Careful attention to risk factors and the appropriate planning of delivery should reduce the incidence of birth injuries to a minimum. Transabdominal and transvaginal ultrasonography facilitate awareness of macrosomia, hydrocephalus, and unusual presentations before delivery. Particular pregnancies then may be delivered by controlled elective cesarean section to avoid significant birth injury. Care must be taken to avoid substituting a procedure of greater risk. **A small percentage of significant birth injuries cannot be anticipated until the specific circumstances are encountered during delivery.** Emergency cesarean delivery may provide last-minute salvage, but in these circumstances, the injury may be truly unavoidable.

SPECIFIC BIRTH INJURIES

Injuries to the Scalp

The three common forms of extracranial scalp injuries are caput succedaneum, cephalhematoma, and subgaleal hemorrhage and are distinguished not only in clinical manifestations but also in pathophysiology (Box 26.4).[98] These three extracranial scalp injuries are included with neurologic birth injuries, not because they have associated neurologic problems, but because the family or health care providers often raise the question of possible neurologic involvement.

PHYSIOLOGY AND ETIOLOGY

***Caput succedaneum* is caused by trauma to the scalp,** usually during a routine vertex vaginal delivery. **The caput is the result of hemorrhagic edema superficial to the periosteum of the scalp.** Therefore, spread of the edema is not restricted to suture lines and is soft and pitting because of its superficial location.[25,95,98]

***Cephalhematoma* is a subperiosteal collection of blood that is confined by the skull sutures.**

BOX 26.4 CRITICAL FINDINGS
Extracranial Hemorrhage

There are three common forms of extracranial hemorrhage but with different etiology and clinical assessment findings, as follows.

1. Caput succedaneum
   a. *Etiology:* Trauma to scalp (usually vertex vaginal delivery) results in hemorrhagic edema superficial to the aponeurosis of the scalp.
   b. *Findings:* Soft, pitting edema that crosses suture lines.
2. Cephalhematoma
   a. *Etiology:* Mechanical trauma; most common in primiparous women, with delivery using forceps or in vacuum-assisted deliveries.
   b. *Findings:* Firm, tense collection of blood confined by the sutures. Area often increases in size after delivery. No significant blood loss. Blood collects beneath the periosteum (subperiosteal).
   c. *Warning:* Associated with linear skull fracture in up to 25% of cases.
3. Subgaleal hemorrhage
   a. *Etiology:* Forces that compress and then drag the head through the pelvic outlet.
   b. *Findings:* Firm swelling that crosses suture lines and is fluctuant to palpation. Blood collection is under the aponeurosis (connective tissue connecting the occipital and frontal muscles). Bleeding (swelling) may continue after birth and dissect along tissue planes into the neck.
   c. *Warning: Acute blood loss may occur.* Presenting symptom may be shock.

Monitor VS for signs of shock:
- Elevated HR
- Decreasing BP

Monitor baby for signs of shock:
- Pallor
- Delayed capillary refill time
- Diminished tone
- Respiratory distress

Transfusion may be necessary: type and crossmatch.
Serial Hct should be followed.
Elevated bilirubin is a common complication as a byproduct of broken-down red blood cells.

BP, Blood pressure; *Hct,* hematocrit; *HR,* heart rate; *VS,* vital signs.

The incidence is 1% to 2% of all live births. The cause is nearly always mechanical trauma, and its occurrence is more common in primiparous women and in forceps or vacuum-assisted delivery. Males are generally more likely to be affected than females. It is associated with an **underlying linear skull fracture in 10% to 30% of cases.** The firm, tense collection of blood frequently increases in size after birth, but significant blood loss does not occur.[25,95,98]

Forces that compress and drag the head through the pelvic outlet are associated with *subgaleal hemorrhage.* Significant acute blood loss can occur with shock as the presenting symptom. Bleeding may continue after birth with enlargement of the accumulated blood and dissection of the blood along tissue planes into the neck. Such a hemorrhage carries the greatest potential for complications, but fortunately it is the least common form of birth injury to the scalp.[25,95,98]

DATA COLLECTION

With caput succedaneum, physical examination reveals soft, pitting edema that is diffuse and crosses suture lines. Laboratory tests are not needed.[95,98]

Cephalhematomas may occur anywhere but are most commonly found in the parietal area on one side. Because the location of the blood is subperiosteal, the blood is confined by suture lines. Symptoms are normally absent. A skull fracture underlying the cephalhematoma is present in 10% to 30% of affected infants. X-ray examination of the skull defines the fracture. Rare complications include infection, osteomyelitis, hyperbilirubinemia, meningitis, and late-onset anemia.[95,98]

Because the subgaleal collection of blood is under the aponeurosis (connective tissue connecting the occipital and frontal muscles) and superficial to the periosteum, subgaleal hemorrhage crosses suture lines. Extravasated blood progresses down to the nape of the neck from the scalp, may result in a protruding ear, and is firm but fluctuant to palpation. **Vital signs should be carefully monitored for symptoms of shock. Serial measurements of head circumference should be documented. Pallor, delayed capillary refill time, diminished tone, respiratory distress, elevated heart rate, or decreasing blood pressure should be observed for and treated promptly.** Transfusion may be necessary. **The hematocrit should be serially followed, and bilirubin levels should be determined during recovery.**[95,98]

TREATMENT

Usually, no treatment is necessary for caput or cephalhematoma. **In subgaleal hemorrhage, treatment of blood loss and shock may be necessary. During resolution, the breakdown of the blood may cause hyperbilirubinemia requiring treatment** (see Chapter 21).[95,98]

PARENT TEACHING

Parents of an infant with a cephalhematoma should be instructed that the cephalhematoma may enlarge but that they should not be concerned unless localized changes occur, suggesting secondary infection (erythema, induration, or drainage). This lesion should not be drained and may be evident for several weeks to months. A small calcification may remain after reabsorption of hemorrhage. The calcification may take months to resolve. The hemorrhage can be significant enough to cause hyperbilirubinemia or (rarely) anemia. **Outpatient evaluation of bilirubin levels and hematocrit may be needed in some cases.**

Parents of an infant with caput succedaneum should understand that the swelling is outside of the cavity of the brain and will usually reabsorb within a few days.[95] **Careful preparation of the parents for the acute side effects of subgaleal hemorrhage is important. Parents should be warned of the possibility of swelling and discoloration of the face, head, and neck.** The purpose of serial hematocrit and bilirubin checks should be explained. **Parents can expect 2 to 3 weeks for the swelling to resolve.**[95,98]

Skull Fractures

Three forms of skull fracture should be identified and differentiated: linear fractures, depressed fractures, and occipital osteodiastasis.[95,98]

PHYSIOLOGY AND ETIOLOGY

Linear skull fracture (a nondepressed fracture) is the most common type of skull fracture. The result of compression of the skull during delivery, **a linear skull fracture most often has no associated injuries and causes no symptoms.** Bleeding may be seen extracranially (common) or intracranially (rare). Intracranial bleeding causes symptoms referable to the bleeding rather than to the fracture itself.[95,98]

The typical depressed skull fracture is of the "ping-pong" type, an indentation without loss of bony continuity. When forceps are used during delivery, the direct cause of injury may result but is often without complications or sequelae. When neurologic signs are present, direct cerebral injury, intracranial bleeding, or free bone fragments should be suspected.[95,98]

Occipital osteodiastasis, a separation of the cartilaginous joint between the squamous and lateral portion of the occipital bone, occurs during traumatic breech deliveries. This injury results in a posterior fossa subdural hemorrhage that is associated with contusion of the cerebellum.[98] Although a planned breech delivery may be considered depending on the health care provider's experience and the patient's wishes, the American College of Obstetricians and Gynecologists recommends a detailed informed consent that includes risks of neonatal mortality or short-term serious neonatal morbidity should be documented.[8]

DATA COLLECTION

A linear skull fracture usually produces no signs or symptoms unless intracranial bleeding has occurred. Skull x-ray films most frequently demonstrate a parietal fracture. **A depressed skull fracture may be noted by** presence of a visible depression or a palpable "ping-pong" fracture in the parietal or temporal area. No other signs and symptoms are present unless intracranial bleeding or focal irritation of the cortex causes them. **Evaluation with MRI or a CT scan is necessary to delineate the type of fracture and identify complications.**

TREATMENT

No treatment is necessary for a linear skull fracture. Treatment of a depressed skull fracture varies. **If free bone fragments or clots are identified, neurosurgical intervention is necessary.** More conservative approaches are indicated when no complications or neurologic symptoms are present. Noninvasive treatments such as vacuum extractors and breast pumps have been used with success to raise the depressed bone segment. Spontaneous elevation of the depressed fracture has been reported.[98]

COMPLICATIONS

With a linear skull fracture, the single complication to be aware of is a "growing" skull fracture. A dural tear may allow leptomeninges to extrude into the fracture site, setting up the possibility of a leptomeningeal cyst. As the cyst enlarges, the edges of the fracture may fail to fuse and even spread apart, giving the appearance of a "growing" fracture. Palpation and x-ray examination demonstrate the lesion. Surgical correction may be necessary to ensure healing and prevent further complications. With a spontaneous depressed skull fracture, intracranial bleeding and direct cerebral injury with seizures or residual neurologic deficit are rare. Intracranial bleeding, specifically epidural or subdural hemorrhages, is more common when the depressed skull fracture was the result of instrumentation at delivery.[98]

PARENT TEACHING

Parents should be instructed to have the fracture site monitored for several months to ensure that reunion of the bone has taken place. Patients will require no other aftercare unless neurosurgical intervention was necessary or complications developed.

Intracranial Birth Injuries

Three major forms of intracranial bleeding occur: epidural hematoma, subdural hemorrhage, and subarachnoid hemorrhage (Box 26.5). Added to these are cerebellar hemorrhages, cerebellar contusions, and cerebral contusions. Each has its own particular set of signs and symptoms, complications, and sequelae. **Shearing forces may cause trauma** and are covered separately in this chapter.

PHYSIOLOGY AND ETIOLOGY

An *epidural hematoma* is pathophysiologically difficult to form in newborns resulting from a relatively thick dura. When present, it is almost always accompanied by a linear skull fracture across the middle meningeal artery.[98]

Subdural hemorrhage **is more common in term infants than in preterm infants, and occurs from trauma tearing veins and venous sinuses.** Although some assume its presence represents birth trauma, several authors indicate that this is not necessarily the case.[42,95] Subdural hemorrhage has been linked with maternal use of aspirin and also to maternal ingestion of phenobarbital. Four major pathologic entities are defined: (1) laceration of the tentorium, (2) laceration of the fax, (3) laceration

BOX 26.5 CRITICAL FINDINGS
Intracranial Birth Injuries

1. Epidural hematoma
   a. *Occurrence:* Rare.
   b. *Location:* Bleeding occurs into the epidural space. Blood is located between the inner area of skull bone and the periosteum.
   c. *Pathophysiology:* Most (not all) with history of traumatic labor or delivery.
   d. *Clinical findings:*
      - Increased intracranial pressure (swollen fontanel).
      - Seizures may occur.
   e. *Associated problems:* Almost always accompanied by a linear skull fracture.
2. Subdural hemorrhage
   a. *Occurrence:* More common in term infants than in preterm.
   b. *Location:* Bleeding is produced from tear of cerebral vein or sinus, which is often accompanied by a tear in the dura. Exact location of the hematoma depends on the location of the bleeding source.
      - Laceration of the tentorium
      - Laceration of the falx
      - Laceration of the superficial cerebral vein
      - Occipital osteodiastasis
   c. *Pathophysiology:*
      - Debate as to whether its presence indicates birth trauma. Volpe indicates that most cases result from trauma.[98]
      - Linked to maternal use of aspirin and maternal ingestion of phenobarbital.
   d. *Clinical findings:* Neurologically abnormal at birth, if massive bleed:
      - Seizures
      - Stupor or coma
      - Skew deviation of eyes
      - Pupil changes: unequal pupils, poorly responsive pupils, fixed and dilated pupils
      - Nuchal rigidity
      - Apnea and bradycardia
      - Signs of increased intracranial pressure
   e. *Associated problems:* Risk for herniation with lumbar puncture.
3. Subarachnoid hemorrhage
   a. *Occurrence:* Most common type of neonatal intracranial hemorrhage.
   b. *Location:* Blood is within the subarachnoid space but not because of extension from other areas. Small hemorrhages are more common than large ones. Source believed to be small vascular channels.
   c. *Pathophysiology*:
      - Term: Usually caused by trauma
      - Preterm: Usually caused by hypoxia
   d. *Clinical findings:*
      - Most common: Minimal or no symptoms
      - Seizures (especially with term infants): "Well baby with seizures"
      - Apnea (especially with preterm infants)
      - For massive bleed (rare): Sudden and marked deterioration; death
   e. *Associated problems:*
      - Usually none for infants without significant trauma or hypoxia.
      - After major bleed:

      Hydrocephalus (most common sequela)
      Neurologic residual
      Death

of the superficial cerebral vein, and (4) occipital osteodiastasis. Tentorial laceration causes a posterior fossa clot with compression of the brainstem. The straight sinus, vein of Galen, lateral sinus, and infratentorial veins may be involved. Laceration of the falx is caused by rupture of the inferior sagittal sinus. The laceration usually occurs at the junction of the tentorium and the falx, and the clot appears in the longitudinal cerebral fissure over the corpus callosum. Laceration of superficial cerebral veins causes subdural bleeding over the convexity of the brain. Subarachnoid bleeding or contusion of the brain also may be present.[42,95]

A subarachnoid hemorrhage is the most common type of neonatal intracranial hemorrhage. In term infants, trauma is the most common cause, whereas in preterm infants, hypoxia is more often the cause. Small hemorrhages are more common than massive ones and usually result from venous bleeding.[42]

Cerebral contusions are uncommon as an isolated event. Focal blunt trauma is necessary to produce a contusion. Pathologically, focal areas of hemorrhage and necrosis are seen. Shearing forces may cause slit-like tears in the white matter.[98]

Cerebellar contusion is usually seen in association with occipital osteodiastasis and infratentorial

subdural hemorrhage.[98] **Intracerebellar hemorrhage was once thought to be uncommon but more recently has been increasingly found on routine neuroimaging of preterm infants. Intracerebellar hemorrhages are more frequently seen in preterm infants but also can be seen in infants born at term.**[23,61] They are usually associated with a supratentorial hemorrhage but also can be an isolated finding. Although mortality has improved, these infants, especially those with larger lesions, almost always have neurologic deficits.[61]

DATA COLLECTION

For epidural hemorrhage, the signs and symptoms may be diffuse (increased intracranial pressure with a bulging fontanel) and may include focal or lateralizing seizures, eye deviation, and hemiplegia syndromes.[98] **Laboratory tests should include x-ray examination to look for fractures and CT scan or MRI to identify bleeding.**

Infants with subdural hemorrhage are often neurologically abnormal at birth. Tentorial lacerations and laceration of the falx tend to produce brainstem signs caused by pressure. These signs include skew deviation of the eyes, unequal pupils, apnea, or coma. Nuchal rigidity and opisthotonus are signs of progressive herniation. Signs and symptoms of subdural hemorrhage from laceration of the superficial cerebral veins are variable. Small clots may produce no identifiable dysfunction. Typical signs are those of focal or lateralized cerebral dysfunction, including seizures, although increased intracranial pressure may occur. **Cranial MRI, including views of the posterior fossa, should be obtained immediately when a subdural hemorrhage is suspected. If MRI is unavailable, a CT scan is recommended. Lumbar puncture is not used as a diagnostic tool because of the risk for herniation.**[42]

With subarachnoid hemorrhage, underlying contusion may cause focal neurologic signs. Often no significant increase in intracranial pressure is found acutely. Irritability and a depressed level of consciousness may persist. **Seizures are common in term infants, whereas apnea is common in preterm infants.** Diagnosis generally is made with MRI or CT scan. If a lumbar puncture is performed, it is generally done for another reason (e.g., meningitis workup) and shows elevated RBCs and protein.[42] For infants without serious injury from trauma or hypoxia, the prognosis is good.[42] Focal signs predominate in cerebral contusions.[98]

TREATMENT

Surgical evacuation of epidural and subdural clots may be necessary as emergency procedures. Subdural taps may be useful in the symptomatic infant with subdural bleeding from laceration of superficial cerebral veins. In the presence of coagulation defects, prompt intervention may require platelets, vitamin K, or replacement therapy for deficient coagulation factors. **Many infants with intracranial bleeding may require treatment for seizures.**[42]

COMPLICATIONS

The complications of epidural hemorrhage range from none to permanent neurologic deficits with or without seizures. Sequelae of subdural hemorrhage occur in 10% to 20% of affected infants. **The most common sequelae are focal neurologic signs.** Seizures and hydrocephalus are seen less often. **Hydrocephalus, although rare, is the major potential complication of subarachnoid hemorrhage.**[42]

PARENT TEACHING

Because long-term outcome is variable and may be abnormal even in infants who appear normal at discharge from the nursery, parent teaching must be individualized. **Emphasize the need for appropriate follow-up and intervention.** Referral to available support groups is usually beneficial.

Spinal Cord Injuries

PHYSIOLOGY AND ETIOLOGY

Injuries to the spinal cord (usually the lower cervical–upper thoracic portion) are seen most often in complicated breech deliveries. Before cesarean deliveries were routinely performed for breech delivery, fatal attempts to deliver vaginally were often associated with intraspinal hemorrhage. **Breech presentation in conjunction with a hyperextended head is the most dangerous situation and is worsened by fetal depression.** Traction, rotation, and torsion cause mechanical strain on the vertebral column. Cephalic deliveries are not entirely safe because of the difference in

mechanical forces; a different clinical picture is seen with an upper to mid-cervical injury.[42]

DATA COLLECTION

Clinical manifestations depend on the severity and location of the injury. Clinical syndromes include stillbirth or rapid neonatal death, respiratory failure, and spinal shock syndrome. High cervical cord injuries are more likely to cause stillbirths or rapid death of the neonate. Lower lesions cause an acute cord syndrome. **Common signs of spinal shock include flaccid extremities (may involve just the lower extremities if the cervical cord is spared); a sensory level, diaphragmatic breathing; paralyzed abdominal movements; atonic anal sphincter; and distended bladder. Useful laboratory tests include MRI, CT scan, or ultrasound of the spine. Response to pinprick and evaluation of deep tendon reflexes are important to determine sensory level involvement.** The differential diagnosis includes dysraphism, neuromuscular disease, and cord tumors.[42]

COMPLICATIONS

After the acute phase, chronic lesions include cysts, vascular occlusions, adhesions, and necrosis of the spinal cord. **Flaccid or spastic quadriplegia is expected.** Some infants with spinal cord injuries are ventilator dependent, and bowel and bladder problems continue.[98]

PARENT TEACHING

Parents should understand fully the implications of severe injury to the spinal cord. Recovery is frequently minimal to nonexistent. Continued specialized care may be necessary, including ventilator therapy. The overwhelming implications for the family cannot be emphasized strongly enough.

An individualized multidisciplinary team approach to discharge planning is vital to parental confidence and a timely discharge. The problems of both patient and family are complex and not limited to medical concerns. **A successful discharge is unlikely unless family emotional, financial, and educational concerns are addressed early in the planning process.** The timely assessment of needs and involvement of supportive agencies allow resolution of problems well before the projected discharge date. Such assistance should include early family referral to available federal programs for financial aid (e.g., Supplemental Security Income [SSI]) and assistance with patient transportation to their multiple outpatient follow-up appointments. Early assessment of equipment needs and home nursing requirements is also of primary importance and should include a determination of the availability of these resources in the community, parent acceptance of their use, and whether the home can accommodate them (i.e., adequate electrical system and space).

Plexus Injuries

PHYSIOLOGY AND ETIOLOGY

Plexus injuries occur more commonly than cord injuries and result from lateral traction on the shoulder (vertex deliveries) or the head (breech deliveries).[98] Risk factors include large infant, fetal depression, breech delivery, and a variety of obstetric factors. **Any factor resulting in a difficult vaginal delivery of the baby can increase the risk for injury** (e.g., prolonged second stage of labor, shoulder dystocia),[95,98] although factors may not be in control of the delivery provider.[98] Estimates of the incidence of brachial plexus injuries range from 0.5 to 2.5 per 1000 live births.[98] Extremely mild cases often have undetectable findings and may remain unidentified.

Pathologic changes range from edema and hemorrhage of the nerve sheath to actual avulsion of the nerve root from the spinal cord. Of the reported cases of plexus injuries, 90% involve the cervical nerve 5 (C5) to C7 nerve roots and are classified as Erb palsy.[98] In a small minority of cases, the C4 nerve root is also affected. The site of injury in Erb palsy is Erb palsy point, where C5 and C6 nerve roots join to form the upper trunk of the brachial plexus. The shoulder and upper arm are involved, and the biceps reflex is decreased or absent. When C4 is involved, diaphragmatic dysfunction is present.

Total brachial plexus palsy occurs in less than 10% of the cases. Plexus involvement is diffuse (cervical 5 [C5] to thoracic nerve 1 [T1] and occasionally C4). **The upper and lower arm and hand are involved. Biceps and triceps reflexes are decreased.** When T1 is involved the sympathetic fibers become affected with an ipsilateral *Horner syndrome* (ptosis, anhidrosis, and miosis) and possible delay in pigmentation of the iris.

Klumpke palsy rarely occurs in the newborn period and involves only the distal upper extremity (lower arm and hand), whereas the muscles in the proximal extremity are normal. The lower part of the

plexus, C7 to T1, is involved. Triceps reflex may be decreased. When both distal and proximal weakness occur, it should be classified as total plexus palsy.[98]

DATA COLLECTION

Signs of brachial plexus palsies vary somewhat, most often because of the overlap of pure clinical syndromes. **Shoulder and arm findings are characteristic of a true Erb palsy.** Involvement of the hand and fingers is seen in total forms or Klumpke palsy. Table 26.3 lists the specific spinal cord levels involved, as well as their various functions that might be assessed.

Evaluation of diaphragmatic function by real-time ultrasound is at times necessary. Spinal cord MRI may be necessary to identify nerve root avulsion, which generally should be suspected when recovery does not occur. Serial electromyography may be helpful in the evaluation process.[98]

TABLE 26.3 BRACHIAL PLEXUS EXAMINATION: DISTINGUISHING FEATURES

PART EXAMINED	SPINAL LEVEL
Diaphragm movement (downward)	C4 (C3-5)
Deltoid muscle	C5
Spinatus muscle	C5
Biceps muscle	C5-6
Brachioradialis muscle	C5-6
Supinator of arm	C5-6
Biceps tendon reflex	C5-6
Wrist extensors	C6-7
Long extensor of the digits	C6-7
Triceps tendon reflex	C6-7
Wrist flexor	C7-8, T1
Finger flexors	C7-8, T1
Dilator of iris (sympathetic chain, *Horner* syndrome)	T1
Eyelid elevator (full elevation) (same as above condition)	T1
Moro reflex (shoulder abduction)	C5
Moro reflex (hand motion)	C8-T1
Palmar grasp	C8-T1

C, Cervical; *T*, thoracic.

TREATMENT

Treatment includes passive range-of-motion exercises followed by a gradual increase of activity to the affected limb. Initially, treatment may include immobilization for 1 to 5 days, followed by gentle passive range-of-motion exercises to prevent contractures. Wrist splints also may be necessary. For infants failing to achieve sufficient functional recovery by 3 months of age, referral to a clinic specializing in brachial plexus injury should be considered. Rarely, nerve graft surgery of the injured nerve root is necessary.[98]

COMPLICATIONS

Associated trauma may occur and should be carefully investigated. **Common associated injuries include clavicle fracture, shoulder dislocation, cord injury, facial nerve injury, and humeral fracture.**[98] Full recovery of plexus function was seen in 88% to 92% of cases in the first year of life during the National Collaborative Perinatal Study.[59]

PARENT TEACHING

Parents should be taught passive range-of-motion exercises to encourage the infant's mobility and prevent contractures. Instructions should begin before discharge from the hospital. Usually a neonatal nurse or occupational or physical therapist gives the instructions.

Parents may equate the presence of a brachial plexus injury with poor obstetric care. This is often not the case. Good communication with parents concerning the variety of risk factors associated with plexus injuries will hopefully alleviate their concerns. Discharge follow-up should include appointments with neurology, physical therapy, and rehabilitative medicine.

Cranial and Peripheral Nerve Injuries

Median nerve injuries usually are postnatal and result from brachial and radial artery punctures. Sciatic nerve injury may be a result of inferior gluteal artery spasm or thrombosis (umbilical artery line drug instillation). Recovery is variable.[98]

Median nerve palsy is manifested by decreased pincer grasp, decreased thumb strength, and the continuous fixed position of the fourth finger. *Radial nerve damage* usually is seen in conjunction with humeral compression or less frequently humeral fracture. Difficult labor may be present.

Congenital amniotic bands also may be causative. Recovery takes place over weeks to months. Radial nerve palsy is manifested by wrist drop (decreased finger and wrist extension) and normal grasp.[98]

Laryngeal nerve palsy may be seen in conjunction with facial or diaphragmatic paralysis. **If the paralysis is unilateral, a hoarse cry may be heard. Bilateral involvement causes breathing to be difficult and the vocal cords to remain closed in the midline.** In these cases, it is essential to rule out intrinsic brainstem disease. Often the presence of other brainstem-related abnormalities such as oculomotor problems, apnea, or facial palsy helps clarify this. In-utero rotation and flex positioning of the head/neck or during delivery may cause injury to the laryngeal nerve. **Laryngeal nerve palsy may also occur after trauma associated with a patent ductus arteriosus ligation, cardiac surgery, placement of neck cannulas for extracorporeal membrane oxygenation and tracheoesophageal atresia repair.**[98]

Laryngeal nerve palsy is manifested by difficulty in swallowing (superior branch), difficulty in breathing (bilateral), and difficulty in vocalizing (recurrent branch). Also, the head is held high and fixed laterally with slight rotation. Severe cases may require tracheotomy and assisted feedings by gavage or gastrostomy tube.[98]

***Diaphragmatic paralysis* is most often seen in association with plexus injuries (80% to 90% have an associated plexus injury) and has the same etiology.** Some series involving unilateral paralysis have a mortality rate of 10% to 20%. **Most patients recover fully in 6 to 12 months.** Although fewer than 10% of patients have bilateral diaphragmatic paralysis, the mortality rate for these patients is almost 50%. Treatment has consisted of using continuous positive airway pressure (CPAP), ventilators, intermittent negative-pressure ventilation, or surgical plication. Because diaphragmatic paralysis may occur in other conditions such as a myotonic dystrophy, attention to the differential diagnosis is important, particularly when an associated brachial plexus problem is not present.[98]

Diaphragmatic paralysis is demonstrated by respiratory difficulty in the first few hours of life. Real-time ultrasound or fluoroscopy shows elevation of the hemidiaphragm with paradoxic movement that may disappear on positive end-expiratory pressure (PEEP) or CPAP.[98]

Facial palsy may be part of intrinsic brainstem disease (see previous discussion of laryngeal nerve palsy), prenatal compression, trauma, malformation of the nerve itself, or other conditions such as Möbius syndrome or myotonic dystrophy. When it is traumatic in origin, facial palsy is thought to be caused by the position of the face on the sacral promontory at the exit of the nerve from the stylomastoid foramen.[98] Normally, both the upper (temporofacial) and lower (cervicofacial) branches are involved. **Facial palsy is seen on the left side in 75% of cases. Features include a widened palpebral fissure, flat nasolabial fold, and decreased facial expression. Most infants completely recover within 3 weeks, although some infants continue to have deficits months later.** Known complications (from lack of total resolution) include contractures and synkinesis.[98]

PARENT TEACHING

Infants with facial palsy may require the **use of artificial tears if unable to completely close the eye on the involved side.** Occasionally it may be necessary to tape the eye to prevent injury to the cornea. **Parents also should be taught to expect some drooling of formula from the corner of the mouth during breast or bottle feedings.**

Most infants with laryngeal nerve palsy recover in the first 6 to 12 months of life. **Symptoms initially require supplemental parent education and support. An infant's risk for aspiration necessitates careful feeding and appropriate response if choking occurs.** Additional education for gavage feedings, a tracheotomy, or an apnea monitor may be necessary for the parents of a few infants. The teaching requirements for the infant with diaphragmatic paralysis also must be tailored to meet the individual needs and circumstances of the infant and family.

HYPOTONIA

Hypotonia is a common presenting symptom in the newborn. It is important to distinguish between hypotonia and muscle weakness. **The majority of infants with hypotonia have a cause centered in the CNS.** In these cases, hypotonia is more prominent than weakness. Hypotonia might be due to a congenital encephalopathy (HIE being the most common), intracranial hemorrhage, a congenital

brain malformation, metabolic disorder, or genetic mutation.[86] Causes of motor weakness may involve cranial nerve motor nuclei (as in Möbius syndrome), anterior horn cells (as in spinal muscular atrophy), spinal cord injury (causing severe weakness), peripheral nerves, the neuromuscular junction (neonatal myasthenia gravis), or muscle itself (myotonic dystrophy, congenital myopathy, muscular dystrophy).[60,86,100]

Data Collection

A cranial MRI is performed to evaluate for a CNS cause for hypotonia. If this is normal, investigation then turns to other causes. Physical examination may reveal congenital abnormalities and, in such cases, consideration should be given to performing a chromosomal microarray.[67] Next-generation genome sequencing (NGS) also has become a powerful tool in revealing causes of hypotonia. Discussion with a medical geneticist or a genetic counselor can be helpful in directing testing.[78] Creatine kinase (CK) level that is quite elevated may determine a dystrophic process, with breakdown in muscle fibers. The CK is modestly elevated for a few days after vaginal birth. An aldolase level rarely adds additional information and is not necessary. A lumbar puncture can be performed to look for elevated CSF protein seen in demyelinating syndromes. **Genetic testing for myotonic dystrophy and spinal muscular atrophy are readily available** and should be performed if clinically indicated. When myotonic dystrophy is suspected, both parents should be examined for myotonia, which can be helpful in diagnosing their infant with the same disorder. **An electromyogram (EMG) and nerve conduction study (NCS) can be performed to help determine whether weakness is due to a nerve or muscle problem.** EMGs are difficult in newborns and require a skilled examiner. A muscle biopsy can be performed if absolutely necessary, although many times it is more helpful when the infant is older. Additionally, because many genetic causes of hypotonia demonstrate overlapping pathologic findings on biopsy, genetic testing may provide more precise diagnosis.[14,75] In general, DNA-based testing should be performed as first-line testing while NCS and EMG are reserved for cases in which genetic testing is unrevealing.[60,67,78,86]

Parent Teaching

Parent teaching will depend on the infant's diagnosis. In general, **infants who have a neuromuscular disorder have respiratory and feeding issues.** These infants may need ventilatory assistance and nasogastric or gastrostomy tube feedings. Physical and occupational therapy should be involved to help with positioning and recommending equipment for the family at home. In the case of a genetic disorder, genetic counseling should be provided to the family. Rarely, an infant with hypotonia will be found to have a diagnosis that is considered life limiting.[78] In such cases, involving a specialist in palliative care can be very helpful for families as they navigate challenging decisions with the medical team.[53,62]

NEONATAL SEIZURES

Seizures are among the most frequent clinical signs, occasionally the only sign, of CNS dysfunction in neonates. The occurrence of neonatal seizures should prompt an immediate search for the underlying etiology as well as an overall assessment of associated medical disorders. Depending on the clinical history, suspected etiology, and seizure frequency, use of antiepileptic medications may be indicated in addition to correcting any underlying metabolic disturbances.

The overall incidence of neonatal seizures is difficult to ascertain, in part because the incidence varies in relation to gestational age and birth weight. For infants weighing less than 1500 g, the seizure frequency is 57.5 per 1000, whereas it is 2.8 per 1000 for infants weighing 2500 to 3999 g. **Seizures occur more frequently during the neonatal period than at any other period of life.**[1,37,93]

Neonates with seizures are at increased risk of having or developing other neurologic deficits, developmental impairments, and an increased risk of death.[36,89] **Aggressive seizure management improves the infant's neurologic and developmental outcome.**[1] **The occurrence of neonatal seizures may also predispose the child to later cognitive and behavioral complications as well as epilepsy.**[37,89] Outcome is largely dependent on the underlying cause of neonatal seizures.

Recognition and treatment of neonatal seizures and their underlying etiology are critical

to improving the child's short- and long-term outcomes. Seizures are commonly related to significant general medical disorders, which may also require specific treatment. Untreated neonatal seizures may interfere with supportive therapies such as assisted ventilation and nutrition. **Experimental data suggest that repetitive or prolonged seizures may cause brain injury and contribute to an adverse clinical outcome.**[3]

Epileptic seizures are the result of excessive synchronous electrical discharges from neurons within the CNS. **In general, neonatal seizures should be viewed not as a specific disease entity, but as a symptom. There are a number of epileptic encephalopathies that may present in the neonatal period, but overall these are rare.**[35] **Seizures may be associated with many disorders that directly or indirectly affect the brain by altering its electrochemical stability.** Intracranial processes that may result in neonatal seizures include meningitis, intracranial hemorrhage (subdural, intraventricular, primary subarachnoid), ischemic cerebral infarction (stroke), encephalitis, and cerebral malformations.[89,93]

Seizures also occur secondary to systemic or metabolic disturbances, including hypoglycemia, hypoxia-ischemia, hypocalcemia, hypomagnesemia, hyponatremia, drug intoxications, drug withdrawal, and inborn errors of metabolism.[10,22] A link between intrapartum fever and unexplained seizure activity in term infants also has been reported in the literature. Presence of fever increased the likelihood of seizure activity by four times normal even when the presence of an infection was not confirmed.[89,95]

Clinically, seizures are characterized by a paroxysmal alteration in neurologic functions, including behavioral, motor, or autonomic functions. These clinical signs are typically accompanied by electrical abnormalities detectable by scalp EEG recordings. A large proportion of neonatal seizures may be subclinical or subtle and only identified on EEG.[16,37] **Clinical presentation of seizures in neonates differs considerably from the well-organized seizure activity seen in older children and adults.**

Etiology and Data Collection

Neonatal seizures may be caused by a variety of acute and chronic disorders of the brain. Table 26.4 lists the general groups of causes of neonatal seizures. A detailed history of perinatal problems

TABLE 26.4 COMMON CAUSES OF NEONATAL SEIZURES

CLASSIFICATION	CAUSES
Acute metabolic conditions (assess blood gases, pH, HCO_3^-, Na, K, Ca, Mg, glucose, blood urea nitrogen)	Hypocalcemia Hypoglycemia, hyperglycemia Hypomagnesemia Pyridoxine dependency or deficiency Hyponatremia, hypernatremia
Inherited metabolic conditions (acidosis is common; assess blood amino acids, blood lactate and pyruvate, blood ammonia [NH_3] galactose, and urine amino and organic acids)	Maple syrup urine disease Nonketotic hyperglycemia Hyperprolinemia Hyperglycinemia Galactosemia Urea cycle abnormalities Organic acidemias
Infections (12% of cases; assess CSF; culture blood, CSF; polymerase chain reaction assay in CSF; imaging)	Viral encephalitis, herpes or enterovirus infection Congenital infections Bacterial meningitis Sepsis Brain abscess Septic venous thrombosis
Intracranial hemorrhage (15% of cases; assess imaging; CSF examination)	Subdural hematoma Cerebral contusion Subarachnoid hemorrhage Epidural hemorrhage Intraventricular hemorrhage (premature)
Hypoxic ischemia (0-3 days) most common (60%) Cerebral infarction Congenital malformations Neonatal drug withdrawal (see Chapter 11) (e.g., opiates) Local anesthetic intoxication Kernicterus Specific nongenetic syndromes Benign familial neonatal seizures Idiopathic (in only 10%, no cause is found)	

CSF, Cerebrospinal fluid.

often narrows the differential diagnosis to one or two likely causes. **Acute, reversible, or treatable metabolic disorders that can cause seizures need to be investigated quickly.** Blood glucose should be checked immediately in the neonatal intensive care unit with a glucometer, and also in the laboratory, because hypoglycemia is a dangerous but treatable cause of seizures (Table 26.5).

Lumbar puncture should be done to diagnose or exclude bacterial meningitis, another dangerous but treatable cause of seizures. Sepsis should never be overlooked as a potential cause of seizures because the responsible infectious agent may directly invade the CNS. Systemic infections may also cause seizures through complications such as shock,

TABLE 26.5 DRUG THERAPY FOR NEONATAL SEIZURES[4]

DRUG	DOSE	COMMENTS
Glucose	10% solution 2 mL/kg bolus IV if hypoglycemic. *Maintenance:* as high as 8 mg/kg/min IV (see Chapter 15).	Treat if hypoglycemic with glucose meter testing (e.g., Accu-Chek; One Touch II).
Phenobarbital (drug of choice for neonatal seizures)	*Loading:* 20 mg/kg IV given slowly over 10-15 min; additional 5 mg/kg can be given 1 hour after dose to maximum of 40 mg/kg total for refractory seizures.	*Therapeutic level:* 15-40 mcg/mL (obtain levels any time); respiratory depressant; incompatible with other drugs in solution.
	Maintenance: 3-4 mg/kg/24 hr in 2 divided doses beginning no earlier than 12 hours after last loading dose.	Maintain adequate oxygenation and ventilation.
Fosphenytoin (Cerebyx) preferred over phenytoin* (added if seizures not controlled by phenobarbital alone)	Fosphenytoin dose is expressed in PE; fosphenytoin 1 mg PE = phenytoin 1 mg. *Loading:* 15-20 mg PE/kg IM or IV† given slowly over minimum of 10 min. Flush IV with normal saline before and after.	*Fosphenytoin advantages:* high water solubility; pH value closer to neutral; faster, safe rate of administration; safe to give IM; absence of tissue injury with IV infusion; easy to prepare in IV solution. *Therapeutic level:* measure trough serum phenytoin (not fosphenytoin) 48 hr after IV loading dose; 10-20 mcg/mL desirable level.
	Maintenance: 4-8 mg PE/kg/24 hr IM or IV slow push (see above for dilution); infuse no faster than 1.5 mg/kg/min. Flush IV before/after with NS. Maintenance should be initiated 24 hr after loading dose. Term infants older than 1 wk of age may need up to 8 mg PE/kg/dose every 8-12 hr.	Monitor blood pressure closely during infusion; can be given with lorazepam or phenobarbital at terminal injection site. Safety with newborns still not clearly established; use with caution in infants with hyperbilirubinemia.
Phenytoin used instead of Cerebyx to control seizures that are not controlled by phenobarbital alone	Loading: 15-20 mg/kg IV infusion over at least 30 min (no more rapidly than 0.5 mg/kg/min). Flush with NS before and after giving. ***Never give IM.*** ***Never give in central lines.*** *Maintenance:* 4-8 mg/kg/24 hr‡ IV slow push (no more rapidly than 0.5 mg/kg/min) or by mouth (PO). Flush with NS before and after. Absorption erratic with PO route. Term infants older than 1 week of age may need up to 8 mg/kg/dose every 8-12 hr.	Phenytoin disadvantages: incompatible with glucose and all other drugs; cannot be given IM (crystallizes in the muscle); rapid administration can result in bradycardia, dysrhythmias, hypotension. The pH of IV solution is 12, which is irritating to veins. Extravasation may result in tissue necrosis. *Therapeutic level:* measure trough level 48 hr after loading dose. Serum level 6-15 mcg/mL initially and 10-20 mcg/mL after the first few weeks.

TABLE 26.5 DRUG THERAPY FOR NEONATAL SEIZURES[4] — CONT'D

DRUG	DOSE	COMMENTS
Pyridoxine (vitamin B_6) as indicated	50-100 mg IV push or IM.	Used to diagnose and treat seizures resulting from pyridoxine (vitamin B_6 deficiency). Monitor EEG while giving. Protect from light. Diagnostic when seizures cease within minutes and the EEG normalizes within minutes or hours.
Lorazepam (Ativan) for seizures uncontrolled by phenobarbital and fosphenytoin (or phenytoin if used)	0.05-0.1 mg/kg IV slow push over several min.	Enters brain rapidly; onset of action in less than 5 min. Monitor for respiratory depression. Monitor IV site for phlebitis or extravasation. Safer to use than diazepam (Valium), which is contraindicated for use in the newborn.
Additional Therapy As Indicated		
Calcium gluconate, 5% solution Magnesium sulfate, 50% solution IV antibiotics (bacterial infection; see Chapter 22) Acyclovir (herpes; see Chapter 22)		

*Appears to be preferred, although safety has not been clearly established.
†Must be diluted in NS or D_5W to a concentration of 1.5 to 25 mg PE/mL for IV use.
‡Volpe cites 3 to 4 mg/kg/24 hr IV in divided doses every 12 hr, starting 12 hr after loading dose.[4]
EEG, Electroencephalogram; *IM,* intramuscularly; *IV,* intravenously; *mcg,* micrograms; *NS,* normal saline; *PE,* phenytoin equivalents.

coagulopathy, impaired oxygenation, and multisystem organ failure. When the CSF is examined, not only should the changes associated with infection be identified but also evidence of bleeding (RBCs) or cell destruction (protein) may be detected. **Peripheral blood glucose always should be compared to CSF glucose *at the time of lumbar puncture***. When the ratio of CSF glucose to peripheral blood glucose is less than 60% or CSF glucose is less than 40 mg/mL, consideration should be given to a diagnosis of glucose transporter 1 (GLUT1) deficiency.[93]

Neuroimaging studies are performed to detect underlying structural lesions. If the infant's clinical status allows safe transport to radiology, MRI or CT imaging can be done. **If the infant cannot be transported safely, cranial ultrasound (CUS) imaging can be done at the bedside.** CUS can detect IVH, periventricular white matter injury, hydrocephalus, and other structural lesions related to seizures.

The infant's clinical history may be the best tool available to the clinician for identifying the etiology. Physical examination may provide further clues to the diagnosis. Blood should be drawn for assessment of arterial blood gases, electrolytes, glucose, calcium, and magnesium.

Appropriate cultures must be obtained of blood, urine, pharyngeal and tracheal aspirates, and CSF. The CSF should be examined for red and white cells, protein concentration, glucose concentration, and Gram stain. In addition, viral cultures and polymerase chain reaction tests may be ordered.

In addition to its initial contribution to identifying the etiology of seizures, **CUS imaging can be used to monitor the evolution of IVH and hydrocephalus.** With ultrasound imaging the infant is not exposed to radiation, and there are no known immediate or long-term risks or complications. **CUS may be repeated as often as needed and has the advantage of being performed at the infant's bedside.**

TABLE 26.6 CRITICAL FINDINGS
Traditional Categorization of Neonatal Seizures

CLASSIFICATION/TYPES	CLINICAL MANIFESTATIONS	DEFINITION/DESCRIPTION
Clonic • Focal clonic • Multifocal clonic	• Rhythmic jerks (1-3/sec) • Rate slows during seizure • + EEG seizure activity	• Focal: well-localized to a body part • Multifocal: several body parts jerking simultaneously or in migrating order
Tonic • Focal tonic • Generalized tonic	• Characterized by posturing • Focal: + EEG seizure activity • Generalized: usually no EEG seizure activity	• Focal: continued posturing of limb or a posturing (asymmetric) of trunk or neck • Generalized: extension of lower limbs with either upper limb extension (looks like decerebrate posturing) or upper limb flexion (looks like decorticate posturing)
Myoclonic • Focal myoclonic • Generalized myoclonic	• Faster jerking than in clonic seizures • Flexor muscles (limbs) involved • Focal: usually no EEG seizure activity • Generalized: + EEG seizure activity	• Focal: flexor jerking of upper limbs • Generalized: bilateral jerking of upper extremities; sometimes lower limbs are involved; often single or irregular jerks
Subtle (more common in the premature infant)	• Abnormal behavioral, autonomic, or motor activities that do not result from the other three seizure classifications • + EEG seizure activity with only some of the seizure activities	• Ocular: nystagmus, horizontal or vertical deviation of eyes, staring episodes, eyelid flutter or blinking • Facial: repetitive sucking, mouth movements, tongue protrusion, chewing, drooling • Limb: bicycling, swimming movements, "boxing" or "hooking" motions, stepping • Apnea: only 2% result from seizures • Autonomic or vasomotor changes

EEG, Electroencephalogram.

Clinical Seizure Types

The use of continuous EEG video recordings and continuous amplitude-integrated EEG recordings allows for a more accurate diagnosis of subtle behaviors, apneic and bradycardic spells, and other jerks and movements commonly seen in preterm newborns and suspected of being epileptic seizure activity. Amplitude-integrated EEG, while convenient, may lead to under-detection of seizures. **Full-set video EEG, with review by a pediatric epileptologist, should be performed whenever feasible and continues to be the gold standard for identification of neonatal seizures.**[1,16,37]

Seizures result from abnormal, excessive electrical discharge or depolarization of cortical neurons. They are most often manifestations of an underlying disorder, rather than being an isolated disorder. As a paroxysmal alteration of neurologic function, these behavioral, motor, or autonomic clinical phenomena are associated with EEG electrical seizure activity. Table 26.6 lists the classification of clinical seizure types and usual EEG findings. **Many neonatal electrical seizures identified by EEG are not accompanied by any motor or behavioral clinical activity, a phenomenon referred to as subclinical seizure activity or electroclinical dissociation.**

Focal clonic and multifocal clonic seizures are the most likely types of seizure activity to be associated with an electrocerebral seizure pattern on EEG. Eye blinking, a type of clonic manifestation, or nystagmus may be seen as the only outward manifestation of a seizure. **Focal clonic seizures are important manifestations of cerebral infarction and stroke in the neonate. Apnea accompanied by electrical seizure activity has been seen as an ictal manifestation, most commonly in full-term infants.** Apneic episodes in the premature population, however, are most often not epileptic events and are not associated

TABLE 26.7 CRITICAL FINDINGS
Seizures Versus Jitteriness

CLINICAL OBSERVATIONS	SEIZURE	JITTERINESS
Ocular abnormalities (eye deviations or staring)	Yes	No
Gentle restraint of the involved body part halts the activity	No	Yes
Activity is easily elicited with stimulation (e.g., voice, motions)	No	Yes
Dominant movement is a slower clonic jerking having both fast and slow elements	Yes	No
Tremor in which the amplitude and rate of the alternating movements are equal	No	Yes
Autonomic changes are present (e.g., apnea, tachycardia, elevated blood pressure, pupil changes, increased salivation)	Yes	No

with epileptiform EEG patterns. **The best EEG-clinical correlation can be made by obtaining an EEG during a period of the suspected seizure activity.**[4,16,37]

A commonly used classification of neonatal seizures is presented in Table 26.6. The classification of neonatal seizures is distinct from the International Classification of Seizures applicable to seizures in older children and adults. **Seizures are more subtle and more difficult to recognize in neonates than in older infants and children.** Further compounding the difficulty of diagnosis are **conditions that mimic epileptic neonatal seizures, such as neonatal jitteriness** (Table 26.7).[3,16]

Prevention

Many neonatal seizures can be successfully prevented through careful attention to possible metabolic changes expected on the basis of the infant's condition. Hypoglycemia, hypocalcemia, hypomagnesemia, and often hypoxia can be anticipated and controlled. Those infants born with brain malformations or brain injuries or who develop neonatal infections, intracranial hemorrhages, or strokes can be observed carefully for the early occurrence of seizures and treated promptly.

Treatment

The initial treatment of neonatal seizures involves stopping seizure activity with a loading dose of an antiepileptic medication, preventing further seizures with maintenance doses of medication, minimizing side effects of seizure therapy, and correcting underlying treatable conditions.

The first goal is stopping repetitive or prolonged seizures. **Frequently recurring and prolonged or persistent seizures may result in injurious metabolic changes in the brain and also lead to cardiorespiratory difficulty.** Seizures are associated with increased energy consumption by neurons, which may interfere with cerebral perfusion and adequate oxygenation. Although the neonatal brain appears to be less sensitive to seizure-induced injury than the adult brain, **repeated seizures may nevertheless be detrimental to the developing nervous system.**[37]

Phenobarbital continues to be recommended as first-line treatment for neonatal seizures. The debate over the best choice of second-line treatment continues, with fosphenytoin and levetiracetam being mentioned frequently (see Table 26.5). **Levetiracetam,** in particular, has gained popularity because of its effectiveness at high doses and relatively benign side effect profile.[64] Other medications such as lorazepam, midazolam, and topiramate are being used with increasing frequency. **When the administration of a single drug fails to result in seizure control, a second or third antiepileptic medication is indicated. Both phenobarbital and fosphenytoin are given initially as an intravenous loading dose of 20 mg/kg,** which produces a therapeutic blood concentration in most infants. Subsequent to the loading dose, maintenance doses of phenobarbital can be continued using doses typically between 3 and 5 mg/kg/day, orally or intravenously. Because the **half-life of phenobarbital in neonates is 40 hours or more, monitoring blood levels can be helpful in guiding dosing frequency and in avoiding dose-related, systemic side effects and neurotoxicity.**

Intravenous levetiracetam in a loading dose ranging from 20 to 60 mg/kg per dose also may be used. Dosing guidelines for levetiracetam have not been well established, but a recent prospective study suggested doses of 45 to 60 mg/kg/day for persistent seizures. This is consistent with the American Epilepsy Society's recent guideline for the treatment of status epilepticus, which suggests levetiracetam be dosed at 60 mg/kg.[31,38,55,64]

The duration of prophylactic antiepileptic therapy is based on the severity and frequency of seizures as well as the presence of other neurologic impairments. **A common approach is to treat with antiepileptic medications for several weeks or months after the child is discharged,** and then reassess the need for continued therapy. Increasingly, medications are being discontinued before patients leaving the hospital, especially when hypoxic ischemic encephalopathy is considered causative.[32,71]

The identification and correction of underlying treatable conditions will assist in seizure management. Empirical administration of glucose, calcium, and pyridoxine may be considered, particularly for frequently recurring seizures or seizures refractory to antiepileptic medications. For seizures that remain refractory to usual therapy, genetic testing may be considered to determine whether the infant has an identifiable gene mutation related to neonatal or early infantile seizures, such as mutations affecting sodium channels, potassium channels, or gamma-aminobutyric acid (GABA) receptors. Knowing that such a mutation is present may assist in selecting antiepileptic drugs that will be most beneficial or in avoiding drugs that might worsen seizure activity.[78]

Complications and Outcome

It is difficult to separate potential deleterious effects of seizures from those of the underlying cause. Some of the **metabolic disorders, such as hypocalcemia, are relatively benign conditions that once corrected allow full recovery without complications.** In contrast, **seizures related to cerebral malformations, hypoxic-ischemic injury, stroke, IVH, or meningitis are likely to persist and evolve into epilepsy.**[34,79,94] Those infants who have an abnormal neurologic examination or who have severely abnormal EEG patterns, such as burst-suppression or diffuse very low voltage, are likely to have seizures that persist into later childhood and beyond.

Parent Teaching

Parents need to know what seizures are and what may be the cause of seizures in their infant. Accurate information should address the specific concerns of each parent. Appropriate first aid measures should be discussed to ensure that the parents have a clear understanding of how their child is being treated in the nursery and how parents will need to manage seizures should they occur after the infant goes home. Parents need to know the significance of tests (e.g., EEG and brain imaging tests), the limitations of these tests, and how future tests will be used to monitor the child's condition. **Parents also need information about the different types of seizures that can occur during early infancy. While the child is still in the nursery, the parents need to be educated on how to recognize and document seizure activity** (Box 26.6). **Handouts written in a clear simple style are useful when parents are learning to care for an infant with seizures. Handouts should be available in a variety of languages to meet the needs of a diverse population.**

While the infant is in the hospital, the parents should become involved in the daily care, including administering medications. In the hospital, parents can be coached and encouraged by the nursing staff. During this time, the parents also can be informed about local and national parent support groups and organizations designed to assist and support families after their infant is discharged from the hospital.

HYPOXIC-ISCHEMIC ENCEPHALOPATHY

Pathophysiology

The combination of hypoxia and ischemia is a common cause of brain injury in both term and preterm neonates. *Hypoxemia* refers to low levels of oxygen in the blood and potentially in brain tissue. *Ischemia* refers to a reduction in cerebral perfusion. *Asphyxia* is impaired exchange of oxygen and carbon dioxide across the respiratory organ (placenta before birth, lungs after birth) resulting

in comorbidities, low levels of circulating oxygen, and high levels of carbon dioxide. **When comparing hypoxemia and ischemia, ischemia is more devastating** because there is impaired delivery of oxygen and glucose to cerebral tissue and impaired removal of lactate and other neurotoxic byproducts of cellular metabolism.[76]

Brain injury due to hypoxemia and ischemia occurs in two phases.[37,96] **Tissue is first injured directly by the initial lack of oxygen and blood flow that leads to a decrease in high-energy phosphate compounds and acidosis. During the second phase, reperfusion injury occurs 8 to 16 hours after oxygenation and perfusion has been restored.** This second period of injury relates to a secondary decrease in high-energy phosphate compounds. During this secondary phase, metabolic derangements develop that lead to further brain injury as a result of elevation in tissue glutamate levels, release of neurotoxic cytokines, inflammation, impairment of mitochondrial function, and generation of free radicals. **The period between the primary phase of injury and the secondary phase is the *therapeutic window* for potential neuro-protective interventions.**[96]

Etiology

Impaired placental or pulmonary function (i.e., asphyxia) is a common, but rarely the only, cause of HIE. HIE occurs in approximately 1 to 2 neonates per 1000 live births with about one-third of these neonates demonstrating significant neurologic sequelae.[68] About 20% of cases are related to antepartum events, such as maternal hypertension, maternal diabetes, or intrauterine growth restriction. About 35% are related to intrapartum events, including placental abruption, cord prolapse, or traumatic delivery; and about 10% are related to postnatal cardiopulmonary failure. **In approximately 35% of cases, there are combinations of antepartum and intrapartum difficulties.**

Guidelines have been published by the AAP and the American College of Obstetrics and Gynecology regarding criteria needed to attribute neurologic injury to intrapartum HIE[7]:

1. **Metabolic acidosis is severe with pH <7.0 and base deficit ≥12 mmol/L.**
2. **The neonate (34 weeks of gestation or later) should have displayed a significant, moderate to severe encephalopathy during the neonatal period.**
3. **For cerebral palsy to be attributed, it should either be spastic quadriplegia or dyskinetic type.**

Other potential causes of neonatal encephalopathy (meningitis, encephalitis, genetic conditions, or thrombophilic disorders) should have been excluded. In addition to these major criteria, **the task force considered the following to be suggestive of timing to the intrapartum period**[6]: **(1) a sentinel hypoxic event** occurring immediately before or during labor; (2) **a sudden and sustained fetal bradycardia or absence of fetal heart rate variability in the presence of persistent, late, or variable decelerations,** usually after a hypoxic sentinel event when the pattern was previously normal; (3) **Apgar scores of 0 to 3 at 5 minutes or more after birth;** (4) **multisystem involvement with an onset within 72 hours of birth;** and (5) **the presence of evidence of acute, nonfocal cerebral abnormality shown on an early imaging study.**

Prevention

Preventing HIE requires the early anticipation, avoidance, and early treatment of those conditions (antepartum, intrapartum, or immediate postpartum) that lead to impaired oxygen delivery and blood flow to the brain. For example, the early detection and treatment of chorioamnionitis may reduce the risk of cerebral injury related to circulating cytokines. **Postpartum cardiopulmonary support is essential to reducing the risk of CNS injury. Keeping blood glucose levels normal is important** because both high and low levels may be deleterious in the setting of HIE.

Data Collection

HISTORY

The diagnosis of HIE depends in part on a detailed history of the antepartum, intrapartum, and postpartum events, as well as a thorough physical examination. Infants may have a history of intrauterine distress evidenced by abnormal fetal heart rate patterns or sudden cessation of movements. The infant may be depressed at birth or have low Apgar scores that persist beyond 5 or 10 minutes. Multiorgan damage may be evident, and there are signs of a significant encephalopathy.

TABLE 26.8 CRITICAL FINDINGS
Stages of Hypoxic-Ischemic Encephalopathy and Neurologic Assessment[7,61,89]

STAGE	NEUROLOGIC ASSESSMENT
Stage I: Mild encephalopathy	Hyperalert, with normal tone and activity, exaggerated response to stimulation, reactive pupils, no seizure activity
Stage II: Moderate encephalopathy	Hypotonic, weak suck, constricted but reactive pupils; periodic breathing or apnea Development of seizure activity or lethargy indicates deteriorated status
Stage III: Severe encephalopathy	Stupor or coma, absent reflexes, pupils nonreactive, no spontaneous activity, requires mechanical ventilation

SIGNS AND SYMPTOMS

The diagnosis of HIE also may be supported by physical findings indicative of encephalopathy[6,47] (Table 26.8). **HIE is also suspected when seizures occur within the first 12 hours after birth.**

LABORATORY DATA

Laboratory information often reflects multisystem dysfunction, including altered electrolyte concentrations, elevated hepatocellular enzymes, altered liver function tests, abnormal renal function tests, and abnormal coagulation studies. **Blood gases may provide evidence of hypoxemia, hypercarbia, and either metabolic or respiratory acidosis, or both. The ECG may be indicative of hypoxic-ischemic cardiac injury.** CSF studies may provide evidence of infection or subarachnoid hemorrhage. Chest x-ray studies may show evidence of pulmonary dysfunction and immaturity. **An EEG will assist in the diagnosis of seizures and the assessment of the neonatal encephalopathy.**[47] Burst-suppression patterns, isoelectric patterns, and very low EEG amplitude all indicate severe CNS dysfunction and are associated with poor prognosis. MRI provides valuable information regarding the nature, distribution, and extent of CNS injury and regarding specific patterns of injury that correlate highly with hypoxic-ischemic injury.[99] MRI scan can also provide valuable sequential monitoring of specific injuries and their evolution.[47]

Treatment

Treatment is focused largely on general supportive care, including the following: support of ventilation; maintenance of normal blood pressure; temperature regulation; maintenance of normal glucose, calcium, and electrolyte levels; and control of seizures.

In addition to general supportive measures, **the use of moderate hypothermia has become standard treatment during the past few years. *Head cooling* or *whole-body cooling* techniques have been used** (Box 26.7). **Inducing modest hypothermia provides neuroprotection of injured CNS cells and also provides a method to control cerebral edema. The use of hypothermia has been shown to improve outcome of neonates with HIE, including lowering the rate of neurodevelopmental disability.** Complications of cooling procedures include disorders of cardiac rate and rhythm, hypotension, thrombocytopenia, coagulopathy, renal dysfunction, and subcutaneous fat necrosis. Procedural details of these cooling methods are beyond the scope of this chapter. Other neuroprotective strategies being investigated include the use of free radical scavengers, anti-inflammatory agents, neurotrophic factors, antagonists of excitotoxic amino acids, and implantation of stem cells.[49,76]

Complications

Neonates who suffer HIE have an increased mortality rate, with up to 20% to 50% dying in the neonatal period. Long-term neurologic complications include epilepsy, hyperactivity, spasticity, movement disorders, dystonia, ataxia, hearing loss, visual loss, and intellectual and cognitive impairments.[18,76,83]

INTRAVENTRICULAR HEMORRHAGE

IVH is a major problem **in preterm infants, with a large percentage of these infants developing neurodevelopmental complications.** With recent medical advances and the increased survival of premature infants, IVH continues to be a significant

BOX 26.7 CRITERIA FOR NEONATAL COOLING FOR HYPOXIC-ISCHEMIC ENCEPHALOPATHY

Screening Inclusion Criteria

- Postmenstrual age ≥36 weeks
- Admitted ≤6 hours of age with a diagnosis of encephalopathy
- pH ≤7 or base deficit >16 mmol/L on cord blood or blood gas within first hour of life (for head cooling)
- pH 7.01-7.15 and base deficit 10-15.9 mmol/L in the first hour of life (for whole body cooling)
- If no blood gas available in the first hour, there also must be:
  - Evidence of an acute perinatal event, *or*
  - 10-minute Apgar score <5 *or*
  - Assisted ventilation (PPV or CPAP) initiated at birth and continued for a minimum of 10 minutes

Inclusion Criteria

- Seizure activity present
- Diagnosis of moderate or severe encephalopathy, which includes any one of the following:
  - Lethargy
  - Decreased tone (may have normal peripheral tone but have central hypotonia), abnormal tendon reflexes, myoclonus, weak suck, abnormal Moro reflex
  - Any evidence of seizures
  - Abnormal breathing
  - Moderate to severe EEG amplitude reduction (lower margin <5 microvolts and/or upper margin <10 microvolts) on a 20-minute aEEG or evidence of seizures

Exclusion Criteria

- >6 hours of age
- Severe intrauterine growth restriction (<1.8 kg)
- Major congenital anomaly
- Head trauma resulting in severe intracranial hemorrhage (head cooling)
- Prophylactic high-dose anticonvulsants (head cooling)
- Parents do not grant consent
- Inability to initiate cooling by 6 hours of age

Data from Gluckman PD, Wyatt JS, Azzopardi D, et al. issue for neonates.[12,87] **IVH is found in 20% to 25% of preterm infants with incidence higher in those with very low birth weight.[12] IVH mainly occurs in infants less than 32 weeks of gestation, with the incidence increasing with decreasing gestational age.[63]** The incidence of IVH in term infants is approximately 3.5%, making IVH both an uncommon and unanticipated diagnosis in this group. Risk factors for IVH include prematurity, chorioamnionitis, hypotension, acidosis, respiratory distress, bicarbonate therapy, and coagulopathy.[66] A recent study of 765 neonates born at less than 32 weeks' gestational age, found that higher gestational age, antenatal steroid treatment, and cesarean section without uterine contraction were associated with a lower rate of IVH. Risk factors predisposing for IVH in this cohort included respiratory distress syndrome, pneumothorax, and use of catecholamines. **If gestational age and birth weight are excluded from the statistical analysis, early-onset sepsis and patent ductus arteriosus are associated with higher rates of IVH. Low Apgar scores have likewise been associated with IVH.[43,81]**

Physiology

Although the bleeding is regularly spoken of as *intraventricular* and *intracranial hemorrhage,* these terms do not accurately reflect its causes. Highly vascularized areas, which have relatively fragile and poorly supported blood vessels, are the source of bleeding. **In premature infants, the *germinal matrix,* in the subependymal area adjacent to the caudate nucleus, is the primary site of bleeding[11,43]** (Fig. 26.2). The anatomy of the deep venous system in this area may play a role in the pathogenesis of IVH, with preterm neonates with increased variability in subependymal vein anatomy being at higher risk for this complication.[88]

The extent of bleeding generally predicts the likelihood of complications and sequelae. Bleeding may be confined to the germinal matrix or the choroid plexus, or it may enter the ventricular system. When filled under pressure, the ventricular system may dilate. Blood may also extravasate out into the brain parenchyma.

There are several classification schemes to assess the degree of bleeding or the amount of blood present. **Volpe listed three grades of germinal matrix IVH using ultrasound scanning to identify the presence and extent of blood in the germinal matrix and lateral ventricles** (Table 26.9).

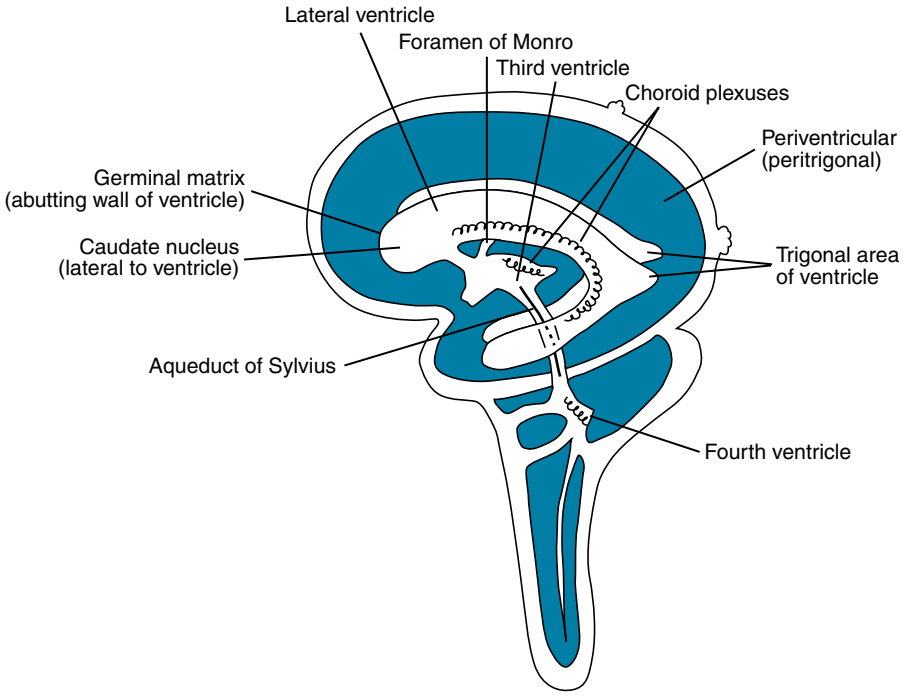

FIGURE 26.2 Central nervous system/ventricular system.

TABLE 26.9 GRADING OF SEVERITY OF GERMINAL MATRIX–INTRAVENTRICULAR HEMORRHAGE BY ULTRASOUND SCAN

SEVERITY	DESCRIPTION
Grade I	Germinal matrix hemorrhage with no or minimal intraventricular hemorrhage (10% of ventricular area on parasagittal view)
Grade II	Intraventricular hemorrhage (10%-50% of ventricular area on parasagittal view)
Grade III	Intraventricular hemorrhage (>50% of ventricular area on parasagittal view; usually distends lateral ventricle)
Separate notation	Periventricular echodensity (location and extent)

From Volpe JJ. *Neurology of the Newborn.* 5th ed. Philadelphia, PA: Saunders; 2008.

A "separate notation" is made for the existence of "periventricular hemorrhage infarction or of other parenchymal lesions." He clarified the use of this separate notation by noting that these abnormalities are not usually the result of simple "extension" of matrix or IVH hemorrhage into "normal brain parenchyma.[97]

An older classification system that grades germinal matrix hemorrhages based on CT scans (Fig. 26.3) is not used as frequently today. Because both grading systems are still cited in the literature, both are included here.

0: No bleeding
I: Germinal matrix only
II: Germinal matrix with blood in the ventricles
III: Germinal matrix with blood in the ventricles and hydrocephalus (ventricular dilation)
IV: Intraventricular and parenchymal bleeding (other than germinal matrix)

Etiology

The etiologic factors identified in infants who have experienced IVH are multiple and can be divided into prenatal, neonatal, and postnatal factors. These include asphyxia, severe respiratory distress, pneumothorax, hypoglycemia, shock, acidosis, blood transfusions, seizures, and rapid

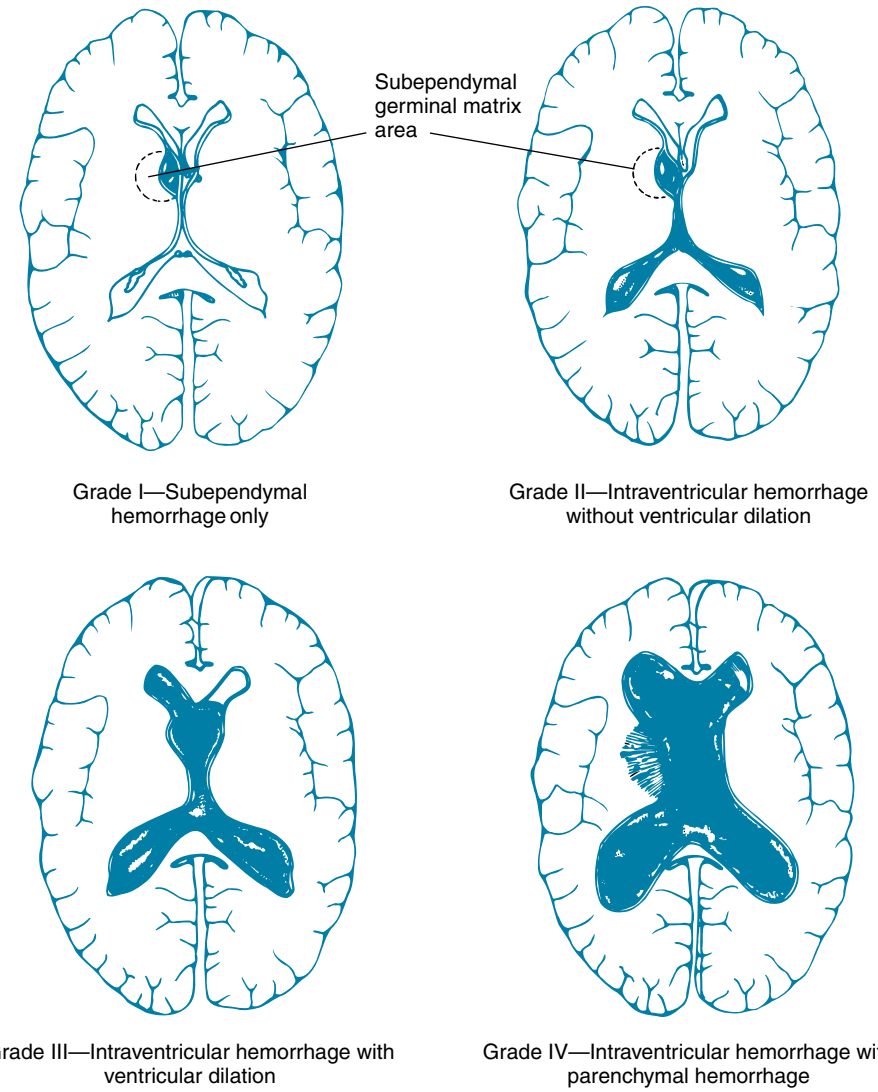

FIGURE 26.3 Periventricular-intraventricular hemorrhage, grades I to IV. (From Rozmus C. Periventricular-intraventricular hemorrhage in the newborn. *Matern Child Nurs.* 1992;17(2):79.)

volume expansion (Box 26.8). What appears to be the **common factor underlying the pathologic condition is a fluctuation/alteration in cerebral blood flow that causes the numerous and thin-walled blood vessels in the germinal matrix to bleed.**[12,46,63] Recently genetic factors have been implicated in development of IVH. Mutations of genes that can predispose to thrombophilia and collagen formation have been found to be involved in IVH.[11,12,63] **Intraventricular bleeding tends to occur in the first few hours or days of life.**

Profound physiologic changes normally seen after birth coupled with multiple problems (primarily cardiorespiratory) typically experienced by the premature infant make intraventricular bleeding common. **The degree to which the aggressive management of premature newborns has a role in the development of bleeding cannot be accurately assessed. Generally, sicker infants both**

BOX 26.8 CRITICAL FINDINGS

Factors That Predispose the Premature Infant to Intraventricular Hemorrhage

Prematurity
- Birth weight <1500 g
- Less than 34 weeks of gestation

Asphyxia (see Chapters 4 and 8)
- Before, during, after birth

Respiratory (see Chapters 8 and 23)
- Idiopathic respiratory distress syndrome
- Hypoxia
- Positive-pressure ventilation
- Pneumothorax
- Apnea

Cardiovascular (see Chapter 4)
- Rapid volume expansion
- Elevated venous pressure
- Elevated or lowered arterial pressure (shock, transfusions)

Hematologic (see Chapter 20)
- Hyperosmolarity
- Coagulation disorders
- Hyperviscosity

Metabolic (see Chapters 8, 14, and 15)
- Hypoglycemia/hyperglycemia
- Hypernatremia/hyponatremia
- Metabolic acidosis
- Rapid pH shifts

Miscellaneous
- Hypothermia (see Chapter 6)
- Acetylsalicylic acid ingestion by mother
- Neonatal pain (see Chapter 12)
- Neonatal environmental stressors (see Chapter 13)

Modified from Gardner S, Hagedorn M. Physiologic sequelae of prematurity: the nurse practitioner's role. VIII. Neurologic conditions. *J Pediatr Nurs.* 1992;6:265.

require more intervention and have a greater likelihood of bleeding.

