusion	
Central α-agonist	Clonidine	Oral	5-10 mcg/kg/day; max 25 mcg/kg/day	TID	May cause mild sedation
Diuretics	Chlorothiazide	Oral	5-15 mg/kg/dose	BID	All: monitor electrolytes
	Hydrochlorothiazide	Oral	1-3 mg/kg/dose	QD	
	Spironolactone	Oral	0.5-1.5 mg/kg/dose	QD-BID	
Vasodilators	Hydralazine	Oral	0.25-1 mg/kg/dose; max 7.5 mg/kg/day	TID-QID	Tachycardia, fluid retention
		IV	0.15-0.6 mg/kg/dose	Q4h	
	Minoxidil	Oral	0.1-0.2 mg/kg/dose	BID-TID	Tachycardia, fluid retention, hypertrichosis, pericardial effusion
	Nitroprusside	IV	0.5-10 mcg/kg/min	Infusion	Risk for thiocyanate toxicity with prolonged use (>72 hr) or kidney failure

ACE, Angiotensin-converting enzyme; *BID,* twice a day; *BPD,* bronchopulmonary dysplasia; *IV,* intravenous; *kg,* kilogram; *mcg,* microgram; *mg,* milligram; *PO,* per os, orally; *Q,* every; *QD,* once daily; *QID,* four times a day; *TID,* three times a day. For ACE inhibitors, only captopril and lisinopril are approved in infancy by the U.S. Food and Drug Administration.

because it can induce an exaggerated drop in BP in premature infants. Moreover, the renin-angiotensin system is critical for normal nephron development. **ACE inhibitors or angiotensin receptor blockers should not be given until nephrogenesis is complete, with some recommending avoidance through 44 weeks' postconceptional age.**

ABDOMINAL MASSES

Abdominal masses in neonates reflect a wide spectrum of pathologies, ranging from small lesions found incidentally to large ones occupying the entire peritoneal cavity; from unilocular cysts to complex solid cysts; from lesions that can cause

significant morbidity and mortality to entities that may be safely observed.[45,62,74,106] This spectrum is further broadened by the variety of organs that can give rise to such masses.

In the era of almost universal prenatal ultrasound, many such masses are identified, and some are even treated, before delivery. Others are discovered during the course of a thorough routine examination of the neonate. **Although most of these babies are otherwise healthy, such a finding is disturbing to new parents. It is incumbent on the infant's physician to determine the nature of the mass in a timely, safe, and cost-effective manner.**

Just over 50% of abdominal masses present during the newborn period are of renal origin.[43,62,74] The literature offers no consistent data on the frequency of abdominal masses in infants, but there is general agreement about the urgent need to comprehensively evaluate these infants to establish an accurate diagnosis and to plan appropriate intervention.

ETIOLOGY

The differential diagnosis in the infant with an abdominal mass is shown in Table 25.6. **The workup of most abdominal masses requires only a thorough physical examination and specific goal-oriented studies. Usually, the location of the mass is a helpful clue to the possible organ involved and the most likely diagnosis:**

1. **Flank: The most common cause of flank mass is renal in origin,** including hydronephrosis, multicystic dysplastic kidney, polycystic kidney disease, or renal artery or vein thrombosis. Other flank masses of importance include solid tumors of the kidney, such as the *benign congenital mesoblastic nephroma,* and *Wilms tumor.*[107] Wilms tumor occurs at a rate of 8 to 9 per 100,000 per year in the United States, with two thirds of patients presenting in the first 3 to 6 months of life. The tumor is described as firm, smooth, and confluent with the kidney. Both kidneys are involved in 10% of cases. Juxtarenal lesions include neuroblastoma, adrenal hemorrhage, bronchogenic cyst, and infradiaphragmatic (extralobar) pulmonary sequestration.
2. **Right upper quadrant (RUQ): Most RUQ masses arise from the liver and biliary tract.** In fact, the classic presentation of the most frequent benign hepatic tumor, *infantile hepatic hemangioma (hemangioendothelioma),* is a palpable RUQ mass. Other masses in this region include the benign mesenchymal hamartomas, hepatoblastoma (the only significant primary hepatic malignancy in neonates), and choledochal cysts.

TABLE 25.6 NEONATAL ABDOMINAL MASSES

TYPE OF MASS	PERCENTAGE OF TOTAL
Renal Masses	
Hydronephrosis	55
Multicystic dysplastic kidney	
Polycystic kidney disease	
Mesoblastic nephroma	
Renal ectopia	
Renal vein thrombosis	
Nephroblastomatosis	
Wilms tumor	
Genital Masses	
Hydrometrocolpos	15
Ovarian cyst	
Gastrointestinal Masses	
Duplication	15
Volvulus	
Complicated meconium ileus	
Mesenteric-omental cyst	
"Pseudocyst" proximal to atresia	
Nonrenal Retroperitoneal Masses	
Adrenal hemorrhage	10
Neuroblastoma	
Teratoma	
Hepatosplenobiliary Masses	
Hemangioendothelioma	5
Hepatoblastoma	
Hepatic cyst	
Splenic hematoma or cyst	
Choledochal cyst	
Hydrops of gallbladder	

Adapted from Kirks DR, Merten DF, Grossman H, et al. Diagnostic imaging of pediatric abdominal masses: an overview. *Radiol Clin North Am.* 1981;19(3):527.

3. **Left upper quadrant (LUQ):** Splenic cysts or hematomas are rarely observed in infancy.
4. **Midabdominal: Midabdominal masses usually involve the intestine. Duplications of the gastrointestinal (GI) tract can occur anywhere from the esophagus to the anus** and are usually cystic or less commonly tubular. **They are typically present as an asymptomatic palpable mass but may also cause pain, intestinal obstruction, GI bleeding, or even volvulus.** Other midabdominal masses include intestinal lymphatic malformations, meconium pseudocyst, and omphalomesenteric remnants. Failure of the vitelline duct to fully resorb can result in a variety of related entities, including *Meckel diverticulum* and omphalomesenteric sinus, cyst, or fistula.
5. **Pelvic: A residual pelvic mass after voiding in a female infant may represent an enlarged vagina (hydrocolpos) or uterus (hydrometrocolpos).** Such findings indicate a need for further examination of the perineum and vaginal introitus. Other pelvic masses include ovarian masses, urachal cysts, and teratomas. Cystic ovarian tumors are more common than solid ones, and the majority of them are benign; however, cystic ovarian masses require further investigation as malignancies have been reported. Urinary bladder masses, although rare in the neonate, typically present with lower tract symptoms and are initially seen on ultrasonography but require tissue sampling in order to verify the diagnosis. The most commonly found malignancy of the bladder in neonates is rhabdomyosarcoma, whereas the most commonly diagnosed benign bladder lesion is papillary urothelial neoplasm of low malignant potential (PUNLMP).[166]

Physical Examination

The infant should be in the supine position for abdominal examination. **Visual inspection of the abdomen before manual exploration enables the examiner to see a mass that may be missed with a tense abdomen.** The shape of the abdomen should be noted, along with the position of the umbilicus and the presence of any hernias. **Bimanual palpation using the flat surface of the fingers while supporting the infant's flank with the other hand facilitates exploration of the abdomen during deep palpation. Characteristics of the mass, including location, size, shape, texture, mobility, and tenderness, should be documented.** The differentiation between solid and cystic masses can be difficult on physical examination. Percussion may outline the suspected area, and transillumination is sometimes helpful.

If gastric distention or intestinal obstruction is suspected, a nasogastric tube is inserted and air and fluid are evacuated. If there is a question of urinary retention, the infant should be reexamined after placement of a urinary catheter or after inducing voiding with a Credé maneuver. Rectal examination, applied judiciously, may provide useful information, particularly for pelvic masses. Clues to the nature of the lesion may be external or distant to the mass.

Signs and Symptoms

Many abdominal masses are asymptomatic in neonates but can be detected by thorough physical examination. Renal masses may be associated with hypertension, abnormal renal function, or hematuria. If not detected by prenatal ultrasound, autosomal-recessive polycystic kidney disease commonly presents with bilateral nephromegaly perceived to be abdominal masses. Liver masses are occasionally associated with evidence of hepatobiliary obstruction or liver dysfunction. **A large mass may affect the infant's ability to feed successfully, particularly the preterm infant, and may also cause diaphragmatic embarrassment.**

Laboratory Data

Assessment of hepatobiliary and renal function may be helpful. However, radiographic imaging is usually the next step. **Plain films** can provide a surprising amount of information, such as organomegaly, calcifications in a number of tumors, or displacement of the intestines as a subtle clue to the presence and sometimes the nature of a mass. **Ultrasound is perhaps the most important tool in the assessment of abdominal mass in the neonate.** Ultrasound is noninvasive, accessible for bedside studies, radiation-free, and painless and can provide detailed information on the location, nature, and vascularity of the mass and adjacent structures. **Doppler sonography is particularly helpful to assess flow in the setting of renal artery or vein thrombosis.** When ultrasound is not definitive, it

may provide clues that help to determine the next appropriate studies. **Renal scintigraphy can be helpful to differentiate a nonfunctioning multicystic dysplastic kidney from a hydronephrotic or cystic dysplastic kidney** but is not frequently needed for this purpose. **A voiding cystourethrogram is the method of choice to diagnose vesicoureteral reflux,** which can be associated with significant hydroureteronephrosis and/or bladder outlet obstruction. **CT or MRI is occasionally indicated,** especially in the evaluation of the origin and extent of tumors.

Treatment and Prognosis

Treatment and prognosis are dependent on the nature of the underlying lesion. Specific renal lesions have been reviewed previously in this chapter. **Wilms tumor generally has an excellent prognosis with treatment, which often includes surgical removal of the tumor, irradiation, and chemotherapy.**[107] Survivors with reduced renal mass warrant follow-up with a nephrologist to screen for the development of chronic kidney disease. The prognosis in malignant neuroblastoma is related to the site of the primary tumor, histologic appearance of the tumor, staging of the disease, and age of the patient. Significant hydronephrosis may be associated with chronic issues with glomerular or tubular dysfunction.

Renal Tubular Disorders

Although most of the renal tubular disorders are congenital, many do not manifest clinically during the newborn period.[42] However, in sick infants admitted to the intensive care unit, **these tubular abnormalities can lead to severe and life-threatening electrolyte disorders and fluid depletion.**

Etiology

The term *renal tubulopathy* encompasses a wide variety of conditions. Proximal tubular defects can include proximal (type II) renal tubular acidosis (RTA), which can be an isolated phenomenon or can occur in the setting of generalized proximal tubular dysfunction *(Fanconi syndrome).* **Isolated proximal RTA rarely causes major difficulties in the neonatal period, although normal anion gap hyperchloremic metabolic acidosis and failure to thrive may be evident in later infancy;** the condition often spontaneously resolves in early childhood. **In contrast, Fanconi syndrome, which is characterized by proximal renal tubular acidosis (RTA), aminoaciduria, phosphaturia, hyperuricosuria, and glycosuria, can be associated with several underlying genetic and metabolic diseases, including cystinosis, Lowe (oculocerebrorenal) syndrome, tyrosinemia, galactosemia, hereditary fructose intolerance, and a variety of mitochondrial cytopathies.**

Bartter syndrome **is a tubulopathy of the loop of Henle,** which in its classic form is characterized by maternal polyhydramnios, premature birth, perinatal salt wasting, chronic polyuria and polydipsia, hypokalemic metabolic alkalosis, and nephrocalcinosis.[128] The metabolic findings are akin to treatment with a loop diuretic. Specific mutations in the distal tubule contribute to *Liddle syndrome* (hypertension with hyporeninemic hypokalemic metabolic alkalosis), pseudohypoaldosteronism type 1 (recurrent episodes of life-threatening hyperkalemia associated with aldosterone resistance), or pseudohypoaldosteronism type 2 (*Gordon syndrome;* hypertension with hyperkalemic metabolic acidosis).

Distal (type 1) RTA can be attributed to a variety of defects in the distal tubule that impair acidification of the urine, resulting in normal anion gap hyperchloremic acidosis with high urine pH, with clinical features including failure to thrive and nephrocalcinosis.[129] Autosomal-recessive distal RTA can be associated with progressive sensorineural deafness. Obstruction of the urinary tract, which is frequently diagnosed prenatally, is commonly associated with RTA, particularly the hyperkalemic type (type IV) from the impaired effect of aldosterone on the epithelial sodium (ENaC) channels. Similarly, defects of the vasopressin V_2 receptor or aquaporin-2 water channels in the collecting duct result in *nephrogenic diabetes insipidus* (NDI), with clinical features including polyhydramnios, impaired urinary concentrating ability, polyuria and polydipsia, neonatal failure to thrive, and a high risk for recurrent dehydration with hypernatremia/hyperosmolality. V_2 receptor mutations are inherited in an X-linked manner, whereas aquaporin-2 mutations are less common and usually autosomal recessive or dominant in nature.

Given the inherited nature of many tubulopathies, a review of the family history can be helpful, particularly with respect to the health of siblings.

Treatment and Complications

Although many tubular disorders are not clinically evident at birth, the clinician should keep a high index of suspicion in those infants with a prenatal diagnosis of urologic abnormalities or serious abnormalities in water and electrolyte metabolism. **Treatment depends on the underlying condition but often requires replacement of the electrolytes or minerals that are lost in the urine.** Therapies to mitigate tubular losses specific to several tubulopathies do exist but are beyond the scope of this chapter to review in detail. It is important to note, however, that **early evaluation and treatment of renal tubular disorders may prevent catastrophic complications such as life-threatening episodes of dehydration and delayed growth and development.**

URINARY TRACT INFECTION

Urinary tract infections (UTIs) affect approximately 1% of full-term infants and 3% of premature infants. Male infants are affected 5 times more frequently than females.[18,24,88] *Vesicoureteral reflux* (VUR) is a common radiographic finding in infants. Primary reflux is seen in abnormalities of the ureterovesical junction, ureteral duplication, and ureterocele. Secondary VUR is associated with PUV, neurogenic bladder, and other causes of bladder outlet obstruction. In addition to causing significant acute illness, UTIs can also lead to long-term renal sequelae, such as scarring with resultant hypertension, decreased functioning renal mass, glomerular hyperfiltration, and/or chronic kidney disease.

Etiology

Abnormalities of the urinary tract are responsible for a large number of UTIs in the neonate.[182] Whether the infection is more commonly spread in an ascending or hematogenous matter is not clear, but certainly the identification of VUR should prompt evaluation for potential secondary etiologies. Reflux is graded on a four- or five-point scale depending on the rating system utilized, with grade IV to V denoting VUR into the kidney with massive hydroureteronephrosis with tortuosity of the ureter.

Maternal urinary infections also have been associated with neonatal UTI.[104] **Symptomatic manifestations include abnormal weight loss during the first days of life, decreased feeding, dehydration, irritability, lethargy, cyanosis, jaundice, and septicemia.** In some cases, the affected kidneys are palpable. **Infected infants also may be asymptomatic.**

Data Collection

Evaluation of a neonate with suspected UTI includes immediate urine and blood cultures and a complete blood count (CBC). The optimum method of obtaining urine for culture is suprapubic aspiration of the bladder or catheterization. Catheterization may not be recommended in the neonate if there is concern for urethral stricture, which is more commonly observed in males. **Urine obtained in a urine bag should not be used for cultures because it is easily contaminated. With a diagnosis of UTI, radiographic evaluation should be undertaken to rule out anatomic abnormality. Evaluation should include renal and bladder ultrasound and may also include VCUG,** as significant reflux may be present without anatomic abnormality. Current recommendations vary depending on the weight given to the sensitivity of diagnosis, radiation exposure, and cost.[98,109] One study in infants suggests that the timing of VCUG does not affect the presence or severity of observed VUR after UTI;[54] however, given the potential risks, the urine should be sterile before obtaining the VCUG. Some have advocated obtaining the VCUG as soon as sterile urine is documented due to the risk of loss to follow-up. Renal scintigraphy can be useful to document the presence and/or extent of renal scarring; however, this is rarely needed in the newborn period.

Treatment

Pyuria (10 to 15 white blood cells [WBCs] per hpf) can be observed in the neonate normally. Treatment for UTI is indicated when an organism is cultured from the urine following sterile collection. However, a low threshold for antibiotic treatment awaiting culture results may be needed, particularly when other concerning symptoms are present. **Any growth in a urine specimen obtained by suprapubic aspiration**

should be considered to represent an infection if the procedure was cleanly performed. Any aspiration of bowel contents must affect the interpretation of culture results. Traditional antibiotic coverage consists of both ampicillin and an aminoglycoside pending culture results. The advent of third-generation cephalosporins has allowed for excellent gram-negative coverage without the nephrotoxicity of the aminoglycosides. ***Escherichia coli*** is the organism most often implicated in neonatal UTIs, followed by ***Klebsiella***.[12] Sulfonamides are contraindicated in the neonate because of their potential to complicate hyperbilirubinemia.

Antibiotic therapy should continue for 10 to 14 days, with a follow-up urine culture 3 days after therapy is discontinued. Many practitioners recommend antibiotic prophylaxis until significant reflux or anatomic abnormality is ruled out. The value of prophylactic antibiotics for the prevention of reflux nephropathy in the setting of documented VUR remains controversial.[189] The potential benefits need to be weighed against risks, knowing that neonates and young infants with acute UTI may present with more vague or nonspecific symptoms compared with older children.

NEUROGENIC BLADDER

Neurogenic bladder is an anatomic interruption of the micturition reflex normally triggered by a full bladder.[19,72] The bladder may be flaccid and unable to empty urine or spastic, hyperreflexive, and unable to store urine. Infants with lumbosacral spinal malformations commonly have neurogenic bladder. Lower motor neuron deficit causes bladder atony, and upper motor neuron deficit can cause spasticity.

Signs and Symptoms

Often there is a mixed presentation of symptoms. The flaccid bladder requires aggressive intervention in the neonate. Diagnosis begins immediately at the bedside when the newborn has no apparent voiding stream or the urine flow rate falls below expectations without other explanations. Further clarification of the diagnosis can be made by VCUG and cystometric studies. If there is concern for bladder dysfunction, renal function should be assessed because obstruction can lead to obstructive nephropathy.

Treatment

Surgical intervention may be indicated in the neonate with neurogenic bladder with associated obstruction, especially in the setting of severe VUR or recurrent UTI. The urologist creates a vesicostomy to allow the free flow of urine into diapers.[171]

Complications

Early diagnosis and intervention for infants with neurogenic bladder can decrease the risks of future complications. Long-term complications of neurogenic bladder include recurrent UTI and vesicoureteral reflux, obstructive uropathy, and associated electrolyte imbalances. Obstructive nephropathy is a leading cause of chronic kidney disease in children and can result in ESRD with resultant dialysis or transplant dependence.