Data Collection

HISTORY

Because premature infants, particularly those weighing less than 1500 g, tend to have multiple problems, it is not surprising that the clinical presentation of IVH may range from subtle (or even undetectable) to catastrophic.[11]

SIGNS AND SYMPTOMS

Common signs of germinal matrix hemorrhage include apnea, hypotension, drop in hematocrit, seizures, flaccidity, areflexia, full fontanel, tonic posturing, and oculomotor disturbances.[12]

LABORATORY DATA

When **intracranial** bleeding is suspected, appropriate studies of intracranial structures should be performed as soon as possible. **For IVH, ultrasonography is the study of choice.**[97] **The American Academy of Neurology practice parameter recommends screening of all neonates younger than 30 weeks of gestation. The first ultrasound should be done between 7 and 14 days looking for IVH and the second ultrasound at 36 to 40 weeks' postmenstrual age to look for a CNS lesion.** Additional follow-up imaging using MRI is indicated because MRI is better at detecting white matter changes, cysts, and bleeding lesions.[63,97]

Prevention

Strategies to prevent IVH have focused on both prenatal and postnatal interventions. Prenatal interventions such as preventing preterm delivery, maternal transport to a regional neonatal center, and prenatal glucocorticoids have been shown to be helpful in prevention of IVH.[12] Other pharmacologic agents studied, including vitamin K, phenobarbital, and magnesium sulfate, have unproven benefit.[11,12,47]

Postnatal pharmacologic treatment of IVH shows varying success in the literature. Agents

studied include phenobarbital, pancuronium bromide (Pavulon), vitamin E, ethamsylate, indomethacin, ibuprofen, and recombinant factor VIIa.[11,12,63] None of these have good data to support routine use. Postnatal prophylactic use of phenobarbital in preterm infants to prevent IVH has been one of the most widely studied therapies. However, because **phenobarbital results in a greater requirement for mechanical ventilation, it is not recommended for use in postnatal prophylactic prevention of IVH.**[11,12,44,63]

Treatment

The primary treatment of IVH is supportive care. Ventilatory support, maintenance of oxygenation, regulation of acid–base balance, suppression of seizures, and treatment of any attendant coagulopathy are all extremely important in reducing mortality and morbidity.[12] However, the role that successful management has in the amelioration or prevention of complications is unclear.

Complications

The complications from IVH relate to the underlying causes and the extent of bleeding. Massive bleeding with dilation of the ventricular system is much more likely to cause an acute change in brain function, with increased intracranial pressure, brainstem abnormalities, and apnea. Milder degrees of hemorrhage may be asymptomatic or associated with seizures, changes in muscle tone, or apnea.

When **bleeding extends into the parenchyma, porencephaly may result from liquefactive necrosis or ischemia-induced encephalomalacia.** Follow-up structural brain studies may show hypodense areas in which blood was present; later they may show areas of porencephaly.[63]

Other complications of IVH are *posthemorrhagic hydrocephalus* (PHH) and *periventricular leukomalacia* (PVL).[12,85] **Evidence of posthemorrhagic hydrocephalus should be investigated in all survivors of germinal matrix hemorrhage.** CT scanning or ultrasonography to assess ventricular size should be used because clinical signs alone are not reliable.[97] **With the hope of avoiding the necessity of placing a shunt, some attempts at control of the hydrocephalus have been made.** Various studies have evaluated intraventricular streptokinase, lumbar or ventricular punctures, and drainage/irrigation/fibrinolytic therapy, with **no interventions being effective.**[63]

The majority of infants with IVH suffer neurologic complications. In general the sickest and smallest neonates tend to have the most complications. **There is a clear correlation between the grade of bleed and the likelihood of significant neurologic complications. Over 50% of preterm children with a grade 3 to 4 IVH will have significant cognitive deficits, with 75% of these children requiring special education.**[85] The presence of white matter damage in the setting of IVH increases the risk of adverse developmental outcomes during infancy.[77] Even those with lower grade bleeds have been shown to have psychiatric and behavioral issues.[12] **The influence of other factors on neurologic outcome may be more significant than that of the actual bleed itself.** Hypoxia, hypoperfusion, and other conditions known to damage the developing nervous system cannot easily be separated as individual factors affecting outcome.

Parent Teaching

Parents of an infant with IVH should be involved with their infant's care plan. The rationale for a minimal handling protocol needs to be explained. Encouraging parents to participate in setting "timeout" and "touch me" times will facilitate their ability to visit and assist with care. **During visits, they should be encouraged to recognize signs of overstimulation and become knowledgeable about the appropriate interventions to take to calm their infant.**

The infant with IVH has both short- and long-term problems of varying degrees. If acute hemorrhage resolves without ongoing problems, possible complications such as hydrocephalus may still occur. **Teaching parents to measure head circumference and alerting them to the signs of increased intracranial pressure** such as poor feeding, posturing, eye movement difficulties, full fontanel, and lethargy enable them to participate more fully in the medical follow-up (see Box 26.3).

Parents need to understand the risk for long-term neurologic sequelae. Despite the difficulty of predicting sequelae with any degree of certainty, parents should understand that mental and motor handicaps, delays in the acquisition of milestones,

seizures, and problems associated with hydrocephalus and potential shunt placement may occur.[45] Specific preparation for these potential problems begins in the nursery, with more education as needed in follow-up visits. **Prompt and appropriate referral to medical specialists and supportive services is important in both inpatient and outpatient settings.** Parents may find support and information from national and state organizations (see "Parent Resources for Neurologic Disorders" at the end of the chapter).

PEDIATRIC STROKE

Pathophysiology

Stroke in the newborn period is defined as a group of heterogeneous conditions in which there is (1) focal disruption of cerebral blood flow secondary to arterial or cerebral venous thrombosis or embolization, (2) between 28 weeks of fetal life through the 28th postnatal day, and (3) confirmed by neuroimaging or neuropathologic studies.[82] **Perinatal stroke can be further divided into three subtypes: perinatal arterial stroke (PAS), cerebral sinovenous thrombosis (CSVT), or perinatal hemorrhagic stroke (PHS).**[39,57]

The most common stroke, PAS, affects both term and preterm infants with an estimated incidence of 1 in 2300 to 5000 births.[57,74,82] The most common site for PAS is the left middle cerebral artery.[74] Some studies have also noted male newborns affected slightly more often than females.[92]

CSVT is less common than PAS, with an incidence ranging from 40 per 100,000 live births per year.[105] As with PAS, there is a male predominance with CSVT.[105] CSVT is diagnosed as "the presence of a thrombus in a cranial venous sinus, a large deep brain vein or a smaller cortical or deep vein with partial or complete occlusion."[39] PHS is the least common type of stroke in neonates with a prevalence of 6.2 per 100,000 live births.[9] There are limited studies looking at etiology, complications, and long-term outcomes from PHS.

Etiology

The mechanisms that lead to PAS are varied and multifactorial.[82] Causes can be divided into emboli that are cardiac in origin, cerebral vessel disorders, and stasis of blood flow leading to thrombosis. **In more than half of newborns with PAS, a coagulation disorder has been identified, with thromboemboli being the most common cause.**[57,92] Newborns are especially at high risk for these emboli because of placental changes at delivery. Neonatal cardiac anatomy allows venous clots to cross the patent foramen ovale and right to left shunts also occur in cardiac disorders.[92] PHS occurs as a hemorrhagic transformation of arterial or venous infarction, from intraparenchymal hemorrhage due to vascular abnormalities or bleeding diatheses, or from unknown etiology.[9,17]

Prevention

Because PAS is multifactorial, one preventive strategy alone is not effective. Preventing any maternal risk factor (i.e., smoking, adequate weight control, and using compression stockings during periods of immobility) in women with a clotting disorder is advisable.[73] Because dehydration is a risk factor for thrombosis, attention to fluid intake during labor is indicated.[57,73]

Data Collection

HISTORY

There are numerous risk factors for PAS with no single factor as the main etiology. Risk factors may include maternal and placental disorders, perinatal asphyxia, blood disorders, cardiac disorders, infections, trauma, and drugs.[39,57,74] CSVT is also multifactorial with antepartal, intrapartal, and postpartal influences. Pregnancy factors include preeclampsia, chorioamnionitis, and gestational diabetes.[50,92] Delivery risk factors include fetal distress and birth asphyxia. The normal process of birth leading to head molding and overlapping of sutures may compress the dural sinus causing clot formation.[50,92] Postdelivery dehydration, sepsis, cardiac defects, and meningitis also may play a role.[50,92] Neonates receiving extracorporeal membrane oxygenation are at risk for CSVT because of disturbed jugular vein flow as a result of cannulation. The role of prothrombotic abnormalities in the development of CSVT in neonates is unclear. Recent studies have identified predictive risk factors for hemorrhagic stroke to be fetal distress and postmaturity of the neonate.[9,17] In addition, congenital heart disease was also a factor in another study.[17]

SIGNS AND SYMPTOMS

Most infants with PAS are normal at birth, with symptoms developing after the first day of life. Many newborns do not show signs of focal deficits; thus a high index of suspicion in at-risk neonates is warranted. Twenty-five percent of neonates with a stroke have systemic illness.[56] **Seizures, on the side opposite the infarction, are the most common presentation of neonatal stroke and occurring in 70% to 90% of cases.**[57,92] As with PAS, **neonates with CSVT present in the first day after birth to the first week of life.**[50] **Seizures are the most common presentation of CSVT.** Lethargy, irritability, poor feeding, apnea, and jitteriness are also common.[50,92] Neonates with PHS present similarly to the other stroke subtypes: seizures, apnea, respiratory distress, fever, and poor feeding are common. Diagnosis is based on CT, MRI, or magnetic resonance angiography.

LABORATORY DATA

Imaging is indicated for diagnosis of neonatal stroke. MRI, using diffusion-weighted sequences, is the imaging mode of choice for PAS, CVST, and PHS.[56,57,82] **MRI detects thrombi and infarcted areas.** Ultrasound is less useful in diagnosing PAS, and CT scan can miss small or early infarcts. CT detects hemorrhage in PHS. For CVST, Doppler flow ultrasound demonstrates decreased flow.[54,92] Pediatric stroke consensus guidelines also recommend noninvasive vascular imaging to diagnose previously undetected vessel abnormalities.[56] **Neonatal seizures require an EEG and laboratory workup for the etiology of seizures: complete blood count, CSF, cultures, and glucose, calcium, and electrolytes.** Coagulation studies are indicated with a family history of coagulopathy.[48,74] Multifocal infarcts seen on MRI or an abnormal cardiac examination (i.e., murmur) require an echocardiogram for congenital cardiac anomaly. Evaluation of the placenta is helpful in discerning sources of thromboemboli and systemic vascular abnormalities.[74,82]

MR venography is needed to evaluate for the presence of a thrombus. Doppler flow ultrasound can support a diagnosis by demonstrating absent or decreased flow.[54,92] Additional workup will depend on clinical presentation and can include laboratory testing, lumbar puncture, EEG, and echocardiography.

Treatment

Management of PAS is supportive and directed at treating any underlying condition. Maintenance of normal hydration, electrolytes, and glucose, oxygen, and pH levels are indicated.[53,86] Seizures are treated acutely with seizure medication, although most newborns do not need to be discharged on seizure medication. PAS is not routinely treated with aspirin or anticoagulation.[56,92] A congenital cardiac defect as the cause of the PAS may require treatment with antiplatelet agents or anticoagulation (i.e., heparin or low-molecular-weight heparin [LMWH]) with the consultation of pediatric cardiology.[56,58,92] If a genetic thrombophilia is diagnosed, pediatric hematology guides treatment with antiplatelet or anticoagulation agents. **Treatment of CSVT focuses on treatment of the underlying cause for thrombus formation. Antithrombotic therapy consists of the use of heparin or LMWH in neonates without significant intracranial hemorrhage,** followed by LMWH for 6 to 12 additional weeks.[69] If hemorrhage is present, radiology monitoring of the thrombus (at days 5 and 7) is followed by treatment with anticoagulation but only if the thrombus increases in size.[69] This treatment regimen is in contrast to the American Heart Association Stroke Council guideline that recommends treatment only if there is increased size of the thrombus.[50,105] Most studies have found significant variability in anticoagulation use, and more research is needed.[48]

Complications

The main complication of PAS is hemiplegic cerebral palsy, which occurs in 20% to 80% of children.[57,82,92] There is also ongoing risk of seizures, which occur in 15% to 40% of children with PAS.[57,82] Deficits in cognition, language, vision, and behavior are common and become evident in childhood.[57,58,82] **A normal or mildly abnormal neonatal neurologic examination is not predictive of future complications because of the plasticity of newborn brains and their greater ability to recover from injuries.**[58] **Neonates with CSVT have a high incidence of significant neurologic complications.** Neurologic deficits include epilepsy, cerebral palsy, and cognitive impairments.[105] Because there are few studies of PHS, long-term complications are difficult to determine. A recent

study did indicate that almost half of PHS survivors had short-term neurologic deficit.[17]

Parent Teaching

For a newborn diagnosed with any type perinatal stroke, parental education focuses on dealing with complications and associated conditions. Neonates with seizures are given antiseizure medications and may be discharged having weaned from them or still taking the medications.[56] **Parents need to learn to recognize seizures in their infant, to safely administer medications, and know the side effects of all medications.** Seizure medications may cause drowsiness/sleepiness, and parents need to know whom to contact if they are concerned about their infant's behavior.

Parents should be encouraged to use the services of multidisciplinary teams for their infant's rehabilitation needs.[58] Encouraging parents to begin early intervention services after discharge helps to lessen motor deficits. If no risk factors are identified, parents need to be reassured that the potential for recurrence of perinatal stroke is less than 1%.[58] If there is an identified cardiac or underlying abnormality, recurrence risk is higher. A small subset of newborns with underlying cardiac or hematologic risk factors will go home on antiplatelet or anticoagulant medication. These parents need to learn to dose these medications properly and know their side effects. **Parents should be aware that stroke morbidity lasts a lifetime, but their child's quality of life can be good because of the plasticity of the newborn brain.**[58]

NEONATAL NEUROINTENSIVE CARE

The advent of hypothermia as a treatment for hypoxic-ischemic injury in term infants provided the first direct therapy for modulation of neurologic injury as opposed to treatment of its symptoms. A number of additional therapies are being investigated, although none has gained the widespread acceptance of hypothermia. Therapies that remain under investigation for use in reducing the neurologic sequelae include erythropoietin, xenon, antioxidants, melatonin, topiramate, interferon-β, and stem cell transplantation.[15,26,104] As the potential for treating neurologic injury has expanded, there is increasing acceptance of the concept of the "Neuro-NICU."[15,51]

The Neuro-NICU, in its most basic form, represents a deliberate increase in communication among neurologists, neonatologists, specifically trained bedside nurses, and ancillary services to identify patients at risk for neurologic complications common to the ill or preterm neonate and to provide increased surveillance for these infants.[15,51] Although implementation strategies have differed from institution to institution, the benefits of a multidisciplinary team focused on neuro-protective strategies is beginning to be elucidated. Thus far, there is **evidence that neurointensive care services for neonates improve the detection of seizure activity and lead to decreased administration of seizure medication.**[84,102] The extent to which these efforts provide standardization of care may also yield improvements in outcomes.[2]

27 GENETIC DISORDERS, MALFORMATIONS, AND INBORN ERRORS OF METABOLISM

ANNE L. MATTHEWS AND NATHANIEL H. ROBIN

A neonate born with a malformation, a genetic syndrome, or an acute metabolic disorder presents a management challenge for the neonatal intensive care unit (NICU) staff. If these conditions are not suspected and diagnosed in a critically ill neonate, an appropriate course of action might not be taken. Thus a specific diagnosis becomes imperative. **An accurate diagnosis provides the staff with information about the cause of the condition, points the way toward appropriate treatment, and indicates the prognosis so that the most appropriate care of the infant can be initiated.** Moreover, **the broader issues of providing supportive care and counseling for the affected infant's family can be addressed.**

Genetic evaluation is a complex process that requires expertise in differentiating normal variations from abnormal findings and knowledge of the principles of embryology and dysmorphology to provide an accurate diagnosis. Skills in obtaining detailed information of prenatal and family histories may be equally important.

The field of genomics and genetic medicine has witnessed an explosion of new knowledge, much of which was generated by the efforts of the Human Genome Project.[17] Advances in understanding of the genetic basis of development and function as well as the interaction of genes and the environment, continue to provide new insights into human health.

This chapter presents a concise overview of the major categories of genetic disorders and the appropriate techniques to establish specific diagnoses. For an excellent review and detailed explanation of concepts, terminology, and specific genetic mechanisms, refer to *Thompson and Thompson Genetics in Medicine*.[51] See Box 27.1 for a comprehensive list of terms.

GENETIC PRINCIPLES

Genes

A *gene* is a segment of a deoxyribonucleic acid (DNA) molecule that codes for the synthesis of a single polypeptide and contains the hereditary information needed for development or function. DNA, which allows the storing, duplicating, and processing of hereditary information, consists of two long strands twisted around each other to form a double helix. Each strand of DNA is composed of four nucleotides: guanine (G), adenine (A), thymine (T), and cytosine (C). **The specific order of the nucleotides determines the precise information that will be encoded at that site.** Genes can (1) regulate other genes by turning them "on" or "off"; (2) specify the exact structure of proteins, which then control the activities of the cells; and (3) specify ribonucleic acid (RNA), which is necessary for protein synthesis. Dorman and colleagues[20] provide a short primer on DNA, genes, and chromosomes.

Chromosomes

Genes are packed in linear order on chromosomes. *Chromosomes* are found in the nuclei of cells. **In humans, normal somatic cells contain 46 chromosomes (diploid number), of which 44 are**

BLUE type highlights content that is particularly applicable to clinical settings.

BOX 27.1 GLOSSARY

Acrocentric chromosome A chromosome with the centromere near the end of the chromosome.
Allele One of a pair or series of alternative forms of a gene at the same locus.
Aneuploid Any chromosome number that is not an exact multiple of the haploid set.
Autosome A chromosome that is not a sex chromosome.
Centromere The primary constriction of a chromosome in which the long and the short arms meet.
Chromatid After replication of a chromosome, two subunits attached by the centromere can be seen; each is called a *chromatid,* and after separation, each becomes a chromosome of a daughter cell.
Chromosomes The microscopic structures in the cell nucleus composed of DNA and proteins that contain the genes.
Congenital Present at birth.
Copy number variant (CNV) Duplication or deletion of a section of DNA. CNVs can be benign (normal), pathogenic, or of uncertain clinical significance. The method used to detect a CNV varies based on its size (see deletion/duplication analysis).
Dermatoglyphics The dermal ridge patterns on the digits, palms, and soles.
Diploid Two copies of all chromosomes; the number of chromosomes normally present in somatic cells. In humans, this is 46 and is sometimes symbolized as *2N.*
Dominant A gene (allele) that is expressed clinically in the heterozygous state. In a dominant disorder, the mutant allele overshadows the normal allele.
Dysmorphic Morphologic abnormality, often a minor physical finding that may or may not have any cosmetic or functional significance and is present in less than 4% of the newborn population.
Fluorescence in situ hybridization (FISH) Molecular cytogenetic method for detection of microdeletions of chromosomes.
Gamete Mature reproductive cell, the egg or the sperm, containing the haploid number of chromosomes.
Gene The functional unit of heredity.
Genotype A person's genetic constitution.
Haploid One copy of all chromosomes; the number of chromosomes present in the gamete; in humans this is 23 and can be symbolized as *N.*
Hemizygous The condition in which only one copy of a gene is normally present, so its effect is expressed because there is no counterpart gene present (e.g., the genes on the X or Y chromosome of the male).
Heterozygote An individual who has two different alleles at a given locus of two homologous chromosomes.
Homologous chromosomes Members of the same chromosome pair; normally they have the same number and arrangement of genes.
Homozygote An individual who has two identical alleles at a given locus of two homologous chromosomes.
Karyotype The standard pictorial arrangement of chromosome pairs, numbered according to centromere position and length.
Locus The position or place that a gene occupies on a chromosome.
Malformation A primary structural defect that results from a localized error of morphogenesis; abnormal development.
Metacentric chromosome Chromosome with the centromere in the center of the chromosome.
Monosomy Absence of one chromosome of one pair.
Mosaicism Presence in the same individual of two or more different chromosomal constitutions.
Mutation A heritable alteration in the genetic material.
Nondisjunction Failure of two homologous chromosomes to separate equally during cell division into two daughter cells, resulting in abnormal chromosome numbers in gametes or somatic cells.
Phenotype The observable expression of traits either physically or biochemically.
Recessive A gene (allele) that is expressed clinically in the homozygous state. In a recessive disorder, both genes at a given locus must be abnormal to manifest the disorder.
Sex chromosomes The X and Y chromosomes.
Syndrome Recognizable pattern of multiple malformations that occur together and have the same cause.
Transcription The process by which complementary messenger RNA is synthesized from a DNA template.
Translation The process through which the amino acids in a given polypeptide are synthesized from the messenger RNA template.
Translocation Transfer of all or part of a chromosome to another location (i.e., on the same or another chromosome) after chromosome breakage.
Trisomy The presence of three homologous chromosomes rather than the normal two.
X-linked A gene located on an X chromosome.
Zygote A fertilized egg that develops into an embryo.

termed *autosomes* and 2 are *sex chromosomes.* Females have two X chromosomes (XX), and males have an X and a Y chromosome (XY). Gametes—eggs or sperm—contain 23 chromosomes (haploid number). In the zygote and somatic cells, chromosomes are paired (homologs). In each pair, one homolog is maternal and the other is paternal in origin. Each chromosomal pair has unique morphologic characteristics that allow it to be distinguished from other chromosomes, such as size, position of the centromere, and the unique banding pattern that is demonstrated by special staining techniques (Fig. 27.1).[25] To pass on the genetic information to daughter cells, the chromosomes must replicate and then divide correctly. Somatic cells undergo *mitosis,* in which cells replicate and then divide chromosomal

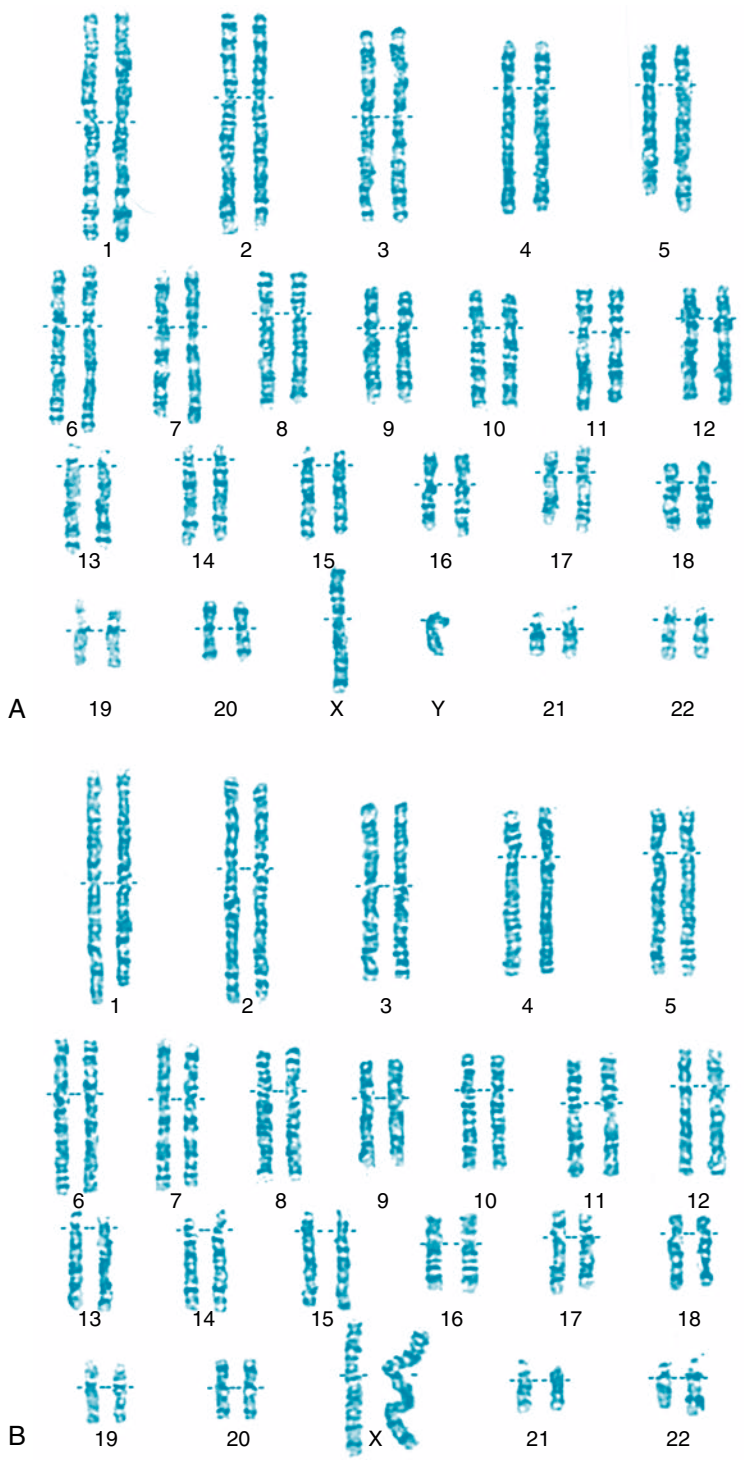

FIGURE 27.1 **A**, Normal male karyotype. **B**, Normal female karyotype. Each karyotype contains 46 chromosomes (44 autosomes and 2 sex chromosomes: XY, male; XX, female). The autosomes are numbered from 1 to 22. Note banding pattern, unique for each chromosomal pair. (Courtesy Dr. Loris McGavran, PhD, Cytogenics Laboratory at the University of Colorado at Denver and Health Sciences Center, Denver.)

material into two genetically identical daughter cells with 46 chromosomes each. In gametes, the process is known as *meiosis,* which is different from mitotic division in that daughter cells contain the haploid number of chromosomes (23) and crossing over or recombination between two homologs occurs, thus facilitating genetic variation in offspring.[51]

An individual's chromosome constitution can be determined by examining dividing body cells under certain laboratory conditions from any accessible tissue such as blood lymphocytes or skin fibroblasts. The resulting *karyotype* (see Fig. 27.1), or pictorial arrangement, demonstrates the number and structure of that individual's chromosomes.

ETIOLOGY

Malformations and genetic disorders caused wholly or partly by genetic factors can be categorized into four major areas: (1) chromosomal disorders caused by **numeric or structural abnormalities of chromosomes;** (2) **single-gene or Mendelian disorders,** which are secondary to single-gene mutations; (3) complex or multifactorial disorders resulting from **interaction of genes and environmental influences;** and (4) abnormalities caused by **environmental exposures of the fetus during development.**

More recently, better understanding of molecular processes has allowed the identification of additional genetic mechanisms contributing to genetic disorders: germline mosaicism, genomic imprinting, and uniparental disomy.

Chromosomal Disorders

Chromosomal abnormalities are relatively common. Approximately 0.5% to 0.7% of all live newborns have a chromosomal abnormality, and 4% to 7% of perinatal deaths result from a chromosomal abnormality. Moreover, it is estimated that at least 50% of all recognized first-trimester miscarriages are caused by a chromosomal aberration.[45] Current cytogenetic and molecular techniques, such as high-resolution banding, fluorescence in situ hybridization (FISH), microarray-based comparative genomic hybridization (array-CGH), and single nucleotide polymorphism (SNP) arrays have increased the detection rate of chromosomal aberrations. Submicroscopic deletions, duplications, or other abnormal rearrangements of chromosome material that may not have been identified a few years previously are now being detected in children with congenital malformations or intellectual disability.

Chromosomal aberrations should be suspected in any of the following situations:

- **Small for gestational age** for weight, length, or head circumference
- Presence of one or more **congenital malformations**
- Presence of **dysmorphic features**
- **Neurologic or neuromuscular dysfunction (i.e., hypotonia)**
- **Family history of multiple miscarriages or siblings with intellectual disability or birth defects** along with one or more of the previous other situations listed here

Chromosomal abnormalities can be classified into two major categories: (1) abnormalities of chromosome number (aneuploidy), in which there is an extra or missing chromosome and **(2) abnormalities of chromosome structure** that result in the loss or duplication of part of the chromosomal material resulting in a loss or gain of genomic DNA (copy number variation). Abnormalities of autosomes usually have more significant deleterious effects on the development of the infant than those seen with sex chromosome abnormalities.

ABNORMALITIES OF CHROMOSOME NUMBER

Numeric chromosomal abnormalities occur as a result of nondisjunction in which aberrant segregation leads to loss or gain of one or more chromosomes. Nondisjunction can occur during either meiosis or mitosis, resulting in an abnormal gamete (egg or sperm) or abnormal somatic cell, respectively (Fig. 27.2). **Fertilization of an aneuploid gamete by a normal gamete produces a zygote with an extra chromosome *(trisomy)* or missing chromosome *(monosomy).* Aneuploidy in somatic cells results in *chromosomal mosaicism* (i.e., the presence of some cells with the normal number of chromosomes and other cells with an abnormal number of chromosomes)** (Fig. 27.3). Although nondisjunction may affect any chromosomal pair, the **most commonly recognized trisomies in liveborn infants are trisomy 21 (Down syndrome), trisomy 18 (Edward syndrome), and trisomy 13 (Patau syndrome).** Conversely, full trisomy 16 has been found exclusively in

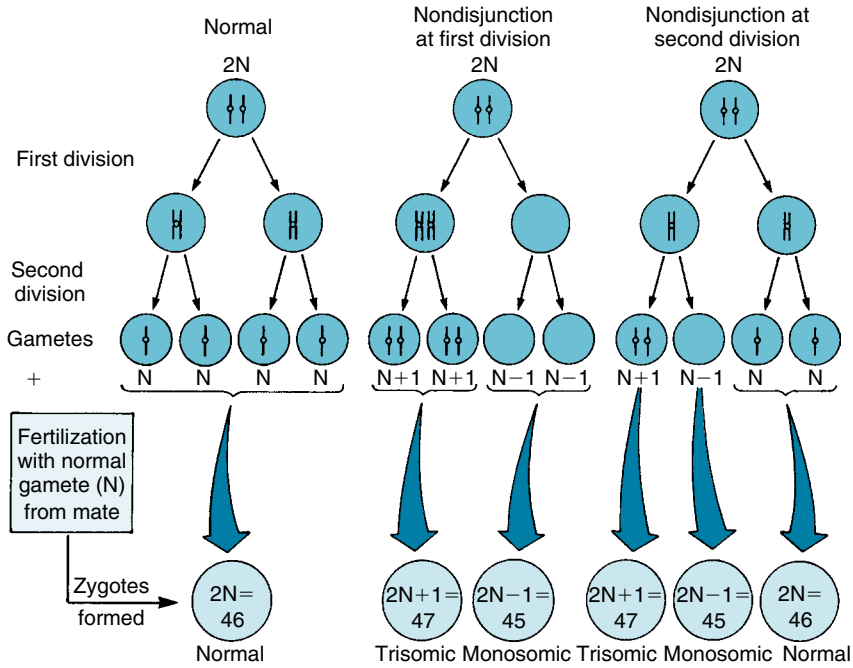

FIGURE 27.2 Nondisjunction. During formation of gametes, errors of nondisjunction can occur during either first or second meiotic division.

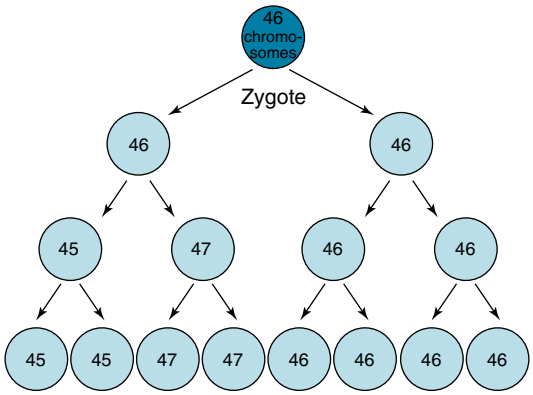

FIGURE 27.3 Mosaicism. Nondisjunction occurring after fertilization and zygote formation results in some cells containing the normal 46-chromosome complement and other cells having an abnormal number of chromosomes.

spontaneous abortions.[45] **The most common monosomy is 45,X, Turner syndrome.** As a rule, numeric chromosomal abnormalities are associated with intrauterine growth restriction (IUGR), dysmorphic features, malformations, and intellectual disability. Physical abnormalities may be milder or absent in the newborn with mosaicism.

ABNORMALITIES OF CHROMOSOME STRUCTURE

Structural abnormalities have been described in all chromosomes. These include deletions, translocations, duplications, and inversions (Fig. 27.4). A *deletion* is a loss of chromosome material and results in partial monosomy for the chromosome involved. Loss of material from the end of a chromosome is known as a *terminal deletion,* as seen in 5p-, or cri du chat syndrome. An *interstitial deletion* involves a loss of chromosomal material that does not include the ends of the chromosome. A terminal deletion of both arms of a chromosome may result in reattachment of the remaining arms, leading to a formation of a ring chromosome. The presence of additional chromosome material results in *duplication* or partial trisomy of a chromosome. **A *translocation* is the detachment of a chromosome segment from its normal location and its attachment to another chromosome.** The translocation is balanced if the cell contains two complete copies of all chromosomal material, although in different order. In an unbalanced translocation, the rearrangement results in partial trisomy or monosomy.

Translocations can be reciprocal or Robertsonian. **A reciprocal translocation involves exchange of**

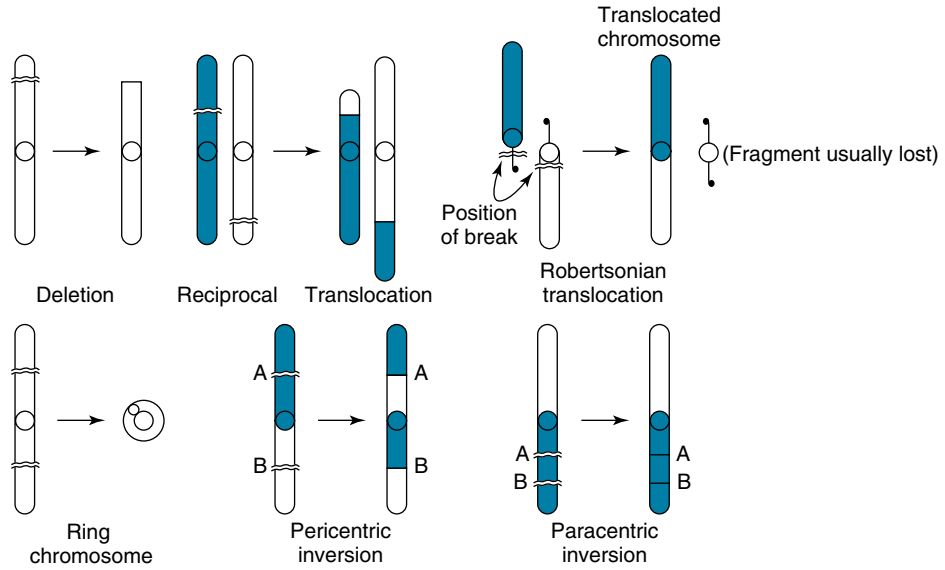

FIGURE 27.4 Schematic example of structural chromosomal abnormalities. (From Hathaway WE, Groothius J, Hay W, eds. *Current Pediatric Diagnosis and Treatment.* 10th ed. Norwalk, Conn: Appleton & Lange; 1991.)

segments between two chromosomes (e.g., part of the short arm of chromosome 4 trades place with a part of chromosome 10). **Robertsonian translocations involve rearrangements between two acrocentric chromosomes** (chromosomes 13, 14, 15, 21 and 22) fused at their centromeres. The most common Robertsonian translocations are formed between chromosomes 13 and 14 as well as 14 and 21.[45]

***Inversions* are the result of a double break in a single chromosome and reinsertion of the chromosomal material that has been inverted.** Inversions are either pericentric (including the centromere) or paracentric (without the centromere). The most common inversion is a small pericentric inversion of chromosome 9, which is considered to be a normal variant, found in approximately 1% of the general population.[51] All other inversions may produce gametes that result in an individual with an unbalanced rearrangement (i.e., having both a duplication and a deletion of some chromosome material, such as that seen in recombinant 8 syndrome).

MICRODELETIONS AND SYNDROMES

At times, structural chromosomal abnormalities are submicroscopic and therefore cannot be detected by conventional cytogenetic techniques. **FISH is a molecular cytogenetic method that facilitates the detection of microdeletions.** FISH uses segments of fluorescently labeled DNA called *probes,* constructed so that each probe can attach only to a specific segment of a chromosome, which then will be fluorescent during a microscopic visualization. In the case of a deletion of that chromosome segment, the probe cannot attach to the chromosome; thus the fluorescent segment is missing from the deleted segment of that chromosome.[67]

The most recent advances being used to detect very small submicroscopic deletions and duplications are array-CGH and SNP array.[60] These technologies blend molecular techniques with cytogenetics and allows the genome to be scanned at a higher resolution than conventional techniques. For CGH arrays, DNA from a patient sample and DNA from a control sample are differentially labeled, mixed in equal proportions, and hybridized to DNA substrates fixed on an array platform (i.e., bacterial artificial chromosomes [BACs] or oligonucleotides [short segments of DNA usually 8 to 50 base pairs]). This technique can measure the difference between two different DNA samples in copy number (dosage) of a particular segment of DNA. Thus, microscopic gains and losses from a patient sample can be quantified.[18] Similar to CGH arrays, SNP arrays label patient DNA, which hybridizes to DNA substrates fixed on an array platform; however, no control DNA is needed to identify dosage of segments of DNA.

Microdeletions result in phenotypic abnormalities. A number of well-recognized microdeletion syndromes may be suspected in the NICU. *Prader-Willi syndrome,* caused by an interstitial deletion of chromosome 15 (q11q13), usually manifests in a newborn as severe hypotonia, feeding difficulties, and micropenis or hypoplastic labia.[14] In fact, Prader-Willi syndrome should be considered in the differential of any neonate with severe hypotonia. *Williams syndrome* is caused by an interstitial deletion or mutation of the elastin gene *(ELN)* on the long arm of chromosome 7 (7q11).[49] The condition is often first seen in an affected newborn in the postterm period; the infant is small for family size. There may be a congenital heart defect, in particular, supravalvular aortic stenosis or peripheral pulmonic stenosis; hypotonia; failure to thrive with gastroesophageal reflux; poor suck and swallow; and vomiting and irritability or colic. Infantile hypercalcemia is seen in approximately 20% of these infants. Subtle dysmorphic facial features may be noted in the newborn.[49]

One of the **most commonly seen microdeletion syndromes is 22q11.2 deletion syndrome (22q11DS),** which is characterized by cleft palate or velopharyngeal insufficiency, hypernasal speech, learning disabilities, conotruncal heart defects, and characteristic facies. 22q11DS actually represents one of a spectrum of clinical disorders all known to be caused by a deletion in chromosome 22q11 (del22q11). These include *velocardiofacial syndrome* (VCFS; palatal anomalies, congenital heart disease, characteristic facial features, and developmental delay or learning difficulties), *DiGeorge syndrome* (DGS; conotruncal heart defect, hypocalcemia, and thymic hypoplasia), and *conotruncal anomaly face syndrome* (CTAF; conotruncal heart defects and typical facies). In addition, del22q11DS has been found in 11% to 16% of cases of nonsyndromic congenital conotruncal heart disease and has been reported to present as apparently isolated neonatal hypocalcemia or learning problems.[43] Overall, del22q11DS has an estimated incidence of 1 in 2000 to 4000 newborns. The availability of molecular cytogenetic testing by FISH and chromosomal microarray (CMA) has led to appreciation of both the high incidence of the del22q11DS, as well as the increasing variety of clinical presentations that can be seen even within a single family.[43,44]

In the newborn period, the characteristic facial features are seldom obvious. However, most affected individuals manifest some of these findings by early childhood. Most prominent is the nose, which is described as long, with a "built up nasal bridge, squared off nasal root, and bulbous nasal tip."[63] The eyes appear narrow and slit-like, the mala (cheeks) are flat, and the jaw is recessed. The ears usually are small and in some way abnormally formed. There may be an overt cleft of the secondary palate, a bifurcated uvula, a subtle submucosal cleft, or cleft lip with or without cleft palate. Other nonstructural palatal abnormalities can be seen, most commonly velopharyngeal insufficiency. In an older child or adult, this presents as hypernasal speech; in a newborn, one sees excessive nasal regurgitation. Congenital heart disease (CHD) is seen in 74% of del22q11DS patients. The type of CHD is fairly specific and includes those lesions classified as "conotruncal heart defects" (truncus arteriosus, interrupted aortic arch, tetralogy of Fallot, left-sided aortic arch, vascular rings, and some types of ventricular septal defects [VSDs]). Additional nonspecific findings include abundant scalp hair, hypospadias, renal abnormalities that can include renal agenesis, tortuous retinal vessels, ectopic/aberrant/unilateral absence of carotid and vertebral artery, microcephaly, and microdontia (there are 166 findings to date).[63]

Developmental delay, learning disabilities, or mental retardation is common and quite variable. Behavioral and psychiatric problems are common but underappreciated findings in VCFS. These individuals have a characteristic personality, marked by a flattened affect and abnormal social interaction, ranging from being intermittently withdrawn to socially precocious. A host of other psychiatric diagnoses have been seen in patients with 22q11DS.

More than 85% of cases of 22q11DS are deleted for a large 3-Mb region of chromosome 22 encompassing approximately 40 genes, including the *TBX1* gene.[43] Point mutations in *TBX1* have also been found when no deletion was identified.[71] Although 93% of cases are de novo, it is important to obtain family histories and examine parents for subtle features of the syndrome because approximately 7% of infants have inherited the abnormality from a parent.[43] Guidelines for the clinical diagnosis and management of patients with the 22q11DS deletion have been published.[9]

CLINICAL EXAMPLES OF CHROMOSOMAL ABNORMALITIES

Down Syndrome. Down syndrome has an incidence of approximately 1 in 600 live births. Approximately 95% of cases are caused by

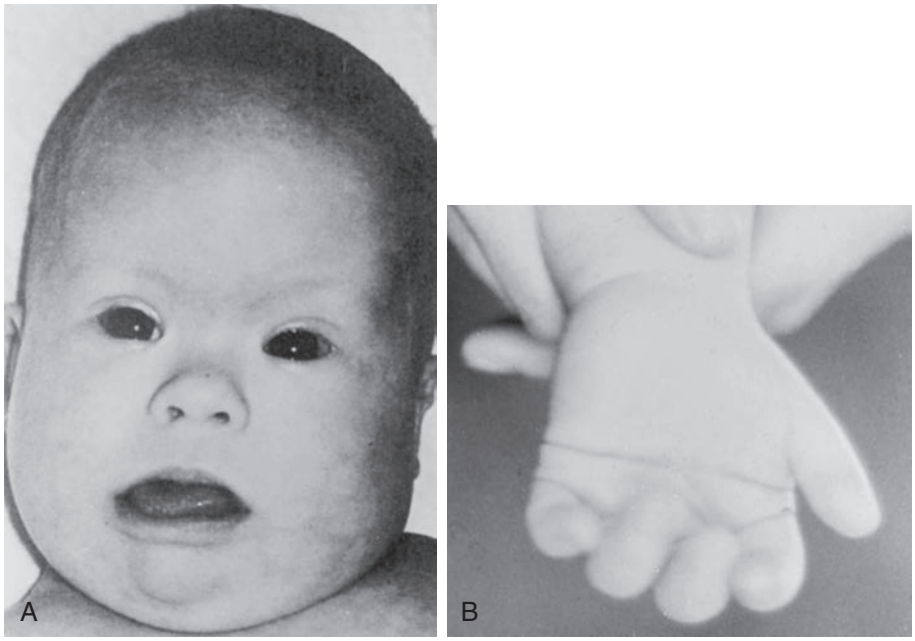

FIGURE 27.5 Infant with Down syndrome. **A**, Note midface hypoplasia, epicanthic folds, and depressed nasal bridge. **B**, Single palmar crease. (**A** from Cohen MM. *The Child With Multiple Birth Defects.* 2nd ed. New York, NY: Raven Press; 1997. **B** courtesy Dr. Eva Sujansky, Genetic Services at The Children's Hospital, Denver, Colo.)

nondisjunction involving chromosome 21, 4% are caused by a translocation, and 1% are mosaic. **Down syndrome may manifest with marked hypotonia; a number of major malformations, most commonly congenital heart defects, duodenal atresia, and tracheoesophageal fistula; and a characteristic pattern of dysmorphic features.** The classic phenotype seen in Down syndrome includes a flattened occiput, midfacial hypoplasia, depressed nasal bridge, upward-slanting palpebral fissures, epicanthic folds, grayish speckling of the iris (Brushfield spots), micrognathia, excess nuchal skin, single palmar creases (simian creases), single flexion creases and in-curving of the fifth fingers (clinodactyly), and increased distance between the first and second toes (Fig. 27.5).

In full-term infants with the classic phenotype of Down syndrome, the clinical diagnosis is usually not difficult. However, it is imperative that cytogenetic studies be done to confirm the diagnosis and to differentiate a nondisjunctional trisomy from a translocation. This distinction has important implications for recurrence risks (see discussion in "Prevention" section). **In premature infants, the classic facial phenotype is frequently missing, making clinical diagnosis more difficult.** The presence of an atrioventricular (AV) canal or duodenal atresia with minor malformations, such as abnormal dermatoglyphics, should alert the clinician to the possibility of Down syndrome.

Trisomy 18. Trisomy 18 has an incidence of 1 in 6000 live births. The major phenotypic features include prenatal growth restriction, complex cardiac malformations, abnormal muscle tone, microcephaly, prominent occiput, short sternum, low-set and malformed ears, corneal opacities, micrognathia, peculiar hand posturing with the second and fifth digits overlapping the third and fourth, hypoplasia of fingernails, abnormal dermatoglyphics, prominent calcanei, and deep plantar furrows between the first and second toes (Fig. 27.6). **The prognosis is poor, and the majority of infants with trisomy 18 die within the first few months of life.** Those who survive into childhood are profoundly intellectually disabled.

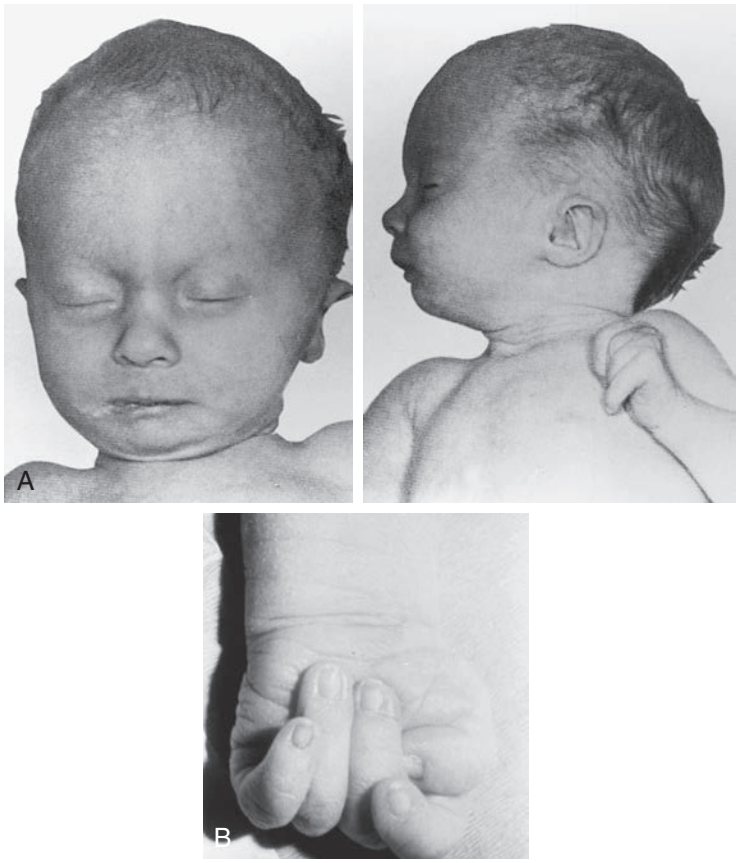

FIGURE 27.6 Infant with trisomy 18. **A**, Typical facies with small chin, abnormal pinna, and prominent occiput. **B**, Typical hand posturing with overlapping fingers. (From Paerregaard P, Mikkelsen M, Froland A, et al. Trisomy no. 17–18: report of two cases. *Acta Pathol Microbiol Scand.* 1966;67:479.)

Trisomy 13. Trisomy 13 is seen in approximately 1 in 15,000 live births. Phenotypic features include prenatal and postnatal growth restriction, microcephaly, sloping forehead, coloboma of the iris, microphthalmia or anophthalmia, low-set or malformed ears, cleft lip and palate, postaxial polydactyly, and abnormal palmar creases and dermatoglyphics (Fig. 27.7). Internal abnormalities may include a number of central nervous system (CNS) malformations, such as holoprosencephaly, cardiac malformations, omphalocele, renal malformations, and urogenital abnormalities such as cryptorchidism in males and uterine malformations in females. The prognosis is extremely poor for these infants, with most dying within the first few months of life.

Although it is well recognized that there is variability in the presentation of findings for infants and children with Down syndrome, it is also important to recognize that there can be variability in the phenotypes of infants with trisomy 18 and 13. Because some infants do survive the neonatal period and may live well into childhood, it is important to include parents along with other members of the management team in ensuring the complex needs of these infants are addressed. Moreover, there are a number of support groups available to families whose child is diagnosed with one of the classic trisomies.[38]

Turner Syndrome. The only monosomy to be seen in live births is that of Turner syndrome—females

FIGURE 27.7 Infant with trisomy 13. Facial clefts and microcephaly; abnormal positioning of the hands. (From Hathaway WE, Groothuis J, Hay W, eds. *Current Pediatric Diagnoses and Treatment.* 10th ed. Norwalk, Conn: Appleton & Lange; 1991.)

with a 45,X karyotype. In addition, it is the only numeric abnormality of the sex chromosome that may be identifiable at birth. Turner syndrome has an incidence of 1 in 5000 female births.[58] Clinical features that may be evident in the newborn period are a short, webbed neck or redundant skin on the back of the neck and marked lymphedema of the dorsum of the hands and feet (Fig. 27.8). Congenital heart defects are seen in approximately half of the patients, with 30% having a coarctation of the aorta. Renal anomalies also may be present.[32] Prognosis is usually excellent but depends on the presence and severity of the congenital heart defect. Intelligence is within normal parameters; however, some females with Turner syndrome have been noted to have learning disabilities in spatial perception or fine motor abilities.[58] Guidelines for the management of infants, children, and women with Turner syndrome have been published recently following an international consortium meeting of the International Consortium Turner Syndrome Group.[26]

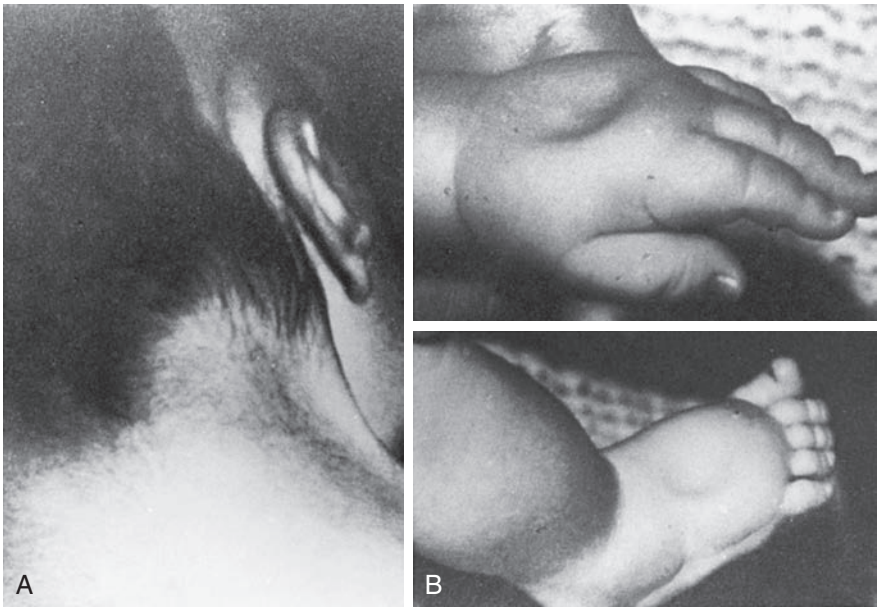

FIGURE 27.8 Female infant with Turner syndrome. **A**, Webbed neck with low posterior hairline. **B**, Lymphedema of the dorsal surfaces of the hands and feet. (From Knuppel R, Drukker JD, eds. *High Risk Pregnancy: A Team Approach.* Philadelphia, Pa: Saunders; 1988.)

Cri du Chat. Cri du chat, or "cat cry" syndrome, is the result of loss of the terminal end of the short arm of chromosome 5 (5p-). The name of the syndrome reflects the unusual catlike, weak cry these infants have in the neonatal period. These infants are usually small for gestational age, hypotonic, and microcephalic and may have ocular hypertelorism, epicanthic folds, downward slant of the palpebral fissures, low-set ears, and micrognathia. They are significantly intellectually disabled.

San Luis Valley Syndrome. *Recombinant 8,* or *San Luis Valley, syndrome,* named for the area in which many of these individuals were first identified, is an example of an unbalanced pericentric inversion with both duplication and a deletion of chromosome 8 material.[65] The pericentric inversion of chromosome 8 found in a parent and other relatives of a child with recombinant 8 syndrome have no phenotypic consequence because it is a balanced rearrangement. However, a carrier is at risk for producing unbalanced gametes during meiosis. In recombinant 8 syndrome, there is a deletion of chromosomal material of the short arm of chromosome 8 and a duplication of chromosome material of the long arm of 8. The phenotype is characterized by unusual facial features, including a wide face, depressed nasal bridge, hypertelorism, down-slanting palpebral fissures, upturned nose, long philtrum, low-set and malformed ears, cleft lip or cleft palate, congenital heart disease, and renal abnormalities.[65]

PREVENTION

The identification of chromosomal abnormalities in the newborn is important, not only for management issues about the infant but also because of the recurrence risks the abnormality carries for the family. In general, numeric chromosomal abnormalities carry low recurrence risks (approximately 1% to 2%).[45] In the presence of structural abnormalities, recurrence risks depend on whether one of the parents carries a balanced rearrangement. **If parental chromosomes are normal, the recurrence risk is minimal. However, if a parent carries a balanced chromosomal rearrangement, the recurrence risk is significantly increased.** The exact risk figure varies with the nature of the specific chromosomal rearrangement and, in some cases, the sex of the carrier parent. In either situation, **prenatal diagnosis for chromosome analysis is available for parents and families concerned about recurrence risk.**

Single-Gene Disorders

McKusick's Online Catalog of Mendelian inherited disorders currently lists almost 25,000 entries, approximately 16,000 genes and approximately 7800 disorders with known patterns of inheritance.[53] Many of these disorders are singularly rare; however, collectively, they affect about 1% of the population. Single-gene disorders are the result of either a single or double dose of an abnormal gene. **Single-gene disorders are classified as autosomal dominant, autosomal recessive, X-linked dominant, and X-linked recessive.** Humans have two copies of each gene located at identical places (gene loci) on homologous chromosomes. In a single-gene disorder, an abnormal or mutated allele (an alternative form of a gene) is found on one or both members of a pair of chromosomes.[51] Individuals with identical alleles at a particular locus are homozygous for the gene. Individuals with different alleles are heterozygous for the gene. Because males have only one X chromosome and most genes located on the Y chromosome do not correspond to those located on the X, males are hemizygous for the genes on the X chromosome. Abnormal genes located on one of the 44 autosomes are the cause of autosomal disorders: **disease-causing genes located on the X chromosome are the cause of X-linked disorders. Disorders are *dominant* when the phenotype is expressed in the presence of only one copy of the mutated gene. In *recessive disorders,* the phenotype is expressed only when both chromosomes carry the mutated gene.**

AUTOSOMAL DOMINANT DISORDERS

Autosomal dominant disorders are ones in which the disorder is expressed in the heterozygous state. Major characteristics include (1) multiple generations are affected (i.e., an infant would have an affected parent); (2) both males and females are affected, and both sexes can transmit the disorder to their offspring (i.e., male-to-male transmission can occur); (3) there is a 50% risk for each offspring to inherit the gene from an affected parent; and (4) individuals who do not have the gene cannot transmit the disorder to their offspring.

A negative family history does not rule out the presence of an autosomal dominant disorder. Possible explanations for a negative family history are (1) the infant's disorder is a result of a new mutation; (2) a parent has a very mild expression

FIGURE 27.9 Ectrodactyly (lobster claw deformity) of the feet. (Courtesy Dr. Eva Sujansky, Genetic Services at The Children's Hospital, Denver, Colo.)

(variable expressivity) of the disorder and may not have been previously diagnosed; (3) nonpaternity; (4) decreased penetrance (i.e., not all individuals with the gene have phenotypic abnormalities, i.e., skipped generation); and (5) germline mosaicism for the mutation (see the "Nontraditional Inheritance" section).

Examples of dominant disorders that may be seen in the NICU include skeletal dysplasias, such as *achondroplasia* (abnormality in the *FGFR3* gene), *osteogenesis imperfecta (OI)* (abnormality in *COL1A1* or *COL1A2*), *Apert and Crouzon syndromes* (abnormality in the *FGFR2* gene), *Treacher Collins syndrome* (abnormality in *TCOF1, POLR1C, or POLRID* genes; mutations in *TOCF1* are responsible for approximately 93% of cases), and ectrodactyly (Fig. 27.9).[51]

AUTOSOMAL RECESSIVE DISORDERS

Autosomal recessive disorders are expressed only in the homozygous state. Thus, to be affected, an individual usually inherits an abnormal gene from each parent. The parent who is heterozygous for a disease-causing gene is usually phenotypically normal and is called a *carrier.* Major characteristics of autosomal recessive inheritance include (1) phenotypically normal parents, (2) affected siblings, (3) both males and females affected, (4) offspring of two carrier parents (25% risk for being affected), (5) unaffected siblings have a two-thirds chance of being carriers, and (6) possibly an increased incidence of consanguinity (mating between blood relatives). **Autosomal recessive disorders that may be identified in the neonatal period include many of the metabolic disorders** (e.g., *phenylketonuria [PKU], galactosemia,* and isovaleric acidemia) and some of the *multiple-malformation syndromes* (e.g., Meckel-Gruber syndrome), *cystic fibrosis presenting with meconium ileus, Zellweger* (cerebrohepatorenal) *syndrome* (Fig. 27.10), and skeletal dysplasias such as achondrogenesis. The specific gene(s) or biochemical defect for many of these disorders is now known.

As noted earlier, **one of the characteristics that may be seen in autosomal recessive disorders is a family history that includes consanguinity.** Thus, it is important to inquire from parents of the neonate whether they are related by blood. In many areas of the world, marriage between blood relatives is a common practice; thus, this becomes a risk factor for such couples because they are more likely to carry similar deleterious mutations that can be passed on to offspring and lead to disease or major birth defects.[50]

X-LINKED DISORDERS

X-linked disorders are caused by an abnormal gene (or genes) located on the X chromosome. Most X-linked disorders are recessive. The X-linked recessive disorders are phenotypically expressed in hemizygous males; heterozygous females are generally phenotypically normal and are called *carriers.* **Affected fathers do not have affected sons (no male-to-male transmission); however, all daughters of affected males are carriers. A carrier female has a 50% chance of having an affected male offspring.**

Occasionally, heterozygous females may be phenotypically affected, although usually less severely than males. If females are severely affected, other mechanisms, including homozygosity for the X-linked gene, may be responsible for the phenotype. **X-linked recessive disorders that may be recognizable in the newborn period include factor VIII and IX deficiency** (classic hemophilia A and B), X-linked hydrocephalus, and Opitz syndrome.

X-linked dominant disorders occur when the abnormal gene located on the X chromosome is expressed in both the hemizygous and heterozygous states. As in X-linked recessive conditions, there is no male-to-male transmission, because the affected male passes his Y chromosome and not his X chromosome to his sons; however, all of the daughters of an affected male will inherit his X chromosome and thus

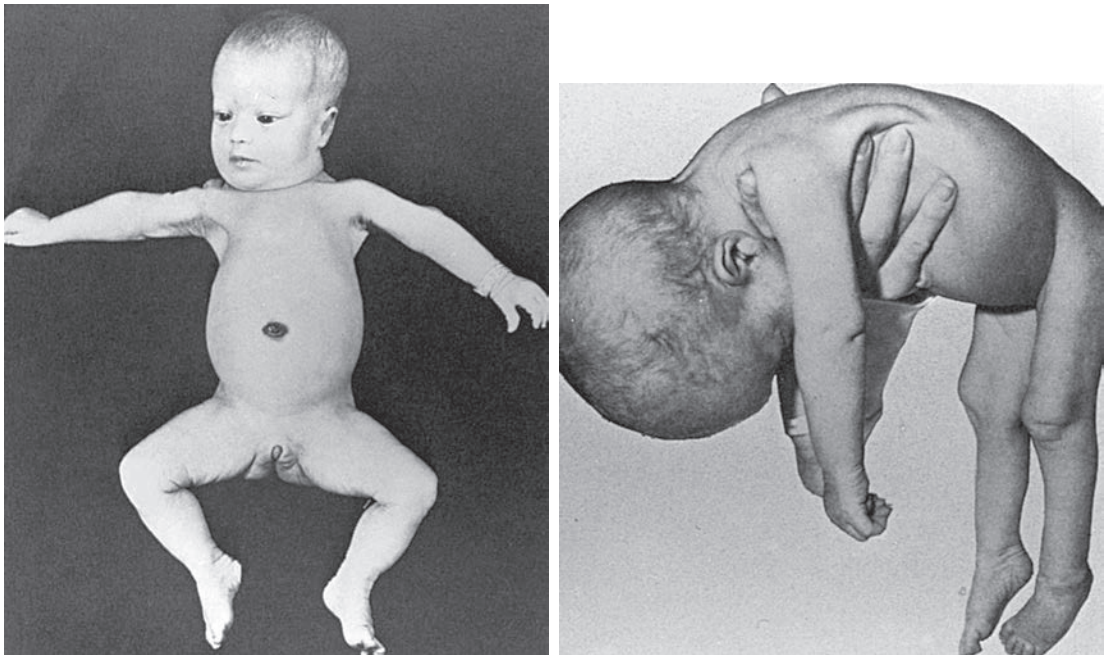

FIGURE 27.10 Infant with Zellweger syndrome, an autosomal recessive disorder. Note the high forehead, narrow facies, and extreme hypotonia. (*Left* from Jan JE, Hardwick DF, Lowry RB, et al. Cerebro-hepato-renal syndrome of Zellweger. *Am J Dis Child.* 1970;119:274. *Right* from Passarge E, McAdams AJ. Cerebro-hepato-renal syndrome: a newly recognized hereditary disorder of multiple congenital defects, including sudanophilic leukodystrophy, cirrhosis of the liver, and polycystic kidneys. *J Pediatr.* 1967;71:691.)

be affected. **Each son and daughter of an affected female has a 50% risk for being affected; males usually are more severely affected than females.** Only a few disorders are known to be inherited as an X-linked dominant, such as incontinentia pigmenti, hypophosphatemia (vitamin D–resistant rickets), and ornithine transcarbamylase (OTC) deficiency. Early diagnosis of OTC deficiency is important because, if untreated, it leads to neonatal hyperammonemia and death in affected males. In affected females, the clinical picture can be variable, ranging from an asymptomatic infant to one who presents in the first week of life with lethargy, vomiting, and protein avoidance, ending in seizures and coma.

Complex and Multifactorial Disorders

Complex, common non-Mendelian disorders, often called *multifactorial disorders,* are the result of both environmental and genetic factors.[27] Most isolated single malformations, including congenital heart defects, neural tube defects, cleft lip and palate, pyloric stenosis, and club feet, are inherited in this manner. In addition, the more complex, common familial disorders, such as diabetes mellitus, coronary artery disease, affective disorders, and mild intellectual disability are the result of multifactorial inheritance. In contrast to single-gene inheritance, multifactorial disorders recur within families without a characteristic pedigree pattern and recurrence risks are based on empirical data.[51]

Multifactorial inheritance is explained as a liability model with a threshold effect.[27] The general population as a whole has an underlying genetic predisposition for multifactorial traits and disorders that follow a normal distribution curve; only in those individuals in whom the genetic predisposition exceeds the threshold will the malformation actually be expressed (Fig. 27.11).

- Major characteristics of complex/multifactorial inheritance include the following: (1) no consistent pedigree pattern exists between families

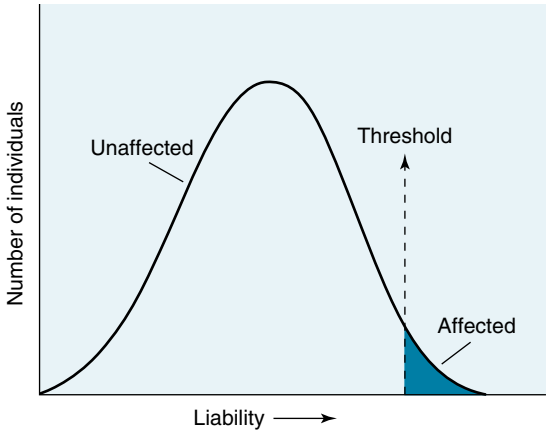

FIGURE 27.11 Multifactorial inheritance. Liability curve with a threshold beyond which the trait is expressed.

(i.e., there may be only an isolated occurrence, or the disorder may be seen among siblings, in multiple generations, or scattered throughout the family); and (2) recurrence risks are not constant, as in single-gene disorders, but are influenced by a number of factors. **These factors include the following:**

- **The number of family members affected** (i.e., the more family members affected, the higher the recurrence risk becomes)
- **The degree of relatedness to those affected** (i.e., first-degree relatives are at higher recurrence risk than second- or third-degree relatives)
- **The severity of the defect** (i.e., the more severely affected an individual is, the higher the recurrence risk)
- **The frequency of the disorder, which may vary with ethnic background** (e.g., neural tube defects have a higher incidence among English and Irish populations)
- **The gender of the individual** (for disorders in which one gender is more commonly affected than the other [e.g., pyloric stenosis is more common in males]; if the less commonly affected gender has the defect, the recurrence risk is higher)

With the increasing sophistication of ultrasound diagnosis during pregnancy, a number of these isolated malformations can now be diagnosed before delivery. Moreover, in the case of neural tube defects, it has been shown that folic acid supplements may decrease the incidence of spina bifida by as much as 70% in women of reproductive age.[48]

NONTRADITIONAL INHERITANCE

Germline Mosaicism. Spectacular growth in the field of molecular genetics and its technologies in only the past few years has enabled the clarification of the inheritance patterns of many genetic disorders and birth defects that were previously unknown or unclear. For example, the lethal form of OI occurring in multiple offspring of unaffected parents was thought to be the result of autosomal recessive inheritance. However, improved molecular techniques have documented that it is an autosomal dominant disorder in which germline mosaicism can result in having more than one affected child. That is to say, the mutation occurs in the gonad (egg or sperm) of one of the parents, who then has some gametes with and others without the OI mutation. This distinction alters the recurrence risks and is important for genetic counseling.[51]

Genomic Imprinting. In the past, little notice was given to whether the sex of the parent who transmitted an abnormal gene to offspring had any effect on the expression of genes. It is **now recognized that maternally and paternally derived genes may function differently, and this is called *genomic imprinting*.**[69] For example, offspring who inherit a mutation in the imprinted region of chromosome 15q, if it results in a loss of the paternal allele the child will have Prader Willi syndrome; the loss of expression of the maternal allele will result in Angelman syndrome.[21]

Uniparental Disomy. Uniparental disomy is the result of inheriting both copies of a chromosome from one parent and none from the other.[69] It is assumed that for normal growth and development, a child must receive both maternal and paternal genes; if both copies of a gene originate only from one parent, the development is abnormal. Uniparental disomy has been seen in cystic fibrosis with short stature and in the Prader-Willi, Angelman, and Beckwith-Wiedemann syndromes. The parental origin of a child's chromosomes can be identified only by molecular analysis; routine chromosome analysis usually is not helpful.

Trinucleotide Repeat Disorders. Trinucleotide (triple) repeat disorders are disorders that result from an unstable expansion of a segment of DNA that consists of three or more nucleotides adjacent to each

other. If a mutation occurs in a gene that contains a segment of repetitive trinucleotide sequences, it can cause the normal number of repeats to increase such that the expansion interferes with the expression or function of the gene.[51] **Repeat disorders have been found to be the cause of more than 20 disorders, including myotonic dystrophy** (an expanded CTG triple repeat in the *DMPK* gene) **and fragile X syndrome** (an expansion of CGG in the *FRAXA* gene). What is important to note is that **the abnormal number of repeats can expand through each generation and lead to a more severe phenotype in the next generation (known as *anticipation*).** The sex of the parent who passes on the mutation that causes the abnormal expansion can also affect the phenotype. For example, the repeat expansion in myotonic dystrophy is often larger in offspring of affected mothers.[33]

The possibility of a nontraditional pattern of inheritance makes genetic counseling more complex than previously thought. Thus, it is imperative that health care providers be aware of such complexities and refer families to a geneticist or genetic counselor for a more detailed discussion when appropriate.

INHERITED METABOLIC DISORDERS

Genetic disorders in which defects of single genes cause clinically significant blocks in metabolic pathways, regulatory proteins, and transport mechanisms are known as *inherited metabolic disorders and include inborn errors of metabolism*.[23] Recognition of inherited metabolic disorders has increased rapidly in recent years, and they are now recognized as important causes of disease in the newborn and pediatric age groups.[66] **Inborn errors of metabolism include defects of carbohydrate, amino acid, organic acid, and purine metabolism; disorders of fatty acid oxidation; lysosomal storage diseases; and disorders of peroxisomes.** Remember that metabolic diseases can present at any time and may affect almost any organ system. Specific disorders that should be considered in symptomatic newborns include galactosemia, PKU, OTC deficiency, and carbamoyl-phosphate synthetase (CPS) deficiency, maple syrup urine disease, nonketotic hyperglycinemia, propionic and methylmalonic acidemias, isovaleric acidemia, carnitine uptake deficiency, glutaric acidemia type II, and mitochondrial disorders, to name a few.[34,46]

Although the majority of infants are not found to have an inborn error of metabolism as the etiology of their illness, early recognition is imperative and may be considered a medical emergency if appropriate treatment is to be initiated. Many of these disorders can be treated effectively; if untreated, they can be lethal in the newborn period. Moreover, without the appropriate diagnosis, parents would not be aware of recurrence risks in future offspring.

Inherited metabolic disorders should be included in the differential diagnosis for any critically ill newborn in the following instances: (1) suspicion of neonatal sepsis; (2) recurrent vomiting or altered consciousness; (3) clinical findings of hypoglycemia, seizures, parenchymal liver disease, unusual odor, hyperammonemia, or unexplained acidosis; or (4) a family history of a sibling affected with similar symptoms, intellectual disability, or sudden infant death syndrome.[34]

In general, laboratory analysis depends on the presenting symptoms seen in the newborn. Laboratory studies that should be obtained before any treatment is begun are electrolytes, ammonia, glucose, urine pH, urine-reducing substances, and urine ketones. Neuroimaging can also provide clues to specific diagnoses.[56] **Clues to a possible metabolic abnormality are (1) hypoglycemia and ketonuria in the newborn, (2) acidosis with recurrent vomiting and hyperammonemia, and (3) acidosis that is difficult to correct and is out of proportion to the clinical state.** If other underlying disorders are not readily apparent, additional laboratory tests that may be appropriate are serum and urine amino acids and urine organic acids.[66] Moreover, molecular (DNA) testing is available for most disorders.[37] In addition, consultation with a metabolic specialist should be included in any evaluation of a neonate with a suspected inherited metabolic disorder.[46]

NEWBORN SCREENING

Inherited metabolic disorders, when unrecognized and untreated, may lead to severe consequences, including intellectual disability and death in some instances. Thus, the goal is to identify, treat, and prevent major sequelae whenever possible. Newborn screening accomplishes this goal for a growing number of disorders (Box 27.2). Screening criteria that should be met are relatively high frequency of the disorder, severity of symptomatology in untreated

BOX 27.2 PARTIAL LIST OF DISORDERS SCREENED FOR IN NEWBORN SCREENING PROGRAMS

Defects Identifiable by Tandem Mass Spectrometry (MS/MS)

Amino Acid Disorders and Urea Cycle Disorders

- Phenylketonuria
- Homocystinuria
- Hypermethioninemia
- Argininosuccinic acidemia
- Citrullinemia
- Argininemia
- Tyrosinemia types I and II

Organic Acid Disorders

- Maple syrup urine disease
- Isovaleric acidemia
- Methylmalonic acidemia
- Propionic acidemia
- Glutaric acidemia type I
- Isobutyryl-CoA dehydrogenase deficiency
- 3-Hydroxy-3-methylglutaryl-CoA lyase deficiency
- 2-Methylbutyryl-CoA dehydrogenase deficiency
- 3-Methylcrotonyl-CoA carboxylase deficiency

Fatty Acid Oxidation Disorders

- Medium-chain acyl-CoA dehydrogenase deficiency
- Short-chain acyl-CoA dehydrogenase deficiency
- Very-long–chain acyl-CoA dehydrogenase deficiency
- Long-chain hydroxyacyl-CoA dehydrogenase deficiency
- Glutaric acidemia type II
- Carnitine palmityl transferase deficiency type II
- Carnitine/acylcarnitine translocase deficiency
- Multiple CoA carboxylase deficiency
- Trifunctional protein deficiency

Disorders Screened by Other Methodologies

- Congenital adrenal hyperplasia
- Galactosemia
- Sickle cell disease and hemoglobinopathies
- Hypothyroidism (congenital)

Data from the National Newborn Screening and Genetics Resource Center; website: http://genes-r-us.uthscsa.edu.
CoA, Coenzyme A.

individuals, availability of treatment, simplicity of obtaining tissue for testing, and availability of a simple screening test with high sensitivity and specificity at reasonable cost. There have been major changes in the laboratory technologies available for newborn screening—specifically, the introduction of tandem mass spectrometry (MS/MS).[15] **Using MS/MS technology, a single blood spot from a newborn can detect more than 60 metabolic disorders.**[10] Although many of the disorders detectable by MS/MS are rare, screening has been instituted in most states because screening remains inexpensive and a variety of disorders can be identified in a single assay. In most instances, additional testing adds approximately $25 to $60 to the cost of the newborn screen.[42]

MS/MS has been used for many years to measure metabolites in blood and urine. The technology is now applied to newborn screening programs. A mass spectrometer is an instrument that separates and quantifies ions based on their mass/charge ratio (m/z). In MS/MS, there are two spectrometers in a series. After sample preparation from the dried blood spot, the process of tandem mass is automated and the analysis is computerized. The process takes only a few seconds, and an entire screen takes less than 2 minutes.[42] The MS/MS system is capable of handling a high volume of samples; thus, it is an excellent technology for use in newborn screening. Currently the false-positive rate is 0.3% for all disorders.[72]

Screening for metabolic disorders is mandated by individual states, and all states require screening for PKU, hypothyroidism, congenital adrenal hyperplasia, sickle cell disease, s-beta thalassemia, and galactosemia.[7] However, the Advisory Committee on Heritable Disorders in Newborns and Children (ACHDNC) has worked with the Secretary of Health and Human Services to formulate the Recommended Uniform Screening Panel (RUSP), which recommend that all states screen for a panel of 35 core conditions and an additional 26 secondary conditions that may be detected by screening.[7] These recommendations are also supported by the American Academy of Pediatrics (AAP) and the American College of Medical Genetics.[5,6] The additional disorders most often screened for include amino acid disorders (homocystinuria, maple syrup urine disease), organic acids (glutaric, methylmalonic, and propionic acidemias), disorders of fatty acid metabolism (medium-chain and very-long–chain acyl-coenzyme A (CoA) dehydrogenase deficiency), hemoglobinopathies including sickle cell anemia, and others such as biotinidase deficiency, congenital adrenal hyperplasia, and cystic fibrosis.[5]

Each state decides individually what will be included in its newborn screening program.

Although some states require all of the tests on their list to be mandatory, other states offer a supplemental program in addition to the mandated program, often called *expanded newborn screening.* Testing for disorders listed on the mandated program is necessary, and only parents objecting on religious grounds may decline the mandated screen (e.g., Ohio Revised Code 3701.501). **In those states offering a supplemental program, parents can choose whether to screen their child for the disorders listed.** The program is optional, and no extra blood or additional tissue is necessary.[36] In most situations, parents are asked to sign a participation form to opt in to the supplemental program. With states now using MS/MS in their newborn screening process,[7] state legislators are constantly changing and updating their screening practices. It behooves the clinician to periodically check with the state newborn screening program for updates. The "Baby's First Test" resource provides up-to-date information for health professionals as well as educational and family resources about newborn screening at the local, state, and national levels.[7]

Any screening test may give both false-positive and false-negative results; this includes those identified by MS/MS. **Thus, a positive screen result must be followed by a confirmatory diagnostic test.**[5] Moreover, if there is clinical suspicion of a particular disorder despite a negative screening result, further diagnostic testing is warranted. **In addition to confirming positive screens, clinicians may have to deal with the concern for increased parental anxiety based on false-positive screens.** Waisbren and colleagues found in a prospective interview study of 254 mothers and 153 fathers that stress levels of parents whose infants had false-positive screening results were significantly higher than those with normal results.[68] Thus, for clinicians in the NICU setting, being cognizant of the potential for an increased number of positive newborn screening results is important for the care of the neonate, as well as for parent teaching. (For an in-depth review of those disorders that may be part of the newborn screening program, refer to the AAP's newborn screening recommendations.[5])

Newborn Hearing Screening. **Newborn hearing screening tests are now available that have high sensitivity when administered properly.**[6] Hearing loss is present in approximately 1 to 2 per 1000 infants. **Research has demonstrated that there are both genetic and nongenetic causes of deafness.** Eighty percent of prelingual deafness has a recognizable genetic etiology, and, of these, the most common cause of autosomal recessively inherited nonsyndromic hearing loss results from mutations in the connexin 26 *(Cx26)* gene, a member of the connexin family of gap junction proteins.[61] Commercial DNA–based screening tests are now available to detect common genetic forms of deafness including *Cx26* and mitochondrial deafness.[1] The AAP recommends that all newborns be screened for hearing loss before the age of 3 months.[4] The American College of Medical Genetics has recommended, in addition to screening and subsequent confirmation of hearing loss by diagnostic tests, that protocols be developed to ensure that appropriate genetic counseling be provided if diagnostic testing includes genetic testing.[1,30] This would provide families with accurate information about causes and recurrence risks for parents, siblings, and other family members.

ABNORMALITIES RESULTING FROM ENVIRONMENTAL EXPOSURES

Environmental exposures may have adverse (teratogenic) effects on fetal development, resulting in malformations and functional neurodevelopmental abnormalities in infants and children. The four major prerequisites needed for teratogenic action are[2]:

1. The agent must have the **potential to be teratogenic.** Few conclusive data are available about the teratogenicity of most chemicals and drugs in humans. Animal studies provide most of the currently available data on the teratogenicity of agents; however, not all are always applicable to human situations. To prove that an agent is teratogenic, a causal relationship between the exposure and presence of a malformation must be documented; just the history of an exposure to an agent is not sufficient. **Although very few agents have been documented to be teratogenic in humans, a few stand out, such as alcohol, cocaine, anticonvulsants, and ISOtretinoin (Accutane)** (Fig. 27.12).
2. The **timing of the exposure** during pregnancy is of major importance. **For the agent to adversely affect the fetus, it must be present during organogenesis or histogenesis.** Exposures occurring within the first 2 weeks

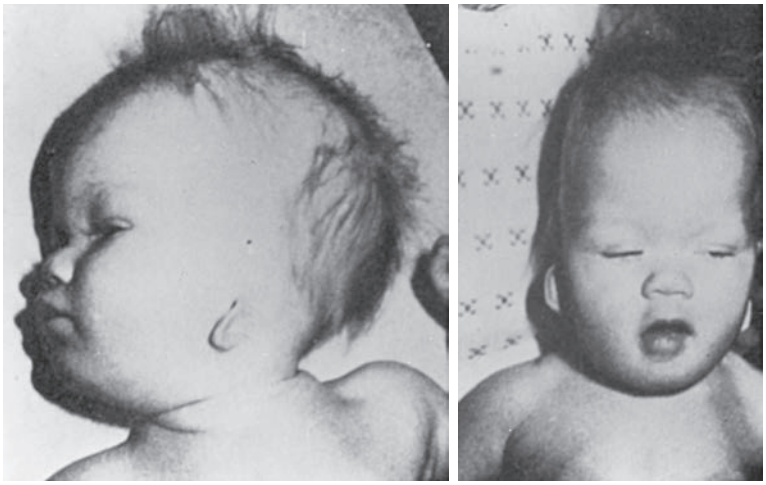

FIGURE 27.12 Infant exposed to Accutane in utero. Note dysmorphic face and auricles with atretic ear canal. (Courtesy Dr. Eva Sujansky, Genetic Services at The Children's Hospital, Denver, Colo.)

after conception, before cell differentiation, will either cause no damage or result in fetal wastage. **Exposures occurring from 2 to 12 weeks of gestation (period of organogenesis) may result in major malformations.** After completion of development of the major organ systems, harmful exposures usually do not result in malformations but can be responsible for organ dysfunction. However, some agents may morphologically disrupt previously intact organs.[16] Conversely, it has been shown that if the harmful exposure to an agent such as alcohol has been discontinued, the damage is less severe than if the exposure continues throughout the pregnancy.

3. **Dosage of the teratogen is related to the severity of the teratogenic effect;** the higher the dose, the more severe the effect and the higher the frequency of affected fetuses.
4. Finally, **genetic makeup or genetic susceptibility of the mother and fetus** may affect the metabolism, as well as tissue sensitivity to the teratogen.

Teratogenic agents may be divided into four categories: (1) infectious agents, (2) chemical agents (drugs and environmental agents), (3) radiation, and (4) maternal factors (such as maternal diabetes or maternal PKU). Chapter 2 provides excellent overviews of most of these exposures.

Traditionally, only maternal exposures to teratogens have been implicated in malformations. There has been a concern that some paternal exposures also may be teratogenic. Theoretically, a teratogen excreted in the semen could be introduced into the fetal environment and potentially be teratogenic to the developing fetus.[2]

Teratogenic exposures should be considered in the differential diagnosis of congenital malformations and CNS dysfunction if one can document fetal exposure and the phenotype is compatible with the known effects of the suspected teratogen. The recognition of exposures is important for genetic counseling; if they can be avoided during subsequent pregnancies, recurrence risk is not increased. Frequently there is phenotypic overlap between the fetal abnormalities caused by specific teratogens and other syndromes. The family should be referred to a genetics clinic to rule out chromosomal, single-gene, and sporadic syndromes with overlapping phenotypes.

DATA COLLECTION

A genetic evaluation consists of the same components found in any medical evaluation; however, the emphasis may be different. Moreover, **to make an accurate diagnosis and assessment, medical information about extended family members may have to be obtained.** For an overview of the

evaluation of the neonate with single or multiple congenital anomalies see the chapter by Jones and Jones[31] on a clinical approach to the dysmorphic child or the article by Jones and Adam[30] on the evaluation of the dysmorphic infant.

History

Prenatal and perinatal histories, from a genetic standpoint, should elicit information about potential teratogenic exposures, including maternal disease and acute illness. Fetal growth and behavior (e.g., fetal movement, swallowing) provide important clues for the assessment of fetal neuromuscular function. Thus, **information about fetal position, movement, and amount of amniotic fluid should be obtained.** Perinatal history should include the duration of gestation; anthropometric birth measurements, including head circumference; and information about perinatal adaptation. In a newborn with abnormal CNS functioning, it may be difficult to differentiate between primary maldevelopment and dysfunction caused by perinatal complications. **An abnormal newborn with a genetic disorder may present with signs suggestive of birth asphyxia (i.e., hypoxia, acidosis, hypotonia, seizures).** Moreover, because many a priori abnormal newborns have an increased frequency of perinatal complications, **a documented birth injury does not rule out the presence of a genetic cause.**

Family history may be extremely helpful in clarifying the causes and risk for recurrence. The information obtained from the parents may have to be complemented by physical examination of the parents and other family members and review of the medical records. This may be necessary because parents may not be aware that different defects in family members may be an expression of the same disorder. For example, an autosomal dominant gene may cause mild hypoplasia of thumbs in one family member and complete absence of thumb and radii in another.

A three-generation pedigree also should be obtained that includes health information about parents, siblings, grandparents, aunts, uncles, and cousins. Specifically, information about miscarriages, stillbirths, childhood deaths, relatives born with congenital malformations and birth defects or who have intellectual disability and other disorders that "run in the family" should be obtained.[11]

FIGURE 27.13 Dysmorphic feature of hypertelorism. Note wide-spaced eyes. (From Gilbert-Barness E, Kapur RP, Oligny LL, et al. *Potter's Pathology of the Fetus, Infant, and Child.* 2nd ed. St Louis, Mo: Mosby; 2007.)

Information about ethnic background and consanguinity also should be collected.

Physical Examination

A physical examination should enable the examiner to detect major and minor malformations (dysmorphic features). *Minor malformations* **are defined as structural variations found in less than 4% of the general population and that have no significant medical or cosmetic effect.** This is in contrast to structural variations that are found in more than 4% of the newborn population and represent a normal variation, such as a Mongolian spot or a capillary hemangioma on the forehead. Minor malformations may provide important clues to the identification of a specific syndrome. **None of the minor malformations as an isolated finding are clinically significant; however, a combination or pattern of minor malformations may indicate a specific disorder.** For example, dysmorphic features such as up-slanted eyes, epicanthic folds, hypertelorism (Fig. 27.13), and abnormal dermatoglyphic pattern (Fig. 27.14) in an infant with a congenital heart defect are suggestive of Down syndrome. **Minor malformations also may alert the clinician to the presence of major malformations.** For example, preauricular ear tags are associated with an increased frequency of inner ear malformations and hearing impairment. In addition, **the greater the number of minor malformations an infant has, the higher the chance is of finding one or more major malformations.**[30,39]

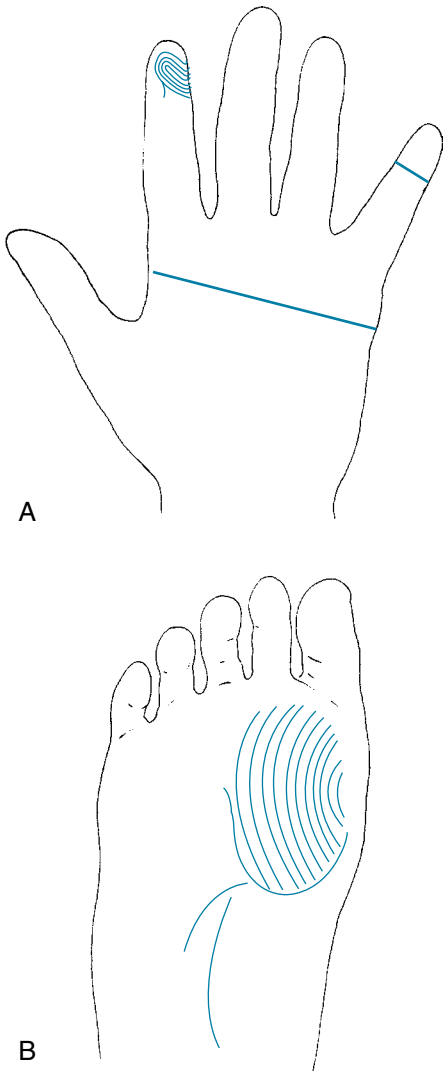

FIGURE 27.14 Dermatoglyphics commonly seen in infants with Down syndrome. **A**, Ulnar loop on the second digit, single flexion crease on the fifth digit, and single palmar crease (simian line). **B**, Tibial arch pattern on hallucal area of foot.

If minor malformations are identified, the parents of the infant should be examined. **Presence of the same minor malformation in one of the parents may indicate a benign familial feature.** Alternatively, **finding the same dysmorphic features in other family members may represent an inherited genetic disorder.** A mild syndactyly between the second and third toes is frequently an isolated, inherited finding without clinical significance. However, syndactyly associated with craniosynostosis may represent an autosomal dominant disorder with variable expression and significant clinical sequelae.

If an infant looks dysmorphic, documentation of specific features should be recorded. Actual measurements compared with age-related norms should be used to measure body proportions, length of extremities, and such facial features as distance between eyes, length of eye fissures, size of ears, and length of philtrum. Description of the other features, such as the shape of the neck (webbed) or the chest size (widely spaced nipples), or a specific description of any skin lesions, including size, shape, location, and color (hyperpigmented or hypopigmented), may provide important clues for a specific diagnosis. **Dermatoglyphic analysis—the analysis of the dermal ridges on the digits, palms, and soles—may prove useful for determining the timing of a fetal insult.**[70] Development of ridges begins during the thirteenth week of gestation and is complete by the nineteenth week. Thus, **many chromosomal and genetic disorders have disruptions of the dermal ridge patterns.** For example, an infant with Down syndrome may have a single palmar crease (simian crease), a single flexion crease of the fifth digit, and an open field pattern (tibial arch) on the hallucal area of the foot.[70] Moreover, specific descriptors or, even more useful, photographs, should be used to describe dysmorphic findings (e.g., as noted in Fig. 27.13).

Photographs are particularly important if the infant is critically ill and the constellation of findings does not immediately suggest a specific syndrome. Thus, the patient's findings may be more accurately shared with other clinicians in the future. Jones and Adam[30] provide a concise review of the evaluation of a dysmorphic newborn.

Smith's Recognizable Patterns of Human Malformation[32] and other texts document a large number of syndromes, some of which are rare and may not be immediately recognized by neonatal staff. It also may be very helpful and important to **consult a clinician who is familiar with dysmorphology and syndromology to help establish a diagnosis.**

Laboratory Data

When a genetic disorder is suspected, a number of diagnostic studies may be useful in delineating a diagnosis, including chromosome analysis; CGH array, which is now considered the first-tier test for

the evaluation of a dysmorphic newborn[47]; molecular DNA testing; biochemical studies to rule out inborn errors of metabolism; radiographs; organ imaging; and, when appropriate, autopsy. Not all of these studies are routinely used in all patients, but selection of studies is based on clinical suspicion of a particular disorder.

CHROMOSOME ANALYSIS

As mentioned, chromosome microarray is now considered the first-line genetic test for neonates and infants with dysmorphic features and/or malformations that are not specific to a well-recognized genetic syndrome per ACMG guidelines.[47,62] **As with a karyotype, results may not be available for 2 or 3 weeks;** however, if results are urgently needed for clinical management, a chromosome analysis from bone marrow can be available within a few hours and preliminary results from blood lymphocyte culture can be obtained in 48 hours. Indications for chromosome analysis and microarray analysis have been listed previously. **Regardless, blood for a microarray and/or karyotype should be obtained in all critically ill infants for whom there is no plausible explanation for their grave clinical course, before death occurs.** For postmortem examination, chromosomes or DNA for a microarray also may be obtained from any tissue—in particular, intracardiac blood, thymus, skin, and gonad. Under sterile conditions, these tissues should be obtained as soon as possible after the infant's demise. Tissue should be transported to the laboratory in a tissue culture medium or sterile saline solution, not in formalin.

MOLECULAR DNA ANALYSIS

There is a **growing list of disorders for which the gene has been identified, and thus molecular diagnostic tests are commercially available.** Although the Genetic Alliance, an international coalition comprising 10,000 organizations, of which 1200 represent disease-specific advocacy groups, research, and health care organizations, has access to databases with over 10,000 conditions at their website *(www.geneticalliance.org),* not all those disorders are amenable to DNA testing. Moreover, often a clinical diagnosis of a recognized syndrome does not require additional diagnostic testing.[30] **However, if the diagnosis is not clear, if there is a need to confirm a diagnosis for management issues, or if additional information about a clinically recognized disorder is needed for family planning and genetic counseling, then DNA testing may be extremely helpful.**[30]

Whenever the health care professional has a reasonable suspicion of a specific diagnosis based on clinical phenotype, it is reasonable to suggest molecular testing if it is available to confirm the diagnosis and provide appropriate genetic counseling. However, **the clinician must remember that mutational analysis is complex, and, although it can confirm a diagnosis when the test result is positive, a negative result may not determine conclusively that the neonate is not affected.**[3] Some disorders (listed with their gene symbol or chromosomal locus) that might be seen in the neonate for which molecular gene testing is available are listed in Table 27.1.

BIOCHEMICAL STUDIES

A critically ill neonate who has a condition suggestive of an inborn error of metabolism or who has no specific diagnosis should have blood and urine sent for appropriate biochemical studies (specified in the "Inborn Errors of Metabolism" section). If such studies have not been obtained, postmortem tissue such as liver should be obtained and frozen for later biochemical analysis. **Care providers should request detailed instructions from a laboratory specializing in testing for inherited metabolic disorders about which tissue is appropriate and how it should be obtained, stored, and shipped to the laboratory.**

RADIOGRAPHS

X-ray examination should be obtained if a skeletal dysplasia or other skeletal abnormality is suspected or if the differential diagnosis includes a genetic syndrome that has skeletal defects as part of the phenotype. Moreover, **if a localized skeletal defect is found, a skeletal survey should be obtained to identify other possible skeletal defects.**

ORGAN IMAGING

Organ imaging by **ultrasonography, magnetic resonance imaging (MRI), and computed tomography (CT) scan should be used to rule out structural abnormalities of major organs** such as the brain, heart, and kidneys. Malformations may be suspected on the basis of clinical symptoms such as anuria or on the basis of known nonrandom associations of certain birth defects, such as the vertebral/anal/tracheoesophageal fistula/renal/radial (VATER) association. In addition, some dysmorphic features are associated with major malformations, and one must rule out these features. For example, there

TABLE 27.1 PARTIAL LIST OF DISORDERS SEEN IN THE NEWBORN PERIOD WHERE DNA MOLECULAR TESTING IS AVAILABLE CLINICALLY

SYNDROME	GENE	CHROMOSOMAL LOCATION
Apert and Crouzon	*FGFR2*	10q26
Achondroplasia and thanatophoric dysplasia	*FGFR3*	4p16
Cystic fibrosis	*CFTR*	7q31
Congenital myotonic dystrophy	*DMPK*	19q13
Miller-Dieker	Microdeletion	17p13.3
Osteogenesis imperfecta	*COL1A1* or *COL1A2*	17q21.3-q22
Pfeiffer	*FGFR1*	10q26
Prader-Willi and Angelman	Uniparental disomy, imprinting, deletion	15q11.3-q13
Smith-Lemli-Opitz	*DHCR7*	11q12-q13
Treacher Collins	*TCOF1* *POLR1C* *POLR1D*	5q32-q33 6p21.1 13q12.2
22q11.2 deletion syndrome	Microdeletion	22q11.2
Waardenburg type 1	*PAX3*	2q35
Waardenburg type 2	*MITF*	3p14.1-p12.3
Williams	*ELN* (elastin)	7q11.2
Wolf-Hirschhorn	Microdeletion	4p16.3

is an increased incidence of underlying midline brain defects associated with some facial dysmorphic features.

AUTOPSY

In the event of a neonate's death, **an autopsy may provide crucial information for the establishment of a correct diagnosis.** As outlined, chromosome analysis, microarray, DNA testing, biochemical studies, x-ray examination, and photographs should all be included. **In the absence of a specific, confirmed diagnosis, the family should be strongly encouraged to consent to an autopsy, and a tissue sample should be frozen for further testing.** Without this valuable information, subsequent genetic counseling of the parents, including clarification of the causes and recurrence risks, becomes impossible.

TREATMENT AND INTERVENTION

For most genetic disorders and malformations, there are no "cures" and only symptomatic **treatment is available; that is, conventional medical and surgical interventions are instituted, although the basic genetic defect is not corrected.** Surgical intervention for specific malformations will depend on the malformation, its cause, and prognosis. For example, surgical repair of a cleft lip and palate usually has an excellent outcome, although the underlying genetic cause has not been altered. In other instances, the diagnosis may provide direction and guidance to the health care professionals and family as to the appropriate course of action. An infant born with a hypoplastic left side of the heart may be considered a candidate for a heart transplant. However, if the cardiac malformation is the result of a chromosomal abnormality with an extremely poor prognosis, such as trisomy 13, the management of that infant may be palliative rather than corrective depending on the health care team's expertise and family wishes.

With the diagnosis of a metabolic disorder, treatment may be one of a nutritional or pharmacologic approach, such as the restriction of phenylalanine in an infant with PKU or the replacement of a deficient hormone, such as thyroid supplements in hypothyroidism. For some conditions,

such as OI, the best approach may be educating the parents on specific techniques of holding and caring for an infant to prevent further fractures. In some disorders, organ or tissue transplantation may be appropriate. **Hematopoietic stem cell transplantation has been found to be effective in treating select genetic disorders,** including a few lysosomal storage disorders[10] and beta-thalassemia.[8] Because specific treatment leading to a cure is not available for most genetic disorders, the use of genetic counseling and available reproductive alternatives, such as prenatal diagnosis, in vitro fertilization, preimplantation diagnosis, and artificial insemination by donor, are acceptable alternatives for some families.

THE HUMAN GENOME PROJECT

The year 2000 marked the announcement that the vast majority of the human genome had been sequenced.[17] This international effort, funded in part by the National Institutes of Health (NIH), began in 1990 with the development of genetic and physical maps of the human genome and completed its initial goals in 2000 with a draft of the sequencing of the 3 billion base pairs of the human genome. Defining the sequence of the human genome is only the beginning of the application of that knowledge to current and future research opportunities that will provide avenues for innovative therapies. With the introduction of massively parallel DNA sequencing (often referred to as NextGen sequencing), the ability to examine the entire genome is now a reality. Tests based on next-generation sequencing (NGS) technologies are rapidly replacing many single gene–sequencing tests. These tests use disease-targeted exon capture, whole-exome sequencing (WES), or whole-genome sequencing (WGS) strategies. *WES* allows for all the exomes in the genome (the coding portion of DNA) to be examined and to identify disease-causing mutations. *WGS* investigates an individual's entire genome (all components of genes such as introns, regulatory elements, etc.) and is available clinically in some instances.[28,64] Moreover, some institutions are using a rapid turnaround time approach with WES and WGS in the neonatal setting, which have been found to provide increasing clinical utility and demonstrate improved outcomes.[1,22,54] **These new powerful technologies for understanding gene expression are also being applied to designing drugs that will moderate disease pathways.** Moreover, the field of genomics is providing opportunities to predict responsiveness to drug therapies, because reactions to drugs often are based on individual genetic variations.[64] With the identification of common gene variants involved in drug action or metabolism, health care professionals might be able to predict an infant's response—good or bad—to a particular drug regimen.[17]

With the numerous advances in molecular genetics, it is predicted that many genetic disorders and malformations may be amenable to treatment in utero or after birth. **In utero correction of such birth defects as urinary tract malformations, myelomeningocele, and diaphragmatic hernia has been successful.**[12,19,52] In 1990, the first human trial of gene therapy was undertaken at the NIH. The treatment was somatic gene replacement in a 4-year-old child with adenosine deaminase deficiency, a rare inherited disorder that destroys the immune system.[40] Successful efforts using improved gene therapy techniques continue with this disorder.[13] Since that time, a number of gene therapy trials for other genetic disorders have been done. Although the arena of gene therapy in general has been somewhat disappointing, the results have led to new areas of research and experimentation with new promising techniques.[59] The development of safer and more effective vectors based on technologies spearheaded by the Human Genome Project should provide significant improvements in gene therapy, such as that seen in an application of gene therapy with hemophilia B.[35] Finally, newer gene editing technologies have provided researchers and clinicians the ability to change the DNA of organisms by altering their genetic make-up. One such technique is CRISPR-Cas9 (clustered regularly interspaced short palindromic repeats and CRISPR-associated protein 9).[24] These technologies are the "wave of the future" in potentially successfully treating and perhaps curing some genetic disorders. In fact, the NIH has approved clinical trials involving humans using CRISPR-Cas9 technology to treat cancers.[57]

PARENT TEACHING

The birth of any infant with a malformation or genetic disorder is a devastating event for any family. Members of the neonatal staff are on the front lines helping families deal with the infant's problems and providing the best environment for both the critically ill newborn and his or her family.

BOX 27.3 PARENT/CAREGIVER TEACHING GENETIC CONSIDERATIONS

- Genetic diagnosis is essential not only for management of the neonate's condition but also for counseling.
- Genetic counseling assists parents and care providers in addressing management issues such as cause and diagnosis, prognosis, treatment and interventions, short-term and long-term care, and follow-up.
- Genetic counseling assists parents in decisions about future pregnancies or the use of assistive reproductive technologies.

In general, the most difficult factor for most parents and families to deal with is the unknown. Thus, once again, the need for an accurate diagnosis becomes paramount (Box 27.3). **Moreover, even when the diagnosis carries a poor prognosis, parents would prefer having the information so they can realistically anticipate and prepare for what is to come.**[29] Currently, many parents obtain information about their infant's malformation or genetic disorder through prenatal screening and diagnosis and have already begun the process of anticipatory grief by the time the infant is admitted to the NICU. **Parental feelings of disbelief, shock, anger, or despair may already have been replaced with a "sense of relief" about confirmation of the abnormalities and a need to deal with the situation at hand.**[41]

Chapter 30 provides an excellent review of the grief and mourning process that parents will experience when their anticipated "perfect baby" is born with a malformation or genetic disorder.

From a genetic counseling standpoint, a number of principles should be incorporated into the plan of care for the neonate and his or her family. First—and it cannot be overstated—**an accurate diagnosis is essential if genetic counseling is to be provided.** Even with what appears to be an isolated malformation, a genetics consultation may be appropriate to rule out other causes, such as single-gene disorders or chromosomal abnormalities. After establishing the diagnosis, one can realistically address the prognosis, treatment, and other management issues with the family. **Finally, at the appropriate time for the family, recurrence risks and options for future pregnancies can be addressed** (see the American College of Medical Genetics practice guideline regarding when a genetic consult may be helpful).[55]

Certainly, the busy and stressful environment of the NICU is not the most conducive atmosphere for obtaining and providing detailed information. **However, it is appropriate for the geneticist to make an initial contact with the family in the NICU, where basic information about the pregnancy and perinatal and family histories can be obtained that will aid in diagnosis and defining the cause.** The neonatal staff and geneticist can then address diagnosis and management. Later, at a time appropriate for the family, such issues as recurrence risks can be addressed. Eventually the family should receive a written summary of all the issues discussed for their own documentation.

The genetic evaluation is a complex and multifaceted process that cannot be done in isolation; it requires a team approach. The geneticist can assist the NICU staff in determining the diagnosis, cause, and prognosis so that appropriate management of the infant can be implemented and aid in future counseling of the families they serve. **The neonatal staff should use the genetics team as a resource for consultation and assistance in providing infants and families with the most appropriate and complete health care available.**

Resource Materials

Gene Reviews: (http://www.genereviews.org). *Gene Reviews* is an online peer-reviewed database developed and maintained by the University of Washington. Gene Reviews currently lists 730 chapters regarding genetic disorders that have information authored by experts for a particular disorder. A wealth of information is presented, including (1) major clinical features of the disorder, (2) what is known about the genetics and inheritance, and (3) suggestions about a differential diagnosis for the findings. Each entry has an extensive reference list and information about support groups and is updated on a regular basis. The site also includes educational materials about genetics, genetic disorders, and genetic testing including an illustrated glossary.

Genetic Alliance: (www.geneticalliance.org). The Genetic Alliance is a coalition of hundreds of genetic advocacy organizations, health professionals, clinics, hospitals, and companies. Type in a disorder and be transported to that support group's website for information about the disorder and resources for people with the disorder.

Genetics Home Reference: (http://ghr.nlm.nih.gov). The *Genetics Home Reference* is the National Library of Medicine's website for consumer information about genetic conditions and the genes or chromosomes responsible for those conditions. Summaries are provided about hundreds of genetic disorders. Each summary also contains information and Web links to other resource materials.

Genetic Testing Registry (http://www.ncbi.nlm.nih.gov/gtr). The Genetic Testing Registry is an online database maintained by the National Institutes of Health as a central repository of genetic tests. The registry lists more than 55,935 tests for 11,437 conditions, 16,451 genes, and 518 laboratories. Information included for laboratories includes the test's purpose, methodology, validity, evidence of the test's usefulness, and laboratory contacts and credentials.

OMIM: (http://www.ncbi.nlm.nih.gov). *Online Mendelian Inheritance of Man* database is a catalog of genetic disorders and human genes. It is overseen by its originator, Dr. Victor A. McKusick, and maintained by the National Center for Biotechnology Information (NCBI). The database contains information about known inherited disorders, including information about the genes responsible for the disorder, a clinical synopsis, and references.

28 NEONATAL SURGERY

MARGARET E. GALLAGHER, ANNETTE S. PACETTI, HAROLD N. LOVVORN, III, AND BRIAN S. CARTER

Congenital malformations may be found in up to 3% of all newborns and are an important cause of morbidity, early infant death and chronic disability.[13] Although overall infant mortality has declined, the **mortality attributable to birth defects has increased, and up to 20% of neonatal deaths have been attributed to congenital malformations.**[2,70] In the last decades, improvements in prenatal imaging and perinatology have allowed earlier diagnosis and intervention for surgically correctable malformations. Because of the complexity of accurate prenatal imaging and diagnosis, many anomalous conditions continue to escape early detection and present to the neonatology and surgical teams with advanced developmental consequences. **The care of a neonate having a major congenital malformation therefore may be resource intensive and costly.** In a study of one regional neonatal intensive care unit (NICU), newborns having major congenital malformations accounted for 27% of NICU referrals, 32% of total NICU days, and 40% of NICU costs. Moreover, **surgery was more frequent in newborns having major malformations and one third required ongoing medical support at the time of discharge.**[62] A more recent study by Centers for Disease Control and Prevention (CDC) researchers found that costs for care for birth defects among infants were the highest, at $9 billion, or 35% of hospitalizations for all children under 1 year of age.[14] **Early diagnosis, comprehensive neonatal care, and a multidisciplinary approach are necessary to ensure an optimal outcome for both parent and child.** This chapter briefly describes the embryology, clinical history, diagnostic evaluation, and therapeutic intervention of common neonatal surgical conditions.

DIAPHRAGMATIC HERNIA

Physiology and Etiology

Congenital diaphragmatic hernia (CDH) is a defect in closure of the diaphragm that occurs in 1 in 4000 live births. A posterolateral defect, or Bochdalek diaphragmatic hernia (Fig. 28.1), accounts for nearly 95% of all CDHs and may be left (95%) or right sided (5%). Much less common is the Morgagni diaphragmatic hernia (Fig. 28.2), which results from a failure of anteromedial closure and resides in a substernal location. Several theories have been proposed to explain the mechanism for how this **malformation of the diaphragm occurs, but currently the most widely accepted theory is failure of the pleuroperitoneal canal to close completely during the 8th week of gestation.** If a patent pleuroperitoneal canal persists through the 11th week of gestation, a period when the intestine returns from its normal herniation into the umbilical cord, the stomach, bowel, and spleen may be forced into the chest. **Resultant compression of the developing lung leads to a variable extent of pulmonary hypoplasia.** Despite many studies in both animal models and infants over the past four decades, the causes of the pathophysiologic changes that occur in the underdeveloped lung are not well understood and are likely multifactorial. Recognition of the associated abnormal physiologic mechanisms has failed to define these alterations as cause or effect for the malfunctioning lung.

In addition to alveolar hypoplasia, abnormal development of the pulmonary vasculature is a major contributor to the clinical challenges in managing CDH and its inherent risk for pulmonary hypertension. Postnatal blood flow through

BLUE type highlights content that is particularly applicable to clinical settings.

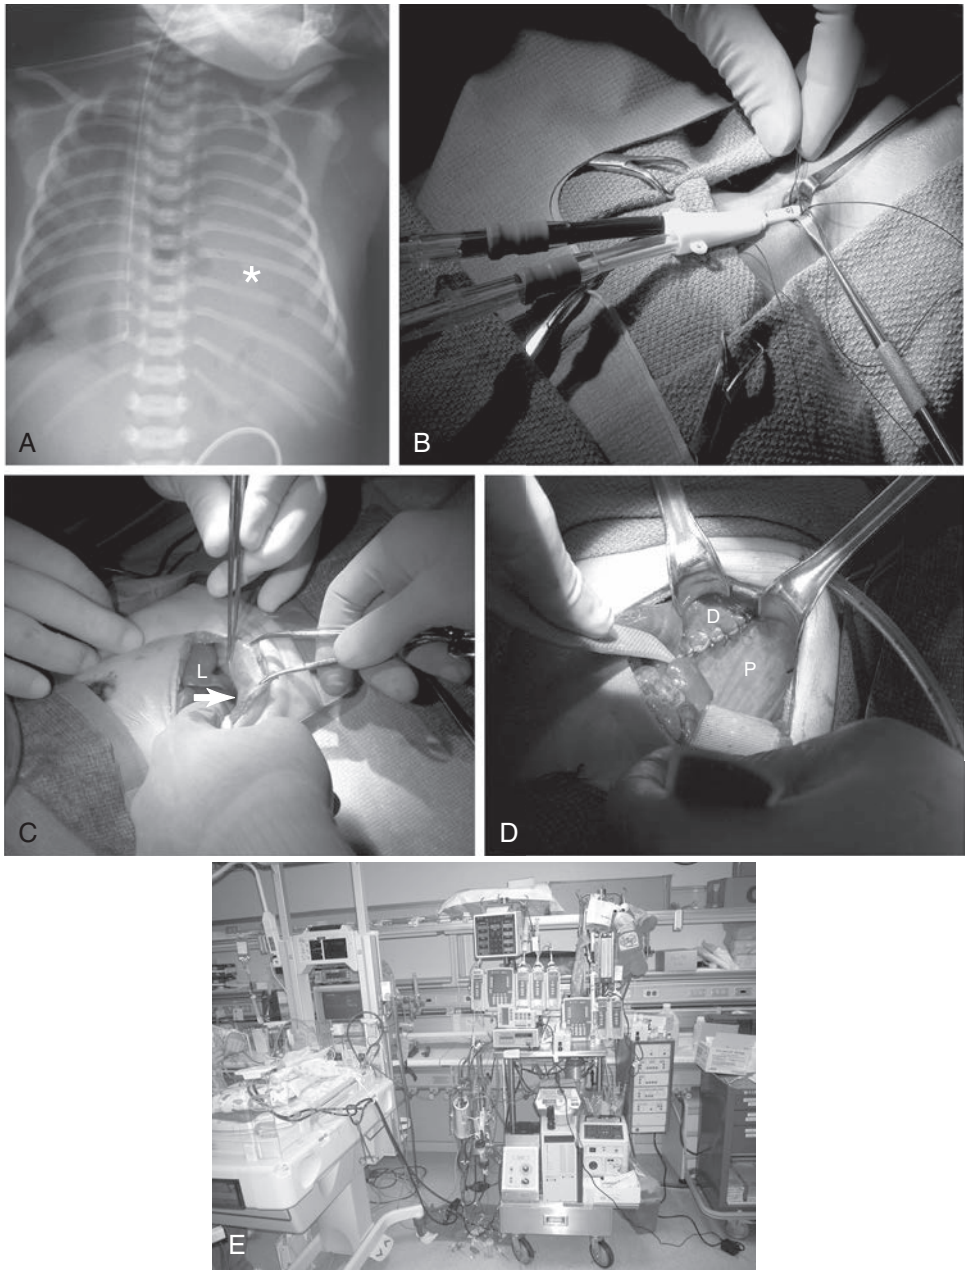

FIGURE 28.1 Newborn with left congenital diaphragmatic hernia (CDH), or Bochdalek hernia. **A**, Chest radiograph shows liver herniation *(asterisk)* into the left chest. Note displacement of heart and orogastric tube to right and minimally aerated lung on left. **B**, Dual-lumen venovenous cannulation via right internal jugular vein for extracorporeal life support (ECLS). **C**, Four days later, baby had stabilized on ECLS, so repair was performed in the neonatal intensive care unit (NICU) on ECLS. Note left lobe of liver *(L)* herniating beneath a diminutive anterior leaflet of the left diaphragm (in forcep). Left lobe of liver is between forcep and surgeon index finger. **D**, Defect required a biosynthetic patch (*P; D,* anterior leaflet of diaphragm). **E**, Panoramic view of neonatal ECLS equipment, which aids in bedside operative planning.

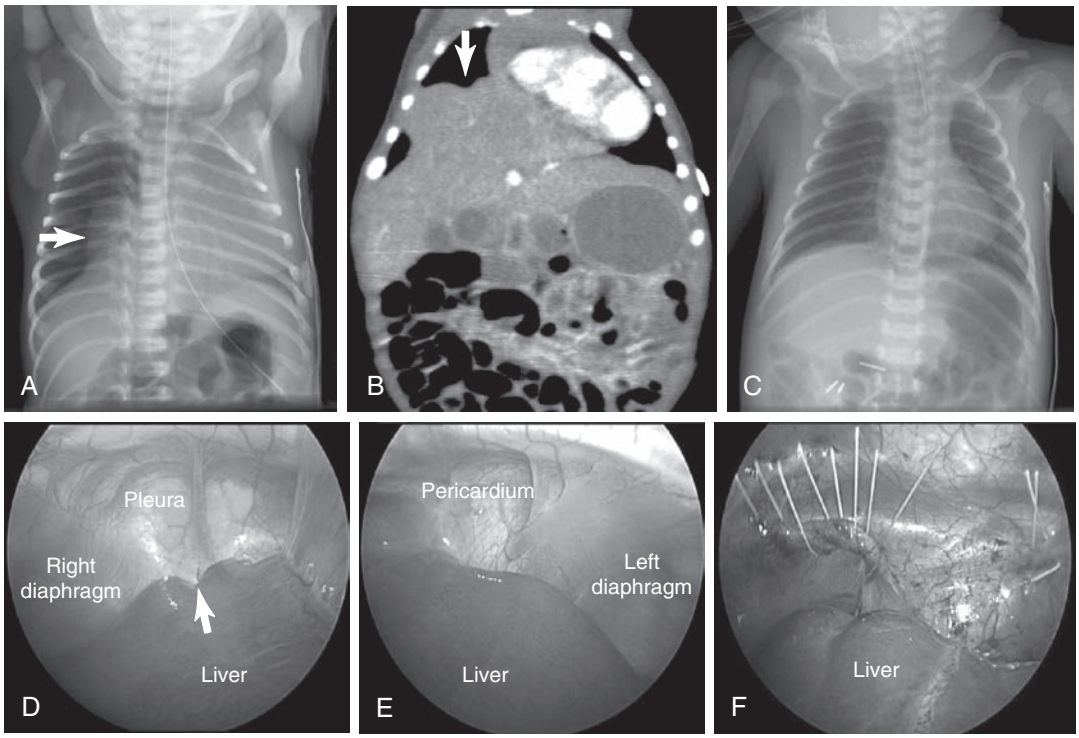

FIGURE 28.2 Newborn with anterior Morgagni diaphragmatic hernia. **A, B,** Chest radiograph and CT scan, respectively. *Arrows* show liver herniation. **C,** Postoperative chest radiograph shows complete reduction of liver and correction of hernia. **D–F,** Laparoscopic technique to repair large anterior defect: Right and left diaphragms are sutured to abdominal wall anteriorly; sutures are passed through the entire wall of abdomen, and knots are secured below skin level. *Arrow* shows groove in liver corresponding with CT scan image.

these hypoplastic lungs is compromised by both a reduced total number of pulmonary arterioles and an increased muscularization of the arteriolar bed. As a result, pulmonary vasculature capacitance is reduced and responsiveness to signals for smooth muscle relaxation may be lost. **Persistent pulmonary hypertension after birth maintains patency of and blood flow through natural fetal shunts. Resultant pulmonary hypoperfusion and systemic hypoxemia may be extreme and is often irreversible and recalcitrant to conventional therapy.**

Data Collection

HISTORY

Technologic advances in ultrasonography have facilitated earlier and more accurate antenatal diagnosis of diaphragmatic hernias, permitting planning of intervention and counseling of parents, as appropriate. High-quality prenatal ultrasound can diagnose a CDH early in pregnancy and also identify high-risk infants who may have worse outcomes. Prenatal lung-to-head ratio (LHR) is a widely accepted prognostic tool that is measured at 28 weeks of gestation using ultrasound. **An LHR of less than 1.2 can identify infants who have a higher risk of requiring extracorporeal membrane oxygenation/extracorporeal life support (ECMO/ECLS) and/or death. An observed-to-expected LHR can be calculated throughout gestation as it normalizes for gestational age. An observed-to-expected ratio of less than 25%, especially late in gestation, portends a poorer prognosis. Identification of the left lateral segment of the liver in the thoracic cavity also identifies infants who have worse outcomes.**[5] Recently, fetal magnetic resonance imaging (MRI) to identify incomplete pulmonary baseline, liver up and retrocardiac stomach[45] and fetal lung volume and lung-to-head

ratio[51] have been shown to be a useful prognostic tool in infants with CDH. **Prenatal identification of high-risk infants with CDH allows the mother to deliver in a high-risk perinatal center with the appropriate level of neonatal and surgical support on standby.** Although in utero surgical techniques to promote lung growth and passive reduction of the herniated abdominal contents seemed promising initially, after a moratorium on fetal surgery, there is now a global trial being conducted into fetoscopic intraluminal tracheal occlusion.[94] At this time, fetal intervention for severe CDH is still investigational. Some fetal surgery centers, particularly European, continue to explore minimally invasive means to promote lung growth in utero and thereby reduce the herniated abdominal contents. The Achilles' heel of fetal intervention, however, is the risk of preterm labor and the consequent morbidity of prematurity, risks which collectively must be weighed against a term delivery but with profound compromise in lung development.

SIGNS AND SYMPTOMS

Respiratory distress may develop immediately after birth or after an initial period of relative stability. If significant pulmonary hypoplasia is present and fetal circulation persists, the newborn may become rapidly symptomatic, heralded by profound respiratory distress and circulatory shock. Because much of the bowel is herniated into the chest, the **abdomen appears scaphoid and the anteroposterior diameter of the chest may enlarge as the bowel distends with air. Breath sounds are diminished or absent on the affected side,** and the mediastinum may be displaced toward the contralateral side. **Associated anomalies of the cardiovascular system** may include patent ductus arteriosus (PDA), aortic coarctation, and hypoplastic left heart syndrome, which require detailed echocardiographic evaluation. Other associated **anomalies requiring evaluation include central nervous system (CNS) malformations, genitourinary anomalies, esophageal atresia, omphalocele, cleft palate, and cardiovascular defects.**[105]

LABORATORY DATA

A chest radiograph is obtained and shows bowel herniated into the ipsilateral thoracic space with contralateral displacement of the heart. An **echocardiogram is necessary to assess cardiac function, degree of pulmonary hypertension, and presence of significant congenital cardiac anomalies. Lung ultrasound at the point of care** enables prompt diagnosis and may assist in decisions about surgical stategy.[21,47] Nonrotation of the intestine is an understood feature of CDH and does not require specific evaluation as a newborn. **Arterial blood gas analysis may reflect a profound degree of hypoxemia and mixed acidemia** (elevated Pco_2 and very negative base excess). **Whole blood lactic acid may rise after birth in concert with the degree of hypoxemia and circulatory shock.**

Treatment

PREOPERATIVE CARE (STABILIZATION)

As soon as a diaphragmatic hernia is suspected, an orogastric tube should be placed to prevent further distention of the stomach and bowel and alleviate consequent compression of the lung. The **newborn having CDH requires endotracheal intubation and mechanical ventilation to reduce swallowed air during spontaneous respirations and to maintain adequate respiratory gas exchange.** Because cardiac function also may be compromised, a combination of **pressor medications such as dopamine, dobutamine, and milrinone may need to be administered** (see Chapter 23). The earlier the infant becomes symptomatic, the more severe the respiratory compromise and the poorer the prognosis may be. **Despite the primary defect in the diaphragm, the major determinants of outcome are pulmonary hypertension and lung hypoplasia.**

A significant number of CDH newborns may have such severe pulmonary hypertension refractory to conventional or alternative (e.g., high-frequency oscillation or jet; inhaled nitric oxide [iNO]) ventilation that ECLS (venovenous or venoarterial) may be required to establish effective gas exchange and end-organ perfusion. The first population-based study of CDH infants found that only 13% were on ECLS preoperatively.[127] After ECLS therapy the simultaneous use of iNO and intravenous (IV) milrinone improves oxygenation and survival.[56] The overriding principle in stabilizing CDH newborns is to reduce barotrauma and oxygen toxicity to the lung that result in chronic lung disease. Strategies now emphasize *gentle ventilation* and *permissive hypercapnia,* so long as arterial pH does not drift significantly low (less than 7.25).[59]

OPERATIVE INTERVENTION

Surgical repair does not alter early outcome. Therefore, the baby's condition should be stabilized and efforts directed toward management of the

associated pulmonary hypoplasia and hypertension. **Early repair within the first 72 hours of life is indicated only in infants having little or no pulmonary dysfunction.** If **severe pulmonary insufficiency is present, medical therapies of conventional or high-frequency mechanical ventilation, iNO, or ECLS is instituted.** If these modalities are successful in stabilizing the baby, surgical repair is generally performed between 4 and 14 days of life.[71] The first population-based study of CDH found that the median age at surgery was 5 days.[127] If ECLS has been needed to stabilize the newborn having CDH, some centers advocate herniorrhaphy while on bypass, whereas other centers recommend repair after decannulation (see Fig. 28.1).

Most commonly through a subcostal transabdominal approach, the surgeon reduces the stomach, intestine, and spleen from the chest to the abdominal cavity and repairs the diaphragmatic defect. **If the defect is large, a prosthetic patch may be required to complete closure of the hernia.** Closure of the abdominal wound also may be difficult because of underdeveloped abdominal wall musculature and loss of abdominal domain. In these circumstances, **if abdominal closure is not possible or may result in abdominal hypertension, simple skin closure or prosthetic silo placement may be necessary to cover the abdominal contents,** leaving a large ventral hernia for future repair when abdominal domain is more adequate and the baby is more stable. Chest tube placement depends on risk for bleeding, which may be significant if repair is performed on ECLS (because of anticoagulation during ECMO therapy) or if risk of pneumothorax is anticipated. Minimally invasive techniques to repair CDH, both Bochdalek and Morgagni types, also may be used in newborns[120] (see Fig. 28.2), but may not be well tolerated in fragile neonates. Appropriate patient selection is a premium. Thoracoscopic and laparoscopic techniques to repair CDH have been described and may be better suited for infants who present out of the newborn period and without physiologically significant pulmonary hypoplasia or hypertension.

POSTOPERATIVE CARE

The principal postoperative concern remains effective ventilation and oxygenation while imparting the least amount of barotrauma and toxicity. If conventional mechanical ventilation fails, high-frequency oscillation and iNO are employed.[38] ECLS is reserved in this setting as a salvage therapy for babies who revert back to fetal circulation and who do not respond to these less invasive modalities.[71]

Complications and Prognosis

The survival rate for newborns having CDH and who require mechanical ventilation in the first 18 to 24 hours of life is approximately 64%. The first population-based study of CDH outcomes found that the 30-day mortality rate postoperatively was 9%.[127] If an infant with a diaphragmatic hernia does not present with respiratory distress in the first 24 hours of life, survival approaches 100%. As improvements in *gentle ventilation* **strategies have emerged, a gradual, albeit small, increase in survival has been realized. The primary, early pathophysiologic consequence of CDH is pulmonary hypertension. Late complications include chronic lung disease with deterioration in exercise capacity,**[115] **recurrent diaphragmatic hernia, gastroesophageal reflux (GER), musculoskeletal deformities (including scoliosis), growth restriction, and protracted need for medical equipment/home health services.**[36,79] Long-term neurologic outcomes have recently become important to evaluate, as perinatal mortality has decreased. **Survivors of CDH continue to have impaired neurologic development as evidenced by hearing impairment, hypotonicity, psychomotor dysfunction,** and the need for special education,[36] **affecting collectively 30% to 50% of children with CDH.** Basic and clinical research continue in an effort to identify improved therapies for the complex pulmonary dysfunction associated with CDH, not only to close the persistent and large survival gap but also to optimize quality of life among survivors.

ESOPHAGEAL ATRESIA AND TRACHEOESOPHAGEAL FISTULA

Physiology and Etiology

Esophageal atresia (EA) occurs in 1 in 3000 to 4500 live births and represents a **spectrum of anomalies that arise early in gestation (3 to 6 weeks) when the trachea normally buds from the primitive foregut.** Failure in the normal development of the esophagus and in complete separation of the

trachea from the esophagus gives rise to EA and distal tracheoesophageal fistula (TEF) in 85% of cases, isolated EA in 8%, TEF without EA in 5%, or EA with proximal or proximal and distal fistulas in 2%. Etiologies for this collection of defects remain unclear, but it is suspected that **genetic alterations in and environmental insults on rapidly proliferating foregut stem cells during this critical period of organogenesis account for such diverse yet predictable esophageal malformations.** Aberrations at the cellular level in muscle fibers of the distal esophagus may help explain the **nearly universal symptoms of dysmotility and GER after operative repair.**[30,34] Because other developing organs are vulnerable to the same insults in this critical period of gestation, associated anomalies are common (46%), particularly vertebral, anorectal, cardiac, CNS, genitourinary, limb, gastrointestinal (e.g., duodenal atresia), VACTERL and CHARGE syndromes.[106] **In 11% to 33% of infants with EA and distal TEF, concurrent and severe tracheomalacia is present and is manifested by stridorous breathing.**[101] Although EA with or without TEF has not been associated with a single-gene defect, a high incidence has been observed in children having trisomy 21, or Down syndrome.[106]

Data Collection

HISTORY

Maternal polyhydramnios may suggest EA or other conditions in which the fetus does not swallow amniotic fluid normally or has a gastrointestinal obstruction.

SIGNS AND SYMPTOMS

Babies having EA are identified soon after birth because of excessive salivary secretions and inability to swallow feedings. Upon feeding, these babies quickly cough, regurgitate undigested formula or breast milk, and may exhibit cyanosis. When attempting to pass an **orogastric tube, obstruction is typically encountered between 8 and 12 cm from the lips, and the diagnosis of EA is established.** If a distal TEF is also present, air passes into the stomach and bowel and is present on plain abdominal radiographs. **Respiratory distress may arise if gastric secretions reflux through the TEF and into the lungs, which may incite a profound chemical aspiration pneumonitis.** Symptoms of an "H"-type fistula in the absence of EA are less obvious and require a high index of suspicion. **Coughing and choking with feedings, or recurrent pneumonia over the first months of life, suggest the presence of an occult TEF** (Box 28.1).

BOX 28.1 CRITICAL FINDINGS
ESOPHAGEAL ATRESIA AND TRACHEOESOPHAGEAL FISTULA

Critical assessment findings for esophageal atresia and tracheoesophageal fistula are:

- Excessive secretions
- Feeding intolerance
- Inability to pass orogastric tube
- Abdominal distention
- Other findings associated with VACTERL (Vertebrae, Anus, Cardiac system, Trachea, Esophagus, Renal [urinary tract], and Limbs)

PHYSICAL EXAMINATION

Once EA has been established, the infant should be carefully examined to exclude other anomalies of the **VACTERL** association, a variable sequence of anomalies affecting the **V**ertebrae, **A**nus, **C**ardiac system, **T**rachea, **E**sophagus, **R**enal (urinary tract), and **L**imbs.[106] Echocardiography permits both the identification of significant cardiac anomalies and the presence of a right- or left-sided aortic arch, which have important implications in the operative approach.

LABORATORY DATA

After obstruction is met with passing of an orogastric tube, a plain radiograph of the chest and abdomen should be obtained with the tube left in place, which is visualized usually at the second or third thoracic vertebra and above the carina. The stomach and intestines may contain luminal air if a distal TEF is present. If no distal fistula exists, the abdomen on radiograph will appear gasless. **In the rare setting of EA, distal TEF, and duodenal atresia, the abdominal gas pattern may show the classic "double bubble" sign, as gas fills the stomach and proximal duodenum only.**

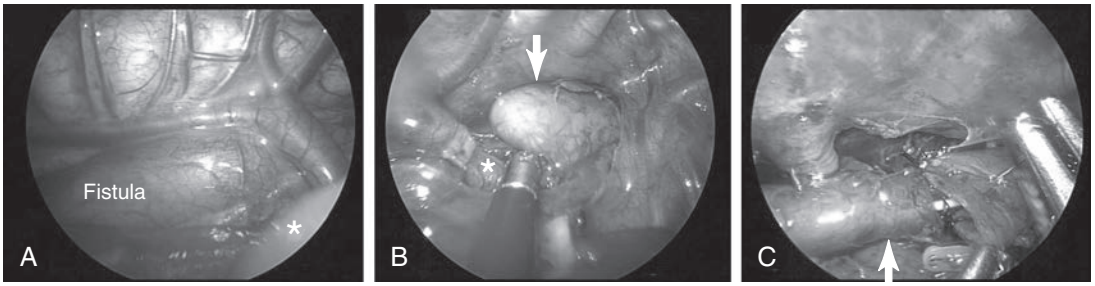

FIGURE 28.3 Thoracoscopic repair of esophageal atresia with distal tracheoesophageal fistula (TEF) in a newborn. **A**, View of TEF (fistula), which is distended from ventilation. Azygous vein is obscuring connection to trachea. **B**, After division of azygous vein, one can visualize the fistulous connection *(asterisk)* of the distal esophagus to the posterior trachea. Upper atretic pouch has been mobilized and is being elevated with instrument. **C**, Suturing of upper esophagus to distal esophagus. Replogle tube has been advanced through anastomosis after approximation of posterior row initially. For perspective of small working space, 3- and 5-mm instruments are used for this procedure.

Treatment

PREOPERATIVE CARE

Once the diagnosis of EA is established, a 10-Fr Replogle tube is placed in the upper esophageal pouch and set to low continuous suction to prevent aspiration of oral secretions. While awaiting operation, the **neonate should be kept in the head-up position and initiated on antireflux medication to minimize GER and the consequent risk of acid-induced pneumonitis.** Operative repair, in general, is not an emergency procedure. Patients first should be **evaluated thoroughly for other associated anomalies by physical examination, echocardiography to delineate the anatomy of the heart and great vessels, abdominal ultrasound of the kidneys and genitourinary tracts, and plain radiographs of the spine and limbs.** Newborns having cyanotic congenital heart disease may require a palliative cardiac procedure before reconstruction of the esophagus.

If babies having EA and distal TEF are born prematurely and have respiratory distress syndrome (i.e., "stiff lungs"), a significant portion of mechanical tidal volumes, delivered under positive pressure, may be shunted preferentially through the fistula and into the stomach. As a result, effective ventilation is lost and critical gastric distention ensues, further restricting diaphragmatic excursion. Emergent ligation of the TEF with gastrostomy tube insertion is necessary in such instances to restore effective ventilation.

OPERATIVE INTERVENTION

The type of esophageal malformation dictates the surgical approach. **Surgical repair of EA with or without TEF is generally not an emergency but should be carried out as soon as the patient is stable.** If the infant is in otherwise good health and the gap between esophageal elements is not too large, primary anastomosis is indicated through a right thoracotomy and retropleural approach. To reduce the pain and potential morbidities associated with a thoracotomy, some surgeons recommend repairing thoracoscopically in appropriately selected patients (Fig. 28.3).

Unfortunately, in isolated EA, the gap distance is generally too long to allow early primary repair. If the gap length is considered too great, with or without TEF, or if the child is too ill, a delayed or staged repair is planned. **An early gastrostomy is placed for decompression and feeding, and the TEF if present is divided to prevent reflux into the tracheobronchial tree.** After a variable period of time to allow resolution of pneumonitis or maximum growth of the distal esophagus, a second operation completes the repair. To promote lengthening and growth of the distal esophagus in cases of isolated EA, dilation and stretch of the proximal and distal esophagus may be performed via the oropharynx and a mature gastrostomy tract, respectively, using Bakes dilators under fluoroscopic guidance (Fig. 28.4).

Multiple options for long gap atresia exist. One strategy is first, after a period of growth in early infancy, to suture and approximate the two ends

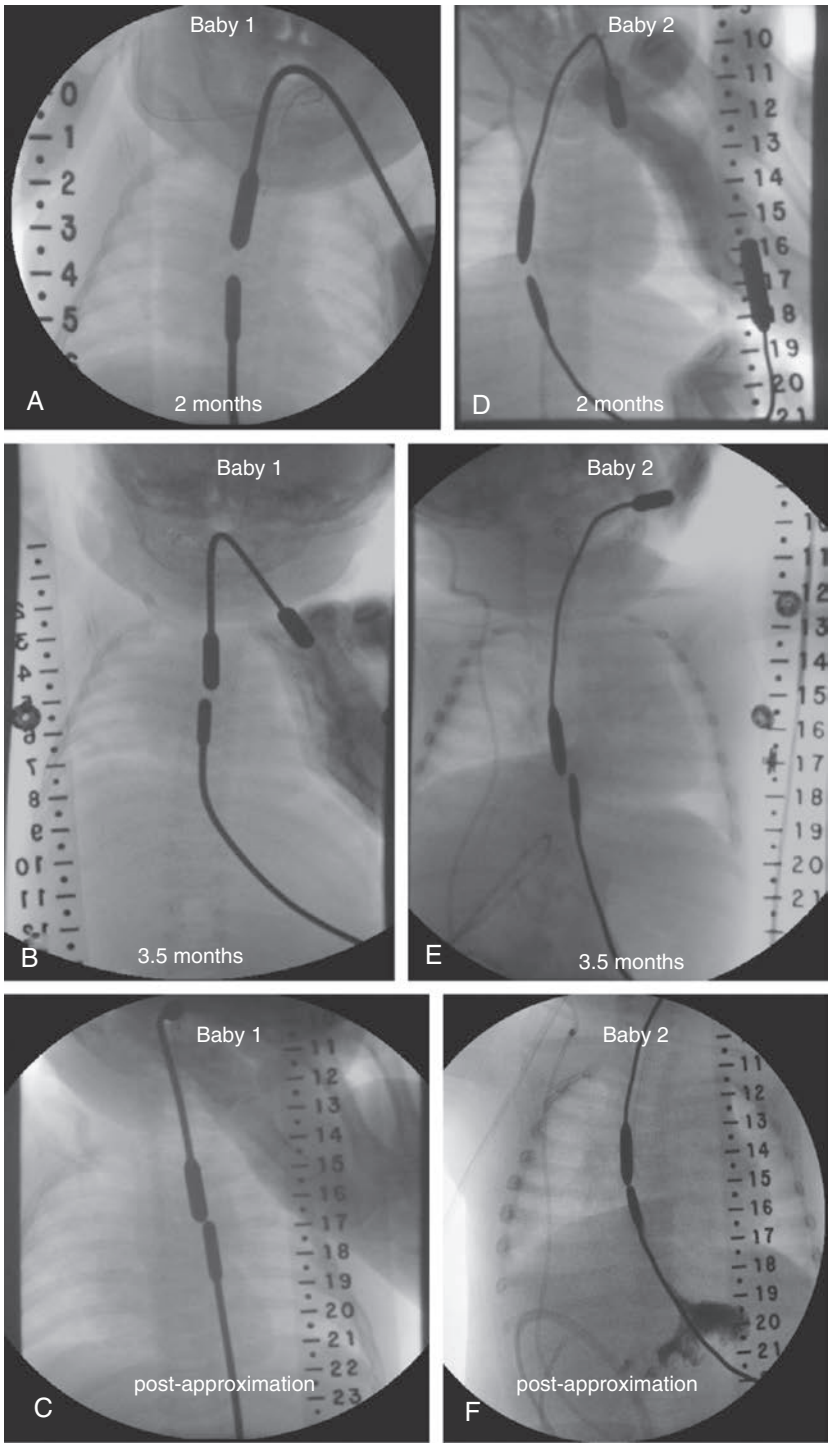

FIGURE 28.4 Representative fluoroscopic images to assess the distance between esophageal pouches (i.e., gap length) for both babies. ***A*** and ***B*** (Baby 1) and ***D*** and ***E*** (Baby 2) show placement of Bakes dilators per os and per gastrostomy in both babies before suture approximation at 2.0 and 3.5 months of age, respectively. ***C*** (Baby 1) and ***F*** (Baby 2) show repeat gap length assessment using Bakes dilators 2 months after suture approximation of the esophageal pouches.

without creating an anastomosis, then perform a repeat thoracotomy 6 to 8 weeks later to establish luminal continuity once tension between the esophageal ends has resolved. An alternative approach is to use magnetic fistulization to create luminal continuity to preserve length and prevent the need for an additional thoracotomy. When this approach is used, the magnetic compression creates a leak-free anastomosis typically within 4 to 7 days. The placement and removal of the catheter-based magnets is simple and well tolerated without general anesthesia (Fig. 28.5). Importantly, when using "magnamosis," the coupling surface of the magnets is only 10 Fr, so the surgeon should anticipate several procedures to dilate the anastomosis to a size compatible with that of the infant to restore appropriate oropharyngeal ingestion and swallowing (Fig. 28.6). To date, our two patients using this magnamosis technique each has her complete esophagus without requiring an interposition, such as colon, stomach, or jejunum, and both are oral feeders.[66]

If delayed or staged repair is planned, secretions must be controlled. Suction catheters placed in the upper pouch are maintained to reduce the risk of aspiration. In rare cases, reconstruction using the native esophagus is not possible. In these circumstances, esophageal replacement using gastric or colon transposition is necessary. If the infant is not a candidate for early operation because of a lethal chromosomal defect or severe congenital heart disease, cervical esophagostomy and gastrostomy are performed to palliate the infant, and esophageal replacement is performed later, as indicated.