NEPHROCALCINOSIS AND NEPHROLITHIASIS

Nephrocalcinosis and nephrolithiasis are common in infants, particularly those who are preterm or who have had a prolonged NICU course.[44,105,132] Studies suggest that nephrocalcinosis/lithiasis may affect 30% to 60% of preterm infants, with increasing risk at lower birth weight and earlier gestational age. Loop diuretics such as furosemide, which increase urinary calcium excretion, appear to be major contributors to these findings. Additional risk factors include relative hypercalcemia in late gestation, low urinary citrate excretion, and renal ischemia or use of nephrotoxic drugs, which can enhance intrarenal deposition of calcium phosphate or oxalate crystals in the setting of tubular injury. Specific conditions associated with nephrocalcinosis include William syndrome, which can be associated with chronic hypercalcemia;[112] neonatal primary hyperparathyroidism; distal renal tubular acidosis; primary hyperoxaluria; and neonatal Bartter syndrome. Thiazide diuretics can be used for the treatment of renal calcium deposition due to their hypocalciuric effect. Potassium citrate may also be helpful in the

setting of documented hypocitraturia but has not been shown to prevent the development of nephrocalcinosis when given on a prophylactic basis to preterm infants.[159] Adequate hydration is generally important in the approach to stone disease; however, this goal should not supersede appropriate nutrition. Whether nephrocalcinosis confers long-term risk for poor renal function and growth in this population remains controversial[105,143] because the prematurity-associated decrease in nephron mass is a confounding factor.

END-STAGE RENAL DISEASE

With advances in fetal therapeutic intervention and neonatal care, **the number of infants requiring chronic dialysis is rising. Such therapy is accompanied by unique ethical dilemmas. Many providers continue to view neonatal dialysis as optional rather than obligatory therapy due to the associated high medical, financial, and psychosocial burdens placed on the family and society, as well as uncertainties about long-term outcomes.**[108,152,192] These ethical concerns are certain to increase in complexity with advances in fetal urologic surgery and the ability of serial amnioport infusions to prevent death from pulmonary hypoplasia in oligo-/anhydramnios, even with complete absence of the kidneys.[28] It is therefore **important to educate parents as comprehensively as possible regarding the anticipated course and potential complications for neonates in whom chronic dialysis is indicated.** Management of these complex neonates requires a multidisciplinary team of pediatric specialists, including the neonatologist, nephrologist, urologist, transplant surgeon, dialysis nurse, renal dietitian, and social worker.

Renal Replacement Therapy in Neonatal ESRD

The goal of dialysis is to permit appropriate growth and health maintenance in infants until they are suitable candidates for kidney transplantation. Hemodialysis (HD) or peritoneal dialysis (PD) can be offered on a chronic basis to support infants with ESRD, with PD preferred at most institutions. Although neonates and infants can tolerate HD routinely, functioning vascular access and intradialytic anticoagulation are required. Moreover, because of the large-volume component of nutrition as well as the metabolic rate in infancy, **most infants will require chronic HD 5 to 7 days/week,** in contrast to older children and adults who require HD three times per week. Families who do not reside within convenient distance of a pediatric hemodialysis center must relocate for such therapy. These factors obviously have major psychosocial and financial implications for the family.

PD is often technically easier to accomplish in the small child and can be performed by the family within the home setting; the home caregiver(s) are trained to provide continuous cycling peritoneal dialysis for a 10- to 12-hour treatment on a nightly basis under the supervision of a pediatric nephrology program. Thus, **PD is the most common choice for renal replacement therapy in small children.**[7,183] Contraindications to chronic PD include documented loss of peritoneal function; extensive intraabdominal adhesions that limit dialysate flow, the latter seen most commonly in children who have required major or recurrent intraabdominal surgery; uncorrectable mechanical defects that prevent effective PD or increase the risk of infection (e.g., omphalocele, gastroschisis, diaphragmatic hernia, bladder exstrophy); and absence of a social support system to perform PD within the home. Although technically challenging, more long-term PD has been performed in very-low-birth-weight infants with birth weights as low as 930 g.[59,150] Despite continued improvement in the availability of infant catheters and dialysis tubing, chronic PD remains extremely time-consuming, challenging, and demanding for the infant, the family, and medical personnel.

Dialysis in the small child is routinely considered to be a bridge to kidney transplantation. Kidney transplantation is rarely performed with recipient body weight less than 7 to 8 kg, and many programs prefer a minimum body weight of 10 kg to minimize technical and other complications because the majority of donor kidneys are obtained from adults. En bloc or single kidney transplants from infant donors have historically been associated with increased risk of major complications and are thus currently avoided by most pediatric transplant programs. **The average 2- to 3-year patient survival rate is approximately 80% for children initiating dialysis before 1 month of age, with infection and cardiopulmonary disease being the**

leading causes of death.[40,180] However, worsened survival is observed in children who begin dialysis before 3 months of age (hazard ratio fourfold higher) compared with those between 1 and 2 years of age.[7,172] These cohorts of ESRD children have similar median age at transplant, likely due to the current standards for recipient body weight as described earlier; thus, the time awaiting transplant is more prolonged with decreasing age at dialysis initiation. **The median survival of a kidney allograft in the current era is 10 to 12 years.**[179] Therefore, neonates with ESRD can anticipate multiple kidney transplants with interval periods of dialysis during their lifetime. Because of antigen sensitization, it is unusual in the current era to receive more than three allografts for any individual patient. Although little is known regarding the life expectancy of neonates with ESRD, all-cause mortality rates in children receiving maintenance dialysis are at least 30 times higher than those of the general pediatric population, with even higher relative risks in very young children.[123] **Thus, the decision to embark on chronic renal replacement therapy in the neonate requires careful consideration and discussion with the family.** With these considerations, we now turn to particular concerns in the management of ESRD in neonates and young infants.

Management of ESRD in Neonates and Infants

Neonates and infants who require chronic dialysis experience the same complications of chronic renal failure that are observed in older children and adults, including anemia of chronic disease, secondary hyperparathyroidism, chronic acidosis, hypertension, and iron and vitamin D deficiency. However, **certain aspects of ESRD are unique to childhood and of particular concern with onset of ESRD during infancy, including altered nutrition, impaired somatic growth, and impaired neurocognitive development.**

NUTRITION AND GROWTH

Appropriate nutrition is a critical aspect of ESRD management during infancy. Multiple factors contribute to growth failure in infants with chronic kidney disease, including anorexia; nausea and vomiting; gastroesophageal reflux, which can be exacerbated by abdominal distention from indwelling dialysate during peritoneal dialysis; altered gastrointestinal motility, including delayed gastric emptying, which can be associated with the use of calorically dense formulas; the need for fluid and electrolyte restriction; salt-wasting nephropathy, renal osteodystrophy; chronic anemia; and developmental abnormalities that affect the mechanics of oral intake. Except for during the gestational period, linear growth is highest in the first year of life and depends primarily on the provision of optimal nutrition.[126] **Although oral feeding is desired and supported, enteral feedings will be necessary in the vast majority of cases to meet protein and caloric requirements sufficient to promote somatic growth and neurocognitive development in the setting of renal failure.**[181,194] ***Gastrostomy tubes* are usually preferred to nasogastric tubes given the anticipated lengthy duration of support.** The timing of gastrostomy placement is important because there is a risk of infection, including fungal peritonitis, as well as the loss of peritoneal membrane function with gastrostomy placement in children already receiving PD. Fundoplication may be required and can be performed concurrently; in our experience, symptoms of gastroesophageal reflux often increase once PD is started because of the pressure associated with increasing volumes of intraabdominal dialysate. **Placement of feeding tubes also supports successful administration of the numerous medications that these infants routinely require.** Tube feedings that are administered as supplements to oral intake can be provided either as daytime bolus feeds given in intervals that mimic usual infant feeding patterns or as continuous nightly infusions at rates that are regulated by a feeding pump.

Energy Intake. There is no evidence to suggest that children with chronic renal failure require increased energy compared with healthy children of the same age. The recommended goal for energy intake is 100% of the estimated energy requirement for chronologic age and sex, adjusted for physical activity level and body size, with a balance of carbohydrate, saturated and unsaturated fat, and protein similar to infant formula (36% to 56% carbohydrate, 40% to 54% fat, 7% to 12% protein).[100] **Low-birth-weight infants and children with established growth delay will require supplemental calories to support catch-up growth.** Glucose absorption from peritoneal dialysate can be significant, providing an

additional 10 to 20 kcal/kg/day,[117] and should be estimated in children with greater-than-expected weight gains.

Protein Intake. Protein goals, calculated in grams/kg ideal body weight, vary by stage of CKD. **Protein goals for children on peritoneal dialysis are set at dietary reference intake (DRI) plus 0.15 to 0.3 g/kg/d to compensate for dialysate-related protein and amino acid losses.** When replacing or augmenting breast milk with commercially available formulas, it is important to consider the type of protein as well; whey protein is more bioavailable than casein, and evidence suggests that whey protein may promote more rapid gastric emptying.[70] Compared with casein-predominant formulas, breast milk and whey-predominant formulas are preferred for their lower aluminum content.[86] Previous reports have documented that excess aluminum intake can lead to toxicity and cause bone disease and encephalopathy.[86,100]

Milk Intake. Additional caloric or protein supplements may be added as appropriate. The patient's renal limitations and gastrointestinal tolerance will guide which infant formula to use. **Breast milk is low in potassium and phosphorus and thus is often well tolerated by neonates with ESRD. Alternatively, specialized formulas for chronic kidney insufficiency that are low in potassium and phosphorus content are available for infants**, older children, and adults (Table 25.7). Similac PM 60/40 (Ross Abbott) and Goodstart Gentle (Gerber) are both appropriate first choices for infants with kidney failure. **Concentration of formula is often necessary to achieve an adequate intake of energy, protein, and other nutrients within accepted volumes.**

FLUID AND ELECTROLYTE REQUIREMENTS

Fluid and electrolyte requirements for neonates with kidney failure vary widely depending on the underlying kidney disease, degree of kidney failure, and mode of renal replacement therapy. ***Anuric or oliguric* children require fluid and sodium restriction. In contrast, children with *polyuric renal failure,* as is often seen with congenital obstructive uropathy, may require sodium and fluid supplementation.** Parekh et al. demonstrated improved growth of children with polyuric, salt-wasting renal insufficiency when they received 180 to 240 mL/kg/d of dilute (0.3 to 0.5 kcal/mL) formula that contained sodium supplementation on the order of 2 to 4 mEq/100 mL formula.[140] **Neonates undergoing peritoneal dialysis may demonstrate significant sodium loss through the dialysate, necessitating sodium supplementation.**[152,176] Restriction of dietary potassium intake may be indicated in some neonates. **When adequate nutrition is limited by potassium intake, breast milk and formula can be treated with sodium polystyrene to decrease the potassium content before feeding.**[34,176] Diluted adult renal formulas can also be provided,[90] but the effect of adult formulas on infants is not known, and thus it may be prudent to use infant formulas in those under 1 year of age.[70]

CALCIUM AND PHOSPHORUS

Normal serum calcium and phosphorus levels are higher in infants compared with older children, and age-specific norms should be targeted to optimize bone health. **Calcium intake from nutritive sources and phosphorus binders should be 100% to 200% of DRI for age and gender,** and phosphorus intake should be decreased if secondary hyperparathyroidism is present, with or without hyperphosphatemia.[100] If an older infant still receiving breast milk presents with hyperphosphatemia, a phosphate binder can be administered to the infant or the breast milk can be treated with a phosphorus binder to effect phosphate reduction.[63,149]

Vitamins. It is recommended that children with CKD meet 100% of DRI for B vitamins; folic acid; vitamins C, A, E, K; and copper and zinc. If this cannot be achieved through dietary intake alone or if there is clinical evidence of a deficiency, supplementation of these nutrients up to DRI is indicated. However, excess vitamin A intake from supplemental feeds or multivitamins may result in hypervitaminosis A, which is associated with hypercalcemia in dialysis patients.[120] **Additionally, it is suggested that children on dialysis receive supplemental water-soluble vitamins to replace dialysate-related losses.**[100] Several commercial renal multivitamin formulations are available, including a liquid that can be easily dosed and added to breast milk or formulas.

Similac PM 60/40, Similac Advance, Suplena, and Nepro are produced by Ross Abbott Nutrition. Goodstart Gentle is produced by Gerber. Renalcal and Renastart are produced by Nestle Health Science.

Polycose is produced by Ross Abbott Nutrition. Beneprotein, Microlipid, and MCT oil are produced by Nestle Health Science. Duocal is produced by Nutricia.

Adapted from Foster BJ, McCauley L, Mak RH. Nutrition in infants and very young children with chronic kidney disease. *Pediatr Nephrol.* 2012;27(9):1432.

Infant Growth. **Half of adult height is realized by 2 years of age, and during this phase, a child may experience a loss in growth potential that cannot be recovered. ESRD is associated with linear growth failure due to relative resistance to growth hormone (GH).** Such resistance is multifactorial in nature but includes reduced density of GH receptors in target organs and reduced levels of free insulin-like growth factor (IGF)-1 due to increased inhibitory IGF-binding proteins.[118] **Growth hormone therapy is essential in pediatric ESRD to attain a normal adult height**[65,66] and is often started in the toddler or early school age years. Although recombinant human growth hormone has not been fully investigated in infants, recent studies suggest that growth hormone treatment in infancy is generally well tolerated and may be useful as an adjunct for children who continue to grow poorly despite optimization of dialysis therapy and nutrition.

The nutritional management of infants with kidney disease is complex. It is recommended that the growth parameters of infants with moderate CKD be monitored twice as frequently as those of healthy infants and that those of children with severe CKD be monitored with even greater frequency.[100] **Frequent assessment is necessary to ensure that timely and effective nutrition intervention and support can be offered to pave the way for the best possible outcomes. For this reason, it is imperative that a skilled pediatric renal dietitian guide the multidisciplinary team in the nutrition plan for this population.**

Neurocognitive Development

Emerging evidence suggests that neurocognitive deficits are common in children with ESRD. A cross-sectional study of children with moderate to severe chronic renal insufficiency demonstrated that approximately one third of participants scored at least 1 standard deviation below the mean on measures of intelligence quotient, academic achievement, attention regulation, or executive functioning.[92] A more recent but small study in children initiating dialysis before 16 months of age showed significant deficits in intellectual and metacognitive functioning compared with sibling controls.[96] **Fewer months on dialysis and younger age at transplant were associated with better outcomes.** Although limited data are available at this time, these results have important implications for long-term educational and occupational outcomes and support the need for early intervention services for affected infants.

NURSING CARE OF THE NEONATE WITH RENAL FAILURE

Clinical and Metabolic Assessment

Nurses play a critical role in assessing and managing the neonate with renal failure.[75,80,169,173] **Changes in the neonate, including decreased urine output, weight gain, and electrolyte imbalance, can signal concern for acute renal failure. Symptoms of fluid overload include generalized edema in the face, extremities, and abdomen; increased work of breathing; and increases in BP and weight.**

Because electrolyte abnormalities are common in renal failure, nurses should note these values and report them, as well as anticipate clinical signs and symptoms that will follow. *Hyponatremia* often indicates excess intravascular volume due to fluid retention in the setting of renal failure; however, some neonates have salt-losing nephropathy, which leads to hyponatremia and dehydration. Treatment for low sodium concentration may therefore include fluid restriction or replacement of sodium depending on the underlying mechanism. *Hyperkalemia* can result in a medical emergency if not appropriately monitored and treated. Treatment includes restriction of potassium intake in formula and parenteral fluids and discontinuation or alteration of medications known to contribute to high serum potassium concentrations. Measures to shift potassium intracellularly, such as IV sodium bicarbonate or insulin and glucose, will temporarily decrease the plasma potassium concentration, but more definitive removal of potassium from the body through the urinary (potassium-wasting diuretics) or GI (cation exchange resins) tracts is warranted. The ***electrocardiogram* should be monitored closely because hyperkalemia can lead to ventricular arrhythmias.** IV calcium can stabilize the myocardium to help minimize the effect of hyperkalemia on cardiac rhythm. Low serum bicarbonate concentrations are

often observed in renal failure because the kidney is instrumental in maintaining acid-base balance in the blood.

Assessment and Management of Peritoneal Dialysis

PD is often the dialysis treatment of choice for the neonatal patient. The process of PD is described in detail earlier in this chapter. Regulation of electrolyte and fluid balance must be closely monitored by following serum electrolytes and by close documentation of intake and output and daily weight. These measures provide critical data for clinical management because fluid removal by PD is inexact, being affected by multiple factors, including the dextrose concentration of the dialysate and individual peritoneal membrane transport characteristics. **PD relies on an intact abdomen for success.** Therefore, hemodialysis or CRRT is occasionally indicated in infants or small children who have abdominal defects or surgery that prevents the use of the abdomen for PD.

Nurses have an essential role when dialysis is initiated. The nephrologist determines the type of dialysate, including any additives that may be required, such as heparin or electrolytes. **The fill volumes are based on the weight of the infant and usually start at 10 to 20 mL/kg with an eventual goal of 40 mL/kg.** These small initial volumes are necessary to prevent leakage of the newly placed catheter and to "stretch" the peritoneal cavity gradually for comfort. Neonates typically start with continuous manual PD, which is a closed system connected to warmed dialysis solution bags that fill the peritoneum by gravity from a premeasured volume control administration set. **The fluid dwells in the abdomen for the designated time prescribed by the nephrologist and then is drained from the abdomen by gravity into a drainage system by turning a stopcock.** Accurate measurement of the drained fluid is crucial, performed by subtracting the fluid that was infused and recording the difference as the net output. The bedside nurse will perform the manual dialysis, which can be a tedious but life-sustaining job. The nurse must also monitor the abdomen, with particular attention to the dressing of the PD catheter to ensure that no leakage of dialysate is occurring along the catheter tract or at any post-laparoscopy sites. The risk for leaks can be decreased by delaying the use of the catheter after placement; however, this is not always clinically possible. When the infant is bigger and can tolerate a fill volume of at least 100 mL, the dialysis can be delivered by an automated PD machine. The machine can be programmed to deliver the prescribed amount of dialysate, allow the fluid to dwell, and automatically drain the abdomen for the designated time. Trained dialysis nurses typically are involved at this point to manage the setup of the machine.