POSTOPERATIVE CARE

Postoperative care includes appropriate pain control and pulmonary care, parenteral nutrition, and a brief course of systemic antibiotics. Tracheal and esophageal suction catheters should *not* come in contact with the newly repaired esophagus and trachea, because suture line disruption may cause a leak or recurrent fistula, both potentially catastrophic complications. Antibiotic therapy is continued based on surgeon preference. A chest tube and/or retropleural drain is placed to control an anastomotic leak, should it occur. **Before initiating oral feedings, an esophagram is usually obtained 5 to 7 days after repair to verify complete anastomotic healing and absence of leak. All EA babies have some degree of esophageal**

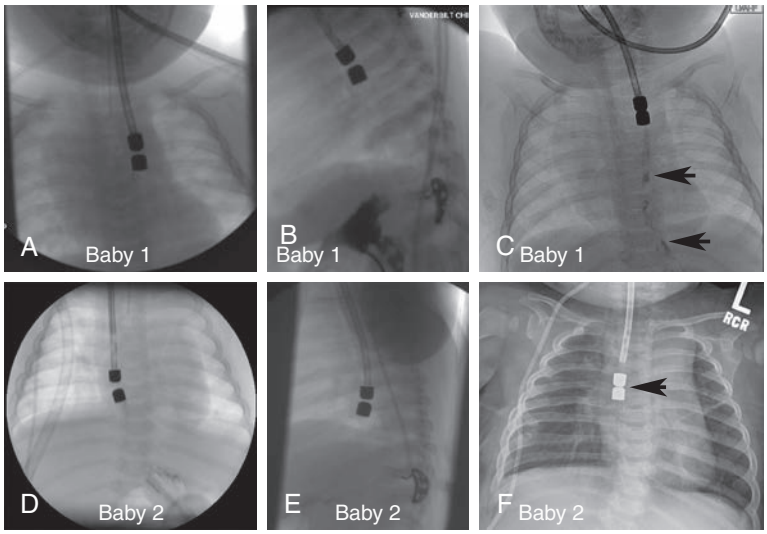

FIGURE 28.5 Fluoroscopic images taken at time of catheter-based magnet placement for both babies. **A** and **D** show anteroposterior projections, and **B** and **E** show lateral projections. **C** shows Baby 1 on magnet day 6; the baby was taken to the fluoroscopy suite to assess canalization of the esophageal lumens. Free flow of contrast through the upper catheter is shown *(arrows)*. The magnets were removed and an orogastric tube was placed under fluoroscopic guidance. **F** shows Baby 2 on magnet day 10; the magnets migrated proximally but were still coupled (*arrow,* note lower position of magnets compared to **D** and **E**). The catheters were removed completely at the bedside, and an 8-Fr orogastric tube was placed until dilation could be initiated the next day.

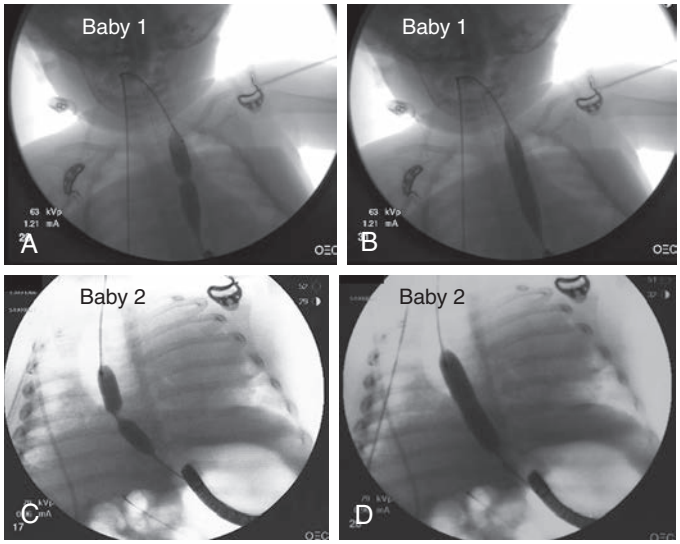

FIGURE 28.6 Fluoroscopic images taken after magnetic compression anastomosis for both babies. **A** and **B** show an anastomotic stricture before and after 12-mm balloon dilation, respectively, in Baby 1 at 6 weeks after magnetic compression anastomosis. After magnetic catheter removal, Baby 2 self-removed her nasogastric tube the day after its placement (11 days after magnetic compression anastomosis). **C** and **D** show her anastomotic stricture before and after 10-mm balloon dilation, respectively.

dysmotility and GER after repair.[30,34] Elevating the head of the bed 30 to 45 degrees, administering histamine (H2) antagonists or proton pump inhibitors, and slow feeding may help control reflux symptoms.

Complications and Prognosis

Postoperative complications include anastomotic leak and/or stricture, as well as esophageal dysmotility. Anastomotic leaks may occur in up to 20% of patients and generally are treated conservatively with chest tube drainage, parenteral nutrition, antibiotics, and tincture of time. **The vast majority of leaks close without operative intervention but tend to heal with some degree of stricture, commonly amenable to dilation. Anastomotic strictures are the most common postoperative complication after EA-TEF repair occurring in 30% to 50% of infants** with EA-TEF. In the **majority of infants who develop a postoperative esophageal stricture, esophageal dilation is an effective therapy to maintain esophageal patency, and only a minority of infants (2% to 10%) require reoperation and reconstruction of the esophageal anastomosis.** Esophageal strictures often are associated with or exacerbated by GER and may be treated successfully by esophageal dilation. **If GER complicates a stricture and is refractory to maximal medical therapy, a fundoplication procedure may be necessary.[34]** Some degree of esophageal dysmotility usually exists because of poor peristalsis in the distal esophagus. In a recent study the rate of dysmotility was 85% at 1 year of age and 100% at 10 years of age.[34] The child may adapt to a poorly functioning esophagus by altering his or her feeding habits or using anti-reflux medications (47% in a recent study).[34] However, **in infancy, gastrostomy feeding may be necessary to prevent vomiting and aspiration. Postoperative airway complications include tracheobronchomalacia and recurrent laryngeal nerve injury with vocal cord dysfunction.**

A recent study of postoperative complications found a mortality rate of 4.2%.[34] With modern neonatal care and surgical techniques, **long-term survival after repair of EA and TEF is excellent.** Prognosis depends on largely two factors: the presence and type of cardiac anomalies and the presence of prematurity and respiratory distress syndrome. **A useful system to predict survival is the Spitz**

classification, which stratifies infant survival by birth weight and major cardiac anomaly[103]:

I: Birth weight greater than 1500 g, no major CHD, survival is greater than 97%
II: Birth weight less than 1500 g or major CHD, survival is 59%
III: Birth weight less than 1500 g and major CHD, survival is 22%

CONGENITAL CHEST MASSES

Physiology and Etiology

The most common congenital chest masses requiring surgical intervention in the newborn period are congenital pulmonary airway malformations (CPAM, also formerly known as congenital cystic adenomatoid malformation or CCAM), pulmonary sequestrations (both intralobar and extralobar types), bronchogenic cysts, and congenital lobar emphysema (CLE). Each of these malformations may exist alone or in combination with other anomalies.

CPAM lesions are thought to arise from focal interruption in coordinated pulmonary progenitor cell growth, resulting in abnormal development of pulmonary tissues and structural distortion. Histologically, CPAM is associated with increased cell proliferation and decreased apoptosis when compared with normal lung tissue. The CPAM lesion receives its blood supply from the pulmonary system but does not communicate with normally formed bronchial structures.

Anomalous development of the foregut is the accepted underlying etiology of both bronchogenic cyst and pulmonary sequestration. Bronchogenic cysts are lined by ciliated columnar and/or cuboidal epithelium. The surrounding tissues resemble those of the normal bronchus and are generally, although not exclusively, located within the mediastinum along the tracheobronchial tree. Extralobar sequestrations are masses of primitive pulmonary parenchyma with no bronchial connection and are supplied by and drain into the systemic and not pulmonary vasculature. Intralobar sequestrations on the other hand are supplied by systemic vasculature, but drain into the pulmonary venous system. They too do not have a bronchial connection. CLE presents in the newborn period as a fluid-filled, overdistended lobe that, under positive pressure ventilation, may trap air and generate tension physiology. In many cases, although not all, CLE is associated with the absence or hypoplasia of cartilaginous rings of the major and segmental bronchi. These structurally underdeveloped bronchi are prone to collapse on expiration, thereby trapping air.

Data Collection

HISTORY, SIGNS, AND SYMPTOMS

Although rare, congenital lung malformations may lead to considerable morbidity, such as infection, hemorrhage, respiratory failure, and pulmonary hypoplasia and may even prove lethal. Some lesions may escape prenatal detection and appear later in development. Failure to recognize a malformation may lead to inappropriate intervention. For example, placement of a chest tube to manage suspected tension pneumothorax in a baby having congenital lobar emphysema may lead to lung injury and loss of tidal volume through the thoracostomy tube instead of into the remaining healthy lung.

Congenital Pulmonary Airway Malformation. CPAMs are increasingly detected prenatally and are nicely characterized on fetal ultrasound, but if not, may be further delineated by fetal MRI, as indicated. In utero, many of these lesions may reduce in size throughout a normal gestational period and cause no respiratory symptoms for the newborn at birth. In such an instance, a simple chest radiograph and clinical assessment is all that is necessary. However, other **such lesions may cause a variety of problems, from pulmonary hypoplasia (both ipsilateral and contralateral) to nonimmune hydrops fetalis with congestive heart failure. Polyhydramnios also may be present if the lesion compresses the esophagus and compromises fetal swallowing of amniotic fluid.** Fetal intervention may be indicated if the gestation has not yet reached 34 weeks, in which case premature delivery might be planned. Large fluid-filled cystic lesions may be amenable to thoracoamniotic shunt placement while in utero to relieve compression of intrathoracic structures and to restore hemodynamic status. Solid CPAM lesions arising early in gestation and causing similar complications have been resected in fetuses with promising results. If these lesions do not manifest with in utero pathophysiology, yet are of sufficient size, the neonate may develop respiratory distress shortly after birth. This process

is responsible for the cystic appearance on radiographs. Babies may have mediastinal shift and large air spaces, easily confused with a pneumothorax or diaphragmatic hernia. **Sonography may be helpful to delineate a solid or cystic mass and should establish the diagnosis. CPAM may result in recurrent infections because mucociliary clearance is poor.** Rarely, malignancy may arise in a CPAM in the form of pulmonary pleuroblastoma, rhabdomyosarcoma, or bronchoalveolar carcinoma.

Pulmonary Sequestration. Pulmonary sequestration accounts for less than 10% of all congenital lung malformations and mostly occurs in the lower lobes. **A sequestration represents a mass of disorganized bronchopulmonary tissue without a normal bronchial communication and has a systemic vascular supply.** Because of the systemic vasculature, large lesions can shunt blood away from other organs and lead to cardiac overload and heart failure. The abnormal sequestered lung tissue may be intralobar or extralobar and is classified according to pleural coverage, either within the pleural investment of the whole lung itself and with pulmonary venous drainage (intralobar) or outside of this normal pleural lining with drainage back into the systemic vasculature (extralobar). Sequestrations rarely may have some sort of communication with the foregut. Infants having an intralobar sequestration not detected prenatally may present outside of the newborn period and often with recurrent respiratory problems, such as chronic cough, or with recurrent pneumonias, either in the lesion or in the surrounding normal but compressed lung tissue. **Plain radiographs may show simply consolidation. Anomalies associated with extralobar sequestration include diaphragmatic hernia and eventration, bronchogenic cysts, pericardial problems, duplication cysts, and may share a similar dysregulated embryologic event because approximately 95% of extralobar lesions are left-sided.**[9] Extralobar lesions may reside either above or below the left diaphragm. Older children may have exercise intolerance if a large systemic arteriovenous shunt exists. Systemic arterial flow through the lesion may produce a murmur, and may lead to congestive cardiac failure. Squamous cell carcinoma, adenocarcinoma, and rhabdomyosarcoma may rarely arise in the sequestration. These lesions are often removed later in infancy because of the risk of recurrent infection and potential malignancy.

Bronchogenic Cyst. Bronchogenic cysts may be considered a foregut duplication and arise from an abnormal budding of the ventral foregut. Approximately 85% are mediastinal and 15% are intrapulmonary. Bronchogenic cysts may be filled with air or fluid and may show air-fluid levels on plain radiographs. As a result, **bronchogenic cysts may become infected or simply grow over time, and so may behave as a space-occupying and compressive lesion.** Many cysts are asymptomatic or have vague symptoms and are discovered on routine chest radiographs. Infection, hemorrhage, and, in rare cases, late malignancy may occur. **Associated respiratory symptoms include stridor or wheezing.** Chronic air trapping may lead to emphysema, atelectasis, or both. Dysphagia, chest pain, and epigastric discomfort may also occur.

Congenital Lobar Emphysema (or Congenital Lobar Hyperinflation). Although generally not discovered in utero, **congenital lobar emphysema typically manifests in neonates as hyperinflation of one or more lung lobes.** Causes include intrinsic absence or abnormality (bronchomalacia) of cartilaginous rings or external compression of a segmental bronchus by a large pulmonary artery that predisposes to air trapping. **Hyperinflation of a pulmonary lobe develops after birth, as inspired air enters the affected lobe but cannot exit, because the positive pressure of expiration collapses the nonrigid airway.** Congenital lobar emphysema most commonly involves the upper lobes. **The left upper lobe is involved in roughly 41% of patients, the right middle lobe in 34%, and the right upper lobe in 21%.** Involvement of the lower lobes is rare, occurring in fewer than 5% of patients. **Neonates may present with mild-to-moderate respiratory distress. Mediastinal shift may develop with progressive air trapping, and decreased breath sounds are noted on the involved side. Infants who have a milder form of lobar emphysema will present with nonspecific findings, including cough, wheezing, respiratory distress, and cyanosis.** Older children may present with recurrent chest infections. **On plain radiographs obtained in neonates, the affected lobe may be hyperlucent or slightly opacified if alveoli remain fluid-filled.** Associated cardiac anomalies may occur in as many as 10% of patients.

Note large vein coursing behind aorta in **A** *(arrowhead)* and large artery supplying lesion directly from aorta in **B** *(arrow)*. **C,** Thoracoscopic view of ELPS (looking toward diaphragm). **D,** Clipping of large artery and vein. Lesion is then removed through one of the port sites.

LABORATORY DATA

Routine chest radiograph is the initial evaluation tool in distinguishing congenital chest masses and is the principle study to establish the diagnosis of diaphragmatic hernia and congenital lobar emphysema in newborns. Sonography and/or computed tomography (CT scan) of the chest are useful means to evaluate CPAM, sequestrations, bronchogenic cysts, and lobar emphysema in older infants and children. The differential diagnosis of a hyperlucent hemithorax with mediastinal shift on chest x-ray in the newborn includes tension pneumothorax, cystic CPAM, diaphragmatic hernia with air-filled stomach or intestine in the chest, and congenital lobar emphysema.

Treatment

Surgical resection of these congenital chest masses is curative. Some small, asymptomatic lesions of sequestration or CPAM may be followed expectantly, as reports of spontaneous regression may be found in the literature. However, most lesions may be removed with little morbidity in an effort to minimize long-term complications of the various lesions. Operative approach to these lesions may be by either thoracotomy or thoracoscopy, depending on the suitability of the baby and the skill set of the surgeon (Figs. 28.7 and 28.8).

Special consideration to resection of the pulmonary lobe involved with congenital lobar emphysema should be given (Fig. 28.9). Extreme caution must be exercised upon induction of general anesthesia and endotracheal intubation with positive pressure ventilation. Because of the malacic airway and the propensity for air-trapping in congenital lobar emphysema, rapid development of tension physiology may ensue, compromising the well-being of the baby and necessitating emergent decompressive

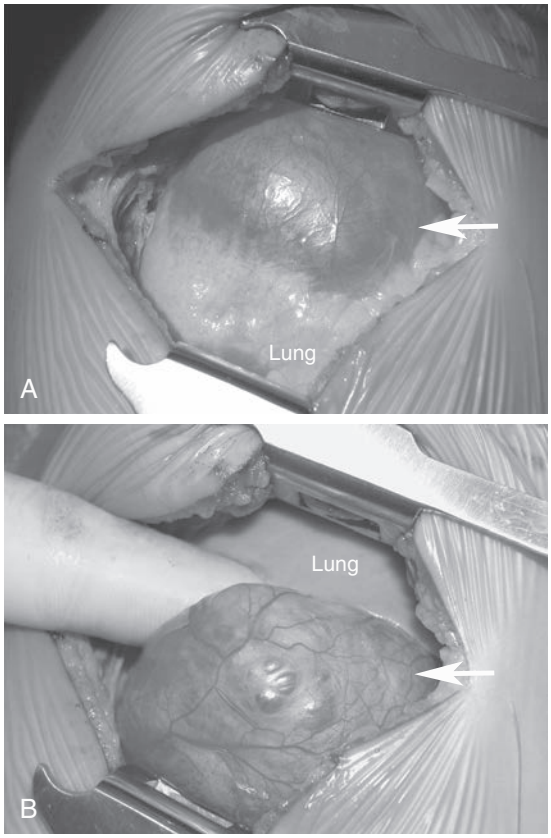

FIGURE 28.8 Thoracotomy in a newborn for congenial pulmonary airway malformation (CPAM). Views of anterior **(A)** and undersurface **(B)** of cystic lesion *(arrows)*.

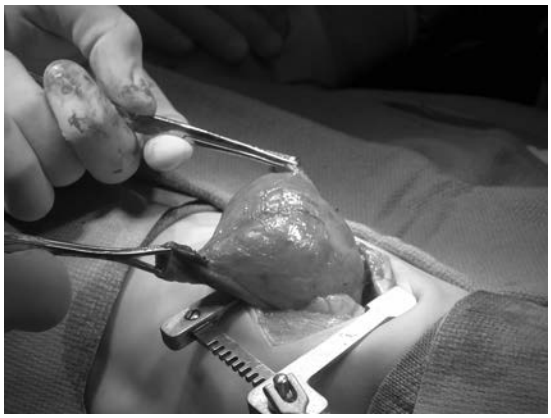

FIGURE 28.9 Thoracotomy in a newborn for congenital lobar emphysema. Note overdistended nature of emphysematous lobe compared with normal lobe just peering out from inferior aspect of wound.

thoracotomy. Such pathophysiology is possible in any neonate having congenital lobar emphysema and requiring positive pressure ventilation.

INTESTINAL MALROTATION AND VOLVULUS

Physiology and Etiology

In the 4th week of gestation, the midgut exists as a straight tube deriving its blood supply from the superior mesenteric artery (SMA). The proximal limb of primitive intestine, representing the future duodenum, jejunum, and proximal ileum, lie in the midline and anterior to the SMA. The distal limb, destined to become the terminal ileum and ascending and transverse colon, lies posterior to the SMA. During the 6th week of gestation, these segments of bowel, known collectively as the midgut, are able to lengthen rapidly by herniating through the incompletely closed abdominal wall and into the umbilical stalk. While lengthening outside of the coelomic cavity, the midgut undergoes a 270-degree counterclockwise rotation around the SMA axis. On return to the abdominal cavity, the duodenojejunal junction comes to rest in the left upper quadrant and becomes fixed in this location by the ligament of Treitz. At the end of the 11th week of gestation, midgut rotation is completed and the cecum resides anterior and to the right of the SMA and is fixed in the right lower quadrant. Because of the counterclockwise nature of this intestinal rotation, the ascending and transverse colon lie to the right of the SMA. The hindgut (splenic flexure of the colon to the rectum) then fixes in the left hemiabdomen and derives its blood supply largely from the inferior mesenteric artery (IMA).

Failure of this rotation and fixation results in the clinical condition termed malrotation, which covers a wide spectrum of rotational anomalies. **Complete nonrotation is characterized by the entire small bowel existing on the right side of the abdomen and the colon principally to the left.** Partial malrotation involves the improper fixation of a single segment. Complete malrotation is thought to occur from a lax umbilical ring allowing the gut to return en masse to the abdomen. Because proper rotation does not occur, the root of the mesentery is not anchored in the left upper quadrant, and the SMA and vein loosely suspend the entire bowel without

fixation. **This unfixed, narrow mesenteric pedicle predisposes the midgut and its tenuous blood supply to twisting or volvulus. If volvulus occurs, the blood supply to the midgut may be compromised, leading rapidly to ischemia and bowel infarction.** The majority of patients with midgut malrotation are diagnosed in the first month of life, but may be seen with decreasing frequency in the older child or rarely the adult.[54]

By definition, malrotation also exists in gastroschisis, omphalocele, and CDH, as the midgut is trapped and unable to rotate and fix properly in these conditions.

BOX 28.2 CRITICAL FINDINGS
MALROTATION AND VOLVULUS

Critical assessment findings for malrotation and volvulus are:
- Lethargy
- Bilious emesis
- Abdominal distention
- Abdominal radiograph suggestive of intestinal obstruction
- Acidosis, leukocytosis, and shock suggest volvulus

Data Collection

HISTORY

Malrotation may manifest in the newborn simply as a proximal mechanical bowel obstruction caused by abnormal attachments, or Ladd bands, between the cecum and porta hepatis. **These babies typically show some degree of feeding intolerance early on with or without bilious emesis.** A more worrisome presentation of malrotation may arise acutely, should the bowel volvulize around its unfixed, narrow vascular pedicle. These babies present with an acute, high-grade proximal bowel obstruction. **In a neonate who develops midgut volvulus, the first few days of life usually are unremarkable, but then the baby develops acute feeding intolerance and bilious emesis in the absence of abdominal distention.** If a delay in diagnosis occurs, **intestinal ischemia sets in, and the symptoms may progress rapidly to an acute abdomen and profound shock as a result of gangrenous bowel. Abdominal wall erythema and distention are usually present in advanced stages of intestinal ischemia and are ominous findings.**[114]

SIGNS AND SYMPTOMS

The symptoms of nonvolvulized malrotation mimic those of duodenal stenosis or atresia, proximal jejunal atresia, or other conditions resulting in proximal intestinal obstruction and result from Ladd bands compressing the proximal duodenum. **These babies develop feeding intolerance followed by bilious emesis and typically have a scaphoid abdomen on examination. Midgut volvulus presents with a more sudden onset of symptoms in a neonate or infant who had been previously feeding normally, suggesting acute proximal intestinal obstruction.** If **diagnosis is delayed, symptoms of intestinal ischemia become evident and include abdominal distention, lethargy, hypovolemic shock, and anuria.** Therefore, **any episode of bilious emesis in a neonate should prompt an urgent evaluation for malrotation and volvulus. The presence of bloody emesis or stools suggests intestinal ischemia with mucosal injury or necrosis.** In this setting, rapid diagnosis and prompt surgical intervention is essential to avoid extensive bowel loss or death (Box 28.2).

LABORATORY DATA

Plain abdominal radiographs may show a dilated stomach and proximal duodenum, or rarely pneumoperitoneum in the presence of advanced intestinal necrosis. However, the **definitive study is an upper gastrointestinal series, which shows both abnormal rotation of the duodenum (malrotation) and partial obstruction** (from Ladd bands), or complete obstruction with a bird's beak, suggesting midgut volvulus. A contrast enema may show an abnormal location of the cecum but is not diagnostic alone of malrotation and provides no information about the presence or absence of midgut volvulus.[64] **Abdominal ultrasound, although user dependent, can be used to identify a midgut volvulus without the need to expose the infant to radiation and reveals a twisting** (i.e., target sign) **of the mesentery, a "whirlpool sign," and abnormal relationship of the mesenteric vessels.**[29,37,43] However, this modality is less sensitive for malrotation without volvulus. **Laboratory data are generally unremarkable, unless bowel ischemia is present, as suggested by leukocytosis, anemia, and metabolic acidosis.**

Treatment

PREOPERATIVE CARE

Although distinguishing between symptomatic malrotation with obstruction (e.g., Ladd bands) and volvulus in its early stages may be difficult, these conditions should be managed similarly. **Gastric decompression, fluid resuscitation, correction of electrolyte and acid–base abnormalities, and parenteral antibiotics are instituted in the preoperative period. Emergent abdominal exploration should be considered in any infant with suspected or confirmed volvulus, because the bowel will be irreparably damaged in as little as 4 hours.** In this setting, prompt surgical intervention with continued intraoperative resuscitation is indicated to maximize the chances for bowel salvage and survival.

OPERATIVE CARE

Operative correction of malrotation without midgut volvulus includes division of Ladd bands (to relieve duodenal obstruction), correction of the malrotation (by placement of the small bowel in the right of the abdominal cavity and the colon on the left), broadening the base of the mesentery by dividing its peritoneum and adhesions, and appendectomy (the appendix and cecum will reside in the left upper quadrant). **This procedure is best performed via laparotomy, and a laparoscopic approach has limited utility in the newborn.** The long-term results of the laparoscopic approach are unknown, and preliminary results are conflicting. More recent studies comparing laparoscopy and open laparotomy found better short-term results (i.e., shorter time to full feedings and shorter length of stay) in the laparoscopy group.[32,49,104] However, there is a higher incidence of postoperative volvulus recurrence in the laparoscopic group (30% recurrence of symptoms versus 40% in the laparotomy group) and a 100% need for surgery to be redone compared to 50% in the laparotomy group.[11,32] Although researchers conclude that laparoscopic surgery is a safe, acceptable option, all agree that more research is needed.[11,32,49,63,104]

If volvulus is present, the bowel is detorsed and allowed to reperfuse (Fig. 28.10). Necrotic segments of bowel are resected and stomas created as indicated. **In selected instances, substantial resection may result in short bowel syndrome.** In these cases, **marginal intestine may be left in place rather than removed and a planned reoperation performed within 24 to 36 hours to re-evaluate the need for additional bowel resection.** The **objective of a second look laparotomy is to allow continued resuscitation and marginally viable intestine the necessary time to recover.** Bowel that is nonsalvageable will become more obviously nonviable within this time window but should not have perforated in this short period. This approach is designed to minimize the amount of total intestine resected and the late risk for short bowel syndrome.

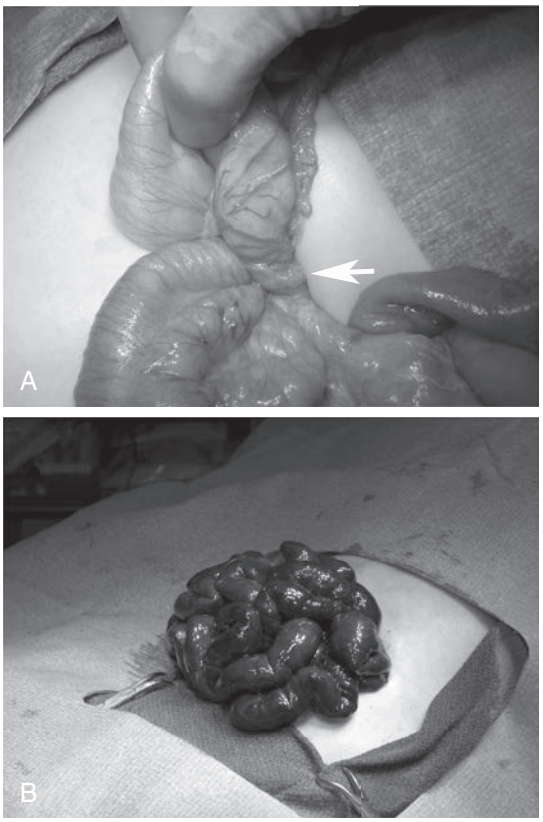

FIGURE 28.10 Two extremes of malrotation with midgut volvulus in newborns. **A,** Volvulus that presented before intestinal ischemia set in. *Arrow* shows 720-degree volvulus. Bowel is entirely viable. **B,** Delayed presentation of midgut volvulus with complete necrosis of intestine, a nonsurvivable injury.

Complications and Prognosis

Proximal obstruction related to Ladd bands is corrected by the Ladd procedure, and recurrent

obstruction is rare. **The risk for subsequent volvulus is greatly reduced with the Ladd procedure but is not entirely eliminated.** Adhesive small bowel obstruction may occur later in life at the same rare incidence as after any other laparotomy.

The **immediate postoperative care from a Ladd procedure consists of nasogastric decompression and IV fluid therapy until the return of gastrointestinal function (4 to 6 days on average).**[31] Conversely, the outcome after malrotation with midgut volvulus is predicated on the degree of intestinal resection.[73] **Midgut volvulus is a leading cause of short bowel syndrome in infants and may render the infant TPN dependent if extensive intestinal necrosis has occurred.** Long-term sequelae of the Ladd procedure include the risk of adhesive small bowel obstruction and a failure to prevent recurrent midgut volvulus, albeit exceedingly uncommon.

INTESTINAL ATRESIA

Physiology and Etiology

Any segment of the bowel may be narrowed (stenosis) or become discontinuous (atresia). Duodenal atresia is the most commonly involved bowel segment, occurring in 1 in 7000 pregnancies,[111] **followed by ileum, jejunum, colon, and stomach.**[55,98]

Sporadic duodenal atresia is thought to result from failure of vacuolization (5 to 6 weeks of gestation) and recanalization (8 to 10 weeks of gestation) of the intestinal lumen; however, a genetic component may also exist.[12] A vascular accident or segmental volvulus occurring later in utero is thought to give rise to jejunal, ileal, or colonic atresia.[92] **Duodenal atresia associated with syndromes is increasingly recognized as having a strong genetic component related to fibroblastic growth factor.**[12,111] **Duodenal atresia is associated with a high incidence (30%) of anomalies that include trisomy 21 (61% in a recent cohort),**[55] **congenital heart disease, and VACTERL association.**[41] **Conversely, intestinal atresia occurs later in gestation and so is rarely associated with significant anomalies.** Atresias are classified as membranes (type I), fibrous cords (type II), gap defect including mesentery (type IIIa), and "apple-peel" atresia (type IIIb).[118] Multiple atresias are classified as type IV.

BOX 28.3 CRITICAL FINDINGS
INTESTINAL ATRESIA

Critical assessment findings for intestinal atresia are:
- Maternal polyhydramnios
- Emesis (nonbilious versus bilious depending on location of atresia)
- Abdominal radiograph suggestive of intestinal obstruction
- Abdominal radiograph with "double bubble" suggests duodenal atresia

Data Collection

HISTORY AND PHYSICAL EXAMINATION

Commonly, a history of maternal polyhydramnios may be provided and the affected neonate may appear small for gestational age (SGA). The more proximal the site of intestinal atresia, the more likely is the history of maternal polyhydramnios. **Newborns having a proximal atresia (duodenum or jejunum) present with early feeding intolerance and emesis and also a scaphoid abdomen. Bilious emesis is present when the obstruction is distal to the ampulla of Vater, as is the case in approximately 85% of duodenal atresias.** However, in **15% of cases, duodenal atresia occurs proximally to the ampulla of Vater and therefore the baby does not show bile-stained emesis or gastric aspirates.**

The more distal the site of atresia and obstruction, the more likely it is that the infant will manifest significant abdominal distention. Babies having a **distal intestinal atresia (ileum or colon) show typical features of a distal intestinal obstruction and develop abdominal distention often with visible intestinal loops.** If the **atresia occurs early in gestation, the infant fails to pass meconium and only mucus is passed after birth** (Box 28.3).

LABORATORY DATA

Initial evaluation of **suspected duodenal atresia begins with a plain abdominal radiograph (flat and left lateral decubitus views), which classically shows a dilated air-filled stomach and proximal duodenum in the double bubble pattern.** A contrast study is not indicated unless air is present in the distal bowel, in which case malrotation with midgut volvulus cannot be excluded. Ultrasound is an adjunctive diagnostic test.[10]

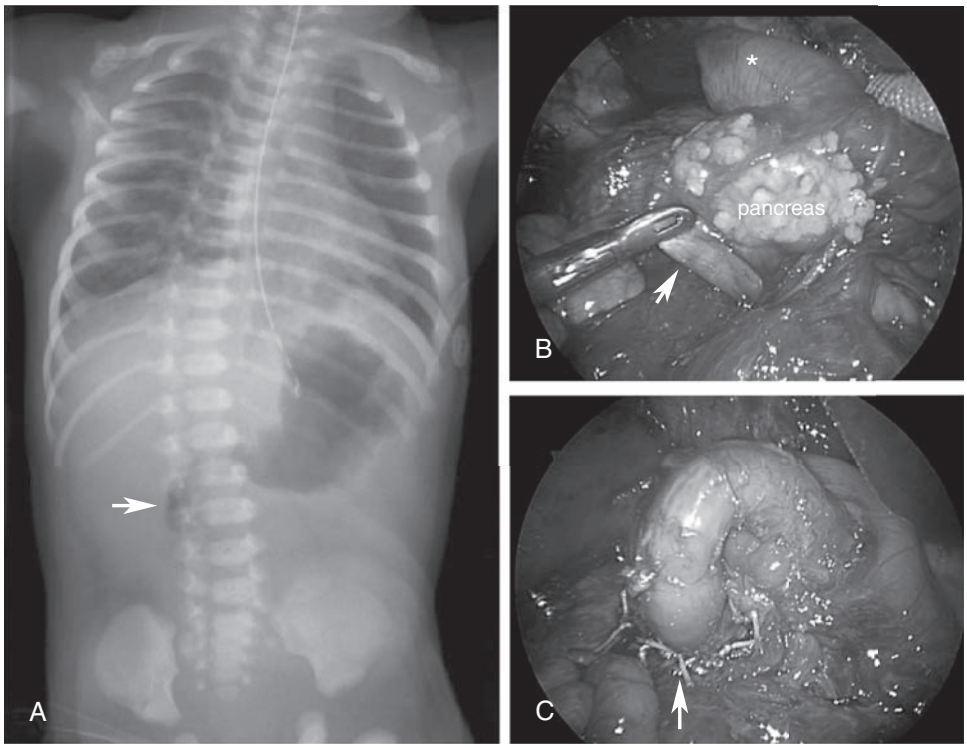

FIGURE 28.11 Duodenal atresia in a newborn. **A,** Abdominal radiograph shows classic "double bubble" sign. Orogastric tube is in stomach, and *arrow* shows air-filled proximal duodenum. **B,** Laparoscopic view of duodenal atresia. *Asterisk* depicts proximal dilated duodenum (compressed by instrument) and *arrow* shows small distal duodenum being elevated by a 3-mm bowel grasper. **C,** Completed anastomosis *(arrow)*.

Abdominal x-ray films that show multiple distended loops of bowel suggest a distal intestinal obstruction. In the setting of **atresia of the small intestine or colon, abdominal x-ray films demonstrate dilation of intestinal segments proximal to the site of obstruction with absence of air in the distal bowel.** For intestinal atresia distal to the duodenum a contrast enema (i.e., per rectum) is generally performed[10] and typically shows a microcolon or unused colon, and no reflux of the contrast agent into the proximal bowel is observed.

Treatment

PREOPERATIVE CARE

Preoperative care includes **orogastric tube decompression to reduce the risk of vomiting and aspiration, fluid resuscitation, and correction of electrolyte abnormalities. Preoperative antibiotics are administered to cover enteric organisms.**

OPERATIVE INTERVENTION

All forms of intestinal atresia require surgical correction to restore gastrointestinal tract continuity. Duodenal atresia is repaired through a diamond-shaped, end-to-end anastomosis of the proximal and distal duodenum, and care must be exercised to prevent injury to the bile and pancreatic ducts. Repair of duodenal atresia may be performed either through a standard transverse right upper quadrant incision or laparoscopically (Fig. 28.11). A recent systematic review and meta-analysis of laparoscopic repair of duodenal atresia found it as safe and effective (i.e., no difference in complications, time to feeding, or length of stay) as laparotomy but with longer operative time.[72] Other intestinal atresias are generally repaired by a standard end-to-end anastomosis. The size disparity between the dilated proximal loop and the decompressed distal loop may require that the proximal bowel be tapered or partially resected, or the distal

bowel may be cut obliquely to allow anastomosis (Fig. 28.12). If these methods are not possible because of size discrepancy, the segments just proximal and distal to the atresia may be brought out as stomas and intestinal anastomosis delayed to allow reduction in size of the dilated proximal segment and growth of the distal segment. When the caliber of the bowel becomes more comparable in size, anastomosis is performed.

POSTOPERATIVE CARE

Postoperatively, an orogastric tube remains in place to decompress the stomach until bowel function begins. Stomas must be protected from desiccation by covering with petrolatum gauze or a stoma appliance. **Ostomies of the proximal intestine have high output because of a lack of absorptive capacity and therefore require replacement of both fluid and electrolyte losses.** The proximal output may be re-fed into a distal mucous fistula, if present, but this technique may be challenging because of problems intubating the distal stoma and securing the feeding catheter to permit infusion. **All infants endure a significant period of bowel dysfunction after surgery, and therefore temporary central venous access should be established to permit nutritional support.** Furthermore, infants with intestinal atresia should undergo screening for cystic fibrosis, which may contribute to both the development of the anomaly and ongoing bowel dysfunction.

Complications and Prognosis

The overall prognosis for these patients is excellent, unless severe associated anomalies are present.[89] **Postoperative complications are also associated with prematurity, sepsis, wound infection, and hypothermia.**[55,89,98] **Prolonged bowel dysfunction is the primary complication after surgical correction of intestinal atresia.** In selected cases, tapering of dilated bowel segments is attempted to enhance the recovery of bowel function.[102] **Some infants fail to recover sufficient bowel function and require long-term parenteral nutritional support,** because of either dysmotility or inadequate bowel length resulting from long segment atresia. Fortunately, **the majority of patients have no long-term problems after postoperative recovery and return of bowel function.**

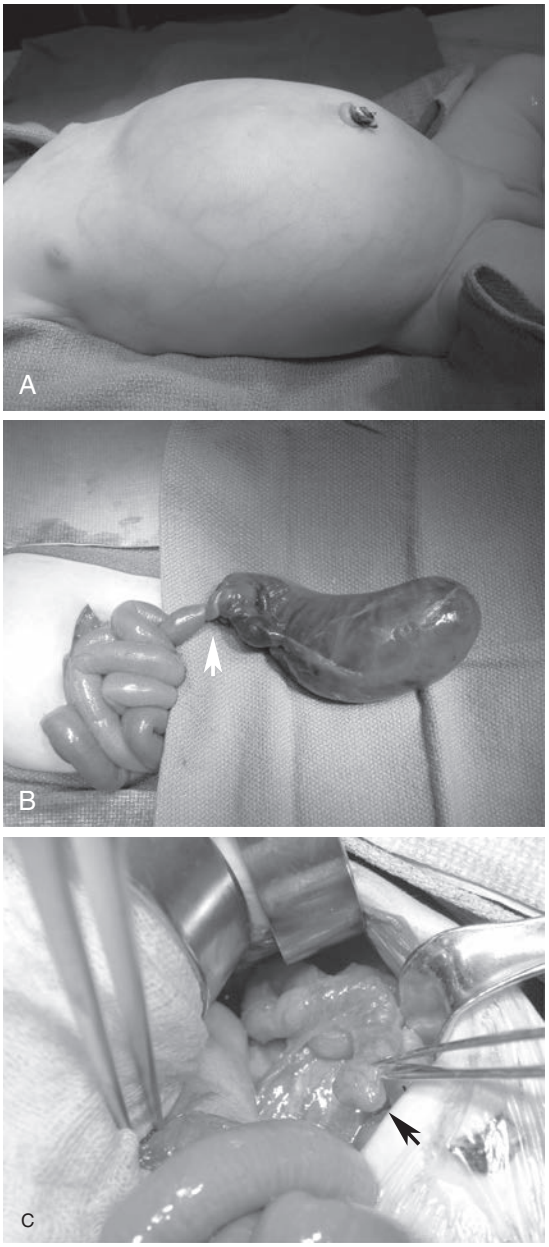

FIGURE 28.12 Newborn with colon atresia. **A,** Markedly distended abdomen. **B,** Atretic colon that has volvulized. *Arrow* shows twist, and note ischemic nature of volvulized colon. **C,** Distal microcolon elevated by forcep *(arrow)*.

NECROTIZING ENTEROCOLITIS

Physiology and Etiology

Necrotizing enterocolitis (NEC) is an inflammatory condition of the bowel of uncertain cause and occurs at a rate of 1 in 1000 live births and in 5% of infants born weighing less than 1500 g (very low birth weight [VLBW]). **NEC is fatal in 17% of all cases, in 20% of VLBW infants who develop the disease, and as high as 40% to 50% in those infants with a birth weight less than 1000 g. NEC is primarily a disease of premature infants, although approximately 5% of cases occur in term babies.** Despite intensive study, major advances in newborn intensive care, and improved survival of the preterm infant in the last two decades, the incidence of and mortality associated with NEC has changed little. **In fact, the increase in survival of preterm infants has increased the size of the population at risk. Perinatal stressors, an immature intestinal barrier, intestinal ischemia, bacterial colonization of the gut, alteration of the intestinal microbiome (intestinal dysbiosis),**[82] **and nutritional substrate in the gut lumen have all been implicated as contributing factors at play in infants who develop NEC.** Other **conditions that result in mucosal injury also have been linked to NEC: hypoxia, polycythemia, hyperosmolar feedings, gastrointestinal infection (bacterial or viral), and severe cardiopulmonary disease.** Current research using animal models implicates upregulation of multiple inflammatory mediators in the injured intestinal epithelia affected by NEC, and the presence of certain anti-inflammatory mediators may be cytoprotective.[48,88]

Inflammation and ischemia initially involve the innermost intestinal mucosa, but as the disease progresses, the muscular and subserosal layers of the bowel become involved. The intestinal wall becomes hemorrhagic and attenuated, with evidence of intramural gas (pneumatosis). Histologically after surgical resection, the intestine shows features of acute and chronic inflammation, with areas of coagulative necrosis. The ileocecal region is most commonly involved (50%), followed by disease limited to the colon (25%) or both large and small intestines (25%). Up to 15% of infants will develop pan-intestinal necrosis, or NEC totalis, which is a nonsurvivable insult. In NEC totalis, gastric pneumatosis, though rare, may be seen on x-ray (Fig. 28.13). Further, **NEC is a significant risk factor for developing short bowel syndrome chronically, if less than 40 cm of small bowel remains in the absence of the ileocecal valve, or in its presence, if less than 20 cm of bowel remains.**

There have been significant efforts to prevent the onset of NEC by modifying the feeding regimens in premature infants. One simple measure to decrease the incidence of NEC is feeding with breast milk instead of formula. In a review of several randomized clinical trials, **breastfed infants had a lower incidence of NEC compared to formula-fed infants.**[22,67,68,87,117] Furthermore, an exclusive human milk diet including fortification with human milk fortifier significantly reduces the incidence of NEC.[4,107] **When compared to preterm formula, donor human milk results in a lower incidence of NEC** (see Table 18.6). In addition to breast milk, **the addition of probiotics (*Lactobacillus acidophilus* and *Bifidobacterium infantis*) to the feeding regimen decreases the incidence of NEC.**[6,19,25,60,108]

Data Collection

HISTORY AND SIGNS AND SYMPTOMS

The **onset of NEC is heralded by the development of feeding intolerance, abdominal distention, and bloody stools in a premature infant receiving enteral feedings.** A history of perinatal hypoxia, respiratory distress, congenital heart disease, or indomethacin administration for PDA closure often is elicited. As **the disease progresses, the infant develops signs and symptoms of septic shock (lethargy, respiratory distress, temperature instability, hypotension, and oliguria). Examination reveals a distended and tender abdomen that may demonstrate erythema, induration, and pitting edema in severe cases** (Box 28.4).

LABORATORY DATA

Complete blood count and serum electrolyte evaluations typically reveal thrombocytopenia, leukocytosis or leukopenia, and metabolic acidosis, respectively. C-reactive protein (CRP) levels are increasingly obtained and appear to be a good marker of onset, persistence, and subsequent resolution of NEC. Stool tests may be positive for occult blood and reducing substances

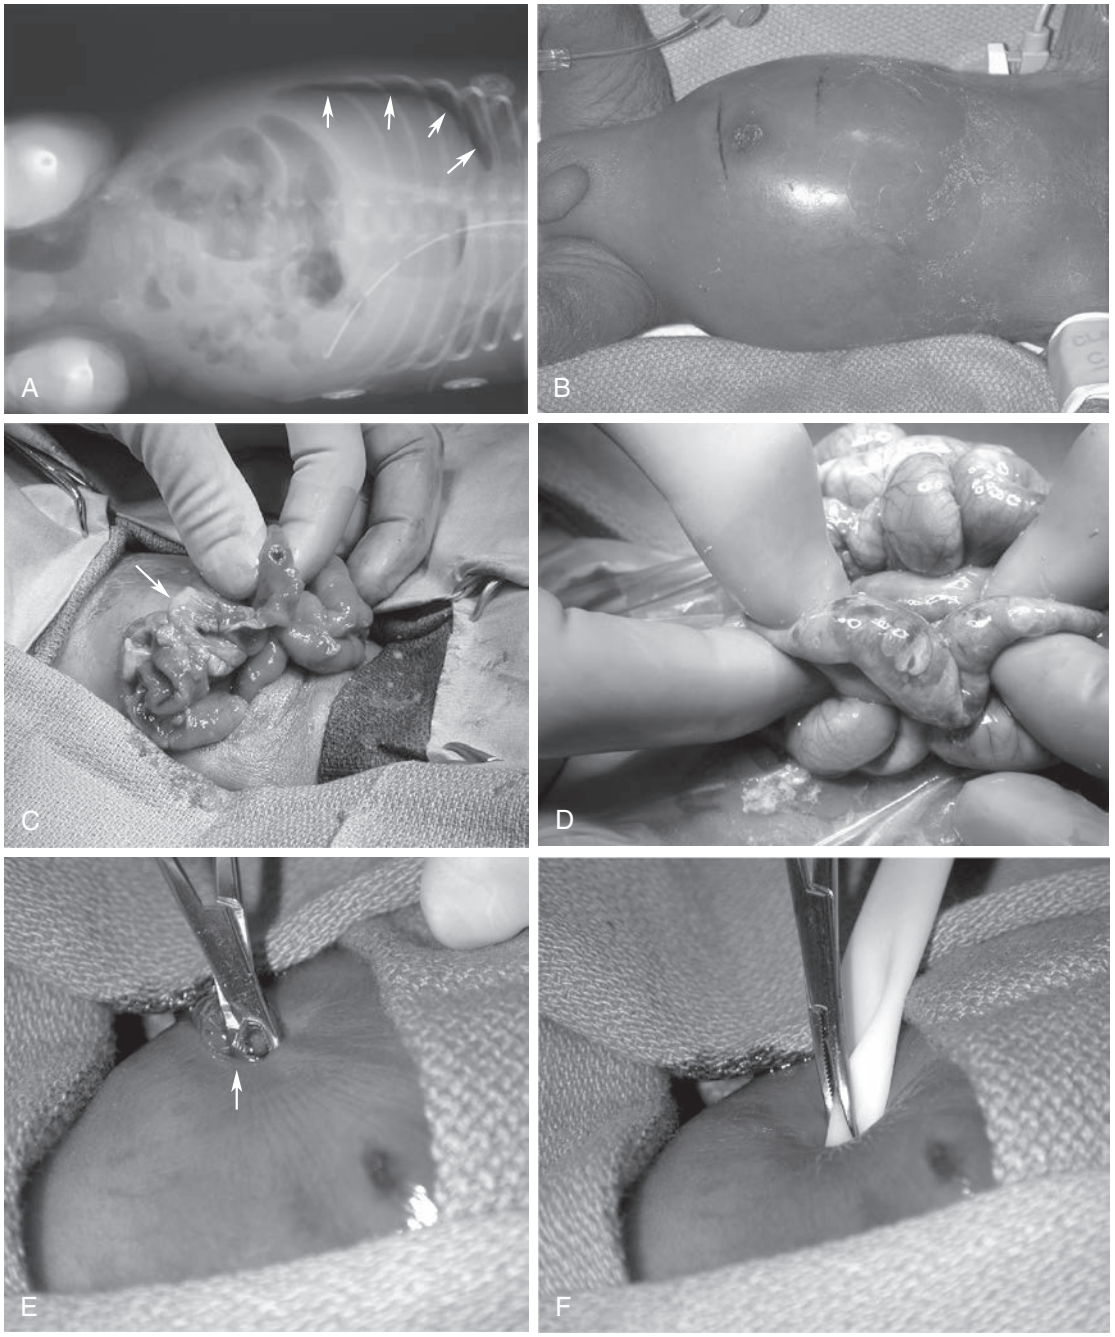

FIGURE 28.13 Several different examples of necrotizing enterocolitis (NEC) in ELBW infants. **A, B,** Pneumoperitoneum on abdominal radiograph (*arrows* in **A**); **B,** Same baby. Note abdominal distention and discoloration. **C,** Findings of NEC at laparotomy: perforation is shown between surgeon's fingers. *Arrow* shows segment of gangrenous bowel. Bowel toward surgeon's middle finger is normal. **D,** Example of pneumatosis intestinalis; this baby had pan-intestinal necrosis. **E, F,** Placement of peritoneal drain in the neonatal intensive care unit (NICU). *Arrow* shows release of pneumoperitoneum (bubbles).

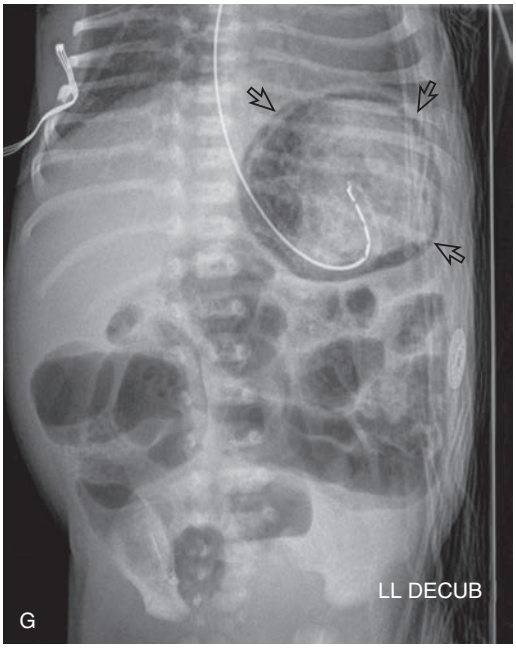

FIGURE 28.13, cont'd. **G**, Gastric pneumatosis instestinalis is a rare finding for NEC, but when present, it indicates a grave prognosis. A lateral decubitus radiograph demonstrates air outlining the stomach *(arrows)* and not collecting in the nondependent portion, confirming intramural, not intraluminal, air.

BOX 28.4 CRITICAL FINDINGS
NECROTIZING ENTEROCOLITIS

Critical assessment findings for necrotizing enterocolitis are:
- Feeding intolerance
- Abdominal distention
- Bloody or hemoccult-positive stools
- Thrombocytopenia, leukocytosis, leukopenia, and metabolic acidosis
- Pneumatosis intestinalis on abdominal radiograph
- Free air on abdominal radiograph in the presence of perforated viscus

in more than 50% of cases. The diagnostic test of choice is the three-way abdominal x-ray series (i.e., flat, left lateral decubitus, and in some instances, cross-table views). Plain radiographs are carefully reviewed for the characteristic finding of pneumatosis intestinalis, or intramural bowel gas. The radiograph should be assessed for free air (pneumoperitoneum), which would suggest intestinal perforation. Other findings may include dilated bowel, portal venous gas, ascites, or a fixed bowel loop that does not change on repeated studies.

A recent systematic review and meta-analysis of the use of bowel ultrasound (US) examination for NEC found usefulness in early identification of high-risk infants with NEC who might benefit from more aggressive treatment, including surgery.[24] More research is needed to establish whether bowel US improves outcomes. Abdominal ultrasonographic evidence of complex fluid collection is predictive of severe NEC requiring surgery.[81]

Treatment

PREOPERATIVE CARE

The only absolute and immediate indication for surgical intervention is intestinal perforation, which may be detected radiographically by the finding of pneumoperitoneum. In a clinically stable infant without findings of perforation, medical management consisting of bowel rest, fluid resuscitation, broad-spectrum antibiotic therapy, and total parenteral nutrition (TPN) is indicated.[90] The infant is monitored carefully (serial abdominal examinations and radiographs every 8 hours) for signs of intestinal gangrene. More than half of infants respond to medical management, but up to 30% of infants treated medically may develop an intestinal stricture requiring surgical management.

A subset of infants continues to deteriorate clinically despite maximal medical therapy, suggesting intestinal gangrene without intestinal perforation. Presence of intestinal gangrene should be considered in infants having persistent metabolic acidosis, thrombocytopenia, leukopenia, refractory shock, erythema of the abdominal wall, or a fixed, dilated intestinal loop on plain x-ray of the abdomen.[69,116]

OPERATIVE INTERVENTION

The principle of surgical management is to resect all necrotic bowel while preserving as much of the intestinal length as possible. In cases of extensive bowel involvement, only necrotic segments of intestine are removed and rarely reoperation at 12 to 24 hours may be planned (a second look). After bowel resection, proximal and distal ostomies are created, and the abdomen is thoroughly irrigated to reduce bacterial and fecal contamination. In severely

premature infants weighing less than 1000 g, primary peritoneal drainage (PPD) to decompress the abdomen after intestinal perforation may be performed in the NICU as an alternative to laparotomy. PPD and laparotomy may have comparable survival rates, but interestingly, infants treated with PPD have substantial improvement in residual bowel length, which may be in part because up to one third of these patients do not require further operative therapy.[26] **Infants with extremely low birth weight (<1000 g) who received PPD had higher survival rates when compared to laparotomy.**[110] A more recent study comparing PPD versus laparotomy for the initial surgery for NEC in infants weighing less than 1000 g at birth found that laparotomy increased the risks of short bowel syndrome without a shorter length of stay or in-hospital survival advantage.[125] Nevertheless, **laparotomy provides more definitive therapy and further aids in establishing the extent of diseased bowel,** which, if NEC totalis is discovered, may reduce futile care. In most cases, **PPD should be considered a temporizing means, or "bridge to laparotomy," to allow complete resuscitation before definitive surgery** (see Fig. 28.13).

POSTOPERATIVE CARE

After laparotomy, **supportive care (i.e., resuscitative fluids, TPN, antibiotics) and bowel rest are continued for 10 to 14 days. At 2 weeks postoperatively, low-osmolar elemental feedings or breast milk may be started once intestinal motility has returned and advanced as tolerated.** A stoma closure procedure is planned for as early as 6 to 8 weeks after the initial surgery. All infants should undergo a preoperative contrast enema before ostomy closure to make certain the intestine and colon distal to the ostomy have not strictured.

Complications and Prognosis

Stomal prolapse or retraction, wound infection, intraabdominal abscess, and intestinal obstruction are early complications. Recurrent NEC is uncommon, but may occur in approximately 5% of infants treated medically or surgically. The **most significant late complication is that of inadequate intestinal length (short bowel syndrome) and the need for long-term parenteral nutrition.** Preservation of the ileocecal valve is critically important to slowing intestinal transit and thereby limiting sequelae of short bowel syndrome. **Babies at highest risk for short bowel syndrome have the ileocecal valve but less than 20 cm of small intestine or have no ileocecal valve and less than 40 cm of small bowel.** For infants treated medically, nearly one third will develop a distal intestinal stricture, most commonly in the colon, that requires operative intervention to resect and to restore intestinal continuity and function. **Survival in infants weighing more than 1000 g has improved from 50% to 80% over the last two decades. Severely premature infants weighing less than 1000 g still have a mortality rate in excess of 51%.**[8,93]

MECONIUM ILEUS

Physiology and Etiology

Meconium ileus is an intestinal obstruction caused by hyperviscous secretions from the intestinal glands coupled with an insufficient excretion of pancreatic enzymes necessary to help digest intestinal contents. The result is tenacious, viscous meconium that creates a sticky plug obstructing the lumen of bowel. The obstruction generally occurs within the terminal ileum, mimicking ileal atresia. **More than 90% of infants with meconium ileus have cystic fibrosis,** a three base pair deletion on chromosome 7.[83] This autosomal recessive gene defect results in alteration of the chloride channel transporter, and therefore fluid flows across the apical surface of epithelial cells. **Meconium ileus occurs in 10% to 25% of patients with cystic fibrosis83,95; prenatally, 20% of mothers develop polyhydramnios. A family history of cystic fibrosis is present in 10% to 30% of cases.**

This ileus of retained meconium is in contrast to **meconium plug syndrome, which manifests as a failure to pass stool with obstruction in the colon and is not specific to cystic fibrosis. Meconium plug syndrome is generally recognized as immaturity of the ganglion cells and generally is benign.**[52] **Rectal dilation and/or contrast enema usually result in passage of the meconium plug(s),** and recurrence is uncommon; however, significant obstruction can develop with rare incidences of perforation. **Meconium plug syndrome, again in contrast to meconium ileus, is associated with Hirschsprung disease in 13% of cases.**[52] A more recent single-center study of meconium plug syndrome found no link with Hirschsprung disease or magnesium tocolysis.[23]

BOX 28.5 CRITICAL FINDINGS
MECONIUM ILEUS

Critical assessment findings for meconium ileus are:
- Abdominal distention
- Bilious emesis
- "Soap bubble" appearance of the bowel on abdominal radiograph
- Microcolon on barium enema

Data Collection

SIGNS AND SYMPTOMS

Meconium ileus is classified as simple (obstruction and obturation) or complicated (volvulus, intestinal atresia, perforation, meconium peritonitis). Uncomplicated meconium ileus presents as distal ileal obstruction caused by inspissated meconium (pellets) and proximal intestinal dilation. The onset of symptoms associated with simple meconium ileus begins 24 to 48 hours after birth. Bilious emesis, progressive abdominal distention, and the failure to pass meconium suggest intestinal obstruction.[83] The differential diagnosis in addition to meconium ileus includes ileal atresia, meconium plug, and Hirschsprung disease.

Physical examination shows a patent anus that may express a small amount of gray meconium. Examination of the abdomen reveals moderate distention with a characteristic doughlike sensation on palpation because of the thickened meconium contained in the dilated bowel. Complicated meconium ileus often manifests more abruptly and progresses more quickly. Symptoms include abdominal distention within 24 hours of birth, respiratory distress (especially if a postnatal perforation has occurred), and an edematous, erythematous abdomen[83] (Box 28.5).

LABORATORY DATA

Abdominal radiograph demonstrates a "soap bubble" appearance of the bowel caused by trapped gas within the meconium and also shows large dilated (with air) loops of bowel with few air-fluid levels because of the viscous nature of the meconium. A contrast enema shows a microcolon and pellets of inspissated meconium at the site of distal obstruction. If in utero perforation has occurred, microcalcifications also may be present on plain abdominal radiographs.

Treatment

PREOPERATIVE CARE

If meconium ileus is suspected, orogastric decompression, IV hydration, and electrolyte replacement are instituted; once appropriately hydrated, a diluted diatrizoate (Gastrografin) or iothalamate meglumine (Cysto-Conray) enema should be attempted.[83] Note that the infant should be adequately hydrated before the enema because of the hyperosmolarity of Gastrografin and Cysto-Conray. Intracolonic instillation of these water-soluble agents draws fluid into the bowel lumen, diluting the viscous meconium and facilitating passage, and may be therapeutic to relive the obstruction. **If the Gastrografin enema results in incomplete evacuation, it may be repeated over the next several days.** However, if the **Gastrografin enema fails to result in passage of meconium, complicated meconium ileus or ileal atresia may be present and operative intervention is indicated.**[83]

OPERATIVE INTERVENTION

The goal of operative treatment is to relieve intestinal obstruction. For uncomplicated meconium ileus, several operative approaches are described to eliminate the obstructing inspissated meconium. Techniques include (1) enterotomy with extraction of the tenacious meconium and irrigation of the bowel with saline solution or 2% N-acetylcysteine (Mucomyst), (2) resection of the affected segment with anastomosis, and (3) formation of chimney ostomies just proximal to the obstruction (Bishop-Koop procedure: bowel is divided to create an ostomy of the distal ileum for continued irrigations; an internal anastomosis of the proximal to distal ileum is fashioned to maintain intestinal continuity). More commonly now, a T-tube enterostomy may be created, in which a soft and small caliber tube is securely placed within the bowel lumen and delivered through a separate wound in the abdominal wall (Fig. 28.14). This tube, like the chimney ostomy, allows continued postoperative irrigations with normal saline or diluted Mucomyst to complete or maintain passage of intestinal contents. In uncomplicated meconium ileus, T-tube enterostomy is as safe and effective as the Bishop-Koop

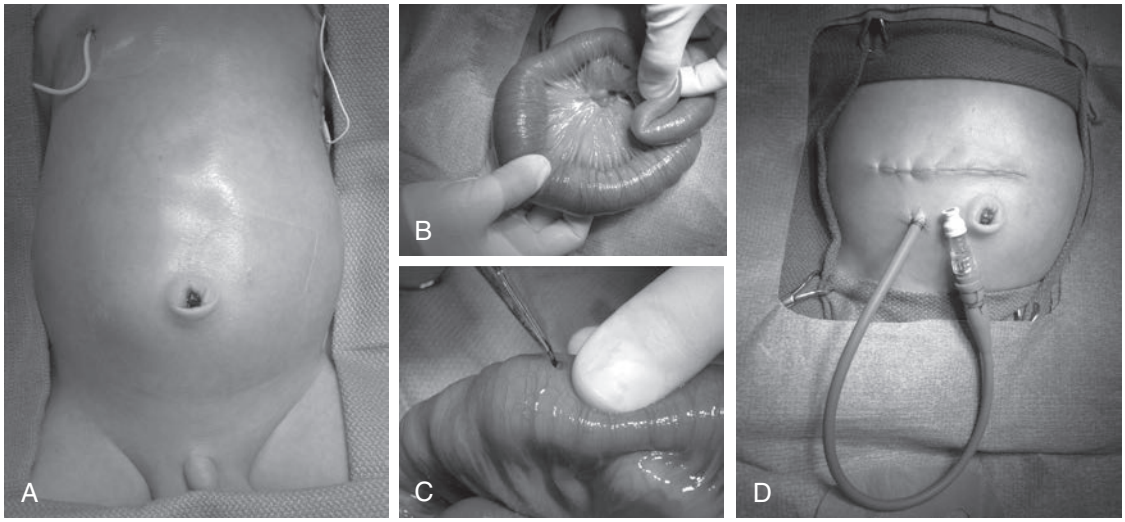

FIGURE 28.14 Newborn with meconium ileus as presenting feature of cystic fibrosis. **A,** Abdominal distention and visible intestinal loops on physical examination. **B,** Equal pressure is being applied to the bowel by both hands of the surgeon. Note how noncompressible the bowel in the right hand is secondary to the inspissated meconium. **C,** Note viscosity of meconium being teased out of the bowel lumen. **D,** After irrigation with Mucomyst and evacuation of the meconium, a tube enterostomy is placed for continued irrigation in the weeks following surgery. Once the baby's bowel is completely cleared of meconium and a full diet is tolerated, the tube may be removed.

procedure.[44] If complicated meconium ileus is identified, the obstructed segment is resected and ostomies are performed to permit postoperative irrigation. **Ostomy closure usually is performed 4 to 6 weeks later.**

POSTOPERATIVE CARE

Postoperatively, nasogastric tube decompression, nutritional support, and irrigation of the rectum or ostomies with saline solution or N-acetylcysteine (Mucomyst) are instituted. Once gastrointestinal function returns, feedings using breast milk (see Chapter 18), predigested or elemental formula, and pancreatic enzyme supplements are started. The diagnosis of cystic fibrosis is confirmed with genetic analysis or sweat chloride testing.

Complications and Prognosis

One-year survival for infants with simple or complicated meconium ileus is favorable (greater than 90%), but long-term survival is limited primarily because of the pulmonary complications of cystic fibrosis.[77] Late gastrointestinal complications of cystic fibrosis include distal intestinal obstruction syndrome (meconium ileus equivalent), appendicitis, intussusception, rectal prolapse, intestinal stricture, pancreatitis, and cholestatic liver disease.[83] A history of meconium ileus is associated with decrease in bone density and fat mass when compared to children and adolescents without meconium ileus.[27]

HIRSCHSPRUNG DISEASE

Physiology and Etiology

Hirschsprung disease is a congenital intestinal disorder caused by a lack of ganglion cells in the bowel wall, principally the colon, which disrupts and abrogates effective peristalsis. A genetic variant is associated with the development of Hirschsprung disease in early fetal life.[42,109,123] During development, neural crest cells (the progenitor or stem cells of the enteric nervous system) migrate along the intestinal tube to populate the entire gut in a craniocaudal fashion, with the distal colon, rectum, and sphincter being the last to be colonized. These progenitor cells divide, differentiate, and proliferate to form the enteric nervous system, of which the ganglion cells are a critical component. Arrest of migration, proliferation, and differentiation

results in the aganglionosis found in Hirschsprung disease, which is a relatively common cause of distal intestinal obstruction in the newborn. **At the site of arrest, a transition from normal to abnormal innervation is present, and all intestine distal to this site will be aganglionic and therefore dysfunctional. The result is a functional obstruction that mimics mechanical intestinal obstruction. In brief, the pathophysiologic consequence of the absence of ganglion cells is failure of the involved rectum and colon to relax, and therefore the fecal stream cannot be passed effectively through the aganglionic region and beyond. Rectosigmoid aganglionosis is most common (85%), with the remainder of patients developing variable lengths of more proximal colonic and, rarely, small intestine disease. Total colonic aganglionosis occurs in roughly 10% of cases.**

Hirschsprung disease occurs in 1 of 5000 live births, having a 4:1 male-to-female predominance. The majority of cases are sporadic (80% to 90%), but familial occurrences are well-recognized and multiple genetic alterations have been identified in affected pedigrees. Associated anomalies are rare in sporadic cases but may be seen in as many as 25% of the familial cases. **Babies born with Down syndrome also carry a higher incidence of Hirschsprung disease than the population at large (2%), and between 5% and 10% of Hirschsprung patients will have Down syndrome.**

Approximately 15% of Hirschsprung neonates will present with meconium plug syndrome (MPS), an obstruction of the colon by inspissated meconium. However, in general, MPS is associated with immature ganglion development and is not indicative of the more serious Hirschsprung disease.

Data Collection

SIGNS AND SYMPTOMS

Ninety-eight percent of normal infants pass meconium in the first 24 to 48 hours of life. Failure to pass meconium early, feeding intolerance, and abdominal distention suggest a diagnosis of Hirschsprung disease. In some babies having a short segment of aganglionic bowel, spontaneous evacuation of stool may be noted, and the infant may appear otherwise healthy. **If vomiting, abdominal distention, and constipation (or paradoxic diarrhea resulting from watery stool escaping around the obstipated stool) continues, further investigation is indicated.** Hirschsprung disease may rarely escape detection during the newborn period, and in older children a history of refractory and chronic obstipation may be the only symptom. **Approximately 5% to 10% of affected infants will present with a picture of enterocolitis (toxic megacolon), characterized by fever, vomiting, abdominal distention/tenderness, foul-smelling diarrhea, and septic shock.** The infant may rapidly deteriorate, with a 50% risk of death if the colon is not rapidly decompressed, either by transanal soft rubber tube irrigations or emergency colostomy. Fortunately, in most cases of Hirschsprung disease, the infant is only mildly ill, allowing time for definitive diagnostic studies before surgical correction is undertaken (Box 28.6).

BOX 28.6 CRITICAL FINDINGS
HIRSCHSPRUNG DISEASE

Critical assessment findings for Hirschsprung disease are:
- Failure to pass meconium within 48 hours of birth
- Feeding intolerance
- Abdominal distention
- Enterocolitis (fever, abdominal distention, foul-smelling diarrhea, sepsis)
- Transition zone on barium enema
- Absent ganglion cells and nerve hypertrophy on rectal biopsy

LABORATORY DATA

The diagnostic evaluation begins with a contrast enema.[10,65] Surgical dogma states that when entertaining the diagnosis of Hirschsprung the first enema should be a contrast enema. This study typically shows a contracted or spastic rectosigmoid colon, with contrast material entering the proximal dilated bowel. The area between the contracted and dilated bowel is called the transition zone.[17] **If the contrast enema is equivocal, an abdominal x-ray film should be obtained on the next day to evaluate extent of retained contrast material. Significant contrast material retained within the distal colon and rectum suggests the presence of Hirschsprung disease. Definitive diagnosis is made by performing a bedside suction rectal biopsy, a well-tolerated procedure in neonates that does not require any analgesics or sedatives. On histology, a biopsy diagnostic of Hirschsprung shows an absence of ganglion**

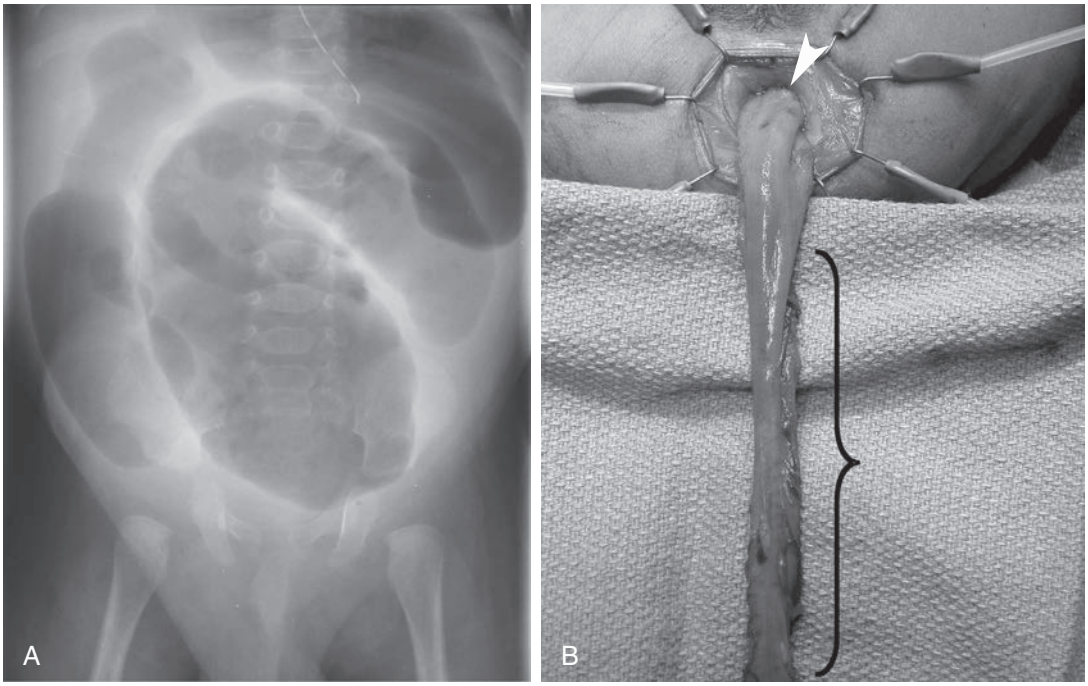

FIGURE 28.15 Newborn with Hirschsprung disease. **A**, Plain abdominal radiograph shows distal intestinal obstruction 2 days after birth in a neonate who has failed to pass meconium. Note absence of gas in rectum/pelvis. **B**, After laparoscopic mobilization and transanal mucosectomy, the diseased bowel may be delivered through the anus. The *bracket* denotes the contracted, aganglionic bowel. *Arrowhead* shows biopsy performed laparoscopically that confirms region of ganglionated bowel. Coloanal anastomosis was performed at this level.

cells and the presence of hypertrophic nerve trunks within the submucosal and intermyenteric plexus. Special immunohistochemical staining is commonly performed by the pathologist to corroborate the diagnosis. Conversely, if ganglion cells are observed on histologic examination, a diagnosis of Hirschsprung disease is excluded.

Treatment

PREOPERATIVE CARE

In infants having Hirschsprung-associated enterocolitis, orogastric tube decompression, IV fluid resuscitation, broad-spectrum antibiotics, and correction of acid-base deficits and electrolyte abnormalities are promptly initiated. Infants who are less ill with symptoms of obstruction are placed on NPO (nothing by mouth) status, and IV antibiotic therapy and orogastric decompression are instituted, permitting time to complete the diagnostic evaluation. Once the diagnostic evaluation is completed, transanal rectal irrigations, not enemas, are performed twice daily until surgery. Babies should have return to normal bowel function with these irrigations and may be fed enterally (so long as rectal irrigations continue) until definitive surgery.

OPERATIVE INTERVENTION

In the presence of profound enterocolitis, an emergency colostomy may be indicated. If necessary, a colostomy is performed at a site of normal bowel (ganglion cells present), as confirmed by a frozen section histologic examination. In selected cases, the neonate will be too ill, so operative time is minimized by the creation of a right-sided colostomy, because most affected babies have more distal colonic involvement. If the neonate presents with milder symptoms, one of several surgical options may be selected: (1) primary laparoscopically assisted endorectal pull-through (Fig. 28.15), (2) primary transanal pull-through, or (3) staged reconstruction (temporary colostomy at the most distal site

of ganglion cells, followed by a pull-through in 3 to 6 months).[97] **In all cases, multiple intestinal seromuscular biopsies are created at the time of operation until the normally innervated bowel is identified. A coloanal anastomosis or colostomy is performed at the site of histologically proven normal bowel. If the anastomosis or colostomy site is missing ganglion cells, the neonate will remain symptomatic—the bowel will not function normally because of aganglionosis.**

Several factors influence the decision to perform a primary pull-through procedure in neonates.[97] The neonate should be of sufficient gestational age and size (generally more than 2 kg), have rectosigmoid disease as demonstrated by contrast enema, not have significant proximal bowel distention, and not have evidence of advanced enterocolitis. Neonates who do not meet these criteria should be treated in a staged manner, with an immediate colostomy and a pull-through procedure (with or without laparoscopy assist) delayed until later in infancy.*

POSTOPERATIVE CARE

The recovery period is generally straightforward, and supportive care is provided until the return of bowel function. **For babies treated initially with colostomy, postoperative care includes teaching the parents about stoma maintenance and hygiene** (Box 28.7). The pull-through procedure entails resecting abnormal aganglionic bowel and bringing ganglionic bowel to the anus. Several variations of the pull-through operation have been described; each has unique advantages and disadvantages, but in general the results are similar regarding long-term stooling patterns. **For neonates having a primary laparoscopically assisted endorectal pull-through, first stool is usually passed within 24 to 48 hours of the procedure, at which time breast milk or Pedialyte may be introduced. Feeds may be advanced to goal (according to tolerance) over the next 24 to 48 hours. Perianal skin care with various barriers is critical in the early postoperative period to prevent excoriation, because defecation is frequent and poorly controlled at this stage of convalescence.** Moreover, **no transanal manipulation (i.e., temperature probes or suppositories) should be performed until after 4 weeks from the date of surgery.**

BOX 28.7 INSTRUCTIONS FOR OSTOMY CARE

Supplies

Skin-prep (United)*
Stoma-adhesive paste (ConvaTec)*
Ostomy setup (skin wafer and bag)
Pattern for stoma

Application Instructions

1. Measure the diameter of the stoma, using the measuring guide circle enclosed in the wafer box.
2. Trace the appropriate circle onto the white paper backing of the wafer and cut out the hole. Gently bend and slightly stretch the opening with your finger. The goal is to have the hole 1/16 to 1/8 inch larger than the stoma. A snug but not constricting fit is needed to prevent stool leaking onto the skin.
3. Clean and dry the skin around the stoma.
4. Apply a generous coat of Skin Prep (United) on the skin around the stoma.
5. Apply a thin border of stoma-adhesive paste (ConvaTec) around the stoma.
6. Press wafer firmly to skin.
7. If using a two-piece appliance, snap on the bag and close the end of the bag with a clip or rubber band if it is open-ended. If using a one-piece appliance, the appliance may be applied directly to the skin or to a skin barrier such as stoma-adhesive (ConvaTec).*

Helpful Hints

1. Change the appliance as soon as there is any evidence of leaking!
2. Rinsing the bags with some type of scented soap (peppermint or spice) will help cut down on the bag odor.
3. Precut several wafers ahead of time.
4. When traveling, always have an extra set of clothes and a complete set of supplies, as well as a new setup with stoma holes already cut.

*Other products may be used in place of the brand names upon recommendation of medical supplier, physician, or nurse.
Courtesy Kris Altzenbeck, R.N., The Children's Hospital, Denver, Colo.

Complications and Prognosis

In a recent population-based study spanning an 18-year period, the mortality rate for Hirschsprung disease was less than 2% during the first year of life.[3] Early complications of the pull-through operation include inadequate blood supply to the coloanal anastomosis, anastomotic stricture, anastomotic dehiscence, and cuff abscess. **Later complications include Hirschsprung-associated enterocolitis,**[40]

obstruction,[57] perianal skin excoriation, and recurrent constipation. The infant usually thrives postoperatively and grows normally. It is not uncommon for the infant to have frequent stools during the immediate postoperative period, which gradually normalize in frequency. However, some children, despite a technically satisfactory operation, will experience recurrent constipation requiring some form of bowel management program with or without placement of a colostomy tube (i.e., Chait button) for antegrade enemas.[122]

ANORECTAL MALFORMATIONS

Physiology and Etiology

Anorectal malformations (ARM) encompass a broad spectrum of hindgut anomalies, from isolated imperforate anus in boys and girls, which may include fistulous communications between the urogenital tract and rectum, to the complex persistent cloaca in females. Although the development of the cloaca and its subsequent septation into urogenital and anorectal tracts is not well understood, each organ system is recognizable as a separate entity by the seventh week of gestation. Therefore, persistent cloaca in females arises from an arrest in development of the gut and its complete separation from urogenital tract between the fourth and sixth weeks of gestation. Cloacal exstrophy arises if disruption of the cloacal membrane occurs before the urorectal septum has separated the urinary bladder from the hindgut. Disruption of the cloacal membrane after septation results in exstrophy of the bladder only. Any insult occurring at this critical period of organogenesis places a number of organ systems at risk and accounts for the fact that 60% of infants with cloaca will have concomitant anomalies.[46,61] A genetic predisposition may also exist.[61]

Imperforate anus is the most common ARM, occurring in 1 in 5000 live births, and predominantly affects males (58%) more than females (42%).[61] Imperforate anus is characterized as low, intermediate, or high, and termination of the rectal fistula varies according to gender. The higher the defect, the more likely the presence of other associated malformations. A high imperforate anus is defined as the end of the rectum terminating above the levator ani muscles. Conversely, in low imperforate anus, the rectum descends below the levator complex. A fistulous connection to the perineum or urogenital tract is almost always present. In high lesions, the rectal fistula enters the membranous urethra in the male or rarely the vagina in the female.[61] In low lesions the rectal fistula empties on the perineum of both boys and girls or the posterior fourchette of the introitus, the most common site in girls.[61,84] Congenital VACTERL anomalies and trisomy 21 are common and require further evaluation. Moreover, a high incidence of spinal dysraphism is observed with anorectal malformation; imaging of the spine is indicated.[61]

Data Collection

SIGNS AND SYMPTOMS

Most anorectal malformations are apparent on physical examination of the newborn but may be missed if a careful inspection of the buttocks and anus is not performed. Once the diagnosis is made, a fistula should be sought. In low lesions there may be a thin membrane over the anal orifice, or there may be a fistula along the perineum and scrotal raphe of boys. In girls, the fistula most commonly terminates in the vestibule or fourchette of the introitus. If meconium passes in the urine of boys or, rarely, from the vagina, a high lesion is present. If the condition remains unrecognized, the infant develops signs and symptoms of distal intestinal obstruction. Down syndrome babies having an ARM usually (95%) have a high type variant of rectal atresia without genitourinary tract communication (Box 28.8).

LABORATORY DATA

A plain abdominal radiograph may show features of distal intestinal obstruction without rectal gas, but it will not reliably show termination of the rectum. Perineal ultrasonography, a colostography,[10,61] may be used to establish the termination of the rectum and its distance from the skin, data that may help operative planning. In boys having imperforate anus without a perineal fistula, a contrast study of the urethra should delineate a rectourethral fistula, if present. In girls without a perineal or vestibular fistula, a contrasted genitogram may help define the anatomic relationships of a persistent cloaca. A perineal fistula visible on physical examination does not usually

BOX 28.8 CRITICAL FINDINGS
IMPERFORATE ANUS

Critical assessment findings for imperforate anus are:
- Absence of anus or presence of anteriorly displaced perineal fistula.
- Signs and symptoms of obstruction if diagnosis not made.
- Perineal ultrasound study will identify the level of defect in the absence of a perineal fistula.

warrant imaging of ARM. However, because of the possibility for VACTERL association, echocardiography and abdominal sonography of the genitourinary tract are indicated, as is a plain radiograph of the spine and limbs.

Treatment

PREOPERATIVE CARE

The infant should be kept NPO while evaluation of ARM is underway, and an orogastric tube should be placed to exclude EA and decompress the stomach. If a fistula is present on the perineum or at the fourchette, an early anoplasty may be performed, assuming the baby has no associated cardiac anomaly and is otherwise deemed to be a suitable candidate for a general anesthetic. If early repair is contraindicated, then a perineal fistula tract may be dilated twice daily to promote elimination of fecal contents and until the baby is a more suitable candidate for surgery. If no fistula is visualized and a high lesion or cloaca is present, a divided colostomy is performed and staged reconstruction is planned for later in infancy.

OPERATIVE INTERVENTION

For low imperforate anus, early reconstruction is performed either in the newborn period or in the first months of life, if the infant can produce stools adequately through the fistulous tract with dilations. After colostomy for high imperforate anus, a formal repair is undertaken when the child is 3 to 6 months of age. Approached most commonly through a posterior sagittal incision (buttock), the fistula is separated from the urethra in boys or vagina in girls, and the rectum is mobilized to lie within the center of the sphincter mechanism. The levator muscles and sphincter are closed anteriorly and posteriorly around the rectum, which is then anastomosed to the perineal skin in a procedure known as a posterior sagittal anorectoplasty (PSARP, or Pena procedure).[85] Alternatively, to minimize wound complications and postoperative pain, a laparoscopic-assisted anorectoplasty may be performed (Fig. 28.16). A Foley catheter always should be placed in boys at time of the definitive repair to assist in separation of the rectum from the urethra and to facilitate bladder drainage in the postoperative period; this catheter will be in place typically for 7 to 14 days after PSARP.

POSTOPERATIVE CARE

After anorectoplasty, simple skin care is all that is necessary, and a program of anal dilation is instituted 14 days postoperatively, which will continue for 4 to 6 months. After a colostomy, stoma care and teaching are begun with the parents. Colostomy closure will be performed within 6 to 8 weeks of PSARP, assuming the neoanus is of adequate size and not strictured.

Complications and Prognosis

Mechanical complications of the stoma (prolapse, stenosis, and skin breakdown) may arise but generally do not require revision and should be temporized until stomal closure. Urinary tract infection (UTI) or hyperchloremic metabolic acidosis may result from the fistulous connection of the rectum to the urinary tract. Antibiotic prophylaxis is instituted, and selected infants may require bicarbonate supplement until the fistula is divided.

Constipation is the primary long-term problem after correction of low imperforate anus.[61] Stricture of the anoplasty should always be considered and may be treated with anal dilation or rarely revision anoplasty.

High imperforate anus is most often complicated by incontinence (or pseudoincontinence) and frequent soiling. Long-term results are influenced by the degree of sphincter muscle development and innervation. Approximately 75% have voluntary bowel movements, 50% have soiling episodes, 40% have voluntary bowel movements and no soiling, and 25% have fecal incontinence.[61] Bowel programs and strategies have been developed to permit some degree of social continence so that permanent colostomy can be avoided.[61]

OMPHALOCELE AND GASTROSCHISIS

Physiology and Etiology

Omphalocele and gastroschisis are distinct defects of the abdominal wall at or near the umbilicus. **Omphalocele is characterized by the persistent herniation of the abdominal viscera through the umbilical ring, and the herniated contents are covered by the normal components of the umbilical cord: the peritoneum, Wharton jelly, and amnion.** Omphalocele, also known as exomphalos, is a defect in abdominal wall development that may result from failure of embryonic enfolding as early as 4th to 7th weeks of gestation or from failure of closure of the exocelomic space, which is usually completed by the 12th week of gestation. **Fifty percent of neonates presenting with omphalocele will have an underlying chromosomal abnormality, most often trisomies 12 and 18 but also trisomy 21.**[16] **Congenital heart lesions, including pulmonary hypertension, are seen in as many as 50% of these affected infants.** Congenital syndromes involving an omphalocele are potentially lethal, usually as a result of the associated abnormalities. Cloacal exstrophy, occurring in 1 in 200,000 pregnancies and the constellation of defects known as the *pentalogy of Cantrell* likely represent the earliest of embryonic failure in the development of this spectrum of anomalies, including omphalocele.

Gastroschisis is a full-thickness defect of the abdominal wall that occurs most commonly

to the right of the umbilicus and exposes the extruded bowel to the amniotic fluid without a natural covering as seen with omphalocele. It has been hypothesized that this defect results from a weakening of the anterior abdominal wall because of a vascular accident involving the right omphalomesenteric artery, which takes over perfusion of the anterior abdominal wall during the seventh week of gestation. Gastroschisis occurs three to four times more frequently than omphalocele, and its incidence is rising in developed countries for unknown reasons.[99] This increasing incidence seems to be occurring in younger mothers, most frequently in those younger than 20 years, although no clear epidemiology has been correlated with this finding. Gastroschisis typically is not associated with major congenital anomalies or syndromes, although 5% to 10% of affected infants have a concomitant intestinal atresia.[16] This atresia is likely secondary to either the initial vascular accident thought to initiate the defect or compromise of the affected bowel segment arising from a constricting fascial defect.

Nonrotation of the intestine, by definition, is uniformly present in all incidences of these two conditions.

HISTORY

Abdominal wall defects are readily diagnosed by antenatal ultrasonography, which is helpful in planning future delivery and therapy. Spontaneous or induced vaginal delivery should be considered in most cases of gastroschisis, because minimal risk of bowel injury during delivery exists.[33,53,35] Babies having an omphalocele may be delivered vaginally, but liver herniation or associated anomalies may dictate cesarean section.

In cases of gastroschisis, severe serositis resulting from exposure of the bowel to amniotic fluid makes closure more difficult and delays the return of bowel function. Early delivery may be recommended for certain fetuses with gastroschisis, if sonographic evidence reveals progressive bowel distention and thickening, suggesting intestinal obstruction or severe serositis.

In cases of omphalocele, prenatal sonography should thoroughly evaluate the fetus for other potential anomalies and may be supplemented by fetal MRI.

BOX 28.9 CRITICAL FINDINGS
OMPHALOCELE AND GASTROSCHISIS

Critical assessment findings for omphalocele and gastroschisis are:
- Typically detected on antenatal ultrasound examination.
- Eviscerated bowel without peritoneal covering in gastroschisis.
- Eviscerated bowel with peritoneal covering in omphalocele.
- Diagnosis of omphalocele necessitates search for other associated anomalies.

SIGNS AND SYMPTOMS

Both anomalies present as a mass of abdominal contents extruding through an anterior abdominal wall defect. Eviscerated bowel without a peritoneal covering characterizes gastroschisis, whereas an omphalocele is defined by a peritoneal covering of herniated bowel and often a segment of liver. Gastroschisis defects are most commonly to the right of the midline and are found adjacent to the umbilical stalk, whereas omphalocele occurs through a central defect at the base of the umbilical cord.

In contradistinction to gastroschisis, omphalocele importantly carries a high incidence of associated anomalies, and cardiac and/or urinary tract malformations are most prevalent. Omphalocele also is a feature of several recognizable syndromes, including Beckwith-Wiedemann, prune belly, cloacal exstrophy, and pentalogy of Cantrell. Chromosomal defects are identified with greater frequency in cases of omphalocele than gastroschisis and include trisomies 13, 18, and 21. Most babies having an omphalocele will deliver at term.

Gastroschisis in contrast is associated with few anomalies outside of the gastrointestinal tract. Malrotation is understood to exist with gastroschisis, and so the most common associated anomaly is intestinal stenosis or atresia (10% to 15%), a rare finding in omphalocele. Babies having gastroschisis are more commonly preterm and small for gestational age (Box 28.9).

LABORATORY DATA

In a neonate having omphalocele, a careful search for associated anomalies is performed before closure is attempted. Echocardiography

and an x-ray examination of the chest and spine are performed to rule out cardiac, chest wall, diaphragmatic, and spinal anomalies. **Abdominal sonography** is obtained to evaluate integrity of the urinary tract. **Gastroschisis newborns do not require routine radiographic evaluations unless otherwise indicated.**

Treatment

PREOPERATIVE CARE

Initial management of gastroschisis includes preservation of body heat and fluid, orogastric decompression, protection of the intestine, and prophylaxis against infection. Covering the exposed viscera minimizes heat and fluid loss. Placing the infant's torso into an impermeable, clear plastic bowel bag is the preferred method to prevent fluid loss. Historically wrapping the bowel in saline-soaked gauze has been advocated. However, if not done properly this method can result in constriction in the blood supply and ischemia to the intestine. **Positioning the infant on his or her side prevents "kinking" of the mesentery at the fascial level and prevents intestinal ischemia.**

IV fluids and broad-spectrum antibiotics should be instituted early. Administration of adequate isotonic IV fluids is essential to the perioperative care of infants with gastroschisis. Given the insensible fluid losses, these infants may require a minimum of 150 mL/kg/day of total fluids. A Foley catheter to measure accurate urine output in the first 24 to 48 hours of life may be useful to modify the fluid requirements of the infant. To prevent bowel distention, an orogastric tube is placed to low continuous suction. In omphalocele, because the abdominal contents are covered naturally, less evaporative and heat losses are encountered.

OPERATIVE INTERVENTION

Rarely, an infant with omphalocele may be too ill (i.e., from pulmonary hypertension or a congenital heart anomaly) to undergo early abdominal closure or may have other lethal malformations or may have a "giant omphalocele," defined as the sac containing a significant portion of the liver (Fig. 28.17). **Under these circumstances precluding early closure, the newborn is given palliative care with a daily application of a dessicant or 1% silver sulfadiazine to the abdominal sac.** The result is eschar formation and subsequent epithelialization in 10 to 20 weeks. After epithelialization has occurred, **gentle compression can be placed on the omphalocele to reduce the contents back into the abdomen. This compression can be accomplished with an elastic wrap or a specially made brace,** which further protects the omphalocele. The brace works to compress the omphalocele to skin level at a safe rate (Fig. 28.18). A large ventral hernia will remain, and the repair may be performed later in infancy. If the infant is allowed to grow without compression, risk arises for progressive "mushrooming" of the sac and loss of abdominal domain, which make subsequent definitive fascial closure highly complex.

Cases of omphalocele not having liver herniation or significant associated anomalies may have the sac removed and primary fascial closure accomplished shortly after birth, or, at a minimum, simple skin closure may be performed, with ventral hernia repair scheduled for later in infancy once abdominal domain has been restored. Some cases of omphalocele will require biosynthetic fascial substitutes to accomplish visceral coverage.

For babies born with gastroschisis, primary surgical repair entails reduction of the herniated abdominal contents into the peritoneal cavity without increasing abdominal pressure to a point that ventilation, venous return, and intestinal blood supply are compromised. If the amount of eviscerated abdominal contents is small or moderate, primary repair is simple and safe. Before closure of gastroschisis, the surgeon searches carefully for associated atresia but may or may not attempt to restore intestinal continuity during the initial operation. If atresia is identified but inflammation and matting of the intestine will not permit safe anastomosis, the atretic bowel may be placed within a silo or returned to the abdomen primarily, and re-exploration may be planned for 4 to 6 weeks later to allow the thickened, edematous bowel wall to normalize, facilitating anastomosis or enterostomy. If atresia is found, but the bowel is not inflamed or matted, intestinal continuity may be restored at the initial operation or an ostomy created, with plans for delayed reconstitution 4 to 6 weeks later.

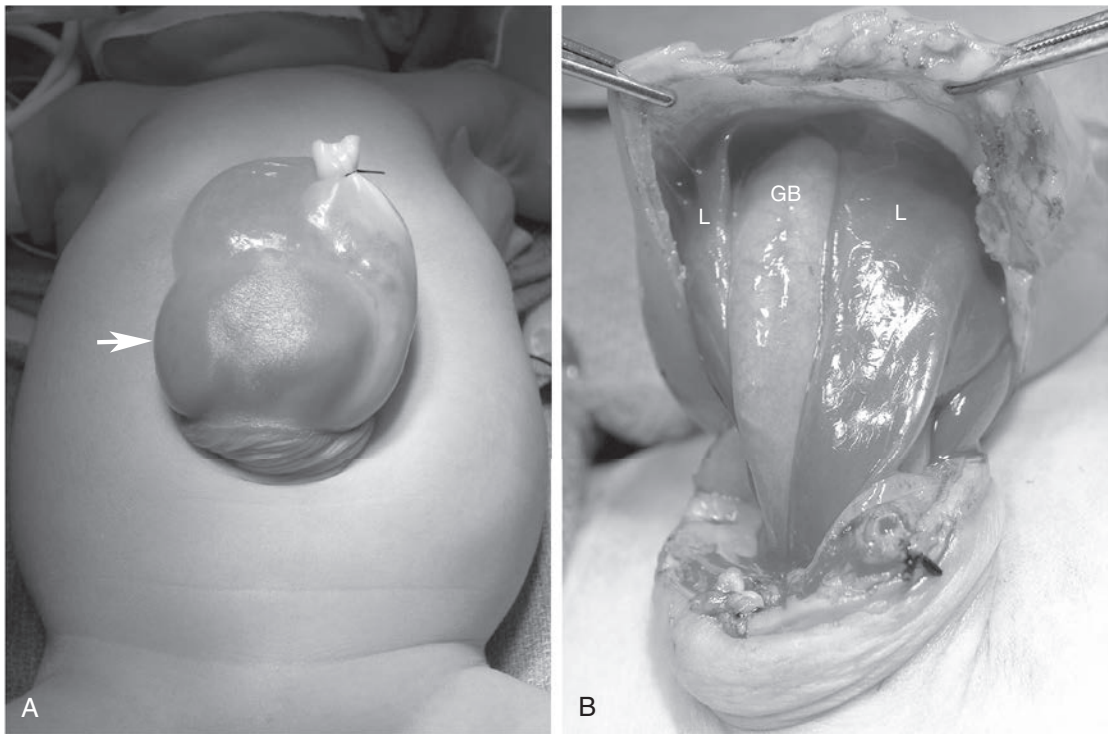

FIGURE 28.17 Neonate with omphalocele. **A,** *Arrow* shows liver contained within omphalocele sac. **B,** Dissection of sac contents. Liver is adherent to lining of sac. Fascial defect was closed primarily. *GB,* Gallbladder; *L,* liver.

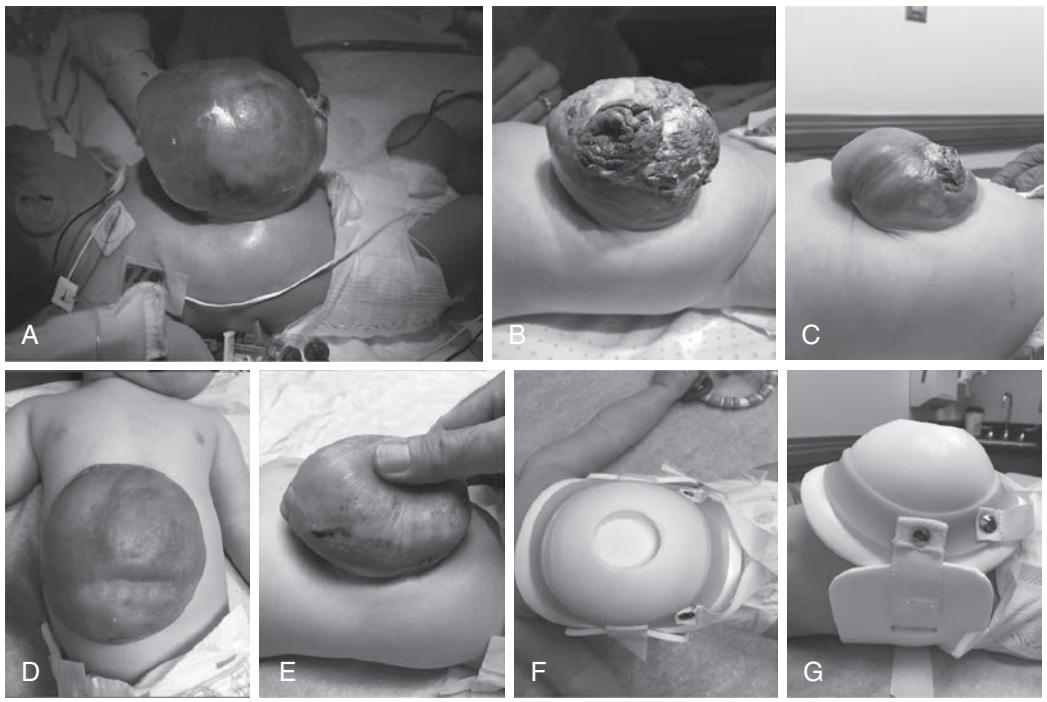

FIGURE 28.18 **A–J,** Neonate born at 31 weeks of gestation with a giant omphalocele. **B–E,** Baby had application of 1% silver sulfadiazine until epithelialization was complete. **F, G,** A protective brace was fitted after complete epithelialization, allowing for safe compression of hernia contents to skin level over time.

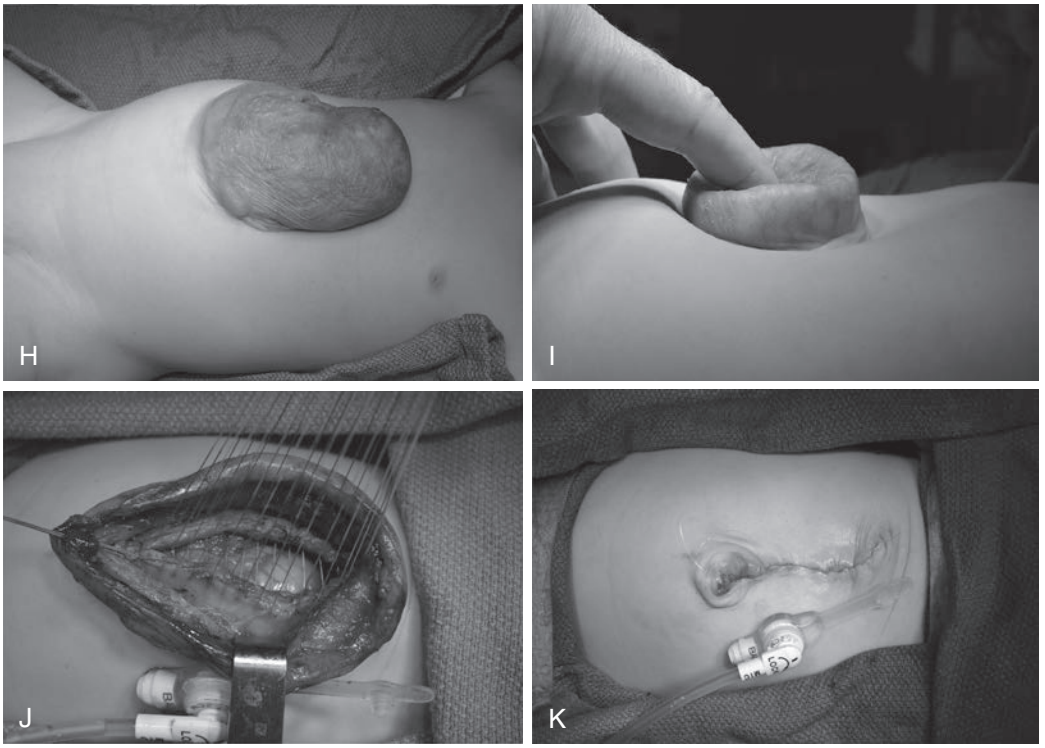

FIGURE 28.18, cont'd. **H, I,** Contents completely reducible to skin level preceding surgical closure. **J, K,** Operative closure that included gastrostomy placement.

In selected cases, the fascial defect may have to be enlarged to allow replacement of the herniated organs into the abdomen because of the small size of the fascial ring, loss of abdominal domain, and the amount of intestinal herniation. The inability to perform primary closure necessitates placement of a **Silastic silo or patch to permit staged reduction** (Fig. 28.19). **Over the ensuing 2 to 7 days, the herniated viscera are gradually returned to the abdomen on a daily basis by gravity (baby remains supine) and by applying gentle and constant pressure to the silo at the bedside (umbilical tape is tied sequentially along the silo until the intestine has reached the fascial level). Once all of the silo contents have been successfully reduced, the infant is returned to the operating room for removal of the silo and closure of the fascia.**[96] **While a silo is in place and for a short period after definitive fascial closure, most neonates will remain on antibiotics.**

Complications and Prognosis

Bowel injury, respiratory compromise, and diminished venous return caused by abdominal hypertension may complicate recovery after primary fascial closure of abdominal wall defects. In this setting the infant is returned to the operating room for placement of a silo. Rarely, a silo may become infected or separate from the fascia, complicating closure by this method.

Recovery of bowel function is uniformly delayed, especially in gastroschisis caused by exposure of the bowel to amniotic fluid. A central venous catheter should be placed at the time of initial surgery for long-term TPN support.[119] Intestinal stricture, incisional hernia, and adhesive bowel obstruction are possible short- and long-term complications.[91] **The principle long-term morbidity associated with gastroschisis is short bowel syndrome.** Morbidity for omphalocele is principally secondary to any associated

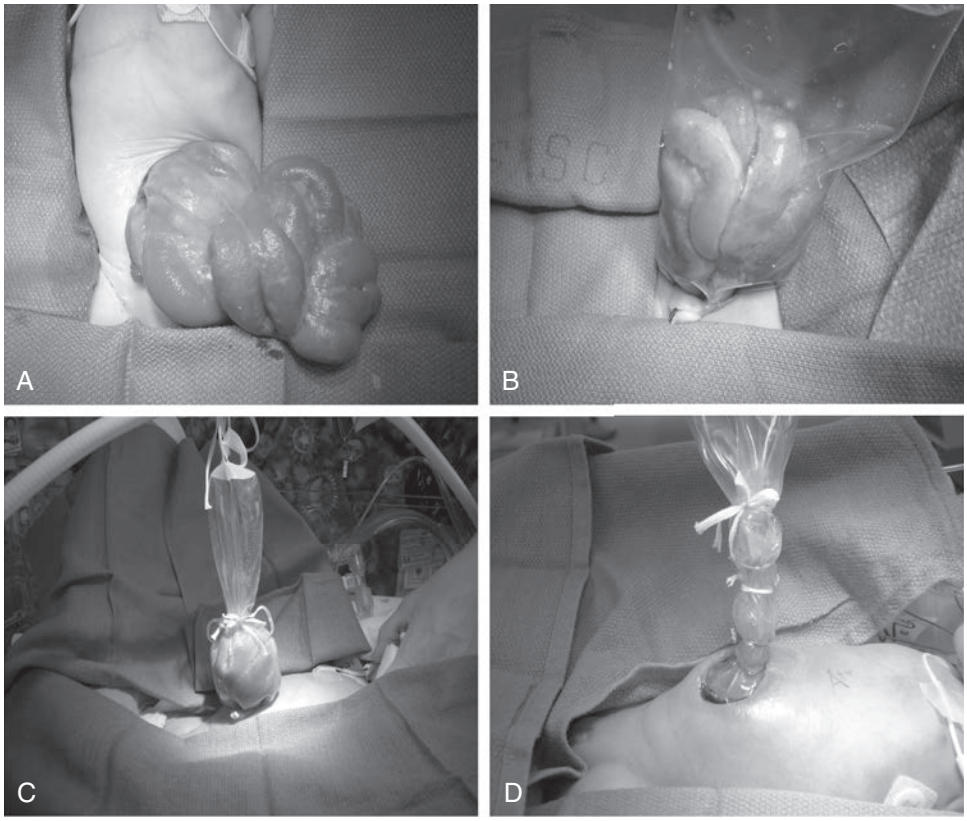

FIGURE 28.19 Neonate with gastroschisis. **A, B,** Note edema and thickening and matting of bowel. Also, note scaphoid appearance of abdomen (loss of domain). As a result, bowel was placed in a Silastic silo. **C,** Postoperative day 1 after placement of silo. Note how the edema has largely drained from the bowel wall (gravity) and how much of the silo contents has reduced spontaneously. The first umbilical tape is placed to prevent bowel from rising in the silo. **D,** Postoperative day 5 (an umbilical tape is applied each day in the nursery), and the bowel has fully returned to the abdomen. The fascia is now ready for closure.

anomalies and the challenges of abdominal closure. **Otherwise, prognosis for both types of abdominal wall defects should be good, unless, again, severe associated malformations are present.**

NEONATAL TUMORS

Neonatal tumors are discovered in every 12,500 to 25,000 live births and account for 2% of all childhood malignancies.[74] The majority of affected neonates present with a mass at birth or within the first month of life, which may or may not have been identified on prenatal screening. **The two most frequently encountered neonatal tumors are teratoma (principally sacrococcygeal [Fig. 28.20] but also cervical [Fig. 28.21]) and neuroblastoma.** Soft tissue sarcomas, infantile myofibromatosis (benign mesoblastic nephroma and malignant Wilms tumor),[7] hepatoblastoma, and CNS tumors follow in frequency. **Malignant tumors rarely arise in the newborn, yet some benign tumors encountered at birth may acquire malignant features later in infancy.** Nevertheless, although a neonatal tumor may be histologically benign, these **tumors may be life-threatening because of size, location, arteriovenous shunts, or rupture with hemorrhage.** Some tumors show invasive or infiltrative characteristics, yet these may not have metastatic potential. Furthermore, screening programs have identified potentially malignant tumors earlier in development, such as for neuroblastoma in Japan,

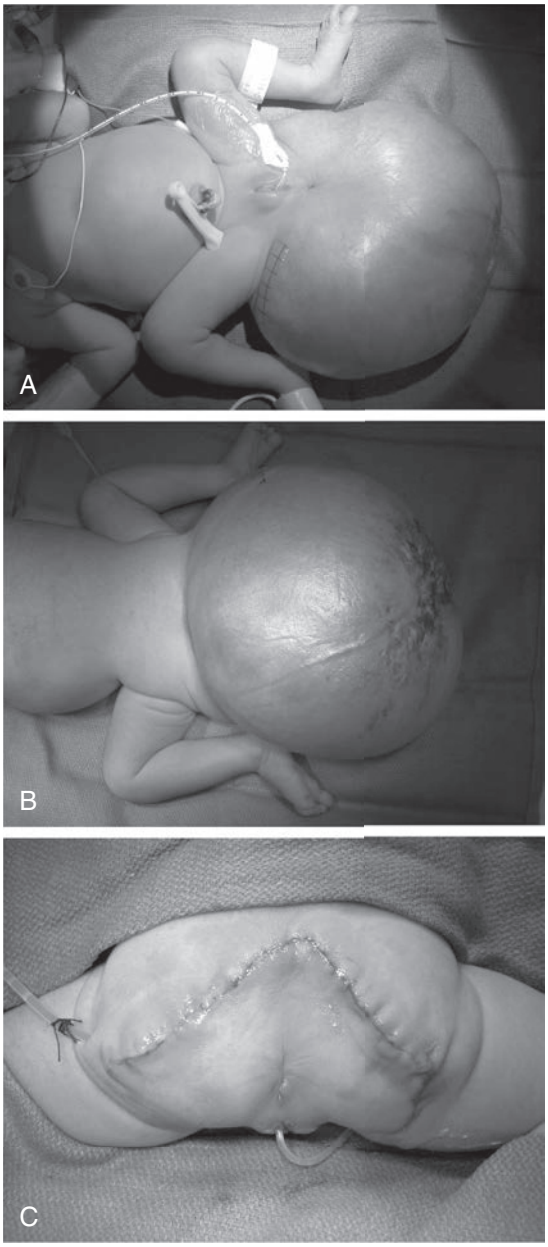

FIGURE 28.20 Female neonate with a huge sacrococcygeal teratoma. **A,** Anterior view. Note anal opening in anterior and just caudal to introitus. **B,** Posterior view. **C,** Immediately after resection. Incision will soften over time.

but have as yet failed to improve overall survival. Some neonatal tumors even show the potential for spontaneous regression. Taken together, neonatal tumors represent a protean mix of diseases that have a low malignancy potential yet the biologic and pathophysiologic behavior may not be entirely predictable.

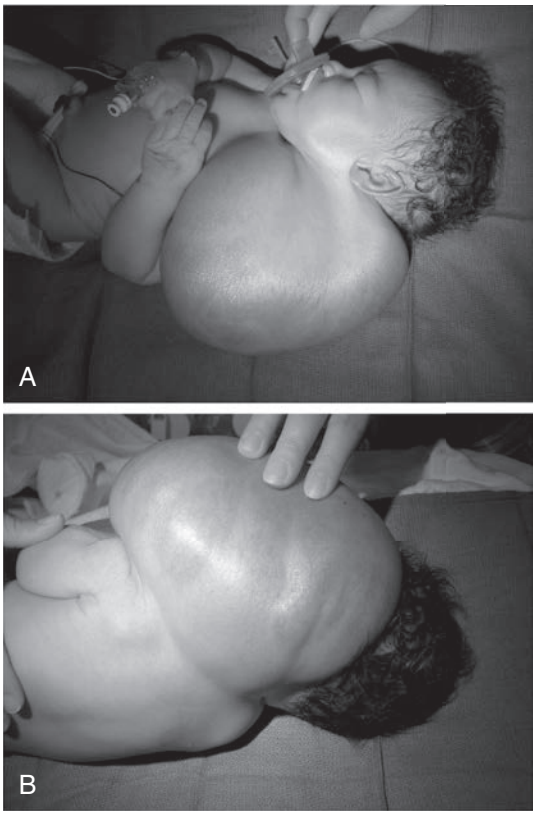

FIGURE 28.21 Huge cervical cystic hygroma. Teratomas show a similar appearance but tend to be more midline than hygromas. Anterior **(A)** and posterior **(B)** views.

The etiology of solid malignancies in infants and children is an area of great interest.[15] Many of these **"congenital" tumors are classified as embryonal tumors because of retained features of embryonic development within the organ in which each tumor arises. Carcinomas, typical of adulthood, are virtually nonexistent in neonates.** Under the microscope, many of these embryonal tumors show a recapitulation of cell types found in early embryonic development of the particular organ, but terminal differentiation of the progenitor cells has not been completed, and so no functional tissue architecture is appreciated. **Associated anomalies may be found in 15% of neonates having congenital tumors, and genetic defects are also relatively prevalent in babies with neonatal tumors.**

Routine prenatal ultrasonography has contributed to an increasing diagnosis of fetal and neonatal tumors. Interestingly, **several fetal tumors, particularly neuroblastoma, have a unique property to undergo spontaneous regression and involution by 12 months of age.** A recent study by the Children's Oncology Group in infants younger than 6 months with small adrenal masses showed that the majority of these lesions will resolve spontaneously without the need for operative intervention.[80]

Commonly, fetuses harboring an embryonal or germ cell tumor will be identified on antenatal US screening.[18,78] Some **tumors, in particular sacrococcygeal teratomas, may be so large as to cause dystocia or may present a significant risk for rupture during delivery, and either scenario could be disastrous.** Further, **a cervical teratoma or cystic hygroma may cause airway obstruction at birth.** Fetuses with these occasionally **huge cervical tumors should be delivered by cesarean section, undergo bronchoscopy, and be intubated before clamping of the umbilical cord, referred to as an EXIT procedure (EX-utero Intrapartum Therapy).**[86] The tumor then may be resected electively once a full evaluation of the disease extent and the presence of any associated anomalies has been completed.

Most neonatal tumors are benign or of low malignancy potential and tend to behave more favorably than the same type of tumor in older children. Neuroblastoma, for example, generally presents as stage I disease in 90% of infants under 1 year of age and is amenable to observation,[80] if small, or complete resection. Hepatoblastomas presenting in the newborn period also tend to behave more favorably than when presenting later in infancy. Despite a collective rarity, presentation of malignant tumors in the newborn period occurs, and much work remains to identify determinants of tumorigenesis and pathogenesis.

MINIMALLY INVASIVE SURGERY

Laparoscopic or minimally invasive techniques are beginning to supplant many surgical procedures previously performed by laparotomy or thoracotomy. Laparoscopic and thoracoscopic procedures have been associated with decreased postoperative pain, earlier return to gastrointestinal function, shorter hospital stays, less wound complications, and improved cosmetic results, when compared with the corresponding open procedures. **Laparoscopic techniques have been applied to many of the neonatal procedures described in this chapter.** Indeed, **laparoscopic Nissen fundoplication for gastroesophageal reflux disease**[58,100] **and laparoscopic-assisted pull-through procedures for Hirschsprung disease**[113,128] **are being performed routinely in the neonate and show shorter time to postoperative feeding, decreased hospital stay, and superior cosmesis.**

Thoracoscopic repair of EA with TEF is beginning to be advocated as an equally effective approach,[124] **and supporters claim improved pain management and skeletomuscular benefits. Additional benefits of the laparoscopic approach include earlier extubation and first oral feeding and shorter length of stay.**[121,124] Laparoscopic repair of duodenal atresia is being performed with good results.[72] Both thoracoscopic and laparoscopic techniques are being increasingly used to repair Bochdalek and Morgagni diaphragmatic hernias with good outcomes in neonates who do not require ECLS.[39,120] Laparoscopy-assisted endorectal pull-through for Hirschsprung disease and for anorectoplasty to correct ARM are becoming increasingly more a part of the neonatal surgeon's armamentarium.[97,113,128] However, pathophysiologic effects of pneumoperitoneum or iatrogenic pneumothorax are only recently being analyzed. Such adverse consequences include reduced intraoperative arterial saturation, increased carbon dioxide retention (CO_2 is used for abdominal insufflation and diaphragmatic excursion may be compromised because of increased abdominal pressure), oliguria or even anuria for up to 6 hours postoperatively, hypothermia, and need for extended postoperative intubation, if procedures exceed 100 minutes, which they often may.[50] As experience increases and technical refinements are seen with improved optical systems and smaller instruments, a broader application of laparoscopy inevitably will occur in the neonatal patient population.

PARENT TEACHING

Preoperative

The advent of ever-increasing mechanisms of prenatal diagnosis allows parents to begin adjusting to the presence of certain malformations,

some minor and others potentially lethal, before birth.[1] Research shows that parents experience various stages of grief, including shock, denial, anger, and sadness when faced with such news. Although the intensity of the negative emotions associated with the initial diagnosis may lessen by the time of delivery, resolution of these emotions should not be expected. Expressions of fear, anxiety, and guilt are likely.

Because parents' fears and fantasies about their infant's surgical diagnosis are frequently worse than reality, they should see their infant as soon as possible after birth and before surgery. Pictures of the infant should be taken before surgery and should include views with and without the defect if possible. **Whenever time and patient condition allow, parents should hold their infant and have pictures made of the family with their newborn.** In the event of a neonate's death, these pictures may be very valuable to the family. In the event neonatal transport from the birth hospital to a referral center is required, **the transport team should do everything possible to ensure that the mother, who may be in the early recovery phase from her delivery, sees her infant before departure.**[20,76]

Not only is breast milk almost always best for the surgical neonate, but this feeding modality also gives the mother a concrete way of helping her ill newborn (see Chapter 18). The new mother should be encouraged to begin pumping breast milk within the first hour after delivery. The key to successful breast milk establishment is to start early, in the labor and delivery suite, and to express milk often, at least 8 times per day with no more than a 5-hour period at night without pumping. The more frequently an infant nurses, the higher is the mother's milk production, so expression of breast milk is the mother's way of "placing an order in advance" for her infant when he or she is able to eat (http://newborns.stanford.edu/Breastfeeding/PMGs.html#sickbaby). Mothers should be taught hand expression and be provided with a pump. **Lactation support should be made available to the mother throughout her infant's hospitalization.**

The planned operative procedure and its expected results, as well as risks and alternatives, are discussed with the parents, ensuring that all questions and concerns are addressed. An informed consent for surgery is signed by the treating surgeon and witnessed by the bedside nurse. The **bedside nurse should be present when the physician meets with the family to discuss the operation, because the nurse is often the most consistent individual hearing explanations from the neonatologist, surgeon, and anesthesiologist, and must answer questions, interpret information, and reassure an anxious family when these teams leave.**

The nurse has a further important role to reassure parents about postoperative analgesia and sedation for their infant. Preoperative teaching can involve educating parents to recognize pain cues in their baby, and they should be encouraged to discuss their concerns if they perceive their baby is experiencing discomfort. Care providers' sensitivity to the neonate's pain and advocating for pain relief are comforting for parents. Toward this end it is the **nurse's responsibility to recognize pain cues in the neonate, including those present in the patient who is therapeutically paralyzed; know the expected duration of severe, moderate, and mild pain associated with various surgical procedures; practice nonpharmacologic intervention; and encourage parents to also provide comfort care where appropriate** (see Chapter 12). Although pain control is essential, side effects can interfere with patient care such as delaying return of bowel function or obscuring an accurate neurologic examination; therefore their judicious use is imperative. **Knowing the effects of narcotic and nonnarcotic pain medications, as well as the potential interactions these medications have with others the patient is receiving, is imperative.**

Parents often fear what the infant will look like on return from surgery. **Providing written material with simple drawings of the defects and operative procedure may help to prevent postoperative surprises. Seeing another patient who has had a similar procedure and has the postoperative equipment that has been described (e.g., colostomy, orogastric tube, chest tube) may be helpful to the family as well. The nursing staff must be careful, however, to protect the privacy of other patients and should get parental consent before using another infant for this purpose.**

INTRAOPERATIVE

Accompanying the infant to the preoperative area and seeing the infant as soon as possible

after surgery are comforting to the parents. Progress reports during the surgery, if possible, are helpful for the anxious family members. After the operation, the pediatric surgeon should immediately see the parents to explain the procedure and any unexpected findings or problems that occurred during the operation. It should be clear to both the family and the surgeon where this important communication will take place, and privacy should be protected during the interchange.

POSTOPERATIVE

After surgery, the nurse should help parents focus on their infant rather than the surrounding intensive care environment. Although the nursing staff should identify the monitors and equipment in the baby's room, and should explain the purpose of each to the family, **encouraging parents in ways to comfort their baby will be of greatest benefit to their postoperative child (and to them). Early involvement in caregiving helps the parents feel as though they are essential to their child's recovery.** Even in the immediate postoperative period, parents can quietly sit and hold their infant's hand or take an axillary temperature.

Mothers should be encouraged to provide breast milk for use as soon as feedings begin. In the majority of cases it will be the feeding that is best tolerated by the convalescing neonate. The nurse acts as a liaison for consultation with a lactation specialist for coaching and instruction if needed. **She should be certain that the mother has access to a pump and supplies and is encouraged to pump every 2 to 4 hours around the clock.** Quiet, private accommodations for breast pumping should be available in or adjacent to the patient care area, and policies should be in place to ensure expressed breast milk is properly identified and stored at all times. **If possible, the mother should also be encouraged to breastfeed her infant, as the infant's improvement allows.**

If an infant is to be discharged home with an ostomy, parents begin to participate in stoma care as early as possible. Consultation with an enterostomal therapy nurse is of further benefit. **Parents begin by learning to cleanse the skin around the ostomy or to prepare the appliance and peristomal salves. Gradually, parents will learn to increase their responsibilities of caregiving as their infant improves. Frequent practice improves proficiency and empowers parents for taking their infant home.** Delay until a few days before discharge does not give parents adequate time for practice and familiarity for home care and does not serve the infant or family well. **The same is true for infants who are discharged with other types of complicated care, such as home TPN or feedings through a gastrostomy tube and/or on a continuous feeding pump.**

Parent teaching includes the possibility of late postoperative complications and recognition of problems that may develop and a plan of action for dealing with them.

The importance of follow-up care is emphasized to the parents. It may be helpful for parents to talk with a "graduate" parent who had an infant with similar problems. Contact information about available resources, such as visiting nurses, graduate parents, and parent support groups are provided to parents before discharge. **A concise history of hospitalization and the discharge plan is made available to all posthospitalization health care providers and a copy provided to parents at the time of discharge.** Encouraging parents to keep a copy of this discharge summary in their diaper bag increases the chances they will have it available should they be required to take their medically complex and vulnerable infant emergently to the hospital.

29 FAMILIES IN CRISIS: THEORETICAL AND PRACTICAL CONSIDERATIONS

SANDRA L. GARDNER AND KRISTIN VOOS

Technical advances in the care of critically ill and premature infants have resulted in decreased morbidity and mortality of the high-risk infant. These developments have been accompanied by a heightened awareness of the psychological strain and emotional stresses encountered by the family of the sick neonate and the profound effect on family functioning.[5,25,158,174] Realization of the need for a family-centered approach to perinatal care has emerged out of an enhanced understanding of individual and family functioning and the challenges in coping and adapting to stress.[7,100,110] It is essential for perinatal health care teams to be cognizant of the overall psychological needs of families who are experiencing the painful crisis of the birth of a sick newborn.[158] This chapter discusses the complex psychosocial needs of families during this stressful period and offers concrete suggestions for intervention.

NORMAL ATTACHMENT

Emotional connection to an infant begins not at birth but during pregnancy. The terms *attachment* and *bonding*[129] are used to describe this process of relating between parents and their infant. Attachment is characterized by the same qualities used to describe love: care, responsibility, and knowledge. Parental love and romantic love activate the same areas of the human brain, result in brain processing of infant cues, and elevate the "bonding" hormone, oxytocin. Attachment is an individualized process and does not happen automatically.[25,187]

The neonate is totally dependent, both physically and emotionally, on the caregivers, whereas caregivers are not dependent on the infant. Recognition of this unique relationship is evidenced cross-culturally by immediate and prolonged contact with no evidence of separation.[116,187] In most animal species, the mother engages in species-specific behaviors[129] that enable her to become acquainted with and claim the newborn. If there is disruption during this critical period, it can result in rejection by the animal mother and death of the young. Recent studies have shown a relationship between stressful environments, the health of the fetus, and caregiving ability (see Chapter 13). Parental attachment and appropriate caregiving behaviors are crucial for the infant's physical, psychological, and emotional health and survival. Ultimately, this influence can affect the infant's well-being as an adult and potential parenting ability.

Critical and Sensitive Period

In the period immediately after birth, healthy mothers and infants are physiologically and

BLUE type highlights content that is particularly applicable to clinical settings.

psychologically ready for reciprocal interaction.[120] Even though labor and birth are tiring, most mothers feel "high" and have an incredible surge of energy after birth. Psychologically, the family is ready to meet and interact with the long-awaited newcomer. The first hour of life can be a time of alertness for the newborn. Before the sleep phase, the newborn is alert, makes eye-to-eye contact, fixes and follows, begins to search unassisted for the maternal nipple, and begins to feed. At birth, all five senses are operational, and the infant is ready to cue and shape the environment (see Chapters 5 and 13).

The period of mutual readiness between parents and their infant(s) has been compared with the critical period in animals. This human "maternal sensitive period"[129] immediately after birth is an optimal time for attachment to develop. Positive effects of early and extended contact, rather than initial separation, have shown significant differences in caregiving behaviors that persist over time.

Sustained and early contact between parents and their infant gives the family the opportunity for interaction. The presence of the infant enables the parents to understand the reality and individuality of their infant. Early parent-infant contact facilitates parent-infant attachment and contributes to the regulation of the newborn's physiology and behavior.[25,31,158,187] Early skin-to-skin contact between mothers and their infants results in significant benefits: (1) better breastfeeding, (2) maintenance of infant body temperature, (3) higher blood glucose, (4) lower respiratory rate, (5) better heart rate stability, (6) more affectionate maternal behavior, (7) lower salivary cortisol levels, and (8) less infant crying.[31,180] Unnecessary "routines" and procedures that interfere with initial contact and bonding should be deferred, if possible, until the family has time for this important interaction (see Chapter 5).

Although the delay of immediate contact for medically necessary interventions does not promote attachment, neither does it undermine the entire process of attachment.[51] Fortunately, human mothers do not automatically reject their infant if they cannot interact immediately. During medically necessary interventions, it is important to give parents as much interaction (or at least visual contact) with their infant as is possible.

Crisis Event: Pregnancy and Parenthood

Pregnancy, birth, and parenthood are almost universally defined as a life transition and crisis.[77,116,187] Becoming a parent requires a major adjustment of the roles, lifestyle, and relationships. Because previous ideas and coping strategies may not be helpful, life crisis situations challenge the individual with the potential for growth as new responses and solutions are used for problem solving. Periods of upheaval, change, and vulnerability can provide a time of openness, receptiveness, and readiness for help and support from significant others (including professionals).

Influences on Parenting

Opportunities to experience parenting and to observe others in that role are essential learning experiences in developing one's own parenting behaviors and style. The ability to parent is influenced by a multitude of factors that occur before, during, and after the birth of the infant. Previous life events, including degree of life stress/patterns of coping,[152,260] genetic endowment, being parented,[87,92,187] previous pregnancies,[121] anxiety and distress about the parental role,[55,70,92,111,187] and interpersonal relationships[87,187] affect the experience of pregnancy and parenthood. The events of the current pregnancy,★ their significance to the parent, and the availability of support and assistance influence parenting ability.[111,158,187]

After birth, infant characteristics (e.g., responsiveness/vulnerability/severity of illness),[58,92,111] appearance,[25,38] parental feelings of loyalty and hope, the behavior of health care professionals,† separation from the infant,‡ an inability to protect their newborn from pain,[117,192] and hospital practices§ may positively or negatively influence parents. Not only the occurrence of these events but also their meaning to the individual and the type of support received influence parenting abilities.

Two recent Australian studies of maternal-infant bonding during pregnancy and after birth examined

★References 55, 70, 92, 111, 178, 187.
†References 55, 70, 91, 120, 142, 174, 178, 261.

the influence of antenatal bonding on postnatal bonding and the sociodemographic and psychosocial predictors of attachment.[221,222] The researchers found that the quality and intensity of maternal bonding significantly increased through pregnancy. Both studies found that a strong maternal antenatal bond to the fetus was predictive of a stronger postnatal maternal bond. Poorer maternal-infant bonding at 8 weeks postpartum was predicted by (1) depressive symptoms in the second/third trimesters, (2) older maternal age, (3) mothers born in non–English-speaking countries (4) mothers not employed full-time, (5) breastfeeding problems, and (6) infant crying.[221,222]

Cultural practices influence maternal and paternal attachment behaviors. ★ Studies indicate that cultural differences influence (1) parental emotional responses and perceptions of their infant's illness and disability, (2) parental usage of services, and (3) parental interaction with health care providers.[28] Research demonstrates that how parents interact with their newborn varies based on their culture[94] (e.g., Japanese mothers look at their babies more than Brazilian mothers do, who touch and interact more with them).[140] A study of Thai mothers in the neonatal intensive care unit (NICU) showed that the most frequent maternal behavior was touching (from the infant's extremities to trunk), followed by inspection (of the infant's appearance and recognition of family traits), verbalization (e.g., to the infant and nurse), and facial expression (e.g., smiling/crying/flat).[247] One must be cautious in viewing parental attachment behavior through one's own cultural filter, because this may result in an incorrect assessment of parent-infant attachment.[247] Differences in parent-infant interaction behaviors reflect cultural differences; therefore health care professionals' observations of these behaviors must be evaluated within the context of the family's culture.†

Steps of Attachment

Klaus and Kennell[129] propose nine steps in the process of attachment.

STEP 1: PLANNING THE PREGNANCY

Planning the pregnancy is the initial step of investment and commitment[187] to parenthood. Pregnancies are planned in one of two ways: consciously or unconsciously. Who planned the pregnancy and why this particular time has been chosen are important indicators of the investment of each individual in the decision and in the pregnancy.

Carrying a pregnancy is not assurance that the baby is wanted. Although it may be a legal option, abortion may not be a cultural, moral, financial, or ethical option for the individual woman. Attachment of the mother (or father) to the infant is not ensured merely by the mother remaining pregnant, giving birth, and keeping the infant.

STEP 2: CONFIRMING THE PREGNANCY

Pregnancy confirmation begins the psychological acceptance of the pregnancy. Delaying confirmation enables the fact of pregnancy to be denied and may influence progression to the acceptance stage.

STEP 3: ACCEPTING THE PREGNANCY

Accepting the pregnancy usually begins early in the pregnancy and is characterized by the emotional changes of primary narcissism, introversion, and passivity. Because the expectant mother is less interested in the outside world and more interested in her own inner world, the mother can become attuned to her own needs. Although she was previously engaged in active, extroverted behaviors, during the pregnancy she may contentedly participate in quieter, more introspective activities.

At this early stage of pregnancy, the fetus is not perceived by the woman as separate from herself but as an extension of her body. The psychological changes of pregnancy have survival significance in that caring for herself ensures caring for the fetus as an integral part of herself.[152,187]

During the early months of pregnancy, the man and woman realize that parenting will require a major adjustment of their pre-pregnancy roles, lifestyle, and relationships. The adaptation of parenthood is characterized by upheaval and change, losses and gains. Bombarded with phenomenal lifelong changes, the future parents experience the normal feeling of ambivalence.

STEP 4: FETAL MOVEMENT

Fetal movement, felt by the mother between 16 and 32 weeks of gestation, is the beginning of accepting

★ References 28, 111, 116, 152,182, 219, 220, 231.
† References 116,182, 219, 220, 231, 248.

the fetus as an individual. Fetal movement is the first concrete evidence to the mother of the existence of another person within her. Hearing the baby's heartbeat, seeing the ultrasound images, or experiencing an amniocentesis also confirms the reality of the fetus.[187] Fetal movement is such a significant event that often a pregnancy that began as unplanned and unwanted becomes wanted.

Perception of the first fetal movement is a happy event. When asked "How did you feel when the baby first moved?" most women respond in a happy tone and with a smile. Use of a negative tone or negative words to describe fetal movement is a concern because the individual (fetus) already may be perceived as an intruder.

STEP 5: ACCEPTING THE FETUS

Accepting the fetus as an individual begins with fetal movement. The fetus shows individuality in controlling the movement; the mother can neither start nor stop these movements. With the realization of the presence of another person, parents begin acceptance of the fetus as a separate individual. Love for the fetus as a separate individual occurs as the parents invest a personality in the fetus and start to establish a relationship. Fantasies about how the baby looks, its sex, and the wish for a perfect, healthy infant are common. Women with a history of perinatal loss have been shown to have disturbances in maternal attachment related to differentiating the self from the fetus in a subsequent pregnancy.[170]

Outwardly, preparations are made for the acceptance of an infant into the home; baby clothes and furniture are purchased, and a room is prepared. The fetus may be referred to by a nickname or a term of endearment. The baby's name may be chosen. Choosing a name is a highly personal and significant event. The meaning of the name and who chooses it illustrate the power holder and decision maker within the family. Prenatal questions such as the following may be asked after the birth to elicit information: "Do you have a nickname for the baby?" "Do you have a name picked out for the baby?" "Who picked it out?"

Whether the newborn meets parental expectations for "the right sex" may be crucially important for the parents to attach to the infant. "Do you have a sex preference for the baby?" may be asked before or after the birth to uncover this information. Often parents with a strong sex preference have chosen no names for a baby of the "wrong" gender. "It doesn't matter as long as it's healthy" is often heard and may indicate no conscious gender preference. However, unconsciously, the parents may have a strong gender preference as evidenced by a predominance of dreams about one gender. If dreams are equally divided between male and female children, there may indeed be no gender preference at the unconscious level.

Most parents are fearful of producing a defective child. This fear is experienced as dreams about dead, deformed, or damaged fetuses and babies or dreams with a central theme of destruction. These unconscious contents often are experienced as frightening nightmares that may be imbued with magical ideas such as "If I think (or talk about) it, it will come true." Both before and after birth, it is reassuring for parents to know that this is a common and scary phenomenon, that they are not "crazy," and that the fears are not magical.

Parental expectations of the newborn are established before birth in the personification and relationship with the unseen, unheard fetus. Research shows that a close, high-quality prenatal attachment to the fetus is associated with fewer depressive symptoms in the last trimester and postpartally.[84] Compared with adult women, pregnant adolescents are slower in developing an antenatal emotional attachment to their fetus.[224] After birth, parents often experience the developmental process of working out the potential discrepancy between the wished-for and the actual infant.[241] Before attachment to the actual infant can proceed, the fantasized child must be mourned.

STEP 6: LABOR AND BIRTH

Labor is a physiologic, maturational, and psychological crisis for the family. Birth is the culmination of pregnancy and the reward for the work of labor. Parents' attitudes about the labor and birth experiences may affect their reactions to the infant.[51] Research shows that continuous physical and emotional support during labor significantly improves birth outcomes for the mother (e.g., shortens labor duration, reduces the need for pain medication and operative vaginal and cesarean delivery) and the newborn (e.g., better Apgar scores, better/longer breastfeeding, fewer NICU admissions, fewer complications of obstetric [OB] interventions because fewer OB interventions used). In addition to better physiologic outcomes, improved psychological outcomes include (1) increase in maternal-infant

attachment behaviors, (2) better confidence and ability to cope with labor, (3) better maternal satisfaction and personal control during labor, (4) enhanced maternal self-esteem, (5) positive attitudes toward mothering and family relationships, and (6) easier mothering (i.e., sees baby as less fussy).[226]

Paternal participation in labor and birth is an important issue. Many years ago, health care professionals saw no benefit to the presence of the father and even wished to exclude him because of imagined "horribles" such as increased infection rate, malpractice suits, and disruption of routines. Birth is a powerfully emotional experience; those who attend birth are more attached to the infant than those who do not attend.[129,158] Benefits attributed to a father's participation at labor and birth include use of less analgesia, a more supportive environment, and a deepened relationship[9] between parents and between parents and their infant.[129] Inclusion of the father in perinatal events may engage him for inclusion in parenting activities.[55,158] Rather than just a financial provider, fathering may be perceived as a psychological necessity for both fathers and children.

Parental behaviors at birth such as the following indicate involvement and investment in the infant[103]:

- How does the mother or father look? At the sound of the infant's cry, parents smile and breathe a sigh of relief at this first breath of life. Support, joy, and happiness are positive feelings shared by couples at birth.
- What does the mother or father say? By speaking in a positive tone with words of affection and endearment, the parents relate to each other and to the new infant.
- What does the mother or father do? When offered the infant, both parents will reach out to take the infant. Spontaneously, parents engage in eye-to-eye contact and touch and explore the infant. Affectionate behaviors such as kissing, fondling, cuddling, and claiming characterize positive parental reactions.

A positive, self-affirming birth experience for the mother enhances her feelings of empowerment and self-esteem and thus her self-concept as a woman and mother.[187,226] A birth experience that does not meet parental expectations may have a negative effect on the self-concept of the mother, her perception of her ability to parent, and her relationship with the infant.[51] In fact, "so intricately are mother and infant entwined in a symbiotic relationship, that what is psychically positive for the mother is positive for the infant. What is psychically negative for the mother will affect the infant."[187]

So powerful is the labor and birth experience that women may be unable to proceed with parenting until psychic closure of the experience has occurred. Even women who experience a normal labor and birth process should recount the experience to others. Maternal perception of the events is obvious in tone and content of the recounting. *Missing pieces*[1] is the term used to describe the aspects of labor and birth that are forgotten or unavailable to recall. Long labor, short labor, or medicated labor can cause missing pieces in the mother's memory of the birth. Labor that did not meet expectations because of difficulty, cesarean delivery, use of forceps, or episiotomy could also affect the mother.[1] To proceed with parenting, these women should be encouraged to fill in their knowledge gaps by asking questions or looking at pictures or films of the birth to reconstruct the situation.

STEP 7: SEEING

Seeing and touching are the species-specific ways in which humans attach to their young.[129] Immediate attachment is facilitated by (1) positive maternal feelings toward the infant; (2) the mother's ability to see the infant immediately after birth; and (3) immediate contact between the mother and infant.[25] Delayed attachment may occur when the infant is ill or premature because he or she does not conform to parental expectations of a healthy full-term baby.[25,51,169,247]

Eye contact between parents and their infant in the initial period after birth may be a positive release of parental feelings of warmth, closeness, and caring. As parents see and inspect the newborn, they begin claiming their infant—"He has my eyes" or "She has your nose." Characteristics of each parent and the family are identified in the infant, and the newborn is claimed as a member of the family.[247]

The term *en face position* is used to describe the mother's (father's) eyes and the infant's eyes positioned in the same vertical plane.[129] This positioning enables the parent and the infant to look directly into each other's eyes, to focus, and to regard each other (Fig. 29.1).

The newborn infant is an active participant; he or she cues the mother with eye-to-eye contact. Even minutes-old newborns see and show a preference for the human face (within 7 to 12 inches from

FIGURE 29.1 *En face position.* The infant is held in close contact (the mother's body touching the infant's); the mother is looking at the infant *en face;* the bottle is perpendicular to the mouth; the milk is in the tip of the nipple. (From Klaus MH, Kennel JH. *Parent-Infant Bonding.* 2nd ed. St Louis, MO: Mosby; 1982.)

their face). The newborn can visually follow the parent's face and voice and signal the parent with facial expressions, movement, and vocalization, including a distress cry when separated from body contact with the mother (see Chapter 13).

Deterrents to the infant's full participation in this "getting to know you" phase include removal to the nursery, medication (from analgesia), and eye prophylaxis. Unless medically indicated (necessary for physical survival), newborns should remain with their parents after birth.[158] Because eye prophylaxis irritates and interferes with vision, the "routine" instillation immediately after birth (in the delivery room) can be delayed until after the initial acquaintance process is completed. Maternal depression also has been identified as a risk factor for poor mother-infant interaction.[135]

STEP 8: TOUCHING

In exploring the infant, parents systematically use fingertip contact with the infant's extremities. Gradually, there is progression to palm contact with the infant's trunk (Fig. 29.2). With the healthy term infant, this progression occurs within minutes of the first contact. After gaining confidence and preliminary knowledge, the parent will hold the infant close in a cuddling position.

With the preterm infant, this characteristic progression may take hours, days, or several visits (see Fig. 29.2). Fear of harming the small, fragile preterm infant often prevents parents from feeling at ease in touching him or her.[247] Until the parents feel confident that their actions will not harm the infant, they may be reticent to use palm contact with the trunk. Not only the use of nurturing maternal touch but also the vulnerability of the premature infant affect how touch is perceived by the infant. One study showed that nurturing maternal touch was associated with more secure attachment in robust preterm infants and with less secure attachment in the most vulnerable infants (see Chapter 13).