Complications that can occur with PD include the following:

1. *Infection:* Infection of the exit site and/or peritonitis (infection of the peritoneal lining) can occur if strict attention to aseptic technique is not followed. At least weekly dressing changes over the exit site using sterile technique are recommended until the catheter site is healed, which can take 2 to 6 weeks. More frequent dressing changes should be performed if drainage is excessive or the dressing becomes soiled or wet. The risk of infection is significantly higher in the presence of a leak. Application of a topical antibiotic cream or ointment at the time of the dressing change is recommended. Immobilization of the catheter below the dressing to restrict movement is helpful to prevent trauma to the insertion site. Daily tubing changes for manual dialysis setup should be performed with sterile technique for connection of bags and tubing. Once the infant is on an automated dialysis machine, trained dialysis staff perform daily bag and tubing changes. Assessment of the quality of the PD effluent during drain cycles is necessary to detect any signs of peritonitis, such as effluent that is cloudy or has increased fibrin. Fever and abdominal pain are also indicators of possible peritonitis. If concern for peritonitis exists, the PD fluid should be sent for cell count and differential, Gram stain, and culture. Antibiotics may need to be administered pending culture results. The nephrologist may prescribe intraperitoneal antibiotics to be directly added to the bags of dialysate; these antibiotics are systemically absorbed and are dosed to reach blood concentrations similar to those obtained with IV administration.
2. *Inflow/outflow problems:* Inflow and outflow problems may occur while performing PD either manually or via the automated dialysis machine. Accurate measurement of the dialysate

is done with each manual exchange. If problems occur with inflow, check lines for closed clamps or kinks. Attempt to reposition the patient to encourage better flow. Manual dialysis relies on gravity, so ensure the patient is positioned higher than the drainage system. Good inflow but poor outflow can signal migration of the PD catheter tip, blockage of the catheter tip by omentum, or constipation. Notify the nephrology team of the problem. An abdominal x-ray can be helpful to detect the presence of stool and determine the location of the catheter tip. Correction of the problem may be as simple as evacuating stool and as complicated as returning to the operating room for catheter revision. In any event, if the problem is not corrected, dialysis cannot continue. The success of the dialysis treatment depends on a functioning catheter.

3. ***Potential fluid overload or dehydration:*** Accurate measurement of the inflow and outflow of each exchange is essential when determining fluid balance. Check weights before and after the dialysis treatments, and review intake and output measurements to ensure fluid balance. Frequent monitoring of vital signs to detect any changes in heart rate or blood pressure will help to determine signs of dehydration or fluid overload. Symptoms of dehydration, including poor skin turgor, sunken eyes and fontanel, delayed capillary refill, hypotension, tachycardia, and weight loss, signal excessive fluid removal with the current dialysis plan. Signs of fluid overload include generalized or increasing edema, rapid weight gain, increasing blood pressure, and potentially respiratory distress. The physician should be notified of any of these discrepancies so that adjustments can be made to the dialysis plan.
4. ***Hernias:*** Hernias are a complication of PD. Umbilical and inguinal hernias are the most common and can occur due to the increased intraabdominal pressure from the dialysate load. Decreasing the fill volume until hernia repair can be performed, as well as immediately postoperatively, is recommended to diminish stress in this area.

Renal failure and its treatment in the neonate with PD require competent nursing assessment and accurate documentation of vital signs, weight, and intake/output. **The chronic nature of dialysis at this young age can be stressful on the family.** Spousal tension, sibling neglect, and financial stress are common. **The family's success in managing the infant's dialysis and nutritional needs requires the support of all members of the multidisciplinary care team.** Successful growth and development over the coming years need to be the goal of all team members to ensure eventual renal transplant and hopes for a long, healthy life.

26 NEUROLOGIC DISORDERS

ARA S. HALL AND DAPHNE A. REAVEY

The developing nervous system provides ongoing challenges for researchers and clinicians. Investigations continue in a wide variety of areas, yet basic mechanisms for a pathophysiologic understanding of common events such as neonatal seizures and intraventricular hemorrhages (IVHs) remains unclear.

Improved neonatal care in recent years has not significantly reduced neurologic sequelae. Whether this is a reflection of survival of sicker and more immature infants is difficult to assess. Primary neurologic disease and secondary neurologic complications from such common conditions as cardiopulmonary disease, metabolic derangements, shock, infection, and coagulopathies still represent major problems encountered in every intensive care nursery. Serious congenital nervous system anomalies still appear with regularity, although in small numbers.

This chapter deals with selected topics in neonatal neurology, including congenital malformations, trauma, seizures, hypoxic-ischemic encephalopathy (HIE), hypotonia, stroke, and IVH.

CONGENITAL MALFORMATIONS

Physiology, Etiologic Factors, and Clinical Features

Congenital malformations of the nervous system occur when the usual sequence of maturation and development is interrupted[13] (Table 26.1). These malformations are present at birth, and the etiology is multifactorial and sometimes unclear. Although strictly destructive lesions (e.g., hydranencephaly resulting from bilateral carotid artery occlusion) are separate from primary failures of morphogenesis, both may be included in the broad category of congenital malformations. The distinction between the two types lies in an understanding of the causes.

Understanding congenital malformations requires an appreciation of the normal embryologic sequence. The clinical and pathologic identification of normal and abnormal structures makes it possible to determine the timing of the insult or development failure. Once timing is established, an appropriate search for the cause can be made.

Neural Tube Defects

The incidence of neural tube defects (NTDs) worldwide is approximately 0.5 to 2 in 1000 births[13,20] (Box 26.1). Although the prevalence of NTDs has decreased, they are **one of the most common congenital anomalies contributing to morbidity and mortality in neonates.**[20] Changes in vertebral, vascular, meningeal, and dermal structures are typically found along with the defects. The more common types of NTDs are anencephaly and myelomeningocele.[25] **Genetic and environmental factors play a role in the development of NTDs.** Familial incidence also plays a role; when one family member is affected, the risk increases to 3% in subsequent offspring and to 12% if two or more family members are affected.[29] **While the etiology of NTDs appears to be multifactorial, the interaction of genetic and environmental factors, including nutrition and teratogens, may determine risk.**[13,92] In 60% to 70% of cases genetic factors play a role.[20,30] Environmental factors associated with NTDs include maternal obesity, diabetes,

BLUE type highlights content that is particularly applicable to clinical settings.

TABLE 26.1 CENTRAL NERVOUS SYSTEM DEVELOPMENT AND RELATED DEFECTS

MATURATIONAL PROCESS	TIME	ASSOCIATED DEFECTS
Neural tube defects (dorsal induction, neurulation)	3-4 weeks	Craniorachischisis Anencephaly Myeloschisis Encephalocele Myelomeningocele Chiari malformation
Prosencephalic development	2-3 months	Cyclopia Holoprosencephaly Arrhinencephaly Septo-optic dysplasia Agenesis of corpus callosum Agenesis of septum pellucidum
Proliferation	2-4 months	Microcephaly Megalencephaly Neurocutaneous syndromes (?)
Migration	3-5 months	Schizencephaly Lissencephaly Pachygyria (macrogyria) Microgyria (polymicrogyria) Neuronal heterotopias
Neuronal organization and functional organization	6 months	Down syndrome (?) Mental retardation (?) Genetic epilepsy (?)
Myelination	2nd trimester	Anoxic/ischemic damage

BOX 26.1 CRITICAL FINDINGS
Neural Tube Defects

- As many as 50% or more of neural tube defects (NTDs) are preventable.
- Two-thirds of American women fail to ingest an adequate amount of folic acid, and enriched grain products supply only one-fourth of daily need.
- All women of childbearing age should consume **400 mcg** of folic acid daily even when not planning to become pregnant.
- **At increased risk:** women with a previous NTD pregnancy. For these women, the recommended dose of folic acid is **increased to 4 mg daily**. It should be taken at least 1 month before conception.
- **Sources:** Dietary supplements, enriched grain products, and consumption of foods with folic acid content (citrus fruit, beans, leafy greens).
- The Centers for Disease Control and Prevention, American Academy of Pediatrics, and March of Dimes have all recommended an increase in the amount of folic acid used to fortify grain products from 140 to 350 mcg per 100 g of grain.
- Inadequate education of women continues to be a problem.

hyperthermia, and lower socioeconomic status.[13,20] Drugs that have been linked to NTDs include valproic acid, carbamazepine, thalidomide, and a fungal product fumonisin.[13,30,92]

The major environmental factor linked to NTDs is a dietary level of folic acid.[13] Folic acid supplements before and during pregnancy have been cited as substantially lowering the incidence of these NTDs. The U.S. Public Health Service issued a **recommendation that women of childbearing years consume 400 to 800 mcg of folic acid each day to prevent NTDs.[91]** The American Academy of Pediatrics (AAP) also supports this recommendation.[7] Such an intake can be achieved by dietary supplementation of folate, adding folic acid to U.S. enriched grain products (e.g., bread, flour), and consuming foods containing folic acid (e.g., citrus, beans, leafy greens). The Food and Drug Administration (FDA) required all enriched grain products to be fortified with[7] folic acid by 1998. In 2016 the voluntary addition of folic acid to corn masa flour was approved by the FDA.[72,90] Corn masa flour is a food staple in the Hispanic population.[7] Studies have demonstrated higher rates of NTDs in the Hispanic population, which prompted the recommendation by the FDA.[33,72] Folic acid fortification has increased folic acid levels in the United States, although a recent study suggested that about 25% of women of reproductive age still had red blood cell (RBC) folate levels that were less than optimal. Half of the women in the study (48%) revealed that the sole source of folate acid was enriched cereal grain products and only 29% took a supplement that included folate.[21]

A 2015 *Cochrane* review confirmed that folic acid prevents NTDs, including second occurrence NTDs.[24] Current recommendations for

folic acid supplementation is 400 to 800 mcg of folic acid daily for all women planning to or capable of becoming pregnant. Supplementation should begin at least 1 month before pregnancy and continue until 12 weeks of gestation. Women at high risk for a pregnancy with an NTD should take 4 mg (4000 mcg) of folic acid daily. Supplementation should begin 3 months before pregnancy and extend through 12 weeks of gestation. Women in the high risk category include women who have had an NTD themselves or previously had a pregnancy affected by an NTD, whose partner has been affected by an NTD, or who have had a previous child with an NTD.[19,91] Improved consumption of folic acid will not completely prevent NTDs because of multifactorial etiologic factors such as the environment and genetics.