Holding and cuddling the infant are significantly different from touching and exploring. The amount of holding influences mother-infant interaction with preterm infants.[136] Mothers who have only seen and touched their infant still experience "empty arms." The species-specific behavior of touch is not completely satisfied until the parent can hold the infant. Most mothers have a preference for holding their infants on the left. Explanations for this preference include hand dominance, importance of maternal heartbeat, left breast sensitivity, and advantages in monitoring the infant. A more recent hypothesis proposes that maternal affective signals (both visual and auditory) are given to the infant's free left ear and processed by the more advanced right cerebral hemisphere.[235]

STEP 9: CAREGIVING

The final step of attachment, caregiving, is important for psychic closure of the task of bonding. A meta-synthesis of nine qualitative studies found two simultaneous processes necessary in the transition to motherhood: (1) engagement, a commitment to mothering that involves active attachment to the infant, experiencing the infant's presence, and involvement in caregiving for the infant; and (2) growth and transformation, which characterize the change of a woman into the new "self" of a mother.[187] Men also make the transition to fatherhood in the early postpartal period. A qualitative study of first-time fathers indicates that those who wanted to be highly involved in the care of their baby reported not feeling supported by the health care provider/hospital policies to engage in paternal and parental behaviors that favor involvement with their infant.[55] Fathers experienced more negative (63%) than positive (37%) interactions with nurses

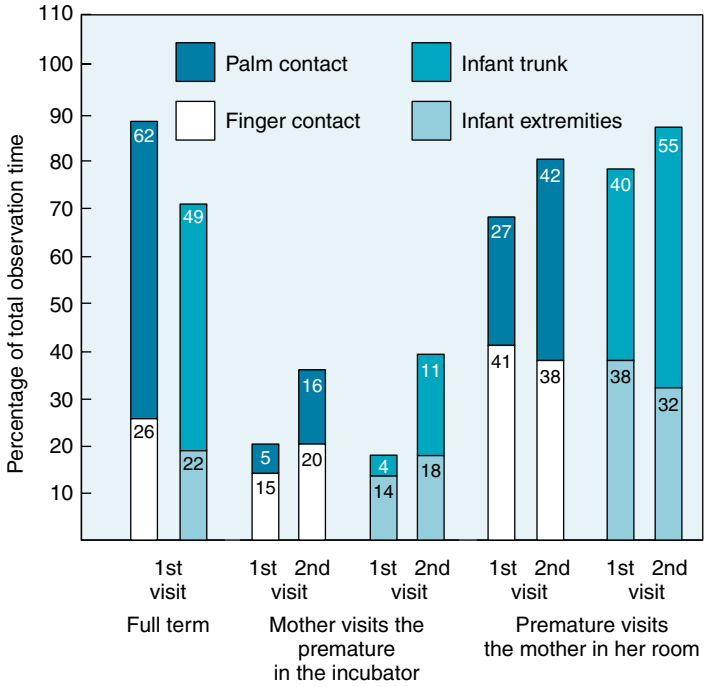

FIGURE 29.2 Fingertip and palm contact on trunk or extremities in three groups of mothers: *(1)* 12 mothers of term infants at their first visit, *(2)* 9 mothers who visited their premature infants in incubators in the NICU, and *(3)* 14 mothers whose premature infants were brought to their maternity rooms and placed in their beds. (From Klaus MH, Kennel JH. *Parent-Infant Bonding*. 2nd ed. St Louis, MO: Mosby; 1982.)

during the postpartum period.[55] Skin-to-skin contact between fathers and their newborns within the first 3 days of life has been shown to enhance father-to-infant attachment when compared with a group of fathers who did not perform skin-to-skin contact with their newborns.[36] In assisting parental transition, nurses and all health care professionals should support, intervene, and use all encounters with both new parents as "teaching moments and opportunities."[55,157] Empowering new parents with knowledge about how to care for their new baby has been shown to have a significant impact on maternal attachment and self-confidence in first-time mothers.[41]

The relationship between the primary caregiver and the infant is reciprocal. In the caregiving relationship, both care provider and infant give to and receive from each other.[91,187] The physical and emotional needs of the helpless infant are satisfied by parental caregiving behaviors such as feeding, soothing, bathing, grooming, and playing. Based on the infant's ability to perceive and receive care, the infant responds to the care provider. Parental expectations of newborn responses include quieting, sucking, clinging and cuddling, looking, smiling, and vocalizing. The parent's capability to soothe and satisfy the infant provides emotional satisfaction and positive feedback about the parent's competency.

Personal needs for comfort, maintenance of homeostasis, and relief from painful experiences are infant expectations of the relationship with the care provider. Care-eliciting behaviors (e.g., crying, visual following, smiling) are neonatal cues used to signal the care provider that attention is needed. Relief from discomfort enables the infant to respond positively to the care provider. The infant experiences the world through the caregiver and quickly learns that the environment is either nurturing and loving or hostile and nonresponsive. Consistent, predictable nurturing and caregiving enable the infant to develop a sense of trust in the caregiver, the world, and the self (see Chapter 13).

Care by parents is the ideal neonatal care situation, because the infant learns and reacts to one set of cues or caregiving behaviors. Cared for by one or two people, the infant can regulate his or her

physiologic behavioral processes (i.e., autonomic, neuroendocrine, behavioral, electrophysiologic) and develop synchrony with the parents.[142,158,187] Single caregiving improves the establishment of biorhythms of the neonate for sleep-wake cycles, feeding, and visual attentiveness. Multiple caregivers confuse the infant, increase distress with feeding, cause irritability, and upset visual attention. Care by parents provides for mutual cuing and acquaintance and a natural setting for observation of parent-infant interaction.[142,158,174]

PSYCHOLOGICAL ADJUSTMENTS TO A SICK NEWBORN

The birth of a child is a major life change. Parents of infants requiring NICU care often experience high levels of stress, and as a consequence their ability to interact optimally with their infant(s) is impaired. For many parents, this may be the first time they have had to cope with a significant challenge in their lives. This may lead to depression, impaired recall, dysfunctional parenting patterns, and poorer developmental outcomes for their child.[69,177,261] The perinatal health care team is presented with a unique opportunity to practice preventive health care. During this stressful time, the families' usual problem-solving mechanisms may not be adequate to cope with the events presented to them.[35] In addition to confronting this situational crisis, the individual or family must master the normal developmental process of parenthood.

Parental behavior and responses are determined not only by preexisting personality factors, social and cultural variables, and interactions with significant others, but also by the immediate situation in which the parents are placed. *The following six major sources of parental stress in the NICU have been identified:

- Preexisting and concurrent personal and family factors
- Prenatal and perinatal experiences
- Infant illness, treatments, and appearance†
- Concerns about the infant's outcome[145]
- Loss of the parental role‡
- Health care providers[5,70,105,111,145,205]

Situational factors can have an important bearing on the family's ability to cope with the crisis and thus affect the overall outcome (Box 29.1). Uncertainty about their infant's future and separation from their infant are sources of parental stress that can dramatically affect the quality of attachment that develops.[5]

Families are psychologically vulnerable after the birth of a sick infant. During this period of crisis, there may be a heightened receptivity to accepting help and being open and responsive to change because the family is struggling for a way to cope with the crisis. Significant potentialities exist for individual and family emotional growth and development.[25,34,70,111] Parental perception of support by nurses has been shown to be significantly associated with maternal depressive symptoms; as the perception of nursing support decreased, there was a corresponding increase in maternal depressive symptoms.[52] The perinatal health team has an opportunity to influence how the individual and family adapt to the crisis.§

BOX 29.1 SITUATIONAL FACTORS AFFECTING PARENTAL COPING*

1. The behaviors and attitudes of the hospital staff (physicians, nurses, and allied health care professionals)
2. The sensitivity used in the process of separation and transfer of the infant to the intensive care unit or, in some cases, the referral hospital
3. The flexibility of hospital policy concerning parental and sibling involvement and visitation in the nursery
4. The instruction of parents in their infant's individual behaviors and characteristics (thus facilitating appropriate parent-child interaction and reciprocity) (see Chapter 13)
5. The staff's comprehension and appreciation of the psychosocial functioning of families and the family's responses and adaptation to stress and crisis
6. The employment of emotionally supportive intervention programs for parents within the nursery setting
7. The development of appropriate discharge planning to provide adequate follow-up care to the infant and family

By providing appropriate supportive interventions coupled with enlightened policies and attitudes that reflect family-centered principles (Box 29.2), the team can have a significant positive influence on the family's ability to cope. Supportive interventions enhance the likelihood for successful adjustment and ultimately a healthy parent-child relationship.*

Family-centered care (FCC) is a philosophy often strived for in the NICU, but current practice and policies often may lag behind philosophy. NICU staff verbalize acceptance of families being involved in care, but their actions do not always reflect their words.[93]

Studies show a discrepancy between nurses' knowledge about the necessity of and their current practice of FCC.[203] Current practice of FCC scored significantly lower than scores representing necessity. Nurses do not consistently practice what they know to be necessary! NICU nurses scored significantly lower on the necessity scale than did pediatric and pediatric intensive care unit (PICU) nurses; nurses with fewer than 10 years of practice scored higher on the necessary and current use of family-centered principles than did nurses with more practice experience.[203] Organizational barriers to implementation include (1) the design of the health care system; (2) lack of emotional support, guidance, and direction for the staff; (3) lack of recognition, confidence, and support for nursing autonomy and skills to perform FCC; and (4) beliefs that dealing with families is stressful, interferes with care of the infant, and is "not part of my job."[70,203]

FCC principles stress that parents are the most important persons in their infant's life, that they have expertise in caring for the infant, and that their values and beliefs should be central during NICU care.[100,110] FCC demands a change from task-oriented, health care provider–centered care to a collaborative, relationship-based model of family advocacy and empowerment.[70,100,142,165] Roles for families in FCC include (1) advocating for their infant, (2) providing peer support to other families, (3) collaborating with and educating clinicians, (4) interacting with other allied health care professionals and therapists, (5) participating in hospital committees, and (6) acting as a change agent in health care settings.[60] Box 29.3 contains key components of FCC desired by families; they are remarkably similar to the Principles of Family-Centered Neonatal Care in Box 29.2. Box 29.4 contains eight principles of patient and family centered care

*References 5, 25, 51, 70, 92, 105, 108, 111, 135, 142, 145, 158, 169, 178, 232, 252.

BOX 29.2 PRINCIPLES OF FAMILY-CENTERED NEONATAL CARE

1. Family-centered neonatal care should be based on open and honest communication between parents and professionals on medical and ethical issues.
2. To work with professionals in making informed treatment choices, parents must have available to them the same facts and interpretation of those facts as the professionals, including medical information presented in meaningful formats, information about uncertainties surrounding treatments, information from parents whose children have been in similar medical situations, and access to the chart and rounds discussions.
3. In medical situations involving very high mortality and morbidity, great suffering, and/or significant medical controversy, fully informed parents should have the right to make decisions about aggressive treatment for their infants.
4. Expectant parents should be offered information about adverse pregnancy outcomes and be given the opportunity to state in advance their treatment preferences if their infant is born extremely prematurely and/or critically ill.
5. Parents and professionals must work together to acknowledge and alleviate the pain of infants in the neonatal intensive care unit (NICU).
6. Parents and professionals must work together to ensure an appropriate environment for infants in the NICU.
7. Parents and professionals must work together to ensure the safety and efficacy of neonatal treatments.
8. Parents and professionals must work together to develop nursery policies and programs that promote parenting skills and encourage maximum involvement of families with their hospitalized infants.
9. Parents and professionals must work together to promote meaningful long-term follow-up for all high-risk NICU survivors.
10. Parents and professionals must acknowledge that critically ill newborns can be harmed by overtreatment, as well as undertreatment, and must insist that laws and treatment policies be based on compassion. Parents and professionals must work together to promote awareness of the needs of NICU survivors with disabilities to ensure adequate support for them and their families. Parents and professionals must work together to decrease disability through universal prenatal care.

Modified from Harrison H. The principles for family-centered neonatal care. *Pediatrics.* 1993;92(5):643.

BOX 29.3 WHAT FAMILIES WANT IN FAMILY-CENTERED CARE[113]

- To be consistently and respectfully involved in decisions about the health care of their family member[73] and their family members to be involved in ways they choose
- Health care providers to listen to the family's observations and incorporate their preferences about treatment into the plan of care
- Useful and understandable information from health care providers; do not "sugar-coat" information[74]
- Personal connection—a relationship with health care providers; need personal connection and to be able to trust those providing care
- Patient comfort and pain control; important to family's (and patient's) perception of the hospital experience
- Information and support for handling transitions in health care

BOX 29.4 EIGHT PRINCIPLES FOR PATIENT- AND FAMILY-CENTERED CARE[223]

- Free parental access 24 hours a day with no limitations resulting from staff shift change or medical rounds (see Chapters 13 and 29)
- Psychological support for parents (see Chapters 29 and 30)
- Pain management (see Chapter 12)
- Supportive environment (see Chapters 13 and 29)
- Postural support (see Chapter 13)
- Skin-to-skin contact (see Chapters 5 and 13)
- Breastfeeding and lactation support (see Chapter 18)
- Sleep protection (see Chapter 13)

proposed by the European Research Network on Early Developmental Care.[223]

A multicenter study was conducted to create an FCC map to enhance the ability of the health care team to work with families to coordinate and deliver care in a holistic manner to meet the developmental, physical, and psychosocial needs of NICU patients and their families. This study led to the development of an innovative Web-based resource to assist individual care providers and family advisors to provide comprehensive FCC to infants and families.[62] The Family-Centered Care Map (available at www.fccmap.org), is based on 63 potentially better practices and is a joint effort of three NICUs (and their families), Vermont Oxford Network's Neonatal Intensive Care Quality Improvement Collaborative, and the Institute for Family-Centered Care. Use of the Family-Centered Care Map results in (1) improved growth for extremely low-birthweight (ELBW) preterm infants, (2) decreased length of stay for ELBW preterm infants by 13 days, and (3) better implementation of FCC principles.[114]

BOX 29.5 POTENTIALLY BETTER PRACTICES FOR FAMILY-INTEGRATED CARE AND/OR NEONATAL INTENSIVE PARENTING UNITS[97]

- Offering antenatal family support
- Providing a warm orientation to the NICU for parents with the first priority reconnection with their baby
- Treating parents as full partners
- Providing staff education on (FIC) principles
- Mentoring parents in developmental care, including skin-to-skin care
- Incrementally increasing parental engagement in all caregiving consistent with the infant's clinical status
- Offering peer and veteran support and a parent support coordinator
- Providing mental health support for parents and staff
- Participating in debriefing sessions after critical events

Family-integrated care (FIC) has evolved from FCC and requires that the family provide all care, except the highest level of technical care, to their newborn. Parents contract to provide 6 to 8 hours of care per day with teaching, counseling, and support from professional caregivers.[194] Parents attend education and medical rounds and are mentored by bedside NICU nurses and "veteran" parents who have had infants in the NICU.[29,160] Specific education for nurses is also necessary for FIC.[76] Potentially better practices for FIC or neonatal intensive parenting units include those listed in Box 29.5.

A pilot program in a Canadian NICU found significantly higher weight gain and incidence of breastfeeding at discharge in infants cared for by their mothers compared with control infants. Parental stress scores in the study group also decreased significantly from admission to discharge from the NICU.[193] Additional advantages of FIC include (1) recognizing the mother's own strengths, (2) increasing parental confidence, (3) developing better problem-solving strategies and attainment of parental roles, (4) developing better emotional preparation for taking the infant home, (5) acquiring the knowledge and tools to parent their infant in the NICU through education, (6) better communication between parents, as well as between parents

and professionals, and (7) the potential to mitigate the trauma and stress of NICU care for both the infant and parents.[29,30,50,161] A clustered randomized controlled trial in Canada, Australia, and New Zealand to measure the primary outcome (weight gain between study and control group preterm infants [<33 weeks' gestational age] at 21 days after enrollment) found higher weight gain in the infants cared for with FIC than in the control group.[195] Secondary outcomes in this multinational study found decreased parental stress and anxiety and higher rates of exclusive breastfeeding at discharge among the families in the FIC system.[195] FIC is currently being studied in clustered randomized controlled trials in 10 Canadian level II NICUs to evaluate clinical infant and maternal outcomes, cost, and length of stay.[23]

Parenting in the NICU is something most families are not prepared for or expect. Finding their parental role in this situation can be difficult and taxing, especially when their infant is critically ill.[70] Such challenges can have long-lasting effects on parental well-being and family functioning.[245] Fenwick et al. reported that mothers perceive their relationship with NICU nurses as either facilitating or inhibiting their ability to mother their preterm infants in the NICU.[70] Actions that facilitate mothering are family-centered. Facilitative nursing actions include fostering the relationship between the mother and infant by (1) assisting mothers to gain intimate knowledge and caregiving opportunities, (2) educating parents about their infant's medical condition, (3) providing ongoing positive feedback to parents, (4) acknowledging the importance of the dyadic mother-infant and father-infant relationship, (5) honoring the mother as the infant's primary caregiver, (6) enhancing mother-infant interaction opportunities, and (7) collaborating with parents and relinquishing control to parents, particularly at the bedside.[70,142]

Family-centered nursing care promotes physical closeness and intimacy with premature infants. Inhibitive nursing action can (1) result in a patriarchal, authoritarian style of care delivery; (2) focus on "protecting" the infant (from the parents); (3) maintain the nurse as the "expert" who retains control by directing and "allowing" parent involvement; and (4) dismiss parental worries, concerns, rights, and skills.[70] In the presence of inhibitive nursing actions, mothers are left with the feeling of "struggling to mother" in the NICU.[70] Mothers who are alienated and disaffected by these encounters feel angry, frustrated, distressed, inadequate, unsure, and anxious.[70] These feelings may result in (1) an inability to resume the relationship with the infant that has been interrupted by the stay in the NICU, (2) a delay in the mothering process, (3) feelings of depression or anxiety, (4) an impact on parenting and caregiving after discharge, and (5) affected perceptions of how they see themselves as mothers.[70] Maternal strategies to deal with highly tense NICU relationships include guarding and speaking out about the situation. Guarding strategies include (1) withholding feelings about inhibitive nursing actions and smoothing over the relationship with the nurse(s), (2) withdrawing from the nursery, and (3) blaming oneself to justify the nurse's actions.[70] Mothers who spoke up did so only after tolerating a number of incidents, and often it was the father who complained. The consequences for speaking out may include (1) earning a reputation with the staff as a "troublemaker," (2) recrimination in the form of sanctions and punitive actions that result in a "struggle to mother," or (3) becoming a disenfranchised mother.[70]

Several qualitative studies examining the "lived experience" of parents of a preterm/sick newborn illustrate parental need for a relationship with care providers in the NICU. A prospective, qualitative study about parental expectations from NICU staff at three NICUs in France studied 30 mothers and fathers of preterm infants younger than 32 weeks of gestation.[95] Fathers in the study described the bond with their preterm baby as more fashioned of words and looks involving distance, whereas mothers experienced the bond more physically. Of prime importance in the ability of these parents to form a bond with their preterm in the NICU was their relationship with NICU nurses. Two aspects of NICU nurses' care were cited by parents: (1) a caring attitude by the nurse toward the baby and parents, coupled with (2) caring communication with the parents about their infant, which decreased parental stress and facilitated interactions. The researchers concluded that the creation of a bond between the parents and their preterm infant is "rooted in their relationship with the caregivers."[95] Another study found that relationships with their baby's caregivers enabled parents to (1) trust that their baby was being cared for well, (2) endure the NICU, (3) feel less isolated and more in control, and (4) have hope.[202] A phenomenologic study of

parents' experiences with kangaroo care in the NICU illustrated the importance of information, communication, consistency, and individualized knowledgeable support and relationship with staff nurses who give parents the "courage" and confidence to hold and attach to their baby.[145] The most recent qualitative study of fathers' needs while their newborn is in the NICU found two prevailing themes: (1) fathers as caregivers and breadwinners and (2) fathers and emotions. Although fathers want to care for their infants and co-parent, they are faced with the dilemma of balancing these desires with the cultural and financial reality of earning an income for the family.[190] Emotions expressed by the fathers included fear of loss, restlessness, a desire to be the stronger parent/partner, a desire for support from other fathers going through the same experience, and a need to be away from the NICU.

Very important in any neonatal illness and subsequent hospitalization is the disruption and stress that is frequently created in the nuclear family system. Just as preterm and sick neonates experience stress in the NICU (see Chapter 13), parents also are stressed when their infant is in the NICU.[43,108,145,174,250] A study of the prevalence of posttraumatic stress disorder (PTSD) in parents with an infant in the NICU found that 35% of mothers and 24% of fathers had acute stress disorder at 3 to 5 days after admission.[144] Thirty days after admission to the NICU, 15% of mothers and 8% of fathers met criteria for PTSD. The severity of parental PTSD was correlated with concurrent stressors and family history of anxiety and depression.[144] More recent studies found an incidence of PTSD in 25% of mothers of high-risk neonates in an NICU, compared with 9% of mothers of healthy infants,[126] and 30% of low-income mothers with very-low-birthweight (VLBW) infants,[79] and it was more common in first-time mothers ofVLBW premature infants in the NICU.[89]

A family's functioning and adaptation to stress have important effects on the family's relationship with the infant and the infant's later development. A premature birth places parents at a higher risk for psychological distress than a full-term birth,[176] and, as a consequence, this can lead to depression, anxiety, and dysfunctional parenting patterns.[69,177,261] A crucial task of the perinatal health care team is to support families and intervene to assist them in adjusting to the unfortunate event of the birth of their sick infant to maximize their own growth, adaptation, and reorganization during this period.*

To assist parents through the difficult experience of having a sick infant, it is helpful to identify the psychological tasks and emotional reactions they experience. This section describes the six psychological issues facing families; it discusses the clinical and behavioral indicators with which parents are struggling and then suggests interventions that the perinatal health care team can employ to help families. It is extremely important to remember that these are generalizations and that each family or person must be approached individually.[187] In addition, in assessing families' reactions, it is critical to look at how they cope over time. Initially, there may be a tremendous amount of upset, disruption, and upheaval within the individual or family system. This can eventually lead to improved functioning and a sense of growth and mastery, "adjustment to the new normal." The key is how the individuals or families reorganize, how able they are to return to a state of equilibrium, the coping strategies they are able to develop, and whether the strategies are adaptive or maladaptive. Attachment and parenthood are complex, interactional developmental processes that must evolve and unfold over time.

Kaplan and Mason[121] describe the following four psychological tasks with which parents of premature infants must deal:

1. Anticipatory grieving and withdrawal from the relationship established during pregnancy
2. Parental acknowledgment of feelings of guilt and failure
3. Resumption of the relationship with the infant that had been previously disrupted
4. Preparation to take the infant home

Two additional tasks also are significant:

5. Crisis events related to labor and delivery
6. Adaptation to the intensive care environment[70]

In general, these six psychological tasks can be applied to any parent's reaction to a sick infant, with additional specific issues arising, depending on whether the infant was premature or born with a congenital anomaly.

Labor and Delivery

The first psychological task involves working through the crisis events surrounding the labor and delivery. Medical problems occurring at any point

*References 25, 51, 70, 92, 105, 108, 135, 158, 169, 192.

during the pregnancy or delivery that threaten the health or survival of the fetus or mother can result in the parents delaying their planning and making an emotional investment in the fetus or infant. Parents may psychologically withdraw from the pregnancy as a way of protecting themselves. The parents of an infant born prematurely often do not have the necessary psychological and physical time to prepare. This deprivation of time may interfere with the parents' ability to complete the final steps of attachment as described earlier.

Parental experiences of giving birth and parenting when the mother is seriously ill have recently been qualitatively studied. Mothers with severe preeclampsia whose premature infants were delivered emergently identified experiences that included (1) conflicting feelings about birth, (2) issues of life and death for them and their infants, (3) longing for the infant despite physical restrictions of access to the NICU, (4) finally becoming a mother by caring for their infants, and (5) being physically exhausted.[254] When both the mother and infant were ill, fathers described the process of becoming a family as a reflection of life and death in a context of separation.[255] These fathers experienced (1) beginning fatherhood grappling with issues of life and death for both the mother and infant, (2) connecting the family, (3) becoming familiar with the infant to establish a relationship, and (4) becoming a father in the public area of the NICU. Facilitating time together for the family to minimize separation, ensuring privacy and individualized care for the father, and providing rest for the mother are key interventions by health care providers.

Parents who have been concentrating on themselves in a healthy, narcissistic way may not yet be ready to transfer their investment to the infant, because they have been prematurely thrust into the role of parents.[111,158] There is an overwhelming sense of losing control of the events of the labor and delivery and their timing.[202]

On the other hand, some parents react in the opposite way. They may wish to be rid of the pregnancy as a way of dealing with their fear of the unknown and the uncertainty facing them. Many mothers of premature infants feel that their infants are alien[25,70,111]; they do not feel that the infant is really theirs, making it easier to have feelings of rejection toward the infant. In addition to feeling insufficient and inadequate about their ability to deliver an infant at term, they feel empty inside, as if something is missing. With a premature birth, there is usually a heightened sense of emergency and concern about the health and survival of the infant and, at times, of the mother, who herself may have suffered complications.

In the case of a full-term infant born with a problem despite a problem-free pregnancy, there is a sense of overwhelming shock and disappointment.[192] Parents immediately sense the problem; as their apprehension mounts, they frequently imagine the worst. Parents of a newborn with a malformation normally experience lowered self-esteem and view this event as an affront to their reproductive capabilities. The mother specifically views it as a failure of her feminine role. Parents often feel that they have failed and that the infant symbolically represents their own defectiveness. Parents not only fear for the infant, they fear for themselves and what this infant may mean to their future. The reaction of the parents is based on the specific psychological, social, and cultural meaning of the defect to the parents and the manner in which it is discussed and handled by the health care team.[129]

The emotional reactions and feelings that parents have at and after the delivery of a sick infant include shock, fright, isolation, panic, anxiety, and helplessness.[158,192,202] Parents may be so overwhelmed by the events that they may initially block any observable emotional response or affect. Staff interventions at this time are extremely important, because they lay the foundation for subsequent interactions between parents and health care professionals. Early comments and influential statements during this critical time can have lasting impressions in the minds of parents. This is also an emotionally difficult time for physicians and nurses, because they too are struggling with their own feelings of inadequacy, failure, and helplessness. Unconsciously, in an attempt to deal with their own feelings, staff may withdraw from parents and not be emotionally available to help. This is a normal response but one that needs to be guarded against, because it only perpetuates a breakdown in relationships and communication with parents that are greatly needed at this time. Many helpful interventions can be employed that are sensitive and supportive and that facilitate the emerging relationship between the parents and their infant.

EARLY COMMUNICATION

In the labor and delivery phase, early communication with both parents is essential. Parents normally are

apprehensive and extremely sensitive to explicit or implicit cues, such as actual statements by the staff, the atmosphere, looks, or a tone of voice that may indicate how things are progressing. Staff behaviors and wording of parent handouts help set the stage for an FCC unit and build family trust.[93] Because of the emphasis on prepared childbirth, parents are extremely sophisticated in their knowledge of labor and delivery practices and immediately sense some deviation from what they expected. Prompt, direct explanations presented in a calm manner are important and reassuring to parents. This explanation of the process of what is or will be happening can be effective because it helps organize the parents at a time when they are extremely vulnerable and feeling out of control. In a review of nursing behaviors identified to assist parents in meeting these needs, emotional support, parent empowerment and education, and a welcoming environment and welcoming parents were all key factors.[43]

Although it is normal for the staff to be guarded, members of the health care team should tell the parents the known facts and what actually is being done for their infant without giving any diagnosis, prognosis, or forecast for the future course of the infant. Avoiding or not talking to parents only accelerates parental anxiety and adds to their growing fantasies or distortions. Parents' fantasies about their infant's problems are usually worse than the reality. Parents often report that when they actually saw their infant, they were relieved because they had imagined that the infant would appear worse.

SUPPORT OF STAFF

It is also important that one of the staff members stays with the parents through labor, delivery, and recovery to offer continuous support and reassure the parents that communication will continue as soon as more information is known. This, again, is an uncomfortable time for the staff, because they may feel helpless and may therefore avoid the parents or revert to performing more technical activities. Some parents may need someone to be with them,[202] not only to talk to them but also, more importantly, to listen. On the other hand, some parents may not be able to talk or verbalize their concerns or fears. Others may wish to be alone with each other or any other significant person in their lives. Because of the varying responses and needs of people, it is extremely important to be sensitive to individual differences in approaching parents.

Parents have expressed their desire to be together when given "bad news."[100,232] As much as possible, talking to both parents at the same time is helpful when discussing the infant's condition. This decreases their distortions and misconceptions, increases the communication and support between parents, and prevents either parent from feeling excluded. The assumption is commonly made that the father is in a better emotional state to hear about the infant; this misconception leads health care professionals to mistakenly exclude or "spare" the mother, which only postpones her ability to begin to cope with the reality of her infant's condition. Sparing the mother may cause the parents to be in different stages of their understanding of the infant's medical condition and in different emotional states. Because emotional support between parents is so critical, the staff should avoid sparing because it can add to the parents' difficulty in being attuned to each other's needs and creates more opportunities for the parents to be out of synchrony with each other. Both mothers and fathers of critically ill newborns generally find each other to be the greatest source of support in the first 2 weeks of NICU hospitalization.[158,260]

SEEING THE INFANT

The question usually arises about the value of the parents seeing their infant, especially if the infant is very small, not likely to survive, or profoundly malformed. Generally, it is assumed that it is psychologically better for parents to have had the opportunity to see their infant, but this must be individualized for each family and newborn. Seeing the infant helps facilitate attachment,[25,158,169,247] decrease exaggerated fantasies, decrease withdrawal from the infant, and enhance the parents' ability to grasp the reality of the situation. Because of the need to respect individual differences in people, the best approach is to give parents the opportunity to decide whether they together or individually want to see and hold the infant.

Contact between mothers and their preterm infants in the first hours after birth is critical for a secure mother-infant attachment. Mothers who saw their VLBW preterm infants within 3 hours after birth showed a higher rate (76%) of secure attachment than mothers with no early contact (41%).[169] These researchers concluded that the 3 hours after birth constitutes a "sensitive period" for mothers of preterm infants to begin a secure attachment.[169] A negative experience for mothers at first sight of

their very preterm baby may result in attachment difficulties at 18 months corrected age.[171] Another study found that only 25% of mothers were enabled by the staff to hold their baby before transport.[68] The opportunity to see and touch the infant in the delivery room or before transport may reduce stressful feelings verbalized by parents who see their infant for the first time in the NICU.

Ultimately this decision should be made by the parents with the support of the health care team. It is not uncommon to find a well-meaning family member, physician, nurse, or social worker advising the parents or making the decision himself or herself and concluding it would be in the parents' best interest not to see the infant. The following arguments are given: "It's better not to get attached." or "It would make them cry or upset them to see the anomaly." or "They could not handle it." or "They would lose control." This decision is for the parents, not the professional, to make.

Some parents may know unequivocally what they want to do; others may be ambivalent or indecisive. It is the role of the professional to give the parents assistance (information and support) in making the decision. The parents may need time to think about it or may have to discuss their fear and ambivalence first, before being able to decide. They may need some factual information and preparation from the professional, such as the appearance of the infant and a description of the equipment. They may need assurance that someone will stay with them. Although time often is a factor and a decision must be made quickly, it is important to move at the parents' pace. The professional should still follow as much as possible the principle of facilitating the parents in seeing the infant. If this is not possible for medical reasons related to the mother's condition, a self-developing or digital picture can be taken, or secure video-conferencing can be used to involve the mother in the NICU admission. If it is medically possible for the parents to touch or hold the infant, the parents should be offered that opportunity. Touching or holding not only facilitates attachment[25,136,158,247] but also can provide parents with an emotional experience that is sustaining and reassuring, helping them proceed through a critical time of separation.

Parents are very sensitive to the staff's attitude toward the infant, as reflected by their comments and the manner in which the staff handle the infant. If the infant is regarded with respect and treated as important, the parent is given the feeling that the infant is seen as valued and worthwhile. This is especially important for parents of an infant with a congenital anomaly; the parents could wonder if their infant is viewed as "damaged goods" by society. In describing the infant to the parent, present a balanced picture of both the normal and abnormal aspects of the infant. In discussing the infant with the parents, staff should refer to the infant by name, if they have named the infant; this helps personalize the infant and establish the infant's unique identity.

CAREGIVING

To reinforce the caregiving needs of parents, discuss with them their plans to feed their infant and provide education to them so that they can make an informed decision. Support should be given whether the parents have decided on breastfeeding or bottle feeding. In most situations, breastfeeding a sick infant is possible and should be encouraged (see Chapter 18). Many mothers can pump their breasts for milk that will eventually be given to the infant. There are many psychological and physiologic reasons why breastfeeding or pumping may be beneficial for mothers and infants alike (see Chapter 18). The breastfeeding or pumping experience helps the mother feel close to her infant and helps her feel that she has some control over what is happening to her infant; she can uniquely contribute to her infant's care in a way that no one else can. Fathers, too, can participate in this activity by their support and interest in the actual breastfeeding or the pumping and milk-collection activities. Many mothers can pump and eventually put the infant to breast, but others cannot because of emotional stresses, the condition of the infant, and the length of time until the infant can feed. Regardless of eventual success, the mother should be encouraged to try if she has an interest; then she can feel that she made an attempt to relate to her infant in this way. If a mother does not plan to breastfeed or pump or if she tries but does not continue, she should not be made to feel guilty or that she failed in her role. She is already vulnerable to these feelings.

After the delivery, when the mother is taken to her room without a healthy infant, she usually experiences a void, as though an amputation has occurred.[92,129] She and those around her are beginning to grieve. The interventions of the staff should be flexible and sensitive to the individual needs of the family. Empathy, responsiveness, and an ability to listen to the parents are important at this time.[158]

Encouraging parents to verbalize and express their feelings and concerns (at their own pace), although difficult to do at times, is useful to the parents. Listening is as important to parents as giving them information.[105] Avoiding their grief gives the mother and father the impression that they are "bad parents" for having feelings of sadness, anger, guilt, or loss; this only increases their level of guilt and isolation. Prescribing tranquilizers also gives the message that is it not permissible to talk about what has happened to them and their infant. Tranquilizers only increase the feelings of unreality that normally are experienced. This stifles the parents' coping mechanisms at a time when the parents should begin to come to terms with what has happened.

Room assignments are a very personal matter, and the mother should be given a choice of where she will stay. Some mothers want to stay in a regular maternity unit; for others, this is too painful and they want to be in a separate area. Flexible visiting guidelines[37,90,158] for the father and other significant persons are essential so they can support one another through a difficult, uncertain period.

In talking to parents, bear in mind that the parents do not remember much of what has been said[202]; it is very difficult for them to assimilate all that has happened, both cognitively and emotionally. Therefore it is important for the staff to move at the parents' own pace. If the infant has been transferred or the chances for survival are limited, the mother should be discharged or given a pass to visit the infant as soon as possible. It is also important to acknowledge to the mother (and father) that they are parents and that they did give birth to a baby. They need the congratulatory cards, gifts, and attention that they would have received normally.

Anticipatory Grieving

After labor and delivery, parents are struggling with the second psychological task of anticipatory grieving and withdrawal from the relationship established during pregnancy. This task requires that parents acknowledge that their infant's life is endangered or that the newborn might die. Events surrounding the labor, delivery, and postpartum period may have indicated to the parents that their infant's chances for survival are diminished. Studies have shown that the decision to transfer an infant to an NICU alone is likely to initiate an anticipatory grief reaction.[51,192]

Parents also may experience feelings of grief and sadness over the loss of the expected, idealized child they had wished for during the pregnancy. For some parents, attaching to a critically ill or malformed infant may be too overwhelming; parents may withdraw from the infant in an attempt to protect themselves from their feelings of hurt, disappointment, and guilt.[25,111] Some parents may feel ambivalent about the infant[111]; they may feel they could not love or cope with an infant who might die or who would have significant physical or mental problems. Feeling uncertain about whether they want the infant to survive can result in feelings of guilt that may cause the parents to withdraw from the infant as a way of avoiding confronting these difficult, painful feelings.

During this period, parents may find themselves in a very stressful position; they are faced with the task of balancing the painful realities of a possible loss against their hopes of survival of their infant.[100] The emotional withdrawal and grieving that parents experience is normal during the critical time that the infant's life is endangered or when parents are faced with the possibility that their infant may have a lifelong problem. This withdrawal becomes pathologic only if it continues beyond the time the infant demonstrates definite signs (to the parents) of improvement and survival. In the case of a newborn with a permanent developmental or physical disability, parents who cannot grieve their idealized infant may maintain this withdrawal, which might lead to attachment difficulties and subsequent cognitive and emotional consequences for the infant.[241]

PARENTAL RESPONSES

Parents exhibit many emotional responses and behaviors that indicate they are struggling with the anticipatory grieving and withdrawal. Some parents are very sad, depressed, and teary, and others may be highly anxious, at times bordering on panic states; others react by having a flat affect, withdrawing, and appearing apathetic. Some parents may exhibit very angry, hostile, confrontational behavior as a way of dealing with their distress. Others may deny the situation by optimistically feeling that "everything will be okay."

Parents who typically are verbal may ask questions reflecting their concerns about their infant's survival; this is especially true after the infant has received medical attention and decisions are being made about treatment, including transfer to the

NICU. The questions they ask physicians and nurses may include "Will he make it?" "What do you think his chances are?" "He'll be okay, won't he?" "Have you seen other babies with this problem?" "Do other babies make it?" and "How long will he be in the hospital?" Parents struggling with their fears may resist seeing, touching, or visiting the infant. If they do visit the infant in the NICU, they may remain distant by having little or no eye contact with the infant, refusing to touch, standing far from the warmer or incubator, and asking few or no questions of the staff. Parents may be reluctant to name the infant; when they do refer to the infant, they say "it," "she," "he," or "the baby." If the infant has been given a special or treasured family name, they may be reluctant to use it.

A common phenomenon occurs when parents, being protective of each other, discourage each other's involvement with the infant. This is especially true at the time of transport, when the transport nurse may suggest to the father or family members that the infant be shown to the mother before leaving. Many fathers are afraid this will increase the emotional attachment to the infant and thus the feelings of disappointment and loss if the infant should die. The father is usually very apprehensive about how to handle the mother's feelings of grief in addition to his own. This type of behavior also is true with regard to medical information; it is not uncommon for one parent to request that all communication go through him or her. The response is "My spouse is too upset or anxious and couldn't handle hearing any bad news." Many times it is actually the parent making the request who is most anxious and who is dealing with this anxiety by projecting it onto the other partner. Work and childcare responsibilities, transportation difficulties, and financial limitations are all legitimate reasons that parents may be unable to have frequent contact with their infant. However, these factors also may serve as unconscious ways to maintain distance from the infant.

Keep in mind that withdrawal and grieving are part of a necessary and natural process.[25] For parents to develop an attachment to and accept the reality of their infant's condition, they must experience their feelings of grief, sadness, anger, guilt, and disappointment over the loss of the expected infant.[231,241] Maternal grief resolution over premature birth, as well as maternal interaction quality, are necessary for secure infant attachment.[231] This grieving serves to free the parents' emotional energy so they can interact with and become attuned to their infant. Grieving enhances the parents' availability to the infant. This availability aids in their feeling competent to handle their infant. The goal, then, of the perinatal health care team's interventions is to help the family realize their feelings are natural and normal and will be accepted.[25] Parents need permission to have their feelings. It is essential to acknowledge to parents that it is normal to be afraid of attaching to an infant who might die or who has a neuromotor impairment. Giving permission diminishes the guilt that the parents may feel about their behavior being abnormal or about being bad parents because they are afraid. Simple statements such as "Many parents tell us they are afraid of getting close to their baby" or "It's scary to attach when you think the baby may die" are helpful.

Sometimes it is useful for parents to verbalize their actual fears. They may fear their infant dying, being cognitively delayed, or being paralyzed. Once their fears are clarified in their minds and either confirmed or refuted by the medical staff, it is usually easier for parents to begin to accept their infant's diagnosis and prognosis and begin relating to the infant. Social workers can provide valuable emotional support to families in helping them deal with their realistic and unrealistic concerns.

COMMUNICATING MEDICAL INFORMATION

Most of the foundational work of FCC rests on effective communication.[209] Health care provider and patient/parent communication behaviors are associated with improved patient health status, recall, treatment adherence, and satisfaction.[122,209] The role of health care professionals in communicating medical information is important. Although the approach should be individualized for each family, some professionals feel a balanced approach is the most beneficial. Parents have stated that information should be accurate, current, and comprehensive but not unduly pessimistic.[105,202] Parents need a realistic assessment of the situation that is honest and direct. Acknowledge the infant's condition and possible problems, but not necessarily every potential problem that can arise.

Parents who hear "brain damage," "retarded," or "the baby will die" are not likely to forget these statements. These statements can linger in the minds of parents and adversely influence how they relate to

their newborn.[107] They may believe that some day "brain damage will show up" or that the infant is susceptible and frail and needs to be treated cautiously for fear of a life-threatening condition. These children may become victims of the *vulnerable child syndrome,*[4,107] a condition in which a child is overprotected by his or her parents and treated as if he or she had a medical problem when it is no longer the case. Parents who are told their newborn may die may have trouble attaching or becoming emotionally invested. When talking to parents, physicians and nurses should be judicious and careful in making statements of a sensitive nature. Definitive statements should be used only when appropriate and necessary. The long-term emotional implications of such statements should be weighed.

There are several other guidelines in communicating medical information to parents. As discussed, parents' perceptions of their infant's condition are extremely important, remain in parents' minds, and can affect their relationship with the infant. Parents easily misperceive information given to them. They may believe that a patent ductus arteriosus (PDA) indicates open-heart surgery and therefore worry that their infant has a heart condition. Or perhaps they think a bilirubin problem means their infant has liver disease. Therefore in beginning any discussion with parents, it is essential to determine and address their perceptions. A staff member might say, "Could you tell me what you understand about your baby's condition?" This will give the physician or nurse the opportunity to correct any misinformation or misconceptions and to hear about the parents' concerns. The perceived morbidity of the baby is a source of stress for both mothers and fathers. Parents' perceptions of the severity of their infant's illness are complex, change over time, and are affected by parental anxiety, infant size, amount and type of equipment and treatments, and amount and type of information received from health care providers.[107] A team member might specifically ask about the parents' concerns or worries: "Could you tell me what concerns you have about your baby?" Asking this can make communication between the perinatal health care team and parents more meaningful and helpful; unless the team deals with the parents' anxiety, discussions become one-sided lectures and benefit only the professional. Discussions should be a dialog between the parent and the professional.

During the course of a discussion and again at the end, it is useful to determine parents' interpretations of what has been said and modify and clarify as needed. The staff should avoid overloading a parent with lengthy explanations that are too technical. It is more productive to move at a pace at which the parent can assimilate the information presented; it is not necessary to describe the entire course of respiratory distress syndrome or bronchopulmonary dysplasia. It is always preferable to use simple language that is understandable. For some parents, the use of statistics is helpful; for others, it is not.[202] Statistics can be confusing, because they do not apply to the individual case and can be misinterpreted easily. When asked about the frequency of brain damage with a grade III intraventricular hemorrhage, a team member might say, "A majority of these babies have some neurologic problem, but some do not." Vivid modifiers such as "This is the worst case of sepsis we have ever had" or "Your baby is the sickest baby in the nursery" are of no real benefit to the parents and only accelerate their anxiety. Finally, if a referring physician and the nursery team are both communicating with the parents, it is essential to coordinate the particular approach. It is very confusing to parents and decreases their trust level for one to be pessimistic and the other optimistic or to receive conflicting information.

CULTURALLY COMPETENT CARE AND COMMUNICATION

Providing culturally sensitive care in a growing multicultural and diverse society is essential and needs to be a constant pursuit in providing perinatal health care to childbearing families and those families who have an infant in the NICU.[102,115] It is important for the health care team to understand the values, beliefs, customs, and behaviors of the particular group(s) they serve. Culture influences beliefs about what causes illness and how that illness should be treated. The perinatal health care team needs to address cultural, linguistic, and spiritual competencies to provide FCC.[83,94,102] The National Perinatal Association has published an extensive resource guide that reviews specific cultural practices and beliefs of several ethnocultural and religious groups.[230] Another excellent resource that discusses health and illness in different populations is the book *Cultural Diversity in Health and Illness.*[242]

In the perinatal setting, some common areas that often emerge center around language, folk practices or traditional beliefs, and nonverbal communication.

Use of Language. If a language or educational barrier is encountered, a qualified interpreter who is

BOX 29.6 GUIDELINES FOR THE EFFECTIVE CHOICE OF INTERPRETERS IN CLINICAL SETTINGS

Interpreter Choice

- Unless thoroughly fluent in patient's language, always use trained interpreter.
- Avoid strangers from waiting room or untrained staff as interpreters because of potential problems with accuracy, confidentiality, and medical terminology.
- Children should be interpreters of last resort because of problems with disruption of social roles, sensitive issues, and accuracy.
- Adult relatives or friends brought specifically to translate are acceptable alternatives when trained interpreters are not available, but there may be problems with accuracy, confidentiality, medical terms, and disrupted social roles.
- Always ask patient whether designated interpreter is acceptable.

Interpreter Use

- Clinician, interpreter, and patient or parent should be positioned in equilateral triangle so important nonverbal cues can be appreciated.
- Speak to and maintain eye contact with patient/parent, not interpreter.
- Ask interpreter to translate as literally as possible.
- If mistranslation or misunderstanding is suspected, return to issue later using different wording.
- Emphasize key instructions and explanations by repetition.
- Use visual aids (charts and diagrams) whenever possible.
- To verify quality and comprehension of translation, have patient/parent repeat information through back translation.

At End of Medical Visit

- Interpreter should write lists of instructions for patient or parent, particularly for prescriptions and other therapeutic interventions.
- Indicate to pharmacists that prescription instructions should be printed in the family's language.
- Interpreter should always accompany patient/parent to schedule follow-up appointments with receptionist.

bilingual and bicultural should be used[115] (Box 29.6). This is especially important in obtaining informed consent. A child or children should not be used as interpreters because they may have inadequate language skills and may be embarrassed by the topics being discussed. Interpreters should be familiar with medical information and terminology. A housekeeper or admissions clerk may be bilingual but have no understanding of the medical issues. Often information that is translated, even by a certified translator, is not understood by families if they are not literate. For example, some undocumented immigrants may have only a second-grade education and may be illiterate in their own native language (and embarrassed about disclosing this to the medical team). However, illiteracy does not mean the family is not intelligent. Some very intelligent parents can comprehend complex information if explained in a relevant manner.

Use of pictures augments what is being explained. Providing a list of common medical terms and educational materials in the native language of the parents is a useful tool. At times, despite numerous discussions about the infant's medical condition, the family may appear unable to comprehend what they have been told. Consider that even if the health care provider and family share the same language, the words may have different meanings depending on core cultural beliefs and values and the families' previous experiences.[9] What is considered an abnormality in our Western culture may not be in another culture.

Folk Practices and Traditional Beliefs. Each culture has their own set of beliefs and traditions about health, illness, and treatment. Many cultures believe that there is a balance between hot and cold forces in nature that are essential for health and harmony. These concepts, which are very prevalent in Latin American and Asian cultures, are unrelated to temperature. Pregnancy is seen as "hot," as are vitamins and iron, and should be treated with "cold" products to regulate a proper balance in the system and avoid medical problems. To treat imbalance, one must know what conditions are viewed as hot and cold. There is no general agreement as to what is a hot or cold disease or food. The classification may vary from person to person, so it is imperative to understand the nature of the situation or problem from the perspective of the family.[242] Many of the following beliefs, however, are commonly accepted causes for illness, birth defects, or anomalies:

- *Mal ojo:* A type of magical occurrence caused by a look; the "evil eye" heats up the infant's blood, resulting in fever, crying, diarrhea, vomiting, and aches and pains. This is often treated by a *curandero* (a folk healer), a healing ceremony, or placing an amulet *(azabache)* or leather strap for protection on the infant.

- *Coraje:* Anger or frustration believed to sour breast milk and affect an infant's intrauterine development. It is treated by wearing a good-luck charm in the bra and having a healing ceremony.[83]
- *Mollera caida:* Fallen fontanel is believed to occur when the breast or bottle is removed too quickly. It is believed the soft palate sinks in, causing feeding and swallowing difficulties. Treatment is performed by pushing up the soft palate with the thumb, pulling the hair, and sucking the fontanel.[72]
- *Susto:* A disease or illness resulting from fright. It is treated by relaxation and a cleansing ceremony or other specific actions to counter the *susto.*
- *Lunar or solar eclipse:* A cleft palate, some respiratory ailments, and birthmarks are often associated with an eclipse. It is treated by the pregnant woman wearing a red undergarment or a coin or key over the belly.

Traditional folk healers are multidimensional. In African cultures, they are diviners, herbalists, faith healers, and voodoo practitioners, as well as traditional midwives and birth attendants. Hispanic cultures use a wide range of *curanderos* (*santeros* in the Puerto Rican community), who vary from massage therapists to faith healers and herbalists. Asians rely on medicinal plants or herbology, acupuncture, and moxibustion (heated pulverized wormwood applied to the skin), which restores the proper balance of yin and yang believed to be most helpful during the period of labor and delivery.[242]

In many cultures, decisions are made by a group of elders, removing the responsibility entirely from a new mother and father. Many societies view the whole family as more important than a single individual. Decisions about life and death may be deferred to the elders or the entire family. Ignoring this social structure can result in problems of mistrust and decreased cooperation and communication.

Nonverbal Communication. One must be aware of body language and nonverbal communication and its meaning. Eye contact with the doctor or nurse or authority figures is regarded as disrespectful in some cultures. Loud vocalization may also be considered disrespectful. Rather than openly contradicting a person of authority, a parent will nod as if to communicate agreement but never follow through. Often the parent is viewed as noncompliant. In most societies, touch and space are regulated by rules and social orders. What is acceptable in one group may be forbidden in another; therefore respect personal boundaries and space issues. For example, Southeast Asians typically do not like to be patted on the top of their head or shoulder because this is where the soul resides. In American Indian and Alaskan Native populations, note taking is a taboo. Indian history has been passed down by means of verbal storytelling, and note taking is perceived as insensitive.[242]

Becoming culturally competent health care providers is an ongoing developmental process. One should be aware of the dimensions and complexities in caring for individuals from diverse cultural backgrounds. It is important to understand the family's core cultural dynamics, the meaning of the infant's illness, and the social context within which these life events are occurring. Specific customs, traditions, and taboos of each individual group are available in resource materials.[230,242]

COMMUNICATING MEDICAL INFORMATION: EVIDENCE-BASED PRACTICE

The principles of family-centered neonatal care clearly promote family participation in every aspect of their infant's care. The first four principles concern communication, medical information, fully informed parental decision making, and parental advance directives (see Box 29.2). Researchers have confirmed that information given to parents in the NICU is often communicated in euphemisms, vague statements, and half-truths, and shields parents from the uncertainties and controversies of NICU care.[100] Professional attitudes that may interfere with open, honest communication include (1) assuming that parents are too emotional to assimilate information and make a rational decision, (2) assuming that information about complications and poor outcomes may disrupt attachment to the neonate, (3) assuming that parental guilt and psychological harm will ensue from decision making (despite research to the contrary), and (4) cultural and language differences.[100,101] A multicenter qualitative study of parental values in decision making about delivery room resuscitation for their extremely preterm infants found that (1) all parents wanted to participate in decision making (although few

recalled discussing options for delivery room resuscitation; even fewer recalled being offered "comfort care," even though this was documented in the chart), (2) parents did not report that physician predictions of morbidity and mortality were central to their decision making, and (3) religion, spirituality, and hope were the guiding values for most parents in making their decision.[27,202]

Many parents desire and can handle complete, specific, honest, detailed, unbiased, and meaningful information—the same facts and interpretation of those facts as the staff—delivered in a humane and respectful manner.[74,100,101] Parents have expressed "remarkably uniform and unambiguous requests . . . to receive early, honest, and detailed information in a comprehensible and sympathetic manner and to be together when given bad news."[201] Prenatal consultation has been found to be useful by 80% of mothers in one study.[201] These researchers concluded that "in our population of educated mothers, most mothers prefer to be told exact statistics, rather than generalizations, concerning major neonatal morbidities."[201] Another study of prenatal counseling showed that 90% of mothers reported a positive experience. This study found that even though policy statements recommend a standardized approach to providing parents with child-centered information, and clinicians follow these guidelines, mothers want personalized information focusing on their individual concerns and questions, how NICUs work, and the integration of their family.[81]

A nurse-led intervention with 42 high-risk antepartum women expecting their infant to be in the NICU included an educational video, detailed description of prematurity and care requirements, family participation in the NICU, and a tour.[183] Within 48 to 72 hours after NICU admission, mothers were surveyed and found to be significantly less stressed about the sights and sounds of the NICU and their infant's appearance and behavior over time.[183] Another group of researchers used actuarial data for counseling parents about infants at the limits of viability and for morbidity counseling.[188] More recently, a multidisciplinary group formulated a prognosis-based guideline to assist parents and professionals in shared decision making about infants born at the threshold of viability.[146] Accuracy of prenatal and postnatal counseling of parents is of concern, because information affects practice management and influences parental decision making.[101,133,146,188,202]

Individuals vary in their desire to be informed and involved in decision making. Individuals also vary in the manner in which they assimilate information. Some parents may want extensive information about their situation, whereas others may not. Some parents may not wish to be decision makers and should be able to delegate decision making to a physician of their choice.[100] However, physicians have an ethical and legal obligation to give parents the facts from which to make an informed choice about their neonate's condition, illnesses, outcomes, and the risks and benefits of various interventions.[101] Proactive risk management strategies include effective communication because legal action in the form of civil malpractice suits (60%) and criminal action may result from poor communication between parents and physicians. Because language and cultural barriers in medical settings are increasing, federal and state governments have established a number of laws and standards to ensure that providers and health care organizations provide culturally and linguistically appropriate care.

Poor understanding by parents may be the result of poor communication techniques, contradictory messages, poor parental health, inexperience with medical terminology, denial, language barriers, inability to ask questions, shock over the birth of a preterm or sick newborn, lack of opportunity to review the information, or impaired recall in times of stress.[133,145,202] In one study, parents claimed that a neonatologist had never spoken to them, but, in fact, the conversation did occur and had been recorded.[131] In this study, parents were given a tape recording of their initial conversation with the neonatologist and any subsequent conversations of importance. The recording proved useful; 96% of the mothers and 68% of the fathers listened to the tape again, an average of 2.5 and 1.8 times, respectively. Eighty-five percent of the parents who listened to the recording had forgotten elements of the conversation, and two mothers did not recall that the conversation had ever occurred. Recorded conversations were found helpful by 99% of parents and grandparents, 76% of nurses, and 36% of neonatologists. Of the physicians, 40% were not happy about having their conversations recorded; "legal implications" was the most frequent reason given. As pointed out in the study, the "legal implications" work both ways; recording encourages precise, organized, clear, and humane communication of information while providing an "alibi" if a legal

complication arises. A randomized, single-blind trial found that mothers in the recorded conversation group had enhanced recall about their infant's diagnosis, treatment, and outcome (for up to 4 months) compared with the group without audio recordings (6 of the 98 mothers did not recall the conversation with the neonatologist).[134]

Research has documented that postpartum women have transient deficits in cognitive function, particularly in attention and memory function.[64] Because verbal communication may be poorly remembered, augmentation with written instructions is recommended.[64] In addition to relistening to a recording, if parents are given written information, such as an evidence-based table of likely outcomes of babies at different gestational ages, they can look at it again to review it. Such an evidence-based table for infants from 23 to 28 weeks' gestational age has been presented in the literature for use with parents.[131] This table contains information about mortality statistics, need for assisted ventilation, prolonged use of oxygen, length of stay, use of phototherapy, PDA needing treatment, outcomes of brain scans, and long-term neurodevelopmental outcomes. An NICU staff member can create a table for parents by using their most recent data.[132] With the advent of computerized databases (e.g., the Vermont Oxford Network database) that compare statistics from multiple NICUs and a large cohort of infants, parents can be provided with statistical information from multiple NICUs to compare with the outcomes from the NICU in which their baby is hospitalized. Parents may need assistance in interpreting statistics and making them meaningful to their individual situation. Again, some parents may want and need this type of information, whereas others may not. All communication needs to be culturally and linguistically appropriate.

Ongoing research on the *outcome of gestation table (OGT)* has documented views of parents, nurses, and physicians.[132] The majority of parents and nurses interviewed favored the table; they agreed that the information was frightening but important for parents to know. Parents wanted to keep a copy, and nurses wanted a copy in the medical record. Parents also thought that the information was easy to understand, the table did not contain "too much" information, and although it was frightening, they still would rather have the information. The majority of physicians thought that the table was easy to understand but had "too much" information, and they were ambivalent about using it in their practice. Parents, nurses, and physicians all agreed that the table and its information were not misleading. Of doctors, 21% disagreed about including a copy of the table in the medical record so that other health care providers would know what had been said to the parents. This finding was surprising to the researchers, who thought that inclusion of the table in the medical record would promote consistency in information given to the parents by different members of the perinatal team.

The Neonatal Research Network of the National Institute of Child Health and Human Development (NICHD) has developed a simple Web-based tool (see the Websites for Parents of Premature Infants section at the end of this chapter) to enable clinicians (and parents) to use multiple factors, not just gestational age, in making decisions about intensive care for extremely preterm infants.[143,252] A prospective study of 22 to 25 weeks' gestational age preterm infants ($N = 4446$) in the NICHD cohort found that the likelihood of a favorable outcome of NICU care was best estimated with consideration of gestational age in addition to sex, use of antenatal steroids, single/multiple birth, and birth weight. Calculation of the risk-to-benefit ratio of use of NICU care for the extremely preterm infant provides both care providers and parents with information that is "less arbitrary, more individualized, more transparent and better justified"[252] for informed decision making than use of gestational age alone.[143,252]

The principles of family-centered neonatal care (see Box 29.2) also advocate full and free access to lay and medical literature pertaining to the neonate's condition, proposed treatments, and probable outcomes.[100] Medical literature, articles, books, and videos (in English and Spanish) should be available in the NICU or in the hospital library for the parents' use. A video called *You Are Not Alone* (see the Resource Materials for Parents section at the end of this chapter) is available to help parents understand the impact on the family of long-term handicaps and to support them in making informed decisions. Access to the Internet has proved to be a source of medical information (some accurate; some inaccurate) for families and professionals. A recent survey found that 97% of parents prefer to find their information on the Internet, accessing it daily, and 81% use their smartphone; both of these technologies are preferred over books and brochures for information.[198]

Users report they can receive information, support, and comfort from their online activities and connections.[63] Parents may be more comfortable seeking medical advice from anonymous people in cyberspace rather than consulting their own health care providers. A study of fathers of premature infants and how they use social media found that they used these venues to discuss their concerns and to receive information, companionship, and emotional support.[125] When recommending the Internet as a resource, professionals should be aware of its benefits and its shortcomings.[57]

Acknowledgment of Guilt Feelings

The third psychological task parents are dealing with simultaneously with anticipatory grieving and withdrawal is confronting and recognizing their feelings of inadequacy and guilt in not delivering a healthy infant. Most parents struggling with these feelings are likely to search for answers to the causes of their infant's situation. The mother may focus on concrete things, such as not eating well, the flu, intercourse, birth control pills, or an unwanted pregnancy. The father also may be concerned about his role in not helping his wife enough, placing too many demands on her, an argument he provoked that precipitated labor, or another family member with the same chromosomal abnormality. Parents search for reasons because they need to find a cause for such an event happening to them. It is harder for them to feel out of control and helpless than to feel guilty. Some parents place responsibility on themselves; however, some shift the blame to others in their external world, such as their spouse, extended family, doctor, nurses, or God. Often both parents are concerned with the disappointment that they have caused the other. They may withdraw from each other at a time when they both need acceptance and support.

Realistic answers from the medical team are helpful for some parents in diminishing guilt feelings; in other parents, the guilt may be so deeply integrated in their thinking that it is less easily overcome. For example, some parents may focus on irrational, unrealistic factors, such as "This is my punishment for not being a good wife or daughter" or "This is my punishment for running away from home when I was 15." Often the more irrational the parent's thinking, the harder it is to assuage and resolve the guilt. Many feelings of guilt and failure are normal and expected; the feelings are a problem when the parent does not respond to the infant's progress, because the infant may continue to represent the parent's failure.

PARENTAL RESPONSES

Parents demonstrate many behaviors that indicate they are struggling with guilt and failure. Some parents directly verbalize these feelings and attempt to obtain helpful answers and support from the staff. Less obvious are the parents who are markedly depressed and remain so despite any improvement in the infant. These parents demonstrate the classic signs of depression, such as apathy, loss of interest in appearance and self, withdrawal, and loss of self-esteem. They exhibit an overwhelming sense of helplessness, feeling personally responsible for causing their infant's problem and are helpless to remedy the situation. Other parents struggling with guilt are highly anxious about their ability to handle their infant; they feel they have harmed their infant and are uncomfortable coming to the NICU or participating in their infant's care. Another manifestation of guilt is hostility and anger that is usually directed toward others, such as the spouse, the staff, or God. Instead of focusing their anger on themselves like a depressed parent, they direct it outward, projecting the guilt feelings onto others in their life. They may be angry at the physicians, nurses, or social workers for not making their infant healthy (if the infant is premature) or perfect (if the infant has a congenital defect). Unconsciously, they are trying to make the staff feel as guilty, helpless, and responsible as they do.

FACILITATING ADAPTATION

To intervene with parents, it is useful to assist them in acknowledging that their feelings of failure and guilt are a barrier to healthy coping and adjustment. The staff can provide them with appropriate information to modify and clarify the perceptions that may be the source of some of the parents' guilt feelings. Many parents directly ask about the causes of their infant's problem, and the medical team should counsel them with appropriate, honest information. Other parents are not as direct and verbal; they need to have the subject introduced. A staff member might ask, "Have you wondered why this has happened?" or "Many parents find themselves feeling responsible for their baby's problem, as if they failed. Have you had these feelings?" As parents begin to talk about their feelings, they can often

test reality and discover the irrationality in their thinking. However, some parents continue to feel guilty even though they have been told they are not to blame. Guilt feelings are very complex and may take a long time to resolve; for some, they may never be completely resolved but at least the intensity of the feelings may diminish. If a child recovers from the illness, guilt can be more easily relinquished. If the child has a chronic problem, the parent has a daily reminder of these feelings of responsibility. The more irrational the source of the guilt, the harder it is to dispel. Because this persistent guilt can cause problems in the parents' relationship with each other and with the child, a referral to a perinatal social worker or other mental health professional may be very helpful.

To facilitate support between parents, it is useful to ask whether they have shared their feelings of guilt and failure with each other. Often a spouse may assume that one is angry at or disappointed with the other. Discussing this may bring a tremendous sense of relief and reassurance. However, if the parents are blaming each other and relationship problems develop, a referral to a perinatal social worker or counselor is appropriate.

In some cases, there may be realistic reasons (either intentional or unintentional) why the parent may feel guilty about the infant's problem. Parental drug or alcohol abuse, domestic violence, an accident, or an inherited genetic problem may be a real reason. In these cases, the staff must acknowledge to the parent that there is a causal relationship and then give the parents support by allowing them to talk about their feelings. If causes were not intentional, it is helpful to acknowledge that fact; if they were, it is important to be nonjudgmental. A judging attitude only reinforces the feelings (e.g., guilt, concern, uncertainty) parents are already experiencing and further alienates them from the infant and staff. When this type of psychosocial issue arises, the involvement of a perinatal social worker or other mental health professional is essential.

POSTPARTUM MOOD DISORDERS

The postpartum period is a time of increased risk for development of mood disturbances in women (and men) that affect the entire family.[42,77,108,148,151] The incidence of postpartum mood disorders is estimated to be 15%, with as many as 50% of mothers still depressed at 6 months and 25% still depressed at 1 year after birth.[148] The incidence of paternal depression is estimated at 4% to 12%, and in a more recent study at 27%; paternal depression is underreported, underscreened, underdiagnosed, and undertreated.[184,207] A longitudinal study of paternal mental health during the transition to fatherhood found depressive symptoms scores increased by 68% in the first 5 years of their child's life.[77] The strongest risk factor and predictor of paternal postpartum depression (PPD) is maternal PPD.[184] At a time of individual and family role transition, neither parent receives the support needed from his or her partner when both are depressed.

Symptoms of postpartum mood disorders may be transient and relatively mild (baby blues) or may be associated with significant impairment of functioning (e.g., postpartum depression and psychosis). Women with a history of mood disorders and those who experience depression during pregnancy are at greatest risk.[148] Box 29.7 lists significant predictors of postpartum mood disorders.

Evidence suggests that mothers of premature infants or infants with problems and those with multiple births experience a higher rate of PPD than women who deliver a single full-term infant.[16,94,108,166] A study of 111 mothers whose infants were in the NICU found positive depression screens in 52%, and 30% received an "at-risk for depression" score.[166] Another study found that 20% of mothers of very preterm infants had clinically significant depression, and 43% had moderate to severe anxiety.[220] Although anxiety was common, the researchers did not find identifiable risk factors, but depression was associated with being married, parental role alteration, and prolonged respiratory ventilation for the preterm infants.[220] Maternal anxiety has also been correlated with prolonged length of stay in the NICU.[38] More recent studies of parents with VLBW infants found an incidence of depressive symptoms in 36% of fathers and 40% of mothers[200]; and 42% of low-income mothers in another study.[79] Parental anxiety at birth was 48% for mothers and 47% for fathers of very preterm infants; both parental depression and anxiety had decreased by 6 months.[200] A longitudinal study (from birth to 2 months after discharge) of fathers with preterm infants in the NICU found (1) 12% with high stress levels on admission and 8% at

BOX 29.7 SIGNIFICANT PREDICTORS OF POSTPARTUM MOOD DISORDERS

- History of previous depression (before and during pregnancy; bipolar disorder)[137,150,153]
- Present depression and anxiety disorders (panic, posttraumatic stress and obsessive compulsive disorders; phobias; neurotic personality)[108,109,264]
- Family history of mental illness[264]
- Depression and anxiety associated with previous perinatal loss that continues after the birth of a subsequently healthy infant[26]
- Low quality of prenatal attachment[54,84,199,221,222]
- Antenatal pessimistic outlook about maternity[217]
- Nonworking women with a history of emesis during pregnancy and depression[85]
- Low self-esteem
- Negative, stressful life events[150] (such as childhood physical/sexual abuse[80]; intimate partner violence[127]; prenatal diagnosis of fetal anomaly[44]; mode of delivery that entails maternal lack of control, such as primary or emergency cesarean delivery[84]; preterm birth[94]; multiple birth[86]; infant death[258]; and no anesthesia during delivery[264])
- >BMI (overweight; obese)[264]
- Gestational diabetes[236]
- Giving birth in the summer or fall months[264]
- Marital discord
- Poor social support[94,150]
- Difficult infant temperament
- Childcare stresses
- History of endocrine dysfunction
- Maternity blues
- Single marital status
- Adolescent pregnancy[42,224]
- Unplanned/unwanted pregnancy
- Low socioeconomic status/low household income[150]
- Minority racial and ethnic groups (Native Americans, African Americans, Hispanic; Arab Americans)[40,42,139,153]
- Immigrant women[42,264]

Data from Beck C. Recognizing and screening for postpartum depression in mothers of NICU infants. *Adv Neonatal Care.* 2003;3(1):37; O'Hara M, Gorman L. Can postpartum depression be predicted? *Prim Psychiatry.* 2004;11:42.

discharge, (2) mild depressive symptoms that decreased from 41% to 10%, and (3) major depressive symptoms that decreased from 16% to 2%.[49]

PPDs usually are divided into three categories: (1) postpartum blues, (2) nonpsychotic PPD, and (3) postpartum psychosis, although these disorders do exist along a continuum.[17]

Postpartum Blues

Postpartum blues (baby blues) affects approximately 50% to 80% of new mothers. Symptoms may include mood swings, sleep and appetite disturbances with periods of feeling anxious, irritability, and tearfulness interspersed with times of feeling well. Symptoms often begin within a few days of delivery and persist up to several days. Postpartum blues is time-limited and relatively benign. The symptoms worsen by the 5th or 7th day and tend to resolve by the 12th postpartum day. The occurrence of the "baby blues" does not necessarily indicate psychopathology; however, if the symptoms persist longer than 2 weeks, a further evaluation is needed because approximately 20% of women develop postpartum major depression.[6] A study of delivery mode and PPD found higher Edinburgh Postnatal Depression Scale (EPDS) scores at 48 to 72 hours after birth (but not at 6 to 8 months postnatally) in mothers after primary cesarean delivery compared with spontaneous delivery.[210]

Postpartum Depression

Postpartum depression is relatively common. Several controlled studies reveal that between 12% and 20% of women experience a postpartum depressive episode, and this rate is as high as 26% in adolescent mothers; rates vary by race/ethnic group.[6,153] Most women begin to experience depressive symptoms within the first month after delivery, although some have reported symptoms during the pregnancy. Signs and symptoms include a depressed mood, lack of interest or pleasure in usual activities, guilt, impaired concentration, appetite disturbance, low self-esteem, feelings of hopelessness and worthlessness, and suicidal ideation.[17]

Postpartum Psychosis

Postpartum psychosis is a rare but extremely serious mental illness occurring in 1 to 2 per 1000 deliveries. It generally occurs within the first 2 to 3 weeks after delivery and requires immediate attention. The symptoms are crying, irritability, restlessness, sleep disturbances, delusions, hallucinations, and bizarre, irrational behavior. For example, a woman may view the baby as the devil, claim the

infant is dead, or accuse the hospital staff of switching babies. There are significant risks for infanticide or suicide.

Paternal symptoms of depression occur after the onset of maternal PPD, are worse during the first 3 to 6 months after birth, and have symptoms similar to those of depressed mothers. However, paternal depression manifests with more subtle symptoms that include negative parenting behaviors, withdrawal from social situations, an increase in relationship conflicts, alcohol and drug abuse, and intimate partner violence (IPV).[184]

The causes of postpartum disorders are multifactorial. Pregnancy is a complex biologic process that takes place within a psychological and social context. Some determinants are the psychological makeup of the mother, hormonal changes associated with pregnancy,[66] genetics, socioeconomic issues, stress, the temperament and health of the baby, marital instability, ambivalence toward the pregnancy, culture, and the emotional support system of the new mother.[94,137,148] When the features listed in Box 29.8 occur in mothers with a sick infant, it may be difficult to differentiate a normal reaction to an adverse situation, a grief reaction, from signs of PPD.

In general, postpartum disorders are often overlooked and not appreciated, thereby putting the mother at risk for development of recurrent depression and altered maternal attachment, which are both associated with deleterious effects on the behavioral, cognitive, emotional, and social development of the infant.* A longitudinal study of first-time mothers (with normal pregnancies and healthy babies) found that 22% who were depressed on day 10 postpartum continued with low mood for the first year of the baby's life and had less closeness, warmth, and confidence in parenting their baby in that first year.[151] Given the inherent stresses and emotional impact the birth of a sick infant(s) has on the mother and her family, it is recommended that universal screening for PPD be a part of every family assessment in the NICU.[16,108,220] "Routine assessment will normalize the process, enhance awareness and increase the health care providers' comfort level and competency."[16] An evidence report and systematic review for the U.S. Preventive Services Task Force about primary care screening and treatment for depression in pregnant and postpartum women found that screening these women for depression may actually reduce depressive symptoms in those with depression and reduce the prevalence of depression in a given population.[196]

*References 16, 17, 106, 107, 147–149, 249, 250.

BOX 29.8 CRITICAL FINDINGS
ADDITIONAL FEATURES OF POSTPARTUM MOOD DISORDERS

- Overly concerned for the baby or excessive anxiety over the infant's health
- Guilt, inadequacy, worthlessness, especially feeling like a failure at motherhood
- Fear of losing control or "going crazy"
- Lack of interest in the baby
- Fear of harming the baby
- Obsession

Assessment Tools

Several assessment tools are designed to identify women with a substantial increased risk for PPD. Ideally it is recommended that these assessment tools be administered at each trimester of pregnancy and periodically after delivery to assess a woman's risk status. The literature contains extensive discussion of the various assessment tools and checklists, and their reliability and predictability of PPD.[12,15] Although many tools are available, three seem to be used extensively: (1) the Postpartum Depression Screening Scale (PDSS)[16]; (2) the Postpartum Depression Predictors Inventory–Revised (PDPI-R) (Table 29.1) (these tools are also available in Spanish)[15,20,21] based on a meta-analysis of 84 studies published to identify significant risk factors of PPD[14]; and (3) the Edinburgh Postnatal Depression Scale (EPDS) (Table 29.2).[46,47]

The PDSS and PDPI-R have different uses. The PDSS is a 35-item self-report Likert scale that assesses seven areas: (1) sleeping/eating difficulties, (2) anxiety/insecurity, (3) emotionality, (4) mental confusion, (5) loss of self, (6) shame or guilt, and (7) thoughts of self-harm.[16,19,20] The scale measures depressive symptomatology. The total score ranges from 13 to 175. If a mother's score is 80 or greater, this is a positive screen for PPD, and a referral for mental health follow-up is

indicated. The mother completes the PDSS herself, and then it is scored. The tool is used only after delivery. The PPDS has been found to be reliable as a depression screening scale for mothers in the NICU.[166]

The PDPI-R is an inventory that (1) assesses a woman's risk status for developing PPD, (2) can be used during pregnancy and after delivery, and (3) should complement a clinician's professional judgment. It consists of 13 risk factors and is designed

How are you feeling?

As you have recently had a baby, we would like to know how you are feeling now. Please underline the answer that comes closest to how you have felt in the past 7 days, not just how you feel today.

Here is an example already completed:

I have felt happy:
Yes, most of the time
Yes, some of the time
Not very often
No, never
This means: "I have felt happy some of the time" during the past week.
Please complete the other questions in the same way.

In the past 7 days:

1. I have been able to laugh and see the funny side of things:
   As much as I always could
   Not quite so much now
   Definitely not so much now
   Not at all

2. I have looked forward with enjoyment to things:
   As much as I ever did
   Rather less than I used to Definitely less than I used to
   Hardly at all

3. I have blamed myself unnecessarily when things went wrong:
   Yes, most of the time
   Yes, some of the time
   Not very often
   No, never

4. I have felt worried and anxious for no good reason:
   No, not at all
   Hardly ever
   Yes, sometimes
   Yes, very often

5. I have felt scared or panicky for no very good reason:
   Yes, quite a lot
   Yes, sometimes
   No, not much
   No, not at all

In the past 7 days

6. Things have been getting on top of me:
   Yes, most of the time I haven't been able to cope at all
   Yes, sometimes I haven't been coping as well as usual
   No, most of the time I have coped quite well
   No, I have been coping as well as ever

for the clinician and the woman to discuss each risk factor that might put her at risk for developing PPD. There is no total score; rather, it is a tool that provides detailed information on symptoms.

With some modifications, as reported by a study in Australia, the PDPI-R has been used as a checklist that the woman administers herself. The information from the checklist was then used to initiate discussions by midwives and nurses with women about their postpartum depression.[99]

The EPDS is a 10-item screening questionnaire that (1) is completed by mothers (and fathers)[108] and then scored by clinicians, (2) is useful as an inventory to identify parents at risk to initiate an open discussion about PPD, (3) requires minimal training to administer, and (4) is completed in less than 10 minutes. The EPDS is a reliable and valid measure of depression or anxiety disorders in fathers during the perinatal period[164] and can be used by pediatric health care providers in the outpatient setting to help identify and assist mothers at risk.[65,75] The EPDS can be used at 6 to 8 weeks after delivery and is easy to score. The items are ordered and weighted to reflect severity of symptoms. One study found that the self-administered EPDS and the directed interview EPDS are equal in their ability to screen for PPD, and either technique should be used to screen for PPD.[120] A score of 12+ indicates the likelihood of depression but not its severity, although with this score, further assessment and possible intervention are recommended. If the woman or man scores positive on item 10, thoughts of harming self, immediate intervention is necessary.[12]

Many studies have demonstrated that mothers of sick or premature infants are at greater risk for psychological distress than are mothers of full-term infants. These studies have looked at depressive symptoms in mothers during hospitalization and after discharge. The goal of these studies, by using assessment tools, has been to identify (and ultimately treat) women at risk for depression, thereby decreasing the negative effect on infant development. General themes emerge from these studies.[16,17,44,94,108] Social support was consistently identified as extremely important, both during the hospitalization and after discharge when the mother has full responsibility for the infant(s) for the first time. Increased stress at discharge, the isolation, and being disconnected from the NICU support network contribute to the risk for PPD. Therefore social support is necessary and can serve as a buffer to the effects of depression. Logsdon and Usui's work[155] supported what other studies have found—that closeness to one's partner, social support, and self-esteem are important predictors of PPD regardless of ethnic diversity. Stress and uncertainty surrounding the birth of a sick newborn increase the need for support. Support provided by the health care team to a mother's adaptation to the NICU environment, information communicated about the infant and his or her treatment, facilitating maternal self-confidence, accurate knowledge of infant development (at the time of discharge), and self-care knowledge about symptoms of depression and who to contact for help can influence a mother's risk for PPD.[148,156] All of these factors indicate the need for enhanced FCC in the NICU and after discharge.

Mothers whose infants have chronic complications and who present long-term management challenges are more likely to experience more severe depressive symptoms. In addition, the role of the hospital environment coupled with the appearance of the infant contributes to maternal symptoms. In a study done in Japan, it was found that close emotional support of the father was much more significant than the existence of other modes of peripheral support.[186] This same study concluded that active intervention for PPD is necessary for the mother to be emotionally available to attach to the infant and cope with the infant's hospitalization and subsequent issues related to discharge. More research shows that chronic exposure to maternal depression has long-term negative effects on a child's emotional, psychological, and cognitive development.[108,147,248,249]

Treatment and Intervention

PPD and its symptoms present themselves along a continuum. Interventions should be guided by the severity of symptoms and the degree of impairment of the individual. Because PPD is a complex biologic and psychological phenomenon, a comprehensive approach is needed, including reassurance and support (from a doula or telephone-based peer support), comprehensive professional home visits in which nurses screen and counsel for PPD, problem-solving education,[237] psychoeducation, individual or group psychotherapy, and psychopharmacology.[10,56,82,204]

Fathers identified the need for both professional support and support from family and friends to be

supportive to a depressed partner and to deal with their own depression.[149,150] Parenting classes enable fathers, as well as new mothers, to learn the skills necessary to care for their infant and feel confident, in control, and less frustrated.[186] Education about PPD, its symptoms, and practical coping strategies were also identified by fathers as helpful.[148,149] Depressed fathers are less able to emotionally support the mother and participate in parenting, which negatively affects their relationship, attachment to the infant, and ultimately the emotional, behavioral, and social development of the infant/child.*

Prior studies have demonstrated that when parents experience less stress they are able to form early attachments to their sick infants.[262] Mothers with greater stress have less positive attitudes and interactions with their infants than those with less stress.[48] This lack of parenting confidence has been associated with lower levels of child competence, poorer developmental outcomes, and altered relationships with children into adulthood, and it affects multigenerational familial relationships.[185,239] Conversely, multiple studies have shown that positive attitudes and parental confidence are associated with secure infant attachments that lead to increased competence and better developmental outcomes.[48] Sensitivity training for parents aimed at recognizing signs of infant stress while infants are in the NICU and thereby promoting better mother-infant attachment and improved infant developmental outcomes may be helpful.[62]

In childbirth classes, PPD should be addressed with anticipatory guidance discussing risk factors and early symptoms. Information brochures with resources should be available. Support groups often prepare mothers (and fathers) for the reality of parenthood and provide anticipatory guidance and counseling, skill building, validation, and acknowledgment of the concerns and frustrations of caring for a new infant. There are often support groups specifically for PPD available in local communities and at the statewide level. Referral to national organizations such as Postpartum Support International and Depression After Delivery enables mothers and fathers to access many additional resources (see the Resource Materials for Parents section at the end of this chapter). Other interventions include visiting nurse services, nurse home visitors, parenting classes, referrals to childcare resources, and mutual aid hotlines. NICU-based cognitive behavioral therapy has been shown to significantly decrease maternal depression, but not anxiety symptoms, in mothers of sick babies.[175] A 4-week, five-step individualized intervention program for parents of an infant in the NICU resulted in less anxiety and no depression in 50% of mothers and 80% of fathers at discharge compared with 100% of parents without the individualized program.[33] A meta-analysis found that *any* psychosocial or psychological intervention (compared with routine postpartum care) reduced symptoms of depression and the likelihood of continued PPD within the first year after giving birth.[56]

Many psychotherapy modalities are recommended to mothers. Couples therapy may be part of the treatment plan if there is marital discord; however, even when there are no particular difficulties in the relationship, including the father can be useful in providing information and support for the mother. Suggestions for increased help around the home can be of tremendous value, allowing the mother to obtain adequate rest and care for herself. If the symptoms are very severe, psychiatric day treatment or inpatient hospitalization may be necessary. (In England, there are mother/baby inpatient units.) In cases in which the infant's life is in danger, protective services may have to be involved.

The use of medications (selective serotonin reuptake inhibitors, mood stabilizers, antidepressants, and antipsychotics) may be necessary.[53] In a recent study, the use of antenatal antidepressant medications resulted in fewer postpartum mothers reporting postnatal depressive symptoms when compared with a group of mothers who did not use medication.[159] The use of hormonal manipulation has been investigated. Referral to a clinician who is familiar with PPD is recommended.

Breastfeeding is associated with a reduced risk for PPD that is maintained over the first 4 months of the postpartum period.[98] However, women with postpartum depressive symptoms breastfeed an average of 2.4 weeks less than women without symptoms.[13] The issue of breastfeeding when considering psychotropic medications needs to be addressed.[138] Parents should be provided necessary information about the effects of these medications on the neonate so that the risks and benefits can be considered on an individual basis. All psychotropic medications enter the breast milk, so careful evaluation with the health care team needs to be undertaken (see Table 18.7).

*References 16, 17, 106, 107, 147–149, 184, 249.

ADAPTATION TO THE INTENSIVE CARE ENVIRONMENT

The fourth psychological task involves adaptation to the intensive care environment.[70,92] All of the reactions of guilt, anxiety, fear, anger, and disappointment become heightened when parents attempt to adapt to this unfamiliar and alien environment.[202] They must learn a new language, establish trust in new relationships, and adapt to their role in this setting.[70,165,202] The intense and sometimes chaotic appearance of a high-risk nursery makes it a frightening experience that serves to increase parental feelings of helplessness and anxiety. Parents should gain a sense of security in this environment before initiating a caregiving role with their infant. There may be cultural and linguistic adaptations and geographic obstacles for families who live in small, rural communities and must travel to large, unfamiliar cities and adapt to large hospitals. Locating the hospital and finding accommodations and meals can become overwhelming to parents who have undergone much emotional turmoil. Meeting the infant's care providers, the competent physician and nurse, sometimes can evoke a mixture of positive and negative feelings. Parents may be reassured and grateful for care being given, but their feelings of uselessness, helplessness, and inadequacy can be reinforced.[192] The sophistication of the highly technical care and heroic measures provided to achieve survival for their infant may be met with both awe and uncertainty.[158,202] Family disruption is exaggerated by distance, especially if the infant was transported, and the father must decide whether he is most needed with the infant, the infant's mother, or perhaps other children at home. Decisions must be made about work responsibilities and childcare. The financial concerns related to providing intensive care become an added stress on families and are often compounded by the travel expenditures necessary to visit the infant.

With the development of high-risk perinatal centers, an increasing number of mothers are transported to the maternity division of hospitals with an NICU just before delivery or shortly thereafter. If there is not sufficient time to arrange for her transport before she gives birth, it is strongly recommended that the mother be moved as soon as possible.

In general, having an infant in the NICU has wide-reaching effects on the entire family system (parents, grandparents, siblings, employment, finances,[73] childcare). Table 29.3, written by a mother of a 28-weeks' gestational age neonate 1 year after their NICU experience lists practical ways "to help preemie parents in the NICU." A social worker providing comprehensive services and interventions is imperative to guide the family during this difficult time.

Parental Responses

In comparing the psychosocial adjustments of parents in the NICU, both parents may experience increased levels of emotional distress.[59,202] Mothers have been found to be more anxious, hostile, and depressed than fathers, with poorer adjustments related to work, sexual relations, social environment, and psychological distress.[59] Mothers and fathers experience the NICU stay differently; mothers found the entire NICU experience and its aftermath more stressful than did fathers.[59,111] It is important to include both mothers and fathers in assessments and interventions and to avoid overlooking the father's needs because he may be less accessible.[59,111,158] A systematic review of qualitative studies of the lived experience of fathers of preterm infants in the NICU found paternal ambivalence and five main themes: (1) emotional roller coaster, (2) paternal needs, (3) coping strategies, (4) self-representation, and (5) caregiving engagement at birth of the preterm infant, during the NICU stay, and after discharge home.[206] Another recent study of the lived experience of fathers of preterm infants less than 28 weeks' gestational age found four main themes: (1) looking in, (2) persevering, (3) holding, and (4) finding my way.[154] Fathers described feeling like an outsider in the NICU while learning to trust others, protect mother and baby, and continue working to provide for the family. Fathers need communication, empathy, expectation by health care providers that father will be involved in care and parenting in the NICU, support in establishing a father-infant relationship, and emotional support for the stressful experience of the NICU in a similar fashion as for mothers.[191,202]

A number of nonverbal and verbal signs indicate that parents are struggling to gain a sense of security in the NICU. Some parents appear frightened, overwhelmed, nervous, and withdrawn, asking few questions or being reluctant to call or visit. Others may be highly anxious and unable to focus on their infant and may instead concentrate on other activities or infants in the nursery. Some parents may ask

TABLE 29.3 SEVENTEEN WAYS TO HELP "PREEMIE PARENTS" IN THE NICU

STRATEGY	RATIONALE
"Preemie parents" are different from "termie" parents so don't go on autopilot	"Preemie parents" have a hospitalized child fighting to survive. The scene isn't jubilant yet. We are neither physically nor mentally prepared for the usual frozen meals, cute onesies or requests for pictures. Wait until we start celebrating (likely after discharge).
Curb your curiosity	Please don't pry. Parents may not know why the baby was born early but feel shock and guilt about it. Talking about the baby's health issues and roller coaster of the NICU is too scary and everything is unknown. The same discretion goes for mom's body and health status. If we share, listen. Until then your curiosity must go unsatisfied.
Respect our privacy and let us announce the preemie's birth.	Parents come out of their post-labor stupor to find their intimate, traumatic news spread far and wide. Be discreet. Let "preemie parents" announce our news on our schedule and our way.
Offer to help but don't be too proactive.	Sitting in the NICU inventing errands or shopping lists to make loved ones feel useful is a burden. Let parents focus. My favorite texts were question-free and read, "Thinking of your family. Here to do anything when you want help. No need to reply now." If parents don't respond, be patient. You might be on standby for a few days—or weeks—but we'll probably take you up on the offer.
Keep baby gear out of the house or at least hide it.	After my delivery, with the baby still in the NICU, I came home to a lovely display of new baby clothes on my kitchen counter. But to my husband's shock I collapsed to the floor and sobbed the rest of the night. The clothes reminded me our baby couldn't come home and his survival wasn't guaranteed. Thanks goodness we didn't have a nursery yet. Wait until we say we're ready and then stick to our registry—some preemies need special gear.
If you must send a gift, shop for the parents	Useful items include a nursing apron (or any cover-up for mom while pumping in the NICU), an insulated lunch bag (filled with snacks), a file box with folders (for the mountain of medical paperwork), a notebook and folder (to track conversations and forms), and a chest freezer (for breastmilk). Subscriptions to Netflix and HBO helped us stay awake during kangaroo care. My husband appreciated cash cards to spend on parking and hospital coffee. I enjoyed a home mini fridge for breastmilk and midnight snacks.
Pack high-protein food to eat with one hand.	We were frazzled parents glued to a hospital chair with no oven in sight, so we couldn't heat large frozen casseroles. Luckily some friends assembled lunch packs of little sandwiches, hard boiled eggs, cheese cubes, nuts, apples, breakfast bars, fresh salads, and chocolates. Those packs kept us going without leaving our son's bedside.
Skip preemie clothes	Younger preemies in incubators don't wear clothes. At our NICU, gifts of new outfits for older preemies required separate tracking by the nurses and extra laundry for me. Unless we request outfits with specific features (yay snaps!), wait until baby is home and then go nuts with fashion.
Be calm and cautiously optimistic in front of "preemie parents".	Crying to us on the phone or telling us you're worried sick makes things worse. Be zen. Our parents kept their cool and it reassured us. And please don't tell us our child's birth was traumatic for you, too. Please sort through your emotions with anyone but us.
Tell "preemie parents" you think of them all the time	From Dominican nuns in Brooklyn to a minyan in Denver to co-workers in Seattle, people rooted for us. Their faith pulled us through the toughest weeks.
Recognize that each "preemie parent" has a unique—possibly competing—coping style.	My husband preferred running errands and being distracted. I loved being left alone to hold the baby in silence. Care for each parent accordingly.
Give "preemie parents" time to get their bearings.	In the NICU, parenting can feel untenable. Our home was the only place we could have control or predictability. Coming home to a cleaned house was wonderful. Coming home to a reorganized one was frustrating. Remember baby was born early but isn't coming home early. There's no need to take over. Protect the normalizing things, like nesting or making a registry, for us to enjoy later.
Let "preemie parents" find their own silver linings.	We heard some well-meaning but demoralizing comments like: "At least you get to sleep through the night." No we don't. "Isn't it a relief not to be pregnant?" Stop. "Small babies hurt less to deliver, right?" Ugh. "Welcome to parenthood!" Hmmm…wanna trade places? Yes, they are blessings. Let us discover them—and we will!

Continued

TABLE 29.3 SEVENTEEN WAYS TO HELP "PREEMIE PARENTS" IN THE NICU—CONT'D

STRATEGY	RATIONALE
Skip asking when the baby will come home.	The due date is the target and we're more impatient than you are. We'll share when the NICU staff give the green light.
Wait until you are invited to meet the baby.	We might not be ready for NICU visitors. After discharge, we'll want quiet time to breathe and hold each other without wires and monitors around. We'll invite you when and where the time is right for us.
Respect the quarantine.	Preemies build immunity with time, not exposure. If you're invited to the NICU (or the house after discharge), get vaccinated and follow sanitizing protocol. These precautions are doctor's orders, not overprotective paranoia. We're taking a risk having you over, so please comply. The best guests wear clean clothes without perfumes and wash and gel up without being asked.
Most of all, tell "preemie parents" you believe in them	Friends and family told us we were good parents doing everything right. Your love is powerful medicine and we need it now more than ever.

Modified from Kagan L. 17 ways to help preemie parents in the NICU. *The Huffington Post.* November 21, 2016. Used with permission of Lisa Kagan. Available at: https://www.huffingtonpost.com/entry/17-ways-to-help-preemie-parents-in-the-nicu_us_582f4d65e4b0eaa5f14d441d. Accessed July 8, 2018.

many questions and become very interested in the technical aspects of their infant's treatment, such as respirator settings and laboratory values, in an attempt to understand and cope with their infant's illness.[58,158] Some parents, uneasy with entrusting their infant to strangers, may initially feel a need to remain at his or her side, maintaining a vigil. Some may wish to read the infant's chart or attempt to read material on their infant's particular condition. Others may become angry or upset at minor differences in the infant's care or the nursery policies, such as a respiratory setting being off a point or discrepancies in enforcing visitation guidelines.[70,90]

Research into the mother's needs in the NICU have found that the mother's priority is to safeguard her infant. Mothers perceive that if they advocate for their own needs (e.g., to mother or care for the infant) in the NICU, they will be labeled as "difficult" or "demanding." Maternal needs in the NICU include information and interaction with their infant, emotional safety, and a supportive NICU environment in which to meet their needs (Table 29.4).[167] When these needs are thwarted, mothers feel helpless, powerless, and emotionally vulnerable and are less able to interact with their infant. A major barrier to implementing FCC is the mother's fear about how her needs, feelings, and actions affect the care of her baby. FCC empowers mothers and fathers through collaboration with health care providers.[202]

For families, the relationship with health care providers progresses through three stages: naïve trust, disenchantment, and guarded alliance.[165,167,202] Naïve trust, the belief that the family will be informed and involved in decision making, becomes disenchantment when unmet expectations, distrust, and anger result in the belief that the sick family member needs to be protected. A guarded alliance develops when families become more able to navigate the health care system and are involved, are in control, and participate in the care of their sick member. Helpful interventions include (1) meeting the individual family's needs, (2) providing a welcoming NICU environment, (3) personalizing the infant, (4) teaching parents to interpret their infant's cues and behaviors, (5) fulfilling the continuing need for information, and (6) forming partnerships with families in all aspects of decision making and caregiving,[165,202] including giving them the option to be present during procedures and participate in pain relief for their infant.[117,167]

Facilitating Adaptation

Many interventions can be employed to familiarize and orient families.[92] First, the obstetrician, transport team, or any other professional who has initial contact with parents can give them preparatory information and a description of intensive care. A booklet or video[92] in the native language of the

TABLE 29.4 MATERNAL NEEDS IN THE NEONATAL INTENSIVE CARE UNIT

MATERNAL NEED	RECOMMENDATIONS FOR NICU STAFF
Empowering information	Give information about the maternal situation in the NICU (e.g., feelings, importance of her role as mother of the baby). Give information on how a preterm baby differs from a term baby and how to read/respond to her individual baby's cues/behaviors. Facilitate opportunities for parents to provide direct care for their infant. Understand parental need for modeling and role-modeling on preterm care tasks (e.g., feeding, bathing). Understand parental need for supportive appraisal—give positive feedback and reinforcement of maternal/paternal caregiving (e.g., feeding, diapering) and infant's responses to parental caregiving.
Continuity of care	Understand difficulty or impossibility of mother to negotiate actions with multitudes of caregivers. Use primary nursing for continuity of physical and emotional care for mothers and infants.
Vigilant watching over	Understand maternal observations and actions to safeguard their infant and prevent injury or harm. Understand that mothers fear being seen as "difficult" by the staff, that voicing their concerns would jeopardize their baby's care. Understand mothers' perceptions that the nurse-to-patient ratio/acuity influences her behavior (i.e., mother is hesitant to advocate for her own needs for information, caregiving opportunities, and support). Mothers would shift their priority from interaction with the infant to safeguarding the infant from danger by delaying/rescheduling the activity with the infant. As a result, mothers often become disappointed and frustrated that a meaningful moment with their infant was denied.
Expert knowledge	Understand that, initially, nurses and other health care providers are seen as "experts" in care of the infant. With increasing confidence and caregiving, mothers become "expert" in knowing their own infant and what works best and are truly the "constant" in the multiple caregiving system of the NICU. Understand that mothers receive conflicting messages from health care providers about respect, acknowledgment, and value of growing maternal expertise.
Emotional safety in the NICU	Understand feelings of extreme emotional vulnerability/exposure experienced by mothers in the NICU. Empathy, emotional warmth, and understanding in interactions with nurses and other health care professionals provide mothers with emotional safety. Feelings of emotional vulnerability were engendered when (1) nurses' actions covertly communicated that the mother was a "bother" or an "intruder,"[167] (2) the mother focused energy on controlling her emotions and behaving so the nurse would approve, (3) the mother attempted to negotiate with the staff for access to her own infant, (4) health care providers were not empathetic about maternal worries, concerns, separation, and distress about their infant and need for frequent information,[167] and (5) there were breaches of confidentiality.

Modified from Hurst I. Mothers' strategies to meet their needs in the newborn intensive care nursery. *J Perinat Neonatal Nurs.* 2001;15(2):65; Hurst I. Vigilant watching over: mothers' actions to safeguard their premature babies in the newborn intensive care nursery. *J Perinat Neonatal Nurs.* 2001;15(3):39.

parent that includes basic information and illustrative pictures is extremely useful and should include a discussion of the type of care being provided, normal feelings and reactions parents experience, financial information, a glossary of terms, breastfeeding information, available accommodations and meals, calling and visitation policies, the discharge policy, and a city map. Both at the time of transfer and later in the nursery, a self-developing picture or picture from a digital camera can be taken of the infant for the parents. If the infant is being transported, information should be given as to the general length of time of transport and by whom and when the parents will be contacted after the infant has been admitted and evaluated. Use of video technology such as a webcam can be used to orient parents to the NICU and staff who will be caring for their baby before the baby is transported.[124,228] A personal phone call from the staff or secure video-conferencing can be used to involve the parents in the NICU admission with an introduction, information about the infant and unit, and an inquiry about parental visitation plans. Parents feel less anxious when they have an orientation and a name to whom to relate. The staff can then be prepared to be available when the parents arrive.

Certainly, the first visit to the NICU is overwhelming and stressful.[202] Members of the health care team should welcome the parents and stay with them to explain the equipment and procedures, answer questions, review the infant's course, give emotional support, and generally orient the parents to this new experience. Mothers who have not previously seen their baby report more stress in seeing their baby first in the NICU. Seeing the infant is stressful and may evoke shock, fear, guilt, and helplessness.[178] Be attentive to the mother's physical needs; comfortable chairs and perhaps a wheelchair if the mother has had a cesarean delivery are helpful. The message needs to be conveyed that parents are welcome, that their presence makes a difference, and that they will be partners in the care of their infant.[93,165] Because many parents are uncertain about what questions to ask, it may be necessary at times to help parents construct questions (e.g., "Do you understand why we start IVs in the head?" or "Do you know what blood gases, hood oxygen, and CPAP are?") and repeat explanations using simple, nontechnical language. Relating to the parent's affect or emotional state seems to establish a rapport with the family and helps them feel that the staff is empathetic and understanding. If parents sense the staff's genuine concern and interest in them and their infant, it is easier for them to leave their infant in the staff's care.[167,178,192,202,241] A team member might say, "You look frightened or scared" or "This can be an overwhelming situation" or "You look like you want to cry." Facilitating the parents' relationship with the infant* is essential and can be done by offering the parents the opportunity to touch or stroke their infant, hold the infant if possible, or at least remove eye patches. Pointing out some of the unique personal characteristics of the infant is helpful. A staff member might say, "Your baby is very active," or "He responds well to touch," or "She seems to prefer lying on her side."

Families coming from out of town should be provided with a list of inexpensive housing and restaurants located near the hospital. In many cities, national and local businesses have established nearby homes run by local volunteer organizations for housing parents on a temporary basis. The homes have several sleeping rooms in addition to kitchen and laundry facilities and provide parents with a comfortable, homelike atmosphere at a nominal charge. A natural support system generally emerges among the parents using the home. A list of apartments, hotels, and boarding rooms reasonably priced and rented by the day or week can also be made available. Social workers are often aware of community resources and support available and can secure food, parking, and cab vouchers to give to families to decrease some of the financial stressors.

Parents are usually concerned with the cost of their infant's hospitalization. Some parents feel that if they cannot pay, their child will receive less attention. Parents should be reassured that their infant's care will not depend on their ability to pay. However, they should be referred to the appropriate funding agencies, such as the Handicapped Children's Program or Health Care Programs for Children with Special Needs, Social Security Disability, Title 19 Medicaid, and state child health insurance programs that provide financial assistance.

Because communication is critical, regular conferences between the family and staff (physicians, nurses, and social workers) should be instituted to give consistent medical information and emotional support[73]; this is especially helpful with both extremely critical and long-term infants. Medical interpreters should be made available if parents do not speak English; the same principle applies for deaf parents. Parents should be given the names of the physicians and nurses taking care of their infant and the personnel's specific role in providing both care to the infant and communication to the family. If the physicians and nurses have a rotation system, this also should be explained from the beginning. At the end of a rotation, the transition can be facilitated by the oncoming physician's participation in even a brief conference with the outgoing physician, primary nurse, and parents.[96]

Primary nursing, especially for long-term infants, this can be very helpful in providing for continuity of care.[96] The primary nurse has been identified by parents as the primary source and facilitator of information to parents and between parents and other health care providers and as the link between the parents and infant. In a study of maternal values, mothers associated nurses with the human quality of the NICU, a wealth of knowledge about technology, and valuing the personal characteristics of the infants.[208] In the same study, mothers identified the most desirable attributes of care providers as (1) technical skill/competency, (2) caring about or "really liking" babies, (3) communication abilities, and (4) patience.[208]

*References 158, 167, 202, 242, 261.

Protection of patient privacy and confidentiality is an ethical and legal (state and federal) obligation. Compliance to protect patient privacy, secure private patient information, and protect patient confidentiality is mandatory (in the United States) under the Health Insurance Portability and Accountability Act (HIPAA96). Violations of patient privacy include (1) overheard conversations; (2) failure to identify a telephone caller; (3) failure to obtain written consent to communicate patient information by fax, e-mail, or any other written/electronic format; and (4) leaving patient charts open/accessible to others.[239] HIPAA violations may result in financial penalties ($100 to $250,000) and/or imprisonment. Parental access to the medical record is a legal right (HIPAA96) that cannot be denied by professionals or the hospital. However, institutions may have a specific policy to deal with parent requests for access to the medical record. Many institutions require the presence of a professional to answer questions and interpret medical language for parents as they read the chart. The principles of family-centered neonatal care advocate not only parental access to the complete medical record but also documentation by parents of their own observations in the medical record.[100] All of these activities must be in compliance with the HIPAA regulations.[238]

For out-of-town families, the telephone or secure video-conferencing plays a major role in staff-parent communication. The establishment of a telephone/video calling schedule with families and a toll-free number, if available, can be useful. If the family lives out of town and cannot visit frequently, the local or referring physician can supplement the communication. This physician often knows the family and can talk with them in person. The physician, of course, should communicate regularly with the nursery team to obtain the current medical information and present a consistent approach to the family.

Resumption of the Relationship With the Infant

The fifth psychological task entails the parents reestablishing a relationship with their infant and initiating their caregiving role. Certain medical events may signal to the parents that it is safe to risk a relationship with the infant. These events may be a regular weight gain, changes in feeding patterns or methods, elimination of life support equipment or use of an incubator, the infant crying for the first time or becoming more active and responsive, or the infant's transfer from the NICU to a level II nursery. The parents may begin to read baby books or pamphlets about their infant's condition, buy clothes, set up the baby's room, send out birth announcements, or name the baby. If the infant has a congenital defect, the parents may become involved with genetic counseling and other parents whose infants have similar deficits.

Ideally parents have been involved as partners and caretakers since their infant was admitted to the NICU. If not, parents must begin to shift their level of involvement and activity from that of passive participants to that of active primary caregivers.★ This shift includes the parents gaining confidence in their ability to care for their infant. The family who has been disrupted must reestablish themselves and recover from the crisis in an environment that is sensitive and supportive to this essential task.† The transfer of care from staff to parent is influenced by (1) the stability or lability of the infant's condition, (2) the physical health of the mother, (3) the level of parental support, and (4) staff expectations.[158,192]

Several formalized intervention programs have been developed and tested for efficacy in assisting parents of NICU infants in relating to and parenting these vulnerable infants. An early educational-behavioral intervention program for NICU parents (Creating Opportunities for Parent Empowerment [COPE]) was developed and tested in a randomized controlled trial with 260 families.[173,174] Mothers in the COPE program had significantly less stress in the NICU, more positive interactions with their infants, and less depression and anxiety at 2 months' corrected age compared with the control mothers. Other study outcomes included (1) stronger parental beliefs about their role, (2) parents who were more able to read their preterm infant's cues and behaviors, and (3) shorter length of both NICU and hospital stays (by 4 days and 8 days for VLBW preterm infants) compared with the control group.[174] Another randomized study of an early intervention program found that parents who participated had a reduction in parenting stress after birth of their preterm infant.[119] The March of Dimes initiative to encourage FCC (NICU Family

Support [NFS] Program) has been studied at eight NFS sites by interviewing parents, NICU staff, and administrators. Findings include (1) culture change within the NICU resulting in increased family support; (2) enhanced overall quality of NICU care; (3) less stressed, more informed, and confident parents; and (4) increased receptivity of staff to the concept of FCC and its benefits.[45]

Another formalized and researched intervention program is the Mother-Infant Transaction Program (MITP). Sixty-three mothers in Australia were randomized to intervention with the MITP or a control group.[189] Compared with the control group, mothers in the MITP intervention group were found to be more responsive to their infants, were less stressed at 3 months, and had better mutual interaction with their infants at 3 and 6 months.[189] Infants in the MITP intervention group were more attentive, were perceived by their mothers as "easier" with fewer regulatory problems (i.e., colic, sleep, crying), and had better communication skills.[189] A more recent randomized controlled trial of the MITP found a reduction in PPD and longer breastfeeding, but no alteration in maternal stress.[211] A Dutch randomized controlled trial of the Infant Behavioral Assessment and Intervention Program found that intervention mothers had higher feelings of social isolation, but they described their infants as happier and less distractible and hyperactive than control mothers.[172] Other interventions to relieve parental stress have recently been reviewed.[39]

Involvement in caregiving lessens the parents' feelings of helplessness and frustration and facilitates their identification with their role as parents.* Alteration in their parental role is particularly stressful for mothers in the NICU.[21,105,107] Maternal stress and anxiety about their parental role is associated with a longer length of stay in the NICU.[38] The sense of parenthood for both mothers and fathers depends on expectations of the parental role, the infant's state of health, and the environment and professional attitudes in the NICU.[111,158] A study by Jackson et al.[111] found that internalization of the parental role with a premature infant occurs over time and often involves initial feelings of alienation and responsibility that change to more confidence (at 3 to 6 months) and familiarity (at 18 months) with the parental role. For weeks after birth, both parents experience alienation: (1) mothers felt ambivalence about their relationship with the baby and their new role as a parent—a concern for the baby's welfare and a need to participate in and control the infant's care; and (2) fathers shared concern for the baby, felt unprepared for the birth, and were confident in delegating the baby's care to the NICU staff.[111] In this qualitative study, neither parent felt ready for the preterm infant's discharge to home. Taking on total responsibility for the baby's care resulted in both parents feeling insecure, fearful, and worried about the baby and the father taking on more responsibility for infant care. By 6 months of age, both parents had developed more confidence in the care and parenting of their preterm infant; by 18 months, parents had developed a feeling of relationship with their child.[111] For mothers of the smallest and sickest infants, concerns and worries about the infant remained, even at 6 months.[111] Beginning as early as possible in the NICU, health care providers should encourage and facilitate parent participation in their infant's care. † A study of parent participation in five NICUs in Sweden found that earlier gestational age of their infant was the most influential factor for parents in interaction with caregivers and nursing their baby.[199] Another study of fathers' experiences with their preterm babies in the NICU showed that the gestational age of the baby was a significant factor in paternal behavior.[243] This research found two types of paternal behavior: 1) "fathers-of-preterm-infants" who touched their baby as soon as possible, without fear and were struck by the baby's appearance and 2) "preterm fathers" who were reluctant to touch their baby for fear of harming the infant, were struck not only by appearance but also the technology surrounding their infant, and feared that their infant would die. All "fathers-of-preterm-infants" participated in care for their infant, and just over one-half of the "preterm fathers" participated.[243]

Parents can provide skin care for their infant, learn to read and respond to infant cues, help turn the infant even if a respirator is attached, diaper the infant, and possibly feed the infant. If the parents are separated by distance, they can send family pictures that can be posted at the infant's bed; periodic pictures of the infant taken by the staff can be sent back to the family. Parents can send clothing, mobiles, simple toys, and even recordings so that the infant can hear the parents' voices. Some mothers who are

*References 51, 105, 142, 158, 167, 173, 174, 187, 248.

†References 51, 107, 158, 167, 174, 191.

pumping send frozen breast milk (see Chapter 18). All of these reminders help the nursery staff be aware of the real family, who are genuinely interested. These personal attempts made by parents that help them feel they are important to their infant's development should be encouraged. Sometimes foster grandparents or volunteers can hold, feed, and talk to infants whose parents cannot visit frequently.

A prospective cohort study of parental presence and holding in the NICU found significant neurobehavioral benefits for the 81 preterm infants 30 weeks' gestational age or younger.[213] Early parenting (i.e., holding) in the NICU resulted in lower arousal and excitability, better quality of movement, less stress, and less hypertonic muscle tone and thus a developmental advantage.[213] Early sensitivity training for parents in the NICU is associated with improved white matter microstructural development in their preterm infants.[179] Kangaroo care (see Chapter 13), skin-to-skin contact between the mother/father and infant by placing the infant in a vertical position between the mother's/father's breasts, has positive maternal/paternal and neonatal responses. Use of kangaroo care activates the maternal processes of a search for meaning and adjustment to the experience of preterm birth, a recovery of self-esteem, maternal confidence, and enhancement in the parenting of a high-risk neonate.[71,107,128] Successive sessions of kangaroo care ease the pain and emotional suffering as mothers deal with loss and letting go and develop competence and confidence. Paternal attachment is also facilitated by fathers holding their infants and engaging in skin-to-skin contact.[154,158] A study by Sullivan[244] indicates that the earlier fathers hold their babies, the sooner they report feelings of love and warmth. The infant may become a reality to the father when he can hold his infant.[154,158,244] Fathers reported delaying attachment until they were certain of the infant's survival.[244] Paternal involvement with the infants is critical[162] and must be supported, encouraged, and facilitated by the NICU staff.[191]

The use of "graduate parents," parents who have had an infant in the NICU and who have successfully dealt with and resolved the crisis of the birth of their infant, can be extremely valuable.[100,107,158,202] They provide support to parents by sharing common feelings, reactions, and experiences about having a hospitalized infant. Graduate parents can provide support and practical assistance for mothers interested in breastfeeding, parents who take their infant home on oxygen, or parents whose infant requires special medical care such as a shunt, tracheostomy, colostomy, or gavage feedings. Organized graduate parent groups in large tertiary settings have become a very popular means of providing support,[92,107] but locating one parent or couple to talk with parents in a small community can be just as helpful. Parenting classes and Internet resources[107] also can be offered on a variety of topics such as breastfeeding, infant development, premature infant development, sibling and family reactions, discharge, cardiopulmonary resuscitation, coping with the hospitalization, and special medical needs. These classes provide specific, didactic information combined with group discussions that are mutually supportive. Social workers, nurses, and other related health care professionals (e.g., respiratory, occupational, and physical therapists) facilitate the group; graduate parents also participate as a resource.

A third type of support is counseling sessions. The purpose of these sessions is to discuss and deal with common issues among parents arising from the hospitalization of their infant and the effects on their marriage and family life. This type of session also has been helpful for parents whose infant has died. The sessions are usually short term and are conducted by the perinatal social worker and another staff member such as a physician, nurse, or chaplain. The focus of the group is not to give specific medical information but, rather, to provide parents with an opportunity to verbalize their feelings about their infant's hospitalization and receive emotional support.

Recently, telemedicine technologies have been used in the NICU to enhance medical, informational, and emotional support for families during and after hospitalization. Baby CareLink[88] is a telemedicine program that incorporates video-conferencing and Internet technologies to enhance interactions among families, NICU staff, and community health care providers. The link contains information for families about relevant issues during and after hospitalization. The video-conferencing module enables distance learning by the family in their home during the NICU stay and remote monitoring after discharge. A recent survey found that families using this technology were more satisfied with the unit's physical environment and visitation policy, possibly because of the ability to facilitate visitation via teleconferencing when

family members could not be present in the NICU.[88] An integrative review of studies of the use of various technologies (such as videophone, video-conferencing, Skype, FaceTime, HIPPA secure programs such as Polycom and Jagger by Cisco, AngelEye, and NICView Webcams) in the NICU found that both parents and professionals were positive about these forms of communication, but research is limited.[67] One study showed that mothers used the web camera to visit their infant in the NICU more than fathers used the camera.[214] Another study showed that nurses in the NICU spent significant time manipulating the web camera and addressing parental concerns over the phone, which disrupted their workflow and initiated concerns about the quality of care they could give to the infants.[118] Websites for parents of premature infants, children, and adults in the family are available so that parents can support each other, discuss common problems, and share solutions; caution should be used, however, when recommending the Internet (see the Resource Materials for Parents section at the end of this chapter).

Visiting in the Neonatal Intensive Care Unit

VISITING GUIDELINES

Besides their spouse or significant other, parents identify their families and friends as the main source of support through the crisis of having a sick neonate.[167,260] Prohibiting visiting by family and friends or limiting visitors to "two at a time" can isolate parents from a major source of support. NICU visiting policies should be used as guidelines, rather than rules, to facilitate visiting and caregiving by parents and families.★

Care providers should use good judgment and discretion about visitation while understanding and respecting the parents' need to be "in charge" of their infant (e.g., make decisions for their infant).†

Lack of perceived control by parents is associated with increased anxiety, hostility, depression, and poorer adjustment.[70,158,167] A sense of parental control in the NICU is enhanced by parental decision making.‡ Parents should designate their infant's "guest list"—that is, other family and friends who can visit and perform caregiving activities in their absence.[167]

NICU visiting policies vary within the United States[37] and among European countries. Two-thirds of surveyed nurseries "allow" parents to visit during medical rounds, whereas visiting during nurse report was more restricted.[37] When parental visits were restricted, confidentiality was cited as the determinant of the visiting policy.[37] In this same survey, 39% of parents "sometimes" or "often" complained about restricted visitation.[37]

FCC recognizes the family as the constant in the infant's life.[2] Liberal visitation policies are accepted as beneficial for patients and families. The American Academy of Pediatrics (AAP) Policy on Family-Centered Care and the Pediatrician's Role states that creating a 24-hour open- unit policy for families and making a commitment to information sharing are beneficial for families and staff.[7] Specifically, a 24-hour open unit has been shown to decrease length of stay, decrease use of the emergency department, improve parent satisfaction, and decrease parental anxiety.[7] A discrepancy exists between parental requests and visitation practices in many NICUs. Before changing to a 24-hour open-unit policy for parents, NICU nurses in one center had reservations and were skeptical.[256] After implementing the 24-hour visiting policy, most nurses were supportive of the change and reported perceived benefits for families. Parent satisfaction increased regarding time spent with their infant.[256] NICU staff should be open-minded and flexible in determining the policy on visitation during rounds, report, and emergencies.[7,90,100]

Many parents are interested in being included in medical rounds to actively participate in the care, discussion, and decision making about their infant.[7,90,100] A qualitative study of 18 NICU parents included in interdisciplinary teaching rounds in a tertiary children's hospital found that parents (1) had a positive experience and were "comfortable" being included, (2) preferred rounds in which nurses were included and lay terminology was used, and (3) welcomed the ability to communicate, understand the plan, and participate with the team in decision making about their infant's care.[141] Another study reported that family-centered rounds (FCRs) were associated with increased provider satisfaction and collaboration for neonatal nurse practitioners and fellows.[257] In addition, FCRs were associated with enhanced communication between providers and parents. Importantly, there were no negative aspects

★References 2, 90, 107, 158, 167, 181.
†References 70, 105, 158, 167, 202, 208.
‡References 70, 82, 158, 167, 202, 208.

to the introduction of FCRs.[257] If parents and the NICU staff agree to parental participation in rounds, patient confidentiality can be maintained by moving rounds away from the bedside, speaking quietly, and inviting parents to participate in only their infant's care planning/medical rounds[7,90,100] in this or a separate meeting. Another way to include parents in health care team rounds is to use video-conferencing so that parents who are unable to travel to the hospital can participate daily in care of their baby.[263] Their ability to ask questions and participate in care for their infant results in parental belonging, increases their satisfaction, and decreases their stress. Parents may be visitors to the hospital and NICU, but they are not "visitors" to their newborn; parents and family are the constants in the life of a child, whereas health care providers are only temporary "visitors" in the life of the child.[2,142,167,181]

Parents may be more comfortable in the NICU if they are accompanied by a family member or friend.[260] A study showed that black teenage mothers establish a relationship with their infant by visiting regularly and learning how to care for him or her.[178] The research states that when these young women bring a friend or family member with them to the NICU, they are more comfortable parenting and caregiving for their infants. Parental visiting patterns may be categorized by care providers as visiting "too much"[90] or "too little."[91] Financial constraints (e.g., transportation and childcare costs, loss of work time), chaotic social situations, or poor physical and mental maternal health may contribute to fewer visits.[107] Parents may fear that the infant will not survive, may feel helpless, or may not think their visits are important for their sick baby. Parents should be taught by example how important their presence and caregiving are to their baby's survival and recovery. In addition, parents need to be taught to interpret their infant's cues and behaviors (see Chapter 13). Maximizing every parental visit by scheduling care by parents* (e.g., bathing the baby, breastfeeding, providing kangaroo care, nipple feeding) communicates the importance of parental care and enables them "to be an expert on how to care for your baby by the time the baby is ready to go home."

SIBLING RELATIONSHIPS

The inclusion of other children in the events surrounding the birth of a sick newborn is important. From a sibling's viewpoint, the anticipated birth of a new infant is a stressful time of noticeable physical and psychological changes within the family. In preparation for the impending birth, the child is told that the mother will be going to the hospital for a few days and will return with a baby brother or sister. With the birth of a premature or ill infant, the mother may go to the hospital unexpectedly, stay a long time, and not return home with the anticipated playmate. Instead of a celebration of the expected happy event, parents are grieving the loss of the normal newborn and facing the current crisis of their sick infant.

Parents are often unsure about what to tell the other children and whether the children should see the infant. The siblings themselves may feel left out, rejected, or worried that they too may get sick. They may feel they are to blame and that their jealous feelings about their new rival may have caused this tragedy. Confused by their parents' distress, the other children may speculate that it is related to them and their "bad" behaviors. They may be disappointed and angry that they did not get the "playmate" they had wanted. Because parents are unsure about how to manage these issues, it is often helpful for the staff to introduce the topic. Most children's hospitals employ child life specialists who can consult with parents regarding siblings. Child life specialists have extensive knowledge of child development and expertise in talking with children, often using a child's own play in the process of providing support.

Because children will make up an explanation for the infant's illness, it is better to have it based on accurate information. Before explaining the infant's condition to siblings, elicit their ideas and perceptions about "what is the matter." Any fears, fantasies, misconceptions, or accurate information are thus used to begin the explanation of "where the baby is." Explanations must be tailored to the individual child's cognitive and developmental level. The child should be told that the infant is sick but in a way that is different from his or her illnesses, the infant's illness is not "catching," and it is not like any of the illnesses that the child has experienced. To allay the siblings' fears about medical personnel, they should also be told that the nurses and physicians are trying to help the infant "get better." Because children between 2 and 6 years of age are involved in magical thinking, they should be told that they are not to blame and that they did not cause the infant's

*References 70, 142, 167, 174, 208, 261.

problem. If the infant is premature, a team member might say to the child, "The baby came out too early or too soon; he needed more time to grow inside." If the infant has spina bifida, a staff member might say, "The baby's spine did not grow right, so he may have trouble lifting his legs or walking."

A child of 3 years of age or younger usually does not understand much about the coming infant. More important to this age group is the separation from parents who are frequently at the hospital. To ameliorate the separation, childcare arrangements should be structured so that the child is cared for by familiar people in a familiar environment. The best care arrangement is with a familiar person in the child's own home; second best would be with a familiar person in the caregiver's home; and third best would be with an unfamiliar person in the child's own home. The least favorable, of course, is an unfamiliar person in an unfamiliar setting. Many hospitals have a childcare facility run by volunteers or child life specialists that allows the child the opportunity to go to the hospital to "see where Mommy and Daddy are going" yet allows the parents the chance to see their infant without having to care for their older child or children. Parents may also choose to include the young child in all or selected visits.

Children 3 years of age and older have more interest in babies and a better grasp of the physical meaning of life. Sometimes a picture of the baby or a look into the nursery through the windows is helpful to the other children. Many children benefit from visits to the nursery to see their brother or sister. The natural curiosity of the child about "what is going on" in the family is answered when the child actually sees the baby. Behavior problems such as bedwetting, sleeping and eating difficulties, and difficult separations from parents may be prevented or reduced by the reassurance of a visit that decreases the sibling's worry about the baby.[1] Sibling visitation must be individualized for every family.

SIBLING VISITS

The decision to include siblings in the NICU depends to a great extent on the views, beliefs, and attitudes of the hospital staff. Generally, the staff's concerns about and resistance to sibling visitation focus on fear of an increase in nosocomial infection, disruption of unit routine and order, and potential harm to young children from exposure to the NICU environment. Infection control is the responsibility of parents and professionals. Parents must be educated about the dangers of infection and instructed on how to screen their children for symptoms such as fever, cough, or diarrhea. Professional staff must inquire about the health of visiting siblings, including their exposure to communicable diseases. Both parents and children must wash their hands before entering the nursery; small stools allowing children to reach the sink are helpful. Cover gowns are no longer used by parents, siblings, or professionals. With vigilance, no increased bacterial colonization and no increased incidence of infection occur with sibling visits.[240]

Because sibling visitation may be beneficial, each NICU must evaluate the center's situation and consider instituting a sibling visitation policy.[90] The following general principles may be used in developing this policy:

- Communication and coordination between staff and family are necessary to promote successful sibling visitation, including a review of unit policies and guidelines for parents.
- Children must be prepared, according to their age and development, for what they will see, hear, and feel in the NICU. Language should be simple and honest; pictures of the infant or other infants can be helpful. Dialog with parents before the visit regarding how long they believe the sibling visit should realistically be based on their age and development also can be helpful.
- Parents and staff screen the visiting sibling for signs of illness that would exclude the child from visiting.
- Parents and child must scrub their hands thoroughly.
- The initial visit should be held at a relatively quiet time in the nursery when a care provider can stay with the family. If the infant can be moved to a private room or family room area, this is preferable.
- The presence of a qualified child life specialist can be helpful to families for sibling visits.

At the bedside, the child is introduced to the infant and seated on a chair or stool at eye level with the infant. The care provider then again explains the equipment the child sees and any of the infant's "interesting" behaviors such as crying because of hunger, sucking on a pacifier, or eyes open "looking at you." Children may even be included in age-appropriate caregiving tasks. Choosing clothes, handling diapers and blankets, holding the bottle, and

touching and talking to the infant are all ways "to help." The child may bring a present to the infant such as a simple toy, music box, or handmade picture or photograph of the family. After a visit, both parents and staff should be available to talk about the visit or answer any questions. Some children, however, will not discuss the visit or ask questions until some later time. A method for enabling children to express their feelings in a nonverbal way is through play or books. A child who receives a book about physicians and hospitals or a "doctor" or "nurse" doll may "play out" feelings about the brother or sister and the hospital experience.

Creating a comfortable environment in which children feel free to ask questions is essential when siblings visit. Every question deserves an answer, even "I don't know," when appropriate. Children are often quite unrestrained in their remarks and questions. Comments such as "He's sure ugly!" or "Will he die?" or "Why is she tied up (restrained)?" are common. These may be embarrassing to parents who hesitate to make the same remarks or ask the same questions. If the infant is hospitalized for a long time, the other children may lose interest or even wish it were all over. This response may upset parents who themselves may be struggling with the same feelings. The longer the infant is hospitalized, the greater the pressure on time and financial resources. Family routines are disrupted by continuing hospitalization, and the disruption may strain family relationships.

Staff and parent response to sibling visitation has been positive in hospitals in which the policy has been implemented. Such a policy may facilitate family integrity and promotes mutual support during the stressful time of hospitalization. Another advantage of visitation is that the older siblings do not endure repeated separations caused by parental visits to the hospital but are included as important and special family members. The presence of siblings in a nursery can be a rewarding experience for family and staff alike and perhaps is the ideal example of providing safe yet comprehensive FCC.

Although a flexible sibling visitation policy is viewed as the best possible situation, some alternatives such as coloring books and children's books should be considered (see the Resource Materials for Parents section at the end of this chapter). Staff should be sensitive to the needs of the siblings and understand that the parents must deal with both time and financial constraints.

Psychosocial Conferences

Psychosocial conferences for staff members to discuss the dynamics of family functioning and the effect of a seriously ill newborn on the family can be quite useful. These conferences, usually led by perinatal social workers or other mental health professionals, can give staff the opportunity to identify current issues of concern by the family and optimal strategies to support the family moving forward. Another function is to enable staff to discuss and better understand their own feelings and reactions to families, infants, and the many stresses related to working in an NICU. A recent study about secondary traumatic stress in NICU nurses found an incidence of 49% with moderate to severe traumatic stress and 35% with symptoms of PTSD.[18] The qualitative part of this study found five themes related to the NICU nurses' descriptions of their traumatic experiences caring for sick babies and their families in the NICU (Box 29.9).

Disruptive behaviors such as intimidation, rudeness, incivility, and harassment are serious stressors in health care organizations. Recently two studies of rudeness toward NICU teams illustrate deleterious effects on the target, the team, and witnesses.[215,216] Rudeness from colleagues[215] and parents[216] both resulted in adverse effects on individual clinician performance and team performance. Individual clinicians exhibited less accuracy in diagnosis and more errors in orders and carrying out orders, resulting in poorer quality of care. NICU teamwork disruptions

BOX 29.9 THEMES USED BY NICU NURSES TO DESCRIBE THEIR TRAUMATIC EXPERIENCES

- NICU nurses' traumatic experiences intensified by: (1) multiple scenarios, (2) the longer the nurse cared for a baby, the greater the impact on the nurse at the baby's death and (3) being the primary nurse also impacted nurses harder when the baby had complications or died
- Parents insisting on aggressive treatment: so distressing
- Baby torture: performing painful procedures—hurting babies that nurses were trying to help was very distressing
- Questioning their skills: Did I do enough?
- The grief of the family is contagious

From: Beck CT, Cusson RM, Gable RK. Secondary traumatic stress in NICU nurses. *Adv Neonatal Care.* 2017;17(6):478.

included less information sharing and workload assistance among team members. The negative impact on teams and individuals may disrupt the ability of a team to compensate for poorer performance by an individual team member. The researchers opine that negative human interactions, regardless of their source, may be an underlying cause of iatrogenic incidents in health care systems. Cognitive bias modification (CBM), consisting of computerized training modules to alter a subject's threat-oriented biases by promoting a benign or more positive interpretation, was effective when used as a preventive rather than a treatment intervention.[216] Daily CBM was effective in shifting clinicians' attention away from perception of rudeness as a threat, thus enabling working NICU staff to preserve their cognitive resources—the critical thinking and psychomotor skills necessary to care for their patients. In the study, daily CBM "immunized" participating staff members for an entire shift.[216] Further research is necessary to determine if CBM attenuates the effects of rudeness over longer periods and to identify and test alternatives to CBM.[216]

Weekly rounds with the entire multidisciplinary team (physicians, nurses, nutritionists, lactation consultants, pharmacists, home health nurse coordinator, social workers, case managers, and financial counselors) are an effective vehicle to discuss and develop medical discharge and psychosocial care plans about each infant and family. Having an infant in the NICU has wide-reaching effects on the entire family system. Families arrive at the doors with their own unique stories and struggles that must be factored into the care and support provided to the family.

The involvement of perinatal social workers to assess and evaluate the psychosocial functioning of families, provide support and counseling services, and coordinate the discharge planning and follow-up care for the infant and family is essential. Social workers should complete a comprehensive assessment at admission for all families with an infant in the NICU. After assessment and discussion with the team, specific focus and interventions for high-risk cases can be identified (Box 29.10), as well as general support needs for all families. Providing support in complicated medical conditions, including the death of the infant, is also extremely important. Programs should be implemented for staff members to increase their competency and comfort level in identifying and intervening with psychosocial issues.[227]

BOX 29.10 HIGH-RISK FACTORS INDICATING NEED FOR SOCIAL WORK INTERVENTION

1. Teenage pregnancy (11–18 years of age)[25]
2. Single parent
3. Substance abuse[25]
4. Psychiatric history that interferes with appropriate functioning (including postpartum depression), especially as related to parenting abilities
5. Mother or father with a history of being physically or sexually abused or early deprivation by own family, or history of having abused or neglected own children
6. Intimate partner violence/domestic violence[168]
7. Mental disability, borderline intelligence, or significant physical handicaps
8. History of loss with previous pregnancy or loss of child because of stillbirth, birth defect, prematurity, abortion, custody case, or death
9. Rejection of or ambivalence about current pregnancy as manifested by requests for termination of pregnancy, attempted abortion, or relinquishment
10. No prenatal care with previous or current pregnancies
11. Pregnancy exacerbating extreme depression, anxiety, or suicidal thoughts
12. Stressful home or personal situation because of marital or financial problems or lack of support
13. Long-term hospitalization during pregnancy requiring intervention in helping family adjust by arranging for younger children at home or for financial assistance
14. Other children with physical or mental handicaps
15. Attachment difficulties with the infant
16. Prior history with social services
17. Inadequate housing and living arrangements and homelessness
18. Inadequate food and other essentials
19. Incarceration of mother/father
20. Military families
21. Undocumented immigrants

Intimate Partner Violence (Domestic Violence)

IPV is recognized as a serious risk factor for adverse pregnancy outcomes.[8,168,246] A study of IPV in first-time mothers participating in the Nurse Family Partnership found prevalence rates of (1) 8.1% in the year before pregnancy, (2) 4.7% during the current pregnancy, and (3) 12.4% in the year after the pregnancy.[229] A meta-analysis of 92 studies found prevalence rates of 28.4% for emotional abuse, 13.8% for physical abuse, and 8.0% for sexual

abuse.[112] Risk factors for abuse during pregnancy in this meta-analysis included abuse before pregnancy, low education level, unintended pregnancy, low socioeconomic status, and being unmarried.[112]

Injuries resulting from physical abuse increase the risks for low birth weight, preterm birth, intrauterine growth restriction, stillbirth, and neonatal complications.[3,61,104] Emotional abuse is associated with a 1.6-fold increase in preterm birth; the combination of physical and emotional abuse increases the preterm birth rate 4.7-fold.[225] Poorer maternal outcomes include antepartum hemorrhage, depression (2-fold to 3-fold increased risk for major postpartum depression; 1.5-fold to 2-fold increase for elevated depressive symptoms),[24] inadequate prenatal care, poor nutrition, poor weight gain, substance use, high maternal cortisol, hypertension, early cessation of breastfeeding, poorer parenting behavior, poorer mother-infant bonding, antenatal/postnatal depressive symptoms, and perinatal death.[3,127,259] Perinatal violence and stress also are significant risk factors for preterm birth in the teen population, with higher rates of IPV than for older mothers.[22] Pregnant women may be victims, perpetrators, or participants in reciprocal violence.[234] In one study, women participating in reciprocal violence had the highest levels of depression, used substances (alcohol, illicit drugs, and tobacco), and were not happy about their pregnancy.[234] This finding is consistent with numerous other studies showing depression before, during, and after delivery, a greater prevalence of substance abuse, alcohol misuse in partners, poor nutrition, lower rates of contraception use, and higher repeat pregnancy.[3,127,229]

Because IPV is so prevalent and has serious negative effects on the entire family system, protocols and procedures (that are compliant with the policies of the setting [i.e., hospital, outpatient clinic, emergency department] and the reporting laws of the state) should be in place. Legal definitions of IPV vary by state, but IPV is *illegal* in all states. The health care team needs to be educated to recognize the signs and behaviors that may indicate IPV (and child abuse).

Because abuse is so pervasive and too serious to remain unidentified, health care providers should routinely ask all women patients about IPV (although men also can be victims). The AAP and the American College of Obstetricians and Gynecologists have position statements and guidelines for routine screening for IPV in all women.[8,246] Battering beginning during pregnancy is a very common phenomenon. Use of standardized screening tools, an anonymous computer-assisted self-interview,[212] and recurrent screening results in higher identification rates (i.e., one study found higher disclosure after birth than during pregnancy).[123,197] For a discussion about the benefits and risks of routine screening, refer to the U.S. Preventive Services Task Force recommendation statement.[253]

Pregnancy offers a unique opportunity for health care professionals to intervene in IPV.[163,168,170,197] Once a potentially abusive situation has been identified, culturally and ethnically sensitive interventions should be initiated.[163] Interventions vary, depending on the disclosures made by the mother or father (or partner) and the needs identified. Recommendations for interventions include (1) educate the woman about community supports, (2) discuss options with the victim, (3) help identify a safety plan, (4) make appropriate referrals, (5) comply with state statutes about reporting responsibility, (6) document assessments and interventions, and (7) refer for treatment and aftercare (essential). Because of the complexity of issues generated by IPV, a multidisciplinary team approach is recommended.

Transfer Back to the Referring Hospital

Transfer of the infant from a tertiary center back to the referring or local community hospital for convalescent care and discharge is a frequent occurrence. This can help facilitate the relationship between the infant and parents, because the infant will be more accessible. Parents generally view the transfer as positive if the hospital is closer to home and if they feel comfortable with the level of care provided. Transfer is stressful, and there is always an adjustment period and difficulty coping any time a transfer occurs.[73] Parents must adapt to different personalities of medical personnel, different procedures, and different visiting policies. Preparing the parents for the transfer, orienting them to the new hospital, and talking to the staff of the referral hospital about the infant and the parents are important to help ease the transition.

Preparation to Take the Infant Home

The sixth psychological task for parents concerns preparation for taking the infant home. Parents must understand their infant's individual needs and

personality characteristics and must feel a sense of competency in relating to and caring for their infant. Discharge is an anxiety-provoking event and ushers in the "crisis" of homecoming, which parents must face and master.[58,107,111,158] The unsuccessful resolution of the previously discussed five psychological tasks can contribute to maladaptive parenting and a poor outcome for the infant, including the possibilities of attachment difficulties, overprotectiveness, failure to thrive, vulnerable child syndrome,[129] emotional deprivation, and battering.[129,171] To achieve a positive parent-child relationship after the hospitalization and through the transitional period that ensues, provision of appropriate follow-up support through the home adjustment period is crucial.[129,158] A recent study found that fathers of preterm infants experience more stress (i.e., higher cortisol levels) than mothers after discharge of their very preterm infants to home.[78]

Several behaviors demonstrate that parents are trying to understand the infant's care in preparation for discharge. First, parents may ask questions verbalizing a variety of concerns. For a premature infant, they might ask, "Do I need an apnea monitor at home?" or "Can the baby have visitors?" or "Do I have to wash my hands when handling the baby?" For an infant with a congenital anomaly such as spina bifida, the parents might ask, "Can I lay the baby on his back?" or "Can I bathe him?" or "Do I have to pump the shunt?" For an infant with a heart defect, the staff might be asked, "Do I need oxygen?" or "Do I have to handle him differently?" or "What about going to higher altitudes?" or "Is my baby at risk for sudden infant death syndrome (SIDS)?" All of these questions on the part of parents are typical and normal and represent the parents' working through their fears and anxieties.

On the other hand, parents who are highly anxious,[58] extremely overprotective, or very indifferent should be a concern to the health care personnel. The inability to deal with the task of taking the infant home may indicate some unresolved feelings related to the previous psychological tasks. Although most parents whose infants have been in an NICU do admit to initially treating their infant differently until they "got to know their child," a group of parents who are excessively overprotective does exist. This type of behavior often stems from parents who are struggling with intense feelings of guilt and failure. These parents either protect their baby from everything because they feel so responsible for having caused the infant's initial problem, or they demonstrate an indifference or lack of concern for the infant and the infant's welfare. Such parents may have an ambivalent attachment to their infant, who may continue to represent the threat of death or the parents' personal failure. This group of parents should be considered high risk for potential parent-child relationship difficulties and should be evaluated to determine an appropriate intervention.

At discharge, there are infants whose medical conditions are still fragile, and there is a substantial indication that these infants may not be normal and may have long-term problems. These infants may be temperamentally difficult to manage, and parents understandably treat them differently. These parents and infants need additional support and appropriate intervention (see Chapter 31).

The perinatal health care team can employ many interventions to assist parents with discharge and through the transitional period that follows (see Chapter 31). Parents' perceptions of the transitions from hospital to home center around three themes: (1) effective parent-to-staff communications, (2) feeling informed and involved, and (3) being prepared to go home.[11] In the hospital, adequate teaching of caregiving skills that enable the parent to develop a sense of mastery and competence is of paramount importance. Parent education regarding the care and needs of their baby is a learning process that begins at admission and continues throughout the inpatient stay. In addition to tasks of care, parents should participate in planning and providing developmentally appropriate care and be able to read and respond to their infant's cues (see Chapter 13). Maternal concerns about the infant's care center on elimination, feeding/weight gain, the infant's health (breathing, development, or ongoing medical problems),[107] and preparation of medications. If parents do not feel comfortable with their infant, their anxiety can cause adverse interactions with him or her. The parent needs to know the infant's mannerisms and behaviors; otherwise the parent may feel exhausted and resentful and then guilty. Teaching caregiving skills often can be facilitated in an environment that is less intense and crisis-oriented than the NICU. Whenever possible, an infant should be transferred to a setting that is more conducive to the parents' initiation of the primary caregiving role, such as a special care or transitional nursery, a level II unit, or a general pediatric ward. Care by parents before discharge enables

parents to assume full responsibility for their infant's care, tests the reality of caregiving, helps them learn caregiving activities and their infant's behavioral patterns, and confirms their readiness for independent parenting and the infant's readiness for discharge.[107,174,187]

Adequate discharge planning and follow-up arrangements should include general pediatric care; home health care; nurse home visitors; referral for early intervention services, if indicated; and parenting classes, especially for young or psychosocially high-risk parents. Numerous studies document positive effects of home visitation programs. Referrals to county social service departments should be made for single mothers who are eligible for Temporary Assistance to Needy Families; the Women, Infants, and Children (WIC) program; Title 19 Medicaid; and state child health insurance programs. For infants with special problems (e.g., spina bifida, cerebral palsy, Down syndrome), referrals should be made for special programs that provide early intervention services for the infants and support groups for parents. Parents whose infants have special medical needs (e.g., gavage feedings, tracheostomy or colostomy care, oxygen, or ventilators) should be evaluated by the medical and nursing teams to determine helpful community resources (e.g., equipment, supplies, respite, emergency care) and to make appropriate referrals. Home nursing care and homemaker services sometimes are covered by medical insurance and may be necessary to provide actual nursing activities and to relieve parents from the emotional burden inherent in caring for an infant with medical problems. For infants who are developmentally or physically challenged or at risk, participation in developmental intervention programs and other follow-up clinics provided by many hospitals that have NICUs are extremely valuable. These infants are eligible for Part C of the Individuals with Disabilities Education Act (IDEA). Locating babysitters who will care for a child with special problems can be an overwhelming task for parents; cultivating a resource list for parents and suggesting that parents exchange services with each other can also be helpful. Graduate parents, neonatal nurses, or respite care organizations can provide a useful service to parents in this situation. Last, parents should be referred to appropriate funding agencies (e.g., Health Care Programs for Children with Special Needs, Title 19 Medicaid, state child health insurance programs, Social Security Disability) that provide financial assistance.

30 GRIEF AND PERINATAL LOSS

SANDRA L. GARDNER AND BRIAN S. CARTER

As a life passage, pregnancy and birth are associated with hopes, expectations, joy, and happiness for the future. Although pregnancy and birth constitute a developmental crisis and a major life change, expectant parents reasonably believe the gains of a healthy, happy child and family life offset any setbacks. Unfortunately, not all perinatal events have a happy ending. Loss of a healthy infant in the perinatal period when premature delivery occurs also affects the parents' friends, family, and professional care providers.

Perinatal loss may be the first time a young adult has had to cope with the illness or death of a loved one. Perinatal loss is especially significant because (1) it is sudden and unexpected; (2) it is the most difficult loss to resolve[34]; (3) it interrupts the significant developmental stage of pregnancy and the situational crisis of pregnancy[34]; (4) it is the loss of a child who did not have the opportunity to live a full life[63,167]; (5) it prevents progression into the next developmental stage of parenting that has been anticipated and rehearsed (at least mentally) during pregnancy[119]; (6) it is fraught with ambiguity and disenfranchised grief[6,112]; and (7) it represents a narcissistic loss, a loss of self, for the parents.[159,188,189] Perinatal loss also often means interpersonal exclusion from the activities of childbearing friends and siblings.