There are four phases that occur in the formation of the spinal cord. The four phases are gastrulation, primary neurulation, secondary neurulation, and dorsal midline closure of the mesodermal-cutaneous ectodermal layers. The presence of the primitive streak is the first evidence of gastrulation. A second streak, the notochordal process, develops alongside the primitive streak. The notochord is responsible for the induction of both the neural plate and the neurenteric canal. Cells proliferate along the lateral margin of the neural plate to form the neural folds around the central neural groove.[30,70]

Cells at the apex of the neural folds make up the neural crest. Schwann cells, pia-arachnoid cells, sensory ganglia, melanocytes, and various secretory cells arise from the neural crest. The neural folds meet and fuse with the rostral neuropore (anterior) and caudal neuropore (posterior) ends, closing by approximately the end of the fourth embryonic week.[30,70]

Failure of development at this stage results in the defects of neurulation (or dorsal induction). The most severe of these defects is craniorachischisis, in which there is significant malformation of the brain (as in anencephaly), absence of the posterior skull, and an open spine along the full length of the spinal cord. Only a few affected embryos survive to early fetal stages.[30]

Anencephaly is similar to craniorachischisis without the spinal defect. **There is essentially no normal brain tissue above the brainstem and thalami,** and parts of those structures are malformed. Onset is thought to occur before 24 days of gestation. Although traditionally anencephaly is thought to be an NTD, there are some who theorize that the defect occurs as a result of a skeletal (mesodermal) defect. About one-fourth of the fetuses survive into the neonatal period, but three-fourths are stillborn.[30] **The majority of anencephalic infants die within the neonatal period.**[30]

Myeloschisis involves the failure of the posterior neural tube to close. There is no well-defined sac protruding from the defect, and there is a continuous leak of cerebrospinal fluid (CSF) fluid.[13]

Encephaloceles are now believed to be caused by disorders of cranial mesoderm that occur during development. They most commonly are found in the occipital region and less commonly in the frontal, temporal, and parietal regions. Meninges, brain tissue, and/or CSF may be found in the lesion, and it is usually connected to the rest of the brain by a narrow stalk of tissue. Many of the lesions may be covered by skin.[30]

Myelomeningoceles (or the more limited meningoceles) are a limited form of myeloschisis with failure of closure at the caudal (tail) end of the neural tube. With meningocele, the meninges protrude through the vertebrae and are contained within a sack. The spinal cord and nerve roots are generally in normal position, which improves the outcomes for these children. Unfortunately, myelomeningoceles, the more common defect, results in protrusion of both meninges and spinal cord through the opening in the spinal column. **Neurologic deficits occur below the level of the protrusion.**[25,30,95] Chiari malformations are typically included in this category. Chiari II malformations are often seen in conjunction with myelomeningocele, and involve the brainstem and cerebellum. A small posterior fossa is the central feature of Chiari II malformations. The hindbrain and midbrain, including the cerebellum, and the cervical spinal cord are involved in the defect. Hydrocephalus occurs as a result of abnormalities in the flow of CSF secondary to aqueductal stenosis, obstruction of the fourth ventricle, and subarachnoid space compression. Dilation of ventricles often occurs without increased head circumference or clinical symptoms of increased intracranial pressure in this group of infants; therefore, serial ultrasound scans should be performed with a fast sequence T2-weighted magnetic resonance imaging (MRI) when surgical intervention is being considered. **Symptoms of brainstem involvement such as central apnea or vocal cord paralysis may be present.** Any defect in which the spinal or cranial

contents are "open" to the outside, such as myelomeningocele or encephalocele, are associated with an elevation of alpha-fetoprotein (AFP) in the amniotic fluid. This is important in prenatal diagnosis.[30]

Segmentation Defects

After formation and closure of the neural tube, the development of different regions of the brain begins to occur. Division of the brain into hemispheres, formation of the ventricular system, and formation of the major gyral patterns all occur between 2 and 3 months of gestation.[28,70] Major areas of the brain, including the cerebellum, basal ganglia, brainstem nuclei, thalamus, and hypothalamus, form at this time.[28] Defects of segmentation and cleavage occur during this phase of neural development. For unknown reasons, defects of segmentation and cleavage are far less common than defects of neurulation. Because these malformations involve abnormalities of ventral induction rather than dorsal induction (e.g., neurulation), the face, eyes, nose, mouth, and hair are also involved. When any of these brain malformations are suspected or when features suggestive of them are seen, careful examination of the hair, eyes, ears, mouth, and nose may reveal other related anomalies.

Holoprosencephaly is characterized by a single midline lateral ventricle, incomplete or absent interhemispheric fissure, absent olfactory system, midfacial clefts, and hypotelorism (abnormally decreased space between the eyes). Various subtypes of holoprosencephaly, including alobar, semilobar, lobar, and middle interhemispheric have been described. The most severe form of holoprosencephaly is cyclopia (a single fused midline eye) and supraorbital nasal structure. At times, the nasal structure and eye are absent. An intermediate form is cebocephaly, which includes ocular hypotelorism and a flat nose with a single nostril.[28]

Migration and Cortical Organizational Defects

The remaining development of the brain takes more than twice as long as previously described development and includes cellular proliferation, migration, organization, and myelination. Cells that later form the cerebral cortex begin in the germinal matrix (near the caudate nucleus around the lateral ventricles). These cells then migrate in a radial fashion to their final positions near the surface of the brain. Abnormalities of cellular migration result in collections of gray matter in unusual places (heterotopias), abnormal gyri and sulci, abnormal spaces in the brain, and clinical signs of gray matter dysfunction. Frequently, these clinical problems are not apparent in the newborn period.

Microcephaly **means "small brain" and is manifested as a head circumference measuring greater than two standard deviations below average for infants at that gestational age.**[13] Microcephaly may be (1) genetic (dominant, recessive, sex-linked) or chromosomal (translocation [see Chapter 27]), (2) caused by teratogens (cocaine, alcohol), (3) caused by infection (rubella, cytomegalovirus, zika), or (4) of unknown cause. Occasionally, there is a paucity of germinal matrix cells or they fail to adequately migrate, resulting in a brain cortex with a decreased number of neuronal cells.[13]

In *lissencephaly,* the brain is smooth in appearance, having few or no gyri (convolutions). An important fact is that the normal fetal brain is smooth early in gestation, with convolutions forming throughout gestation, creating the sulci and gyri seen in term infants. Lissencephaly is a cortical migrational abnormality, resulting in agyria, pachygyria, and other issues in term infants.[80]

Although not generally present at birth, poor head growth resulting in microcephaly usually occurs within the first year in type I lissencephaly. Neonatal seizures may also occur, but seizures are more commonly present at 6 to 12 months of age. A general phenotype is marked by hollowing at both temples, a small jaw, and generalized hypotonia. Several generic disorders involving chromosome defects of the 17p13.3 gene and Xq22.3 gene have been associated with type I lissencephaly. *Miller-Dieker syndrome,* a major form of type I lissencephaly associated with 17p13.3 gene have characteristics including narrow forehead, long philtrum, upturned nose, retrognathia, retinal hypervascularization, and digit abnormalities. In type II lissencephaly, macrocephaly is generally present at birth or develops soon afterward. Retinal, cerebellar, and muscular abnormalities always are present. Fukuyama congenital muscular dystrophy, Walker-Warburg syndrome, and muscle-eye-brain disease are disorders that are consistently associated with type II lissencephaly. Other clinical features of lissencephaly include hypotonia, feeding problems, and decreased movement sometimes presenting with

arthrogryposis in the newborn. Abnormalities on the electroencephalogram (EEG) are noted. Later, significant intellectual disability and severe spasticity may be noted and death may occur.[80]

Additional Defects

Cerebellar malformations are quite varied. Most often, at least a portion of the cerebellum is preserved, but total absence is possible. Hemispheric hypoplasia-dysplasia or vermis hypoplasia-dysplasia or agenesis is seen, and familial forms have been reported. *Dandy-Walker cyst* is another complex malformation involving the cerebellum in which the fourth ventricle is dilated into a cystic structure, hypoplasia-agenesis of the cerebellar vermis, and posterior fossa enlargement. The foramina of Magendie is atretic, and hydrocephalus results. The cerebellum is small and displaced upward. Associated anomalies include heterotopias, agenesis of the corpus callosum, aqueductal stenosis, and syringomyelia. The differential diagnosis includes an arachnoid cyst of the posterior fossa. In the case of an arachnoid cyst, the fourth ventricle is not part of the malformation and is normal, although it may be displaced.[27] Clinical features of Dandy-Walker cyst include progressive hydrocephalus, enlargement of the occipital shelf and posterior part of the skull, and clinical symptoms of increased intracranial pressure. Symptoms may be absent in the newborn period. Malformations in other organ systems such as the renal and cardiac systems are frequently associated.[27]

***Craniosynostosis* is the abnormally early closure (fusion) of the bones of the skull.** The cause in most of these malformation is unknown. Familiar or complex syndromes make up about 10% of craniosynostosis cases. In these cases a mutation in the processing of fibroblast growth factor is thought to be the etiology. **The premature closure of sutures may involve one or multiple sutures, with resulting deformity of the skull.** Various skull shapes such as brachycephaly, scaphocephaly, and acrocephaly may result depending on which sutures are prematurely fused.[101]

Craniosynostosis should be suspected in the presence of microcephaly or misshapen head. **Appropriate evaluation requires a clinical assessment with palpation of the sutures to determine whether they are overriding or fused** and x-ray films of the skull and/or a computed tomography (CT) scan to define which of the sutures are stenosed and whether there might be an associated brain malformation or hydrocephalus.[78] **Craniosynostosis should be differentiated from positional deformities occurring from an infant lying in one position for a prolonged period of time.** A classic example is dolichocephaly (narrow and elongated shape) seen in premature infants and plagiocephaly in term infants.

Hydrocephalus may occur as a result of various etiologies. **Hydrocephalus results when the normal flow of CSF is obstructed.** This may be the result of an atretic portion of the ventricular system, blockage from the outside, inflammation within the ventricular system causing a permanent blockage, or, rarely, overproduction of CSF. An inherited X-linked form of hydrocephalus exists. Intrauterine infection is another cause. Hydrocephalus may be associated with many of the malformations described previously.[103]

Data Collection

The diagnosis of malformations of the central nervous system (CNS) may be quite obvious (as in anencephaly) or very subtle. **Careful examination of all newborns results in the identification of most malformations.** At times, the diagnosis is suspected not based on examination findings but with the presence of accompanying signs such as seizures.[25] Prenatal diagnosis of congenital malformations of the nervous system can be made using imaging studies. Ultrasonographic examination (an abdominal ultrasound scan of the mother) or fetal MRI, which is now available at many large centers, provides an opportunity to identify certain malformations by viewing the fetus during development. Hydrocephalus, encephaloceles, myelomeningoceles, cerebellar malformations, hemorrhage and stroke, and anencephaly may be identified prenatally.

Determination of AFP levels in the amniotic fluid and maternal serum allows the identification of anencephaly and open myelomeningoceles. A nonenclosed nervous system is associated with a significant rise in AFP in the amniotic fluid. Amniocentesis provides the amniotic fluid necessary for this determination. Testing of maternal serum for AFP is also an option and may be used along with ultrasonography or fetal MRI for diagnosis, allowing amniocentesis to be omitted.[13,30] Elevated AFP levels can be found in other fetal conditions,

including fetal wall defects.[29] Clinical signs and symptoms have been described for each individual nervous system malformation presented earlier in this chapter.

Treatment

Limited treatment is available for congenital malformations of the nervous system. A variety of strategies are available for reducing secondary complications or providing earlier management to handle these complications more efficiently.

The greatest efforts and accomplishments have been made for infants with congenital malformations who might be expected to have productive lives. When secondary complications are managed appropriately, the majority of children with myelomeningoceles are ambulatory (total or partial) and continent of urine.[30]

Myelomeningocele generally is surgically repaired as soon as possible (within 24 to 72 hours).[25,30,40,95] Prevention of infection is paramount. In addition to sterile technique, prophylactic antibiotics have been shown to be beneficial.[30] **Trauma to the area should be avoided by keeping the infant in the prone position and maintaining sterile gauze moistened with warm, sterile normal saline. Preventing fecal contamination is vital.** Several authors recommend the use of a sterile, plastic drape fastened above the anus but below the lesion to keep fecal material isolated from the site.[25,95] **Latex precautions also should be initiated because these infants have an increased propensity for developing sensitivity to latex.**[19]

Spina bifida has been repaired in utero at early gestational age. Such repairs have risks for both mother and fetus but have resulted in a significantly lower risk of infants requiring a ventriculoperitoneal (VP) shunt for hydrocephalus. The National Institutes of Health (NIH) sponsored Management of Myelomeningocele Study (MOMS) trial was a multicenter, prospective, randomized controlled trial comparing prenatal surgery with standard neonatal treatment. The trial was stopped early because of the efficacy of the prenatal surgery. **The study demonstrated that surgery before 26 weeks of gestation decreased the need for VP shunts, decreased hindbrain herniation, and preserved neurologic function.** Improved ambulation without the need for orthotics or devices was noted in the prenatal surgery group compared to postnatal surgery group. However, there were complications of premature delivery and some maternal complications as well. The MOMS II study will continue to follow the cohort of 183 babies to monitor neurologic and cognitive function as well as bowel and bladder function to determine whether benefit is sustained.[5,41]

Some of the malformations are lethal soon after birth (anencephaly), limiting management options to **comfort measures and family support** (see Chapter 32). When appropriate, genetic counseling should be requested. **For other malformations, treatment requires management of symptoms such as seizures, signs of increased intracranial pressure, and infection.** A consult to neurosurgery and neurology is indicated. Other helpful consults may include physical therapy, urology, and orthopedics.[25,40] For hydrocephalus, shunting may become necessary (Boxes 26.2 and 26.3 and Fig. 26.1).[30]

Generally, **skull deformity is present in infants with craniosynostosis.** It is prudent to consider the presence of craniosynostosis in any infant with an abnormal cranial shape.[25,95] If present, total craniosynostosis, or premature fusion of all the sutures should be treated surgically.[95]

The management of congenital hydrocephalus consists primarily of early shunting as soon after birth as possible. Fetal surgery for placement of a ventriculoamniotic shunt has been done in a few studies, but an improvement in outcomes compared with surgery after birth is uncertain. In addition, hydrocephalus in a fetus is often associated with serious developmental abnormalities that may increase morbidity and mortality.[29]

Shunting soon after birth often produces a far better outcome than would be assumed with minimal motor deficit and only a mild to moderate deficit in intellect.[30] Monitoring of pregnancies with fetal ultrasound allows the detection of congenital hydrocephalus. In the past it had been recommended to give antenatal steroids and deliver a fetus prematurely if there was evidence of rapid ventricular dilation and to proceed with postdelivery shunt placement. That is no longer recommended because of evidence that late preterm delivery may be associated with adverse neurodevelopmental outcomes.[30]

BOX 26.2 POSTOPERATIVE VENTRICULOPERITONEAL SHUNT CARE

- Positioning:
  - Place infant on unaffected side (may position on shunt side with "doughnut" over operative site once incision has healed). Keep head of bed flat (15 to 30 degrees) to prevent too-rapid fluid loss.
  - Support head carefully when moving infant.
  - Turn every 2 hr from unaffected side of head to back.
- Shunt site:
  - Use strict aseptic technique when changing dressing.
  - Pump shunt if and only as directed by neurosurgeon.
  - Observe for fluid leakage around pump.
- Observe and document all intake and output. Watch for symptoms of excessive drainage of cerebrospinal fluid:
  - Sunken fontanel
  - Increased urine output
  - Increased sodium loss
- Observe, document, and report any seizure activity or paresis.
- Observe for signs of ileus:
  - Abdominal distention (serially measure abdominal girth)
  - Absence of bowel sounds
  - Loss of gastric content by emesis or through orogastric tube
- Perform range-of-motion exercises on all extremities.
- Observe and assess for symptoms of increased intracranial pressure (shunt failure):
  - Increasing head circumference (measure head daily)
  - Full or tense fontanel
  - Sutures palpably more separated
  - High-pitched, shrill cry
  - Irritability and/or sleeplessness
  - Vomiting
  - Poor feeding
  - Nystagmus
  - Sunset sign of eyes
  - Shiny scalp with distended vessels
  - Hypotonia and/or hypertonia
- Observe and assess for signs of infection:
  - Redness or drainage at shunt site
  - Hypothermia and/or hyperthermia
  - Lethargy and/or irritability
  - Poor feeding and/or poor weight gain
  - Pallor
- Parent teaching:
  - Demonstrate and receive return demonstration of drug administration.
  - Teach parents side effects of medications.
  - Document on neonatal intensive care unit's routine discharge teaching checklist with routine care.

Complications

Many of the expected complications were dealt with previously in the sections describing the malformations and their associated problems. It is **difficult to separate true complications from problems resulting from the malformation.** For example, hydrocephalus develops in many infants with myelomeningocele and may be present at birth.[25,40] Other complications or associated problems of myelomeningocele include bowel and bladder incontinence, urinary tract infections, and paralysis.[25,30]

Malformations carry with them altered anatomy and physiology that is reflected in abnormal function. Common comorbidities may include seizures, intellectual disability, sensorimotor abnormalities, disturbances in primary sensory function such as vision and hearing, urologic, and orthopedic problems.[30]

Associated problems encountered are ordinarily explained on the basis of the malformation and the anatomy involved. Often midline defects in the brain (particularly at the base of the brain) result in clinical problems involving the hypothalamus and the hypothalamic-pituitary axis. This dysfunction may manifest itself in impaired temperature regulation, thyroid abnormalities, diabetes insipidus, and adrenal insufficiency. When absence of the septum pellucidum is diagnosed, the optic nerves should be evaluated to rule out septo-optic dysplasia, which is frequently associated with hypothalamic and electrolyte abnormalities.

Involvement of the cortex causes seizures, cognitive deficits, and sensorimotor problems. White matter damage can cause spasticity. If the brainstem is involved in the malformation (e.g., Chiari or Dandy-Walker malformations), apnea, deafness, sleep disturbance, oculomotor disturbances, and problems with sucking and swallowing

PARENT/CAREGIVER TEACHING

Wolfson Children's Hospital Parent Handout: Newborn Ventriculopertoneal Shunt (For Use With Ventriculoperitoneal Shunt Teaching Checklist)

Purpose of Ventriculoperitoneal Shunt

- Ventricles are compartment-like spaces located in the normal brain. Spinal fluid forms daily in these ventricles. This clear fluid flows out over the brain and down around the spinal cord. Spinal fluid helps cushion the brain from injury, keeps the brain moist, and carries away waste products.
- Hydrocephalus is a condition in which an abnormally large amount of spinal fluid builds up in your baby's ventricles and usually is caused by a blockage in the spinal fluid path. Because the ventricles continue to make spinal fluid daily, a buildup of fluid occurs when it cannot escape. This excess fluid can cause pressure on the brain and result in permanent damage to the brain unless it is properly treated.
- The purpose and function of your baby's VP shunt is to allow the excess spinal fluid to drain through a tube from the ventricle into the abdomen, where it is absorbed.

Pathway of the Ventriculoperitoneal Shunt (see Fig. 26.1)

- A small incision is made on the scalp, and the tube is passed through the skull and into the ventricle. Located under the skin, the tube passes behind the ear, passes down the side of the neck, and continues to the abdomen, where a second incision is made to put the end of the tube into the abdominal cavity. A third incision is sometimes needed in the neck area with some babies.
- The scalp incision will be hidden as your baby's hair grows. You will see and feel the shunt tubing (like a large vein under the skin), but it is barely noticeable after the baby gains weight.

Signs and Symptoms of Shunt Infection

- The shunt is at risk for infection because it is a foreign object located inside the body. You will have to watch for these signs of shunt infection and report them **immediately** to your doctor:
  - Temperature of 101°F or higher
  - Swelling, redness, or drainage along the pathway of the shunt tube
  - Lethargy or irritability (change in behavior)
  - Loss of appetite or poor feeding

Signs and Symptoms of Shunt Failure/Increased Intracranial Pressure

- The spinal fluid contains proteins and chemicals that may build up and block off the shunt. It is also possible for tissue within the brain or abdomen to block the shunt or for the shunt device itself to fail. This shunt failure (malfunction) means that the spinal fluid will once again build up and result in pressure on the brain and possible irreversible damage. Therefore it is very important for you to watch for the signs of increased pressure in the brain that occurs with shunt failure and report them to your doctor immediately:
  - Lethargy or sleepiness
  - Unusual irritability, fussiness, or excessive crying
  - Repeated vomiting
  - Poor feeding
  - Bulging soft spot when baby is sitting up quietly
  - Shrill, high-pitched cry
  - Eyes that look downward
  - Increase in spaces between the bones of the skull
  - Seizures/posturing

Reason and Importance of Prompt Treatment of Health Problems

- Prompt treatment of your baby's health problems (e.g., ear infections, skin infections) is important to prevent infections spreading to the shunt. It is also vital to seek medical care for signs of shunt infection or failure as noted.

Importance of Close Medical Follow-Up

- Your baby will have to be followed up by a neurosurgeon and your pediatrician after being discharged. Bring the baby to every follow-up appointment so that your baby's head can be measured and physical condition can be evaluated. Your baby will also go to the Developmental Evaluation Clinic, where a specialist in baby development can examine him or her. If development problems occur, this will ensure early diagnosis and treatment.

Care of the Shunt

- You can handle, cuddle, and play with your baby like any baby. Your baby also can sleep in any position after the initial postoperative period.

may be seen. Spinal cord lesions cause quadriplegia or paraplegia. Genitourinary problems and, to a lesser extent, gastrointestinal problems also are seen.

Most of the complications occur after the newborn period. In many circumstances, the problem is already present but functional expression such as impaired ambulation, intellectual disability, or deafness, is lacking. In the infant's follow-up examinations, careful attention must be given to problems likely to develop or intensify with age. When a specific malformation is diagnosed, it is necessary to become familiar with potential sequelae, not only to anticipate problems as they appear but also to lessen any secondary damage that might occur if the diagnoses go unrecognized.

Parent Teaching

Parents of an infant born with congenital malformations are faced with a stressful event that may develop into a major life transition. Parents, especially mothers, report feelings of guilt and self-blame, although they may not initially share these feelings with hospital staff. **After the birth of a malformed child, they go through stages of grief (see Chapters 29 and 30): shock or denial, anger, bargaining, depression, and acceptance.** Chronic grief over their loss of a healthy child can be seen in parents who have a child with a disability. Symptoms of acute posttraumatic stress disorder also can be seen.[52]

Social support received from hospital personnel, family, and friends can help parents in dealing with the stress of having an ill infant. **The ability of the staff to accurately anticipate and assess parental feelings and concerns can be invaluable when assisting families through this difficult time.** Parents often need to be supported to verbalize their feelings and fears. Reassurances, when appropriate, are provided (e.g., parents were not responsible for the congenital malformation; it is normal for the mother to experience [or at least report] more fears than her husband). **The ultimate goal of intervention is to reduce stress, assist families to confront fears, improve coping, and facilitate the parent-infant bonding process.**[52]

Infants with congenital malformations present such a complex variety of problems that parent teaching and emotional support need to begin as early as possible. With improved surveillance such as ultrasound and fetal MRI, parents often know from the time of birth or earlier that a major problem exists. In other circumstances, the anomaly is detected only after appropriate studies are performed.

When the infant is not viable, care should be directed at meeting the emotional needs of the family. **Every effort should be made to give family members positive experiences and memories by encouraging early parental holding of the infant and, whenever possible, participation with care** (see Chapter 30). Anticipatory counseling from social services, the palliative care team, and chaplain staff can help the family during grieving and with funeral arrangements. If there are also questions about etiologic factors and genetics, these questions should be dealt with according to the family's wishes (see Chapter 27).

If serious handicaps are anticipated and the infant is expected to survive, the parents should be encouraged to participate in the care of the infant from the beginning. Both adjustment and

specific aspects of care within the circumstance will be enhanced, and learning will be more effective if parents are supported. **A multidisciplinary team approach to parent education and support allows individualized hospital resources for specific needs of the patient and family.** In addition to medical, nursing, social service, palliative care, and chaplain involvement, team members can be drawn from psychology, developmental specialists, physical therapy/occupational therapy, and other services based on specific needs and circumstances. **Parent teaching and support must be individualized according to the anomaly.** When available, support groups, integrative discharge planning, and specialized clinics can help with postdischarge care and parent education.

Parent teaching for mothers and fathers of infants with congenital anomalies should (1) be started early, (2) involve the parents in the care of the infant, (3) use the resources of the hospital and community for specialized help, and (4) continue after the infant has gone home from the hospital or dies.[65]

BIRTH INJURIES

Physiology and Etiology

Birth injuries (birth traumas) are the direct result of difficulties encountered during the delivery process. These may be minor injuries without expected sequelae or the direct cause of death in the neonatal period. Classification of birth injuries usually is etiologic (predisposing factors or mechanisms of injury) or anatomic. An anatomic classification is used in this discussion to illustrate commonly encountered problems (Table 26.2).

The timing of birth injuries can be used to identify and describe causes. Etiologic classification of birth injuries includes uterine injury (antenatal), fetal monitoring procedures, abnormal or difficult presentations or methods of delivery, and multifactorial injuries. It should be recognized that an injury might have multiple causations. Thus, a cephalhematoma could be the result of forceps delivery, vacuum extraction, or routine vaginal delivery. A variety of specific predisposing factors increase the risk for birth injury, as follows:

- Macrosomia
- Cephalopelvic disproportion
- Uterine abnormalities
- Dystocia
- Prematurity
- Prolonged or precipitous labor
- Breech presentation/abnormal lie
- Instrumented delivery: forceps/vacuum
- Rotation of fetus
- Version and extraction
- Handling after delivery

Multiple factors often are present. When multiple predisposing factors are present, a single underlying maternal disease often links them. A common example is that of a premature, macrosomic fetus with a diabetic mother in whom labor is not progressing properly.

The common factors that are present in deliveries complicated by birth injuries are as follows:

TABLE 26.2 ANATOMIC CLASSIFICATION OF BIRTH INJURIES

SITE OF INJURY	TYPE OF INJURY
Scalp	Caput succedaneum Cephalhematoma Subgaleal hemorrhage
Skull	Linear fracture Depressed fracture Occipital osteodiastasis
Intracranial	Epidural hematoma Subdural hematoma (laceration of falx, tentorium, or superficial veins) Subarachnoid hemorrhage Cerebral contusion Cerebellar contusion Intracerebellar hematoma
Spinal cord (cervical)	Vertebral artery injury Intraspinal hemorrhage Spinal cord transection or injury
Plexus injuries	Erb palsy Klumpke paralysis Total (mixed) brachial plexus injury Horner syndrome Diaphragmatic paralysis Lumbosacral plexus injury
Cranial and peripheral nerve injuries	Radial nerve palsy/nerve injuries Medial nerve palsy Sciatic nerve palsy Laryngeal nerve palsy Diaphragmatic paralysis Facial nerve palsy

- **Unusual progress of labor**
- **Unusual size or shape of the fetus (large for gestational age or hydrocephalus)**
- **Problems encountered during delivery (dystocia or forceps application)**
- **Unusual or unexpected presentations (breech or unexpected twin)**

The maternal history always must be explored for an underlying disease process or condition that might increase the risk of a birth injury.

Prevention