Unfortunately, loss and grief often are thought of only in relation to death. However, as final and irreversible as death is, it is just one form of separation and loss. Although less obvious, other loss situations may have an equally crucial effect. Loss comes in many forms, and during the perinatal period, loss may occur without necessarily resulting in death. Circumstances of perinatal loss are parallel and, at the same time, different because they all entail grief and mourning, yet each has unique dimensions and characteristics. The process of grief, its stages, and its symptoms are reviewed next as a framework for understanding one's own feelings and those of others experiencing a loss. A desire to help and an idea of what is and is not helpful are essential for effective intervention by professionals.

THE GRIEF PROCESS

Grief, the characteristic reaction to the loss of a valued "object"—a person or thing—is not an intellectual and rational response.[65] Rather, it is personally experienced as the deep emotion of sadness and sorrow. To the individual, grief feels overwhelming, irrational, out of control, "crazy," and all-consuming. Mourning occurs in phases over time. After acknowledgment that the person no longer exists, gradual withdrawal of emotion and feeling occurs, so that eventual psychologic investment in a new relationship is possible.

A literature review of the theoretical perspectives of parental grief from the United States and the United Kingdom reveals a change from a traditional to a "newer" model of grief in the Anglo-American culture.[50] Traditional models of grief emphasize the severing of bonds with the deceased, whereas "newer" understandings of parental grief emphasize parents retaining a relationship with their dead child.[176,194] After reviewing nursing, medical, and social science publications and choosing relevant ones, Davies states: "the concept of continuous bonds challenges the dominant assumption that resolution of grief is achieved through severing bonds with the deceased."[50] Parents wish to know that their child's birth and death have meaning and

BLUE type highlights content that is particularly applicable to clinical settings.

purpose and that their child "mattered" and will be remembered by them and by others who have been "touched" and "changed" by the child.[35] After the death of a child, parents may develop approaches to "making meaning" from their loss in order to maintain a connection to the child, honor and keep the child's memory alive, and help others facing similar circumstances.[55] Parents in one study said that intergenerational acknowledgment of the ongoing relationship with the deceased child by grandparents was very important, especially during a subsequent pregnancy.[142,176]

For grief to occur, the individual must have valued the person who is lost so that the loss is perceived as significant and meaningful. Because, prenatally, there is an investment of love in the fetus or newborn, the neonate is a valued person. To the extent that prenatal attachment has occurred, grief should be expected and felt at the loss of the fetus or newborn. Therefore, loss at birth is a significant loss of a valued (although as yet only imagined) person.

Loss, whether real or imagined, actual or possible, is traumatic. The individual is no longer confident in him- or herself or in his or her surroundings because both have been altered. Mourning and grief are forms of separation reactions. Fear of separation and abandonment is a universal aspect of childhood regardless of age or developmental stage. Perhaps the loss of a significant other awakens these childhood fears and reminds us of the basic "insecurity of all our attachments."[125]

Life changes are stressful for the individual because they threaten to disrupt continuity and a state of equilibrium.[150] Significant changes in the family configuration, such as the accession of a new member, are normally a stressful occasion for family members. Perinatal complication or loss is an even more stressful event for which the family has little or no preparation. The result of this type of crisis may be personal growth, maintaining the status quo, regression, or mental illness.[34,151] Often, the outcome depends on a combination of coping skills and the type of help received during the crisis.[49]

Decreasing the element of surprise through preparation for the situation to be encountered may modulate the effect of the event. Anticipatory grief[116,166] functions to both prepare and protect the individual from the pain of impending loss. Prenatal diagnostic procedures, such as ultrasonography,[80] amniocentesis, and fetoscopy, can detect a variety of severe or lethal birth defects. When there is forewarning that the pregnancy/fetus or the newborn is not healthy, parents may begin a process of and psychologically prepare for the loss of their baby while at the same time hoping for the child's survival.[15,16,185,204]

Parental withdrawal from the relationship established during pregnancy may accompany the intense emotions of anticipatory grief. Detachment protects and defends the parent from further painful feelings associated with the investment of self in a doomed relationship. If anticipatory grief proceeds, the parent may detach to the point of being unable to reattach to the infant if he or she survives. In this situation, the infant survives, but the relationship with the parents may be significantly impaired. Maintaining even a remote hope that the fetus or newborn will survive protects the parents from the full experience of grief and total detachment from the baby. Accordingly, antenatal counseling suggesting "the baby will not survive delivery" or "will live only a few minutes" may be detrimental to adjusting to a fairly fluid situation at the time of birth (i.e., a lengthier survival for which some attachment could be anticipated as valuable).

The degree of parental anticipatory grief is correlated with positive feelings about the pregnancy and the mode of delivery but generally not with the severity of the infant's illness. The greater the parental investment and the higher the expectations for the pregnancy, the more anticipatory grief can be expected should perinatal complication ensue. The relative severity of the medical problem itself, however, is not associated with the degree of anticipatory grief.

PERINATAL SITUATIONS IN WHICH GRIEF IS EXPECTED

Loss is a fact of life, not just of death. Every stage of development requires a loss of the privileges of the preceding stage and movement into the unknown of the next stage. Any life event involving change or loss is accompanied by grief work, including moving, divorce, separation, death of a spouse or family member, injury or illness, retirement, job change, menopause, and even success.[150] The concept of loss is even applicable to the physiologic and psychologic events of normal pregnancy and birth. Certainly, when pregnancy fails to produce a live, healthy infant, a perinatal loss situation exists

BOX 30.1 PERINATAL SITUATIONS IN WHICH GRIEF REACTION IS EXPECTED

1. Pregnancy
2. Birth
   A. Normal
   B. Cesarean delivery
   C. Forceps
   D. Episiotomy
   E. Medicated
   F. Prolonged or short labor

   E. Selective reduction (for multiple gestation)
5. Stillbirth
6. Loss of the perfect child
   A. Premature
   B. Baby with an anomaly
   C. Sick newborn
   D. "Wrong" sex
7. Neonatal death
8. Relinquishment

(Box 30.1). These perinatal losses, including stillbirth, loss of the perfect child, and neonatal death, are discussed in detail in this chapter.

Stillbirth

Stillbirth is the demise of a viable fetus that occurs after fetal movement when the parents have often thought of the fetus as having personality and individuality. For parents, a stillbirth is a life-changing event that may result in psychologic, social, and physical costs and affect interpersonal relationships and subsequently born children.[30,105] From the crisis of a stillbirth, parents may also develop resilience, new life skills, and new capacities. Because stillbirth occurs later in pregnancy than most pregnancy terminations, there are increased parental expectations about the baby and the birth process. Selective pregnancy termination for genetic indications is often performed in the second trimester of pregnancy and involves the death of a wanted child. Although parents understand the validity of the reason for terminating the pregnancy, sadness, guilt, social isolation, and self-blame often accompany the decision to terminate.[122] The anxieties related to termination procedures, which may include labor and birth, and the feelings of helplessness, isolation, and depression should be acknowledged and handled as in a stillbirth.

Fetal demise in utero happens either prenatally or in the intrapartum period. For 50% of stillbirths, death is sudden, is without warning, and results from unexplainable causes. The majority of women who experience the death of a fetus in utero spontaneously begin labor within 2 weeks of fetal demise. Carrying the dead fetus while waiting for spontaneous labor or induction is sad and difficult for the woman and her entire family. Feelings such as helplessness, disbelief, guilt, and powerlessness characterize this period. There often is an almost uncontrollable urge to flee and escape the unpleasant situation.

For the family that experiences intrapartum demise, the joyous expectations of labor and birth suddenly change to fear, anxiety, and dread that the "worst" could have possibly happened to them. The suddenness of fetal demise in labor and birth affects both parents and professionals with feelings of shock, denial, and anxiety. Whether the fetal loss is early or late, the woman and her family maintain hope by believing that the professional has made a mistake and that the fetus is still alive.[164] The onset (or continuation) of labor is approached with both hope and dread: hope that the infant may be born alive and dread that the infant's death will soon be a stark reality.

The discomfort of labor and birth is particularly difficult for the woman whose fetus has died because her work will not be rewarded with a healthy infant. However, overly solicitous use of drugs at birth is not recommended because they relegate the experience to unreality and give it a dreamlike quality.[203] Keeping parents together through this crisis is important for mutual support and sharing of the birth.[163] The deafening silence of a stillbirth forces the reality of the infant's death on both the parents and the professionals present at birth.[163] A recent study of communication and staff

presence at stillbirth deliveries found that bereaved mothers were less likely to have family members and hospital staff present at delivery and that African American mothers were half as likely to have heard about their stillbirth from a midwife or physician.[76.]

In the past, at the birth of a stillborn, the mother was heavily sedated or anesthetized, and the neonate was hidden and whisked away immediately. These women were often left with fears and fantasies: "Was the baby normal?" "What was the baby's sex?" "What did the baby look like?" Seeing, touching, and holding the infant, when culturally appropriate, can promote completion of the attachment cycle, confirm the reality of the stillbirth for both parents, and enable grief to begin.[21,164,203]

Because it can be easier to grieve the reality of a situation than a mystical and dreamlike fantasy, contact with the stillborn enables parents to grieve the infant's reality rather than endure their most frightening fantasies about the baby.

After confirming the reality of the infant's death, a search for the cause, characterized by the universal question "Why did the baby die?" begins. Either or both parents may blame themselves or feel guilty about real or imagined acts of omission or commission. An autopsy may determine the cause of death, but most often the cause is unknown, even after an autopsy. However, an autopsy may be useful in reducing parental guilt and uncertainty about future pregnancies, as well as in aiding the recovery from the loss.[43,130, 203] The "empty tragedy" of stillbirth forces the mother to deal with both the inner loss of the fetus and the outer loss of the expected newborn. Fathers who experience stillbirth as a "waste of life" are especially appreciative of the tokens of remembrance from the baby and need help in expressing their grief.[163]

Loss of the Perfect Child

Although pregnancy ends in the birth of a live newborn, the pregnancy outcome may not be what the parents had anticipated. The birth of an infant who does not meet parental expectations represents the realization of the parents' worst fears: a damaged child. Newborns who are preterm, have an anomaly, are sick, or those with the "wrong" gender or who ultimately die represent the loss of the imagined or hoped-for perfect child.

After the birth of such an infant, parental reactions include grief and mourning for the loss of the loved object (the perfect child) while adapting to the reality and investing love in the baby with an anomaly.[69,71,175] This reaction is analogous to parental mourning at the death of a child.[175] However, unlike the finality of death, the birth of a living baby with an obvious anomaly entails a persistent, constant reminder of the feelings of loss and grief because of parental investment of time, attention, and care for either a short time (preterm or sick newborn) or a lifetime (physically or mentally impaired child).[153,175]

The psychic work involved in coping with the reality of the imperfect child and the inner feelings of loss is slow and emotionally painful.[67,153] The process is gradual and proceeds at an individual pace that cannot be hurried but can be facilitated and supported. Detachment from and mourning the loss of their fantasized child are necessary before parents are able to attach to the actual child.

The birth of an imperfect infant represents multiple losses for parents. A primary narcissistic injury, a threat to the woman's self-concept as a woman and mother, and a threat to the father's self-concept as a man and a father all occur when a less-than-perfect infant is born.[47,48,67,108] Because the child is an extension of both parents, a less-than-perfect (i.e., deformed) child is equated with the perceived less-than-perfect part of the parental self. In the mind of the parent, the imagined inadequate self has failed and caused the birth of the damaged baby.[108]

Prematurity

Every woman expects to deliver a normal, healthy infant at term. Therefore, the onset of premature labor is both physiologically and psychologically unexpected. Premature birth is a crisis and an emergency situation characterized by an increased concern for the survival of the newborn and often the mother. Premature labor and birth are accompanied by feelings of helplessness, isolation, failure, guilt, emptiness, and lack of control.[108,175] The negative and dangerous atmosphere surrounding the premature birth experience may influence the relationship with the premature infant, who also may be perceived as dangerous and negative.

Normal adaptations to pregnancy are abruptly terminated by the birth of a premature infant.[108] Prenatal fantasies about the infant and the new roles of mother and father are interrupted by a premature birth. This forces parents who are "not ready to not

be pregnant" to grieve the loss of a term infant and imposes premature parenting on individuals not yet ready for the experience.

As discussed in Chapter 29, anticipatory grief is one of the normal psychologic tasks accompanying premature birth. Anticipatory grief may be decreased by early contact between parents and neonate and, conversely, increased by separation of parents from preterm newborn.[108] Prolonging anticipatory grief with failure to progress through the other tasks results in altered relationships with the parents if the preterm infant survives.

Infants With a Birth Anomaly or Syndrome

In approximately 2 of every 100 births,[108] an infant is born with a congenital anomaly. Because society values physical beauty, intelligence, and success, the birth of a physically or mentally impaired baby is seen as a catastrophe in our culture.[200]

Antenatal use of ultrasound now makes it possible to identify potential fetal problems in utero. As parents receive the information antenatally, they begin the process of anticipatory grief.[16] They experience feelings of shock, anger, guilt, and hope. At the birth of the baby, there usually is the confirmation of the anomaly, and parents must deal with the reality of the situation. Whether anticipated or not, however, the birth of a baby with a congenital anomaly is accompanied by ambivalent feelings for all concerned (parents, relatives, friends, and professionals). The first reactions to the reality of the situation are feelings of disbelief and shock. Feelings of shame, revulsion, and embarrassment at creating a seemingly damaged and potentially devalued child are common.[171] Guilt, self-blame, and a search for a cause or reasons for the tragedy are intermixed with feelings of anger.

The severity of loss and feelings of disappointment heavily burden the parents, a burden they may believe that no one else has experienced.[108] Their loneliness and isolation may be intensified by their self-imposed withdrawal from others. Unlike the birth of a healthy infant, the birth of a sick baby or one with an anomaly is not celebrated with announcements, visits, and gifts from friends and family. The negative responses of society's representatives (family, friends, acquaintances, and professionals) may increase the parents' negative feelings for an impaired child.[200]

The extent of the infant's anomaly cannot be used as a criterion for the degree of parental grief reaction, although a gross, visible anomaly may elicit more emotional reaction than a hidden or minor one.[108] A seemingly "minor" anomaly as defined by a health care professional may represent a severe impairment to individual parents. The professional, who has had more contact with infants with a wide range of anomalies, views the individual infant's anomaly in a different context than that typical for the parents, who may have limited or no experience with such an affected child or adult. The professional also views the infant's anomaly from a less personal, more objective, and less narcissistic position than the new parents.

When the newborn is sick, the degree of mourning and parental feelings of grief and loss are not equated with the severity of the neonate's illness.[15,173] Even seemingly minor illnesses such as jaundice or respiratory difficulty requiring phototherapy or minimal oxygen supplementation are associated with parental concern for survival and feelings of grief and loss.[140] These feelings often are not acknowledged by the parents or professional care providers because of the nonserious medical nature of the condition. In the mind of the care provider, self-limiting and treatable conditions are compared with more serious and often fatal neonatal illnesses. The care provider feels relieved about the minor nature of the neonate's condition and conveys this to the parents: "This is an easy condition to remedy. You don't have anything to worry about. The baby will go home in a few days."

Thus, only the medical aspects of the newborn's illness are dealt with, whereas parental feelings remain unspoken and unresolved.[31] In an altruistic attempt to reassure and comfort the family about the newborn's complete recovery, the professional unwittingly may discount the parents' real feelings. If the care provider is not concerned, parents may feel that they, too, should not be concerned and thus distrust and discount their own feelings.

Neonatal Deaths

The reactions accompanying neonatal illnesses are similar to the grief reactions experienced by parents whose infant dies.[15,49] Failure to acknowledge (even minor) neonatal illness as a loss situation and to work through the associated grief can prevent parents from detaching from the image of the perfect

child and taking on the sick newborn as a person to love. This may result in an aberrant parent–infant attachment. The liveborn infant who is critically ill or has a severe anomaly will be the focus of a "painful time of waiting"[15] for the family. They must deal with the uncertainty of whether their child will live and be healthy, live and continue to need extensive medical or special care, or die.

More deaths occur in the first 24 hours after birth than in any other period of life. Yet the death of a newborn is not the expected outcome of pregnancy. The majority of neonatal losses are caused by congenital anomalies incompatible with life (20%) and prematurity (17%).[86] Regardless of the cause of death, even infants who live only a short time are mourned by their parents.[101] Prenatal attachment and investment of love in the newborn result in a classic grief reaction at the newborn's death.

Even a short period of life between birth and death gives parents an opportunity to know and take care of their infant. Completion of the attachment process enables parents to psychically begin the next process of detachment. Attachment to the baby's reality encourages detachment from that reality rather than from the parents' most dreaded fears and fantasies about their infant. Parental contact with the child before death enables them to share life for a brief time.

In the case of multiple births, when one or more infants die and the others live, parents simultaneously grieve the loss of the deceased infant or infants while attaching to the survivors.[114,145,146,187] In many situations of multiple births, the surviving infant or infants are in an intensive care nursery. The contradictory feelings of love and attachment and grief and detachment, as well as the anxiety associated with the care and well-being of the surviving infant, are emotionally draining for new parents. The process of grief may slow the parents' ability to become intimately involved with their surviving infant(s).[146,147,187,195] They may have ambivalent feelings toward the infant(s) who survives or toward the infant(s) who dies. With the loss of one infant of a multiple birth, there is less support for the grieving parents because the frequent response is that they should be thankful for the survival of one (or more) of their infants. Research shows that the death of a twin (or higher-order multiple) is as great a loss for a mother as the death of a singleton.[59,145,146,181] Helpful interventions include (1) acknowledging the uniqueness of every baby; (2) viewing, holding, and photographing the babies together—living and dead; (3) allowing for private time with each deceased infant; (4) giving similar mementos and keepsakes from each infant, deceased and living, to the parents; and (5) providing reassurance about the health of their surviving child.[145-147,187] One study found that farewell rituals do not influence the intensity of perinatal grief.[60]

Generally, the death of a newborn occurs despite everything done to prevent it. This provides parents with some measure of comfort in knowing that they did everything possible. Yet when the neonate is so severely ill or deformed that a decision about initiating or continuing life support is necessary, the parents have an extra burden. The situation may involve conflicts between physicians, nurses, and family wishes, causing significant personal anguish. Professionals who convey information sensitively, compassionately, and honestly facilitate care transitions toward comfort/palliative care. Such a situation is tenderly conveyed in the article entitled "Four Wishes for Aubrey."[36] Aubrey's parents are asked what they would like to do with their little boy to make lasting memories. Without hesitation, Aubrey's mother states the following wishes for her 5-month-old terminally ill son:

1. Allowance of more than three visitors in his room at one time
2. The ability to hold Aubrey to her chest and lie down with him; the mother wanted a bed large enough (in his private room) for her and her son to lie down together (Fig. 30.1).
3. The ability to take Aubrey outside so that he can feel the sun and a breeze

All of Aubrey's mother's wishes were made possible by caring, compassionate professionals who actually suggested and accommodated the fourth wish: arranging for special photography of the family with Aubrey, such as *Now I Lay Me Down to Sleep*.[139] Aubrey's family has participated in local and national education for health care providers learning about palliative care and in numerous teaching forums with other parents.[36] The authors enumerate the lessons learned from and with this family: (1) the importance of asking each individual family what is important to them; (2) the caution to never presume that we know what any family needs or wishes; and (3) the cruelty of presuming and minimizing every family's uniqueness, power, and right to their own experience.[36] The article ends with the lesson that fulfilling the family's wishes was profoundly moving

FIGURE 30.1 **Aubrey and his mother.** (From Carter BS, Brown JB, Brown S, Meyer EC. Four wishes for Aubrey. *J Perinatol.* 32[1]:10–14, 2012.)

and gratifying for the health care providers who were creative, engaged, and caring for Aubrey and his family.

As a consequence of the federal Baby Doe regulations, most hospitals now have ethics committees that address a variety of the medical, legal, and ethical controversies (see Chapter 32). The decision-making process may be collaborative, parent initiated, directive, or nondirective.[145] Regardless of who makes this decision, it is primarily the parents who will live with its ramifications, including feelings of grief, an ongoing void in their lives, and a desire to live better lives to honor their infant.[9] When parents are involved in the decision-making process, they wonder if theirs was the right decision regardless of what it was. Whether the baby lives or dies, they wonder how a different decision would have changed their lives.

STAGES OF GRIEF

The experience of grief is a staged process that occurs over time. To detach both externally and internally from the lost loved object, emotional investment is withdrawn so that it may be invested in new love relationships.[116] Each stage of grief represents a psychologic defense mechanism used to help the individual adapt slowly to the crisis. This slow adaptation is purposeful because it prevents the individual psyche from being overwhelmed by the pain and anguish of loss.[144]

Although each stage of grief is recognizable, the process of grief is dynamic and fluid rather than static and rigid. Parents, families, and professionals progress cyclically through the stages of grief rather than in an orderly progression from beginning to end. However, each person experiences the process of grief uniquely and at an individual pace. Knowledge of each stage is necessary to assess where an individual family member, the family as a unit, and the staff are in their grieving process. This information is then used to support individuals when they are in their particular stage of grief. Rather than attempting to maneuver grieving individuals from stage to stage, contributing to their defense, or stripping individuals of their defenses, knowledgeable professionals are prepared to understand and honor the individual's grieving process. Regardless of the type of perinatal loss, the experience of that loss through staged grief work closely parallels the grief stages described by Elisabeth Kübler-Ross.[110]

The feelings of disbelief and rejection of the news are reflected in the responses "No! This couldn't happen to me!" and "It isn't true! They've made a mistake!" This immediate response protects the individual from the shocking reality of loss by postponing the full effect of reality until the psyche can handle it.[164] By holding on to the fantasy of a positive outcome (e.g., the loss of the heartbeat is only temporary, or the dead infant belongs to someone else), facing the awful truth and the grief associated with it is delayed, at least temporarily.[164]

The initial stage of grief is characterized by overwhelming feelings of being stunned and surprised. This often is seen as emotional numbness, flat affect, or immobility.[203] Emotional detachment often is expressed as an inability to cope or respond with activities of daily living, an inability to remember what others have said, and a tendency to repeat the same question.[56,63] For the tragedy to be handled in manageable pieces without overwhelming the individual, the mind may acknowledge the event only intellectually, and there is a corresponding lack of emotional reaction,[203] or the event may be compartmentalized so that only a part of the situation rather than the whole becomes the focal point of attention.

Anger is the result of a gradually developing awareness of the situation's reality. As the significance of their perinatal loss begins to dawn on them, parents (and significant others) experience the diffuse emotions of anxiety and anger.[108] With the

full effect of their loss comes more focused feelings of bitterness, resentment, blame, rage, and envy of those with normal pregnancy outcomes.[110]

Social prohibitions against the expression of anger, especially for women, encourage this powerful emotion to be turned inward toward the self. Anger directed inward results in depression and a deepening sense of guilt. "Why?" and "What did I do wrong or not do right to have caused this to happen?" are the hallmarks of the self-examination and self-blame that accompany perinatal loss.[108,203] Answers often are irrational and have no cause-and-effect relationship with the reality of the circumstances. Irrational, feared causes include sexual intercourse (common worry of both men and women), career (of the mother) outside the home, superstitions, dietary habits, or lifting heavy objects.[203] Ideas of punishment (for past wrongs, for negative or ambivalent feelings, or for an unwanted pregnancy)[17] often are thought to be the reason for the failed outcome. The search for a reason to answer the question "Why me?" requires correct information to dispel unrealistic fantasies of causation. However, the question does not require a literal answer (often no concrete answer exists) but is merely a wish for a change in the situation.[17]

Anger directed outward is usually expressed as overt hostility to those in the immediate environment (family, children, care providers, and infant)[203] or toward God.[144] Fathers exhibit more anger than mothers.[77] Blame and anger may be destructive forces in the relationships among family members and may prevent these relationships from being a source of comfort and support. Venting of angry feelings toward professional care providers protects these family relationships for more positive interactions. Anger moves the grieving process along, but the persistence of anger may prevent grief work from progressing to subsequent stages.

Bargaining may occur concomitantly with denial and shock as an attempt to prevent or at least delay the loss. Bargaining usually occurs with whoever the parents (family or staff) believe the Supreme Being is. The "Yes, but" of this stage is a form of "conditional acceptance" while still attempting to make the reality other than what it is.[17,110] With an infant who has a congenital anomaly, bargaining may take the form of shopping for a physician or searching for the magic cure.[200]

The onset of depression and withdrawal marks the stage of a greater level of acceptance of the tragedy. With the true realization of the effect of the loss, the individual acknowledges that indeed there is a reason to be sad. The predominant feelings of this stage are overwhelming sorrow and sadness,[130] evidenced by tearfulness, crying, and weeping.[164] Feelings of helplessness, worthlessness, and powerlessness contribute to the sense that life is empty and futile. Withdrawal may be evidenced by requests to be left alone, by decreased or complete cessation of visits to the infant, and by silence.[110] The degree of withdrawal may be indicative of the depth of depression and the extent to which there is guilt and self-blame.[164]

Acceptance is the resolution stage of the grief process that is heralded by the resumption of usual daily activities and a noticeable decrease in preoccupation with the image of the lost infant.[116] This stage usually is not witnessed by perinatal professionals. The acceptance stage is characterized by emotional detachment of life's meaning from the lost relationship and reestablishing it independent of the lost object.[110,125] The lost relationship is seen in a new light—as giving meaning to the present.[125] The aggrieved person relinquishes that part of him- or herself that was defined in the lost relationship and establishes a new identity that is emotionally free to attach in another relationship.

For the family of a child with a congenital anomaly or disability, acceptance is not an all-or-nothing proposition but, rather, a daily adaptation and coping with the child and the effects of the anomaly or disability.[169] For the family, periods of frustration and sorrow alternate with periods of delight and enjoyment of the child. Because of the chronic sorrow experienced throughout the life of a child with an anomaly, the final stage of resolution of the family's grief is possible only after the child's death.[141,200]

The acceptance stage represents the ability to remember both the joys and sorrows of the lost relationship without undue discomfort.[65] With gradual integration of the loss, there are progressively fewer attacks of acute, all-consuming pain.[125] When recalling the lost infant, there are fewer feelings of devastation and more feelings of sadness. The ability to "celebrate the loss" also identifies grief resolution. Celebration of the loss does not mean recall without sadness and sorrow but with an ability to find some meaning, some good, and some positive aspects in the situation (e.g., "At least we had our child for a time, even though it was a short time").

SYMPTOMS OF GRIEF

Although each person copes with grief in individual ways, there are expected reactions to loss situations. Knowledge of the differences and commonalities of the grief experience enables care providers to understand their own reactions, as well as to share their thoughts and feelings with the grieving family. The professional care provider must learn to "hear" what the family says about how and where each member is in the process of grief resolution. Often the "message" is not a direct reference to the loss or one's feelings but, rather, nonverbal communication. The professional must learn to recognize that individuals often communicate more by what they do and what they omit than by what they say.

The signs and symptoms of acute grief have been well described and include both somatic and behavioral manifestations of the emotional experience of the loss (Box 30.2).[143] The behavior of the bereaved is characterized as ambivalent.[125] In certain perinatal situations, parents simultaneously hope that the infant will live and wish for the infant to die; they want to love and care for the infant and at the same time wish to reject him or her.[108] These feelings are frightening and socially unacceptable and therefore often remain unspoken.

Often the intensity of grief is greater when the relationship with and feelings about the lost person are ambivalent.[104,125] Even with the most positive of pregnancy outcomes, taking a newborn into the family results in ambivalent feelings for all family members. The degree of disruption that a perinatal loss brings to the family is equated with the severity of grief, especially because reproduction and a healthy perinatal outcome are highly valued in our society.[125]

MALE–FEMALE DIFFERENCES

Although members of both genders have the same grief reactions, women express more symptoms (crying, sadness, anger, guilt, and use of medications)[61,127,156] than men. This difference in symptomatology does not represent a different experience of grief but merely a different expression of it. Understanding these differences and the reasons for them is crucial for care providers working with parents at the time of perinatal loss. Explaining these differences to parents is also crucial so that diverse grief responses do not become divisive in the relationship.[61,156,176]

The father's degree of investment in the pregnancy, impending parenthood, and the circumstances of birth all affect his feelings of loss. Because the father's body does not directly experience the changes of pregnancy, the pregnancy initially may be less of a reality to him than to the pregnant woman. This lag in the physiologic reality contributes to a lag in the psychologic investment of the father in the baby. The father's lag in psychologic investment often contributes to incongruent grieving, a difference in mother's and father's grief reactions. Fathers often comment that the infant became real when he felt the fetus move in the mother or at the first sight of the new infant. Fathers who form an early attachment to the child feel sadness, disappointment, and often anger at being denied the expected son or daughter.[77,99,127,128,163] Conversely, fathers who have been normally ambivalent or overtly negative about the pregnancy may feel guilt and responsibility for the failed outcome.

Participation of the father in the events of labor and birth also influences his attachment and, ultimately, his feelings of loss. Exclusion decreases his involvement in these life-crisis events, whereas inclusion has many advantages for the mother, infant, and self (see Chapter 29). If the infant is ill, the father may initially have more and closer contact than the mother.[15] In the birth place, the father may see, touch, or hold the infant before the mother does. The father observes the initial resuscitation and stabilization and may accompany the infant to the nursery and on transport to a regional center. Often the father receives the first information and support about the infant's condition and returns to the hospitalized mother with the news. This early, prolonged contact coupled with the father's increased responsibility often contributes to the development of a closer and earlier bond between father and infant than between mother and infant. The initial lag in prenatal investment may be offset after birth by concentrated contact between the father and the baby, thus making the loss highly significant to the father.

Societal expectations about masculinity and femininity markedly influence the expression of grief. Society's message to men starts early in life: "Big boys don't cry" and "Don't cry, you'll be a sissy" (i.e., girl). The preferred male image

BOX 30.2 CRITICAL FINDINGS
Signs and Symptoms of Grief

1. Somatic (physiologic)
   a. Gastrointestinal system
      Anorexia and weight loss
      Overeating
      Nausea or vomiting
      Abdominal pains or feelings of emptiness
      Diarrhea or constipation
   b. Respiratory system
      Sighing respirations
      Choking or coughing
      Shortness of breath
      Hyperventilation
   c. Cardiovascular system
      Cardiac palpitations or "fluttering" in chest
      "Heavy" feeling in chest
   d. Neuromuscular system
      Headaches
      Vertigo
      Syncope
      Brissaud disease (tics)
      Muscular weakness or loss of strength
2. Behavioral (psychologic)
   a. Feelings of:
      Guilt
      Sadness
      Anger and hostility
      Emptiness and apathy
      Helplessness
      Pain, desperation, and pessimism
      Shame
      Loneliness
   b. Preoccupation with image of the lost infant
      Daydreams and fantasies
      Nightmares
      Longing
   c. Disturbed interpersonal relationships
      Increased irritability and restlessness
      Decreased sexual interest and drive
      Withdrawal
   d. Crying
   e. Inability to return to normal activities
      Fatigue and exhaustion or aimless overactivity
      Insomnia or oversleeping
      Short attention span
      Slow speech, movement, and thought process
      Loss of concentration and motivation

Data from Colgrove M. *How to Survive the Loss of a Love.* New York: Lion Publishing; 1976, Lindemann E. Symptomatology and management of acute grief. *Am J Psychiatry.* 1944;101:144; Marris P. *Loss and Change.* New York: Pantheon Books; 1974.

in our society is the autonomous, independent achiever who is always strong and in control, even in the face of disaster.[77,78] In keeping with this image, the father may feel that he must make all the decisions and have all information filtered through him to protect the mother. However, this altruistic gesture prevents full disclosure to and involvement of the mother. Assuming the role of a strong protector also involves a heavy price for the father in the suppression of his own feelings and delay of his own grief work.[61,128,156] The role of a "tower of strength" often engenders feelings of resentment from the mother. Although he attempts to live up to his (and society's) expectations of himself, the woman views his apparent lack of feelings and emotions, especially crying, as "He doesn't care." A recent study showed that distress experienced by the mother but not by her partner resulted in longer-term marital dissatisfaction for the mother.

Many men have difficulty dealing with irrational behaviors, as well as with the normal ambiguity and conflict of life. This difficulty makes the emotional response of grief and its accompanying ambivalent feelings and conflicts produce discomfort and anxiety in many men. The expression of appropriate human emotions becomes threatening and makes them feel vulnerable. To decrease the anxiety associated with grief and its expression, men often deal with feelings by denying them, increasing their workload, grieving internally, or withdrawing from the situation and refusing to discuss it.[127,156]

The father's attitude and ability to communicate about the loss may help or impede the mother's grief work.[166] Lack of communication between a couple

may contribute to intense mourning, psychiatric disturbances, and severe family disruption.[101,156,186] Synchrony of grieving between the mother and the father is important in an ultimate healthy resolution for the family.[29,44,156] If the father denies and suppresses his own feelings of loss and grief, he may react to the normal signs and symptoms of grief in his partner as if they were abnormal. Often the father can resolve his grief faster than the mother, and he may become impatient with her continual "dwelling" on the loss. Grief decreases over time: for mothers, the decrease occurs from 3 to 13 months, whereas the decrease for fathers occurs from 3 to 6 months.[202] Sometimes fearing the woman's prolonged grief, the man decides to "spare her" from his feelings and does not discuss them with her. Instead of being comforting as intended, failure to share grief leads to isolation and alienation within the relationship.[108,156]

In some situations, the man may experience intense emotions several months after the death, not unlike those his partner experienced at the time of the crisis. Because these intense emotions occur so long after the crisis, he may not even associate them with the death.[56,108] A recent study found that at 30 months after the death of a baby, fathers were more distressed than the mothers, who were the more distressed initially after the death.[186]

TIMING OF GRIEF RESOLUTION

Parents

Emotional recovery from the pain of perinatal loss occurs with time. There is no complete agreement on the length of time necessary for the individual to resolve grief. Indeed, a specific timetable for mourning may be impossible to establish.[17] However, some general time frames are available for the duration of a normal grief reaction.

Acute grief reactions are the most intense during the first 4 to 6 weeks after the loss,[116,125,144] with some improvement noted 6 to 10 weeks later. Normal or uncomplicated grief reactions may be expected to last from 6 months to 1[14,65,104,108,144,182] or 2 years.[104,125] A recent study found that maternal resolution of grief occurred at 1 month in 38.2% and at 18 months in 62.6 % after the birth of a preterm infant.[199] In this study, unresolved maternal grief at 18 months was associated with mothers who had higher maternal stress at 1 month after preterm birth.[199] Indeed, significant losses of a spouse or child may never be completely resolved[50,159,188]: "I'll never get over it."

One parameter for differentiating normal from pathologic grief has been the length of time for grief to be resolved. Grief work may still be categorized as normal/uncomplicated even if it lasts longer than a year, especially if the person is working through unresolved grief from the past. Grief work is normally energy draining. Dealing with more than one grief or loss situation compounds the intensity of mourning and may prolong the grief reaction. Because perinatal loss represents more than the loss of the newborn (loss of the perfect child, loss of plans for the future, and loss of self-esteem), feelings of sadness and depression may still be evident for a year or longer.[108,127,186,203] A study of white, Hispanic, and black parents (176 mothers and 73 fathers) examined their health and functioning at 1, 3, 6, and 13 months after the death of their infants. At 13 months after the death, one-third of the responding parents had clinical depression and posttraumatic stress disorder (PTSD).[201] At every time period, more Hispanic and black mothers had PTSD symptoms and more moderate/severe depression at 6 months. In the first 13 months, 98 hospitalizations for anxiety, depression, panic attacks, chest pain, and cardiac problems were reported, and 29% were stress-related.[201] A more recent study found that 75% of women had high PTSD scores after perinatal loss.[93] In another study, 9 months after a perinatal loss, bereaved women had a four-fold higher risk for depression and a seven-fold higher risk of PTSD, with a minority receiving any type of psychiatric treatment.[73] The presence of negative thinking about life and the world is associated with persistent depressive and grief symptoms for up to 10 years after perinatal loss.[109] During the first 6 to 13 months after the death of an infant or child, parents have an increase in acute and chronic illnesses, hospitalizations, and medication use.[26,53,201] Two Danish studies have shown that the birth of an infant with a congenital anomaly[39] and a perinatal loss increase maternal mortality, especially from cardiovascular disease.[92] In another study, mothers experiencing perinatal bereavement were 3.5 times more likely to have symptoms of elevated anxiety and 3.6 times more likely to have more depressive symptoms when their very preterm infant was 7 years of age compared to mothers without perinatal bereavement.[181]

Sorrow and grief may even last a lifetime. For families of children with anomalies, "chronic sorrow"[46,56,87,141,153,175] is a natural phenomenon and experienced as long as the child lives. These parents live with the constant reminder of what is not and what the child will never be and can never do. The grief of death is final—parents do the work and go on; chronic sorrow is grieving on a daily basis. Expecting the parents to adjust to or accept their child's defect without any elements of lingering sadness is unrealistic. Although hampered by small sample sizes, research on the gender differences in chronic sorrow show more intense chronic sorrow in mothers than in fathers.[46,87,123] Chronic sorrow is a normal and justifiable reaction to the daily stresses and coping necessary when a child is living with a birth defect or major impairment. The final stage of grief resolution is possible only with the finality of the death of the child.

Even when grief has been resolved, anniversary grief reactions are normal.[191] Feelings of sadness, crying, and normal grieving behaviors may be reactivated at certain times. These anniversary reactions may not be limited to the infant's date of death but also may be felt on the expected date of delivery, on the actual birthday, or on seeing an infant of the same age and gender as the lost infant. Holidays may also reactivate grieving behaviors, especially those that bring together family and friends and recall memories of joy and happiness.

Staff

Those sharing a crisis (complication, illness, or death) often become closely attached, so that the loss is felt not only by the family but also by the professional care providers.* Repeatedly dealing with death and infants with anomalies increases the professional's exposure to personal feelings of grief and loss. This may be perceived either as a threat or a personal opportunity for growth.

The critical variable in the ability to face or assist others in handling loss is the manner in which the care providers have been able to resolve their own personal losses. Unless the care providers can cope with personal feelings of loss and grief, they may not be able to give of the "self" to others. Care given without genuine involvement and responsiveness to the family's feelings does not facilitate and may actually impede the mourning process. Professionals who can deal honestly with their own feelings will be able to help others cope with theirs.[41,146]

Helping parents deal with their grief may be difficult for professionals because of their attitudes and feelings about perinatal loss. For professionals trained to preserve life, loss of the best pregnancy outcome or death itself represents both a personal and professional failure.[108] When success is equated with life, the failure of death (or loss) is associated with feelings of guilt, anger, depression, and hostility.[203] Just when professionals are expected to be supportive and therapeutic, they may be overwhelmed with their own feelings. A recent qualitative study of nurses' reactions to being present at a perinatal loss found recurring themes: (1) getting through the shift, (2) symptoms of pain and loss, (3) frustrations with inadequate care, (4) showing genuine care, (5) recovering from traumatic experience, and (6) never forgetting.[149] Professionally, care providers may feel helpless when all efforts inevitably result in no change in the outcome.

The feelings and stages of grief experienced by the family are the same ones felt by the staff who are attached to the parents and their newborn. Many professionals working in perinatal care are of childbearing age, so identifying with the parents and their plight is relatively easy. Because the sick, anomalied, or even dying or deceased infant could easily be that of the staff member, they share with the parents the special stress of the loss of a child. The care provider often experiences the same fantasies of blame as the parents: "What did I do (or not do) to cause this?"

Repetitive contact with loss situations and death exposes the staff to recurring feelings of frustration, guilt, self-doubt, depression, anger, classic grief reactions, helplessness, sadness, hopelessness, loneliness, PTSD, and covert relief.[57,70,82,129,133] Such uncomfortable feelings often lead to behaviors of avoidance and withdrawal as a means of self-protection; this has been called "compassion fatigue."[41,82,146,159] Adequate medical care may be given, but psychologic care of the family may be neglected.[119] The involved primary care providers may decrease their attachment to both parents and infant when an unfavorable outcome is inevitable. Withdrawing emotional support and involvement may spare the professional but only adds to parental feelings of isolation, inadequacy, and worthlessness. Professionals who have risked family attachment and shared grief work may be more cautious in

*References 41, 57, 146, 149, 154, 156, 159.

future involvements to protect themselves from the pain of loss.

Asynchrony and individual differences in handling grief reactions also may cause problems among the professional staff. Constant exposure to perinatal loss may desensitize some individuals until they are blasé or even callous about the crisis, whereas the grief reactions of others parallel the family's reaction. Some staff members may have reached the stage of acceptance, whereas others who cannot let the infant go persist in the idea of a magical cure, a characteristic of denial. The rationale of prolonging the child's life may in reality be prolonging death, and inevitably one needs to accept death's finality.

Staff members cannot offer support to families experiencing loss unless they receive support in dealing with their own grief reactions.[41,66,70,129,131] Those who receive support learn about their feelings and how to handle them and so have no need to displace their pain to others. The three most effective ways that neonatal intensive care unit (NICU) nurses have identified to manage their stress after a neonate's death are (1) discussing with coworkers, (2) supporting and comforting the grieving family, and (3) talking with their own families.[57] Various formats are available for meeting staff needs, such as mutual support of colleagues or group sessions involving peer counseling on a long- or short-term basis.[41,57,66,108,154] Group meetings provide a vehicle for support and for sharing information and feelings among staff members.[41,57,66,108,154] Facilitated by an objective person with expertise in group process and the concepts of grief, such "debriefing" meetings have the goal of helping the staff members deal with their reactions so that they will be better equipped to help the parents.[54,129] Group sessions also serve to decrease stress, increase job satisfaction, and ultimately help prevent burnout and PTSD.[82,133] A systematic review of 16 qualitative studies on how nurses cope with the death of a patient found that both intrinsic and extrinsic resources, listed in Box 30.3, are used. A national survey of 490 critical care nurses, interviewed after unsuccessful resuscitation, found that the coping behaviors of denial, self-blame, self-distraction, and behavioral disengagement were significant predictors of PTSD symptom severity.[131] In this study, the availability of institutional support affected the severity of post-code and PTSD symptoms. Staff members are encouraged to retain their humanity when an environment is created in which emotions are valued and their healthy expression facilitated, both at the time of loss and in its resolution.[54,97,129,154]

BOX 30.3 COPING RESOURCES USED BY NURSES AFTER THE DEATH OF A PATIENT[205]

- Intrinsic:
  - Setting boundaries
  - Reflection
  - Crying
  - Death beliefs
  - Life and work experience
  - Daily routines and activities
- Extrinsic:
  - Talking and being heard
  - Spiritual practices
  - Education
  - Programs
  - Debriefing

Sharing grief work with a family gives the care provider a chance for personal growth, to review past personal losses, and to evaluate the adequacy of their resolution. Helping others with loss or grief provides the professional with the opportunity to contemplate present and future losses, including one's own mortality. By working with those who have suffered a significant loss or death, a health care provider may gain a deeper perspective about life.[96]

INTERVENTIONS

Those in a crisis feel an openness to help and assistance from others, so that they emerge either stronger or weaker, depending on the help they receive.[32,151] This increased openness also makes those in a crisis more vulnerable to the reactions of others—to their facial expressions, tone of voice, and choice of words. Helpful professional interventions provide psychologic assistance during a highly vulnerable period of personal development. The goals of intervention are to maintain the precrisis level of functioning and to improve coping and problem-solving skills beyond the precrisis level (i.e., to facilitate personal growth). Effective intervention is characterized by helping grief work get started, by supporting those who are grieving adaptively,

and by intervening with individuals who display maladaptive reactions.[44,49,62]

For professionals, understanding parental perspectives of the experience of the death of a newborn should enable the provision of more sensitive and evidence-based care for grieving families. The results of two research studies provide some insight into what is helpful and what is not helpful for grieving families. The first study was a systematic review of 61 studies and more than 6000 parents who suffered a neonatal death.[72] This study found that parents valued emotional support, grief education, and attention to mother/baby. Nonhelpful and distressing behaviors from health care providers included avoidance, thoughtlessness, insensitivity, and poor staff communication.[2,72] Another study conducted semistructured interviews with mothers/fathers (n = 19) a mean of 1.9 years after the death of their infant. This exploratory study found a low level of grief, effective coping, and factors important to parents in end-of-life care for their infant.[28] Review of the data from this study, provided in Table 30.1, instructs health care professionals in helpful and nonhelpful interventions during the stressful experience of a dying infant.[35] Because 76% of the dying infants were in the NICU or pediatric intensive care unit (PICU) and 42% of the families had hospice/palliative care team involvement,[28] perhaps the low level of grief and the positive adaptation displayed by this small group of parents were because of the sensitive, helpful interventions of their health care providers. A more recent French survey of parental experiences (after the death of their newborns) found that half of the parents did not think that their feelings and decisions were respected.[64] Parent responders also felt that parental autonomy (in palliative care situations) was difficult for professional caregivers to respect.[64]

TABLE 30.1 PARENTAL PERCEPTIONS OF GRIEF AND IMPORTANT FACTORS AT THE TIME OF INFANT DEATH: RESEARCH BASIS[28,42,176]

STUDY FINDINGS	COMMENTS
1. Parents scored significantly lower than other parents who had lost a child and other adults with grief experience.	1. Lower levels of grief were measured by the Revised Grief Experience Inventory (RGEI), a 22-item Likert scale.
2. Study investigators viewed parents as positively adapting after loss of their infant.	2. Mean scores were 33.16 (out of a highest possible score of 36) on the Post-Death Adaptation Score, a 10-item scale rated by professionals.
3. Seven important aspects of care:	3. Identified by parents:
A. Honesty	A. Parents expect professionals to be honest in giving information about the infant/condition to them. Parental anger results when (parental) perception is that honest information was not given.
B. Empowered decision making	B. Parents want to be involved in medical decision making, especially about withdrawing life support. Parents who had been involved were glad they had been part of the decision process and felt supported by the medical team. Parents felt anger and abandonment when the decision to withdraw support was not believed to be respected by professionals.
C. Parental care	C. Parents needed care as much as their baby; when staff was insensitive to their needs, parents felt upset.
D. Environment	D. Parents appreciated comforts of sleep/family rooms as well as private, quiet areas where the infant died with family/parents. People present at the death were more important than the place of death. Parents expressed fear when left at home with their dying infant; parents wished they had held the infant longer.

TABLE 30.1 PARENTAL PERCEPTIONS OF GRIEF AND IMPORTANT FACTORS AT THE TIME OF INFANT DEATH: RESEARCH BASIS[28,42,176] — CONT'D

STUDY FINDINGS	COMMENTS
E. Faith/trust in nursing care	E. Parents had greater trust in nurses than other providers; most had positive experiences with their infant's nurses. Parents appreciated nurses personalizing and respecting the infant (using baby's name) as well as providing for the infant's comfort and opportunities for parental care (such as skin-to-skin care at the end-of-life)[111] for their baby. Negative experiences included mistakes in care and unprofessional behavior.
F. Physicians bearing witness	F. Parents thought it important that the physician be with them throughout the process, including being present at the time of the infant's death. Parents perceived the absence of the physician at the time of the child's death as negative, especially if they had been told that the physician would be there for them. Parents found it meaningful when the physician and other medical staff had contact with them after they had gone home.
G. Support from other hospital care providers	G. Parents appreciated support that they received from chaplains, social workers, and palliative care and child-life workers. Parents also appreciated support and help from these providers in dealing with siblings.
4. Seven coping strategies:	4. Identified by parents:
A. Family support	A. Parents relied on family support to cope with the death, appreciated family presence at the hospital/home when the infant died, and found it helpful to talk to extended family about their infant. When extended family members were not supportive and avoided talking about the infant, parents were distressed.
B. Keeping the memory alive	B. All parents showed researchers mementos of their dead infant and emphasized the importance of bringing things home (e.g., photos; plaster castings of hands/feet; blanket/clothes) from the hospital that had been used/belonged to the infant who died. Parents especially appreciated tangible reminders (e.g., garden/tree) and rituals to remember their infant.
C. Spirituality/faith	C. All families were comforted by their religious beliefs and found meaning and purpose in their infant's life and death. No families reported negative spiritual experiences or abandonment of their religious beliefs.
D. Altruism	D. Many parents wanted to and did "give back" to the hospitals that had cared for them and their dying infants. These altruistic acts took the form of monetary and equipment donations, volunteering, and becoming resource families to other parents with sick children.
E. Refocusing on life	E. The presence of other children in the family assisted parents in continuing to focus on life and the daily requirements of their surviving children. All parents acknowledged that having another child would never replace the infant who died.
F. Validation of decision	F. Parents were comforted by autopsy results that validated that they had made the correct decision for their infant. Parents also appreciated when physicians communicated to them their support of the parents' decision.
G. Bereavement support groups	G. Bereavement support groups resulted in positive experiences for most families, especially in being able to talk freely about their dead infant with others who understood and were not uncomfortable. However, some parents did not feel validated in their grief/loss of an infant by other parents in the group whose children were "older" when they died.
H. Follow-up	Follow-up of the family after perinatal loss is important to parents and health care providers

Nonhelpful Interventions

Caring for pregnant women and their infants is supposed to be a "happy" job. Birthing and caring for infants are supposed to be times of joy and celebration. Because no one expects death or loss to occur in maternity or nursery areas, when it does, both staff and families are shocked. To protect themselves from the reality of the situation or to "spare" the family, professionals may engage in interventions that do not help themselves or their patients. Such interventions may be meant altruistically but do not have the characteristics of effective intervention.

Maintaining the state of denial arrests grief work by preventing or delaying the acceptance of the reality of the loss situation. Progress toward resolution is not begun until the stage of disbelief is relinquished. Using drugs, not talking or crying about the loss, and using distraction all contribute to maladaptive reactions by maintaining the state of denial. The use of tranquilizers, sedatives, and other drugs does not help the recipient but, rather, benefits the giver. Excessive use of these medications prolongs the denial stage by making the feelings and emotions foggy and dreamlike.[101] The energy needed to begin the grief work is dissipated by the effect of the medications. Avoiding the reality of the situation becomes easier when mind-altering drugs make the tragedy even more unbelievable.

Not talking about the loss is a powerful way of denying that the child ever existed.[146,156] The inability of professionals to acknowledge that the loss has occurred and that the family is in pain maintains denial and repression.[31] Not discussing the loss prevents parents from learning the facts and facing their reality. Because a fantasy will be created to substitute for the unknown, the fantasy of what happened and why will be worse than the reality. By receiving truthful, honest communication, parents are not left to spend energy dealing with frightening fantasies.

Professional avoidance and unwillingness to talk with parents after a loss communicate other powerful messages that impede grief work. If the loss is not important enough to discuss, then perhaps it is not important at all. Not talking about the loss serves to reduce it and communicates to the parents, "I don't care; therefore, neither should you." Avoidance of the topic or a hurried, businesslike, or social communication that skirts the issue tells the parent that grief work is dangerous, that grief emotions are dangerous, and that others are afraid of grief and those experiencing it. In essence, not discussing the loss gives a clear nonverbal message to not grieve.

An inability to cry in response to a significant loss is not helpful and impedes grief work. The prohibition against crying may have been learned early in life or may be the result of unresolved grief work. Parents may feel the need to be strong for each other, their family, or the staff and thus do not cry. Sometimes role reversal occurs, and the grieving person feels the need to support others rather than be the recipient of support. Often the significance of parental loss is neither recognized nor acknowledged by the professional for fear that he or she will cry. Rather than talking about the loss as a technique to facilitate tears, no one says anything so that no one will cry, and no one's grief progresses through the grief stages.

Distraction is another way of denying the loss or its significance. Professionals, a spouse, or other family members try to distract parents from the feelings and emotions of acute grief by engaging in light, social conversation or by keeping them busy with work or recreation. Dealing only with the physical care and not the need for psychologic care after birth is a form of distraction used by care providers.[81] Parents are preoccupied with their shattered expectations of the past and the stark reality of the present, and they are not interested in distractions.

After an unfavorable perinatal outcome, the couple is often confused about their status: "Am I a mother or father . . . or not?" This experience has been called the "ambivalent transition into motherhood."[120] Failure to acknowledge the newly acquired role of mother or father (even if the fetus or newborn dies) discounts the parent's psychologic investment in the pregnancy, fetus, and newborn. Quickly removing the infant from the maternity or nursery areas or removing all the baby items from the home negates the infant's existence.[108] This is not helpful for grief resolution and prevents parents from making choices and decisions and thus maintaining control over the reality of the situation.

Isolation of the grieving family prevents the development of dependent relationships with others who might potentially provide support and comfort. Without others, parents cannot share their grief and may thus increase their feelings of guilt, anger, blame, and lack of self-worth at their failed

pregnancy. Those directly experiencing a perinatal loss may be isolated from the rest of society, including their families, who do not view the loss of a pregnancy or neonate as significant.[21,108,112,156] Empathy with the parents' definition of the loss is important and necessary for society to be supportive. The goal of recent research, professional literature, and education has been to sensitize the care provider to the effect of perinatal loss. Only recently have books and Internet sites specifically about perinatal loss become available to inform and assist parents.

To decrease contact with the grieving mother, the staff may neglect her or perform cursory physical care, or there may be overconcern for providing physical care.[128] Assigning a room at the end of the hall, not going into the room, delaying answering requests, and placing the mother on another floor are ways of avoiding families. Use of private rooms and room assignments off the maternity floor may be helpful but may allow staff to remove themselves from the unpleasant and uncomfortable situation. Early discharge to a supportive environment may be helpful but, without plans for follow-up, may merely be a way to remove the constant, painful reminder.

Keeping the childbearing couple together throughout the perinatal events facilitates a shared experience of the reality of the situation. Separation of the mother and father or of the couple from friends, family, and other children is not helpful. Exclusion of family members from the experience also prevents them from providing support for the mother and the couple. Relaxed visiting policies and as much contact as possible between the hospitalized mother and the father (and other family members) are important.[38,146]

Prohibiting contact between the parents and the infant allows fearful fantasies of the truth that are always more frightening than the reality of the situation. Delayed contact prolongs the state of disbelief and denial.[44] Restrictive visiting policies in the nursery, institutionalizing an infant without looking at all alternatives, or any other policy that separates parents from their infant does not facilitate grief. Especially in the case of an anomalied, stillborn, or dead infant, the message of delayed contact, or none at all, is that the infant is too horrible and unacceptable to be seen or touched. Because parental egos are so symbiotically attached to their offspring, an unacceptable child is equated with an unacceptable and unworthy self. The fantasy that the damaged or dead child is representative of the damaged and defective self is borne out in the behavior and separation policies of the care providers.

In an attempt to offer the grieving family comfort, friends, relatives, and even professionals often make comments that are *nonsupportive* and *nonhelpful*:[108,146]

- "Well, you're young. You can have more babies."
- "Just have another baby right away."
- "Well, at least you have others at home."
- "It's better to lose her now when she's a baby than when she's 4 years old."
- "He never would have been totally normal anyway."
- "He was born dead. You didn't get a chance to know or get attached to him anyway."
- "It's God's will."

Clichés and platitudes such as these do not help because of the message they give about the parents and the infant.[164] These comments at best reduce and at worst negate the effect of prenatal attachment to the fetus. The importance of psychologic investment and attachment by the parents to this fetus or newborn is said to be basically unimportant and essentially nonexistent.[108] Because infants are viewed as an extension of the parent's self, "by a not very subtle process of identification, the parents see a part of themselves in the baby, and nobody likes to be told that part of them is better off dead."[164] Also, comforting parents whose infant has died with the information that the child was not perfect and never would have been normal and healthy reinforces their belief that they are as defective and unsatisfactory as their dead child.[108]

Such comments also convey a message about the importance of an individual life. Essentially, they say that one fetus or newborn is fairly interchangeable with another. They negate the importance of and indeed the existence of the infant for the parents, siblings, family, and society. The life of the individual is devalued because "another baby" easily replaces him or her. Comparing one infant's illness or anomaly with another's is not helpful for parents whose own infant's anomaly is certainly more important than any other infant's problem.

The power of words to help during grief is outweighed only by their power to not help. Because parents are increasingly open during a perinatal crisis, they are sensitive not only to what is said and how it is said but also to the nonverbal

message. Giving premature or false reassurance may be more for the relief of the professionals than for the parents.[32] Comments such as "It's okay" and "Everything will be all right" must be genuine and timed appropriately for the parent. Telling parents that they have a child with Down syndrome and then saying "But everything will be all right" is hardly helpful. Giving reassurance that subsequent pregnancies and infants will be all right or unaffected is not helpful before the parents are ready to think about and project into the future. It is important to remember at these times that in the future, these parents may not remember specifically what you said, but they will remember how you made them feel.

The basic terminology accompanying perinatal grief situations may be upsetting to parents. Instead of *dead,* professionals often substitute less frightening and less final words. The use of *loss* when *death* is appropriate may be misinterpreted (especially by children). The terms *lose, loss,* and *lost* connote misplacing, so comments such as "I'm sorry you lost your baby" may be responded to by "I didn't lose (misplace) my baby. My child died." Medical professionals skirt the use of the words *dead, died,* and *die.* Care providers are taught as students to use the word *expired* when referring to a patient who has died. Meant to soften the effect of *dead,* the word *expired* may have its own effect, as a mother whose infant son died wrote in a poem: "The baby expired they said, as if you were a credit card."[180]

Other situations that do not facilitate grief work include dealing with multiple losses or stresses and ambivalence or mental illness.[104,203] The reaction to the loss of a significant relationship is intensified in the context of multiple losses, stresses, and problems.[146,199,203] Because perinatal losses represent not only a loss of the wished-for perfect child but also a threat to the parental self, self-concept, and self-worth, they represent situations of multiple loss.[188,189]

Helpful Interventions

Professionals have an opportunity to make a significant difference in the outcome after the crisis of perinatal loss for the individual, the couple, and the family. A care provider who is knowledgeable about the grief process and comfortable in sharing another individual's grief is equipped to assist the family and its members toward a long-term healthy adjustment rather than a dysfunctional and pathologic adjustment. Interventions that are helpful for family members also assist staff members in their own grief work.

Factors that influence an individual's personal experience of grief (and ultimately, appropriate interventions) are outlined in Box 30.4. Care for the grieving is individualized through assessing these factors, planning, and continually evaluating the individual.[61,62,146,155,159] Eliciting such personal information may not be as difficult as it first seems. Those in crisis often spontaneously share crucial data with little prompting. The importance of active listening to questions and comments or a more formalized therapeutic interview process may provide the needed encouragement and permission to begin communication.

A history of previous losses and their type and timing in the life cycle are important data for the care provider dealing with the current loss. Past experiences with a crisis or loss influence an individual's behavioral and coping style with current problems.[190] Experiencing a previous perinatal loss affects a subsequent pregnancy.[12,45,158] A recent nationwide cohort study in Finland found that parents with very or extremely premature, singleton infants (23 weeks to 27 completed weeks of gestation) actually have fewer subsequent children.[4] These pregnancies are characterized by guarded emotions, elevated levels of anxiety and depression, marking the progress of the pregnancy, and seeking out or avoiding various behaviors.[45,88,190] In a subsequent pregnancy, greater grief intensity as measured by the Perinatal Grief Intensity Scale (PGIS) is associated with symptoms of depression, higher pregnancy-related anxiety, posttraumatic stress and a poorer quality of the relationship with the intimate partner.[89] The PGIS is valid and reliable in predicting women who may have future intense grief associated with perinatal loss[89,90] and in predicting women in need of follow-up for severe anxiety and depression after perinatal loss.[91] A previous perinatal loss may compound the individual's reaction to a current loss. Dealing with problems alone, receiving help and support from others, and withdrawing altogether are possible ways of coping with the loss. Pregnancies after stillbirth or neonatal death require special emotional support from caregivers. A national United Kingdom survey of women with subsequent pregnancies found four themes relevant for caregivers to improve the quality of services: (1) sensitive

BOX 30.4 FACTORS TO EVALUATE IN INDIVIDUALIZING GRIEF INTERVENTIONS

1. Previous losses
   a. Type
      Separation
      Divorce
      Death
      Spontaneous abortion (miscarriage)
      Elective or selective abortion
      Period of infertility
      Relinquishment of child
      Perinatal loss
   b. Timing in the life cycle
      Distant
      Recent
   c. Coping styles[49] (of each individual and the family as a unit)
   d. Grief work
      Resolved
      Unresolved
2. Prenatal attachment
   a. Degree of psychologic investment in relationship with fetus or newborn
   b. Decision making about pregnancy and infant
      Planned or unplanned
      Wanted or unwanted
   c. Meaning of pregnancy and infant to individual and family
   d. Parental expectation about childbearing
3. Nature of the current loss
   a. Timing
      Sudden and expected
      Anticipatory grief
   b. Definition and meaning of the event (death, anomaly) to individual members of the family
   c. Multiple losses
      Self
      Perfect child
   d. Nature and severity
      Of loss
      Of defect
4. Cultural influences (also see Chapter 29)
   a. On experience and the expression of grief
   b. Societal expectations dictate acceptable and unacceptable behaviors of mourning
5. Strengths (individual and family)
   a. Support system (family, friends, religious, community, or social agencies) mobilized when necessary[37]
   b. Stable relationships: couple supportive of each other
   c. Financial stability
   d. Coping abilities: can evaluate, plan for, and adjust to novel situations
   e. Good health
   f. Receptive and intelligent
   g. Realistic expectations about childbearing and childrearing

communication and conduct from health care providers, (2) appropriate organization and delivery of services, (3) heightened monitoring and surveillance, and (4) perception of standard versus special care.[134]

The degree of attachment and the meaning of the pregnancy and impending parenthood to the family define expectations and influence reactions if an optimal outcome does not occur. The experience of grief depends on whether the loss situation was sudden and unexpected or if there was forewarning about a problem or complication. The definition and meaning of the crisis (e.g., the nature and severity of an anomaly, the finality of death, or the chronic sorrow of an infant with an anomaly) reflect the individual's and family's value system and previous crisis experience. The process of grief is affected by the event itself, the previous and current coping mechanisms, and the family's definition of the event. Consideration of all of these factors is crucial in instituting appropriate intervention.

Cultural practices among families and professionals often differ (see Chapter 29).[157] For example, in some cultures, it may not be acceptable to see or hold the baby (as in some Native American cultures). A literature review of the experiences of African American parents after the death of their child found four emergent themes: (1) emotional response to the death, (2) factors that added to the burden of death, (3) coping strategies, and (4) the health consequences of grief.[22] In the Muslim culture, the family is the primary system of support, and it is rare to see a Muslim family emote publicly. A phenomenological study of Muslim women experiencing perinatal loss found them to have experienced a lack of communication and privacy in the hospital during their initial grieving; feelings of confusion, emptiness, anxiety, anger, and guilt;

and agreement that husbands and families were the decision makers.[178] It is critical for health care practitioners to recognize cultural and religious differences to minimize misinterpretations and conflicts with families. With increasing immigration, practitioners must be able to respond with a more ethnic and culturally sensitive approach.[27,38,62,117,137,171] It is essential to be creative and flexible, thus respecting families' cultural and religious belief systems.[7,27,197] Studies show that cultural differences influence (1) parental emotional response to and perception of their infant's illness and disability, (2) parental use of services, (3) parental interactions with health care providers, (4) the ceremonies and rituals surrounding death, and (5) whether perinatal loss is culturally taboo or readily acknowledged.[24,27,62,117,124]

A review of published studies over the past 30 years of perinatal grief and loss in Latino parents has been published.[193] Latina women have a 1.5 times higher risk of experiencing perinatal loss due to (1) higher teen birth rates, (2) births to unmarried mothers, and (3) receiving no prenatal care or receiving prenatal care late in the pregnancy.[193] Grief responses among Latino cultures vary by country of origin, religious beliefs/practices, and acculturation (i.e., newer immigrants grieve in traditional ways, whereas subsequent generations incorporate the customs of the predominant culture).[193] Emotional expressions of grief, such as crying, are seen as healthy in Latino cultures. Because members of Latino cultures receive the majority of their emotional support from their families, numerous family members may be in attendance. Instead of the Anglo concept of "letting go" after a loss, Latina women believe in the concept of maintaining connections with the dead and are comforted by pictures, seeing/holding their dead infants, naming, and baptizing.

The national association SHARE: Pregnancy & Infant Loss Support, Inc. has revised the "Rights of Parents When a Baby Dies" and "Rights of the Infant" (Box 30.5). These documents serve as guidelines for the creation of protocols, checklists, and bereavement programs; affirmation and empowering tools for bereaved parents; and communication points for parents and care providers initiating the grief process.[148]

ENVIRONMENT

The first step in facilitating grief work is to create an ethical environment that is safe, supportive, permissive, and conducive to the expression of feelings.[31,41,146,156,194] This type of environment does not depend on physical surroundings but, rather, is created and maintained by a warm, receptive, accepting, and caring staff. Such an environment centers its concern more on the people giving and receiving care than on the tasks of care.[108] This type of environment is nonjudgmental and is characterized by an attitude of openness and freedom.[35,164] People feel safe enough to ventilate a full range of feelings—sadness, anger, despair, and even humor—without the fear of condemnation or rejection. Staff members become role models of open communication, facing grief, and feeling comfortable in an uncomfortable situation. The safety of such an environment generates feelings of acceptance and understanding so that grieving and healing may proceed.

Professional presence and support are essential to families in crisis because of the increased dependency needs that accompany grief and loss. Yet certain aspects of a conducive environment, such as privacy, quiet, and comfort, may be difficult to obtain in a noisy and busy perinatal setting. The recommendation to never leave the family alone must be balanced with their need for privacy and personal time alone with their infant (stillborn, ill, or dying). Simply saying "I will stay with you unless you ask me to leave so that you can have some private time alone with your child" or "Would you like me to leave for a while so that you can be alone with your baby?" offers both support and privacy. Many parents later regret not having time alone and not thinking to ask for that alone time.

A quiet place away from the hustle and bustle of the routine may facilitate both attachment and detachment. The mother of a stillborn child who is quickly shown her infant in the delivery room as her episiotomy is being repaired is not in an optimal physical (or psychologic) environment. Attaching to and saying goodbye to her infant are better accomplished in a quieter and more private setting with significant others present.[119,145] Active participation of parents at the death of their newborn may not optimally occur in a busy intensive care unit. Rather, adaptation of hospice concepts to neonatal care provides a private, homelike room, with focus on palliative (comfort) care, rather than cure, to the dying newborn and the family (see Chapter 32).[41,159,177,194] Optimally, parents are able to hold and comfort their dying infant. A recent

BOX 30.5 RIGHTS OF PARENTS, INFANT, AND SIBLINGS WHEN AN INFANT DIES

Rights of Parents

1. To be given the opportunity to see, hold, and touch their baby at any time before or after death, within reason
2. To have photographs of their baby taken and made available to the parents or held in security until the parents want to see them
3. To be given as many mementos as possible (e.g., crib card, baby beads or bracelet, ultrasound and/ or other photos, lock of hair, baby clothing and blankets, footprints and handprints, and/or permanent molds and record of weight and length)
4. To name and bond with their child
5. To observe cultural and religious practices
6. To be cared for by an empathetic staff who will respect their feelings, thoughts, beliefs, and individual requests
7. To be with each other throughout hospitalization as much as possible
8. To be given time alone with their baby, allowing for individual needs
9. To be informed about the grieving process
10. To be given the option to donate their baby's organs for transplant or to donate their baby's body to science
11. To request an autopsy; in the case of a miscarriage, to request to have or not have an autopsy or pathology examination as determined by applicable law
12. To have information about their baby, including autopsy results, presented in terminology that is understandable by the parents and family
13. To plan a farewell ritual, burial, or cremation in compliance with local and state regulations and according to their personal beliefs, religion, or cultural tradition
14. To be provided information on support resources that assist in the healing process (e.g., support groups, counseling, reading material, and perinatal loss newsletter)

Rights of the Infant

1. To be recognized as a person who was born and died
2. To be named
3. To be seen, touched, and held by the family
4. To have the end of life acknowledged
5. To be cared for and put to rest with dignity

Rights of Siblings

1. To be acknowledged and treated as individuals who have feelings that need to be expressed
2. To be given the choice/opportunity to see and hold the sibling before and after the death with parental input and support
3. To be considered in the choices parents are given (e.g., they may have ideas about names, funerals, memorials for their sibling)
4. To be informed and educated about grief according to their ages and developmental stages and offered the opportunity/choice to participate in support groups or counseling sessions
5. To be recognized by the family and society that they will always love and miss their sibling

Modified from *SHARE Pregnancy and Infant Loss Support*. http://www.nationalshare.org/about-loss/rights-parents. Accessed September 18, 2018.

phenomenological study of Scandinavian NICU nurses found a strong belief in offering skin-to-skin care for dying preterm infants and their parents as a way to provide mutual proximity and comfort.[80] When the family is too emotionally drained, they may elect to "say goodbye" and leave the hospital before life support is removed; the nurse then disconnects, holds, and rocks the baby so that the infant does not die alone.[146] In some situations (e.g., chromosomal anomalies), parents and professionals may opt to provide end-of-life care, ideally with hospice care at home.[135]

Supportive, Trusting Relationships. A relationship with a caring individual who offers consistency and support is the foundation of a therapeutic environment.[194] During periods of crisis, when there is a temporary increase in dependency needs and feelings of loneliness, it is an adaptive behavior to seek emotional support from family, friends, and professionals.[31,125,146] Even the crisis of normal childbearing prompts many cultures to provide a doula[152] to teach the new mother and give her emotional support. For a family in mourning, the relationships established with helpful professionals are more important than the physical care received.

Support, "sharing one's ego strength with another in a time of need,"[79] is particularly helpful in perinatal loss because of the threat to self-concept and self-esteem suffered by parents. Support may be as simple as remaining with the parents. "Being there" indicates not only a physical presence but also an emotional availability and willingness to share their

experience of loss. Professionals, family, and friends are often hampered by not knowing what to say. Usually, words are initially unnecessary or do not adequately describe the moment, and silent presence may better convey the message. Often it is not what is said but the mere presence of loving others that conveys empathy and support to parents and colleagues. Yet presence is not enough; meaningful interaction between parents and professionals is also necessary for a trusting relationship to develop.

The initial meeting with the professionals, including verbal and nonverbal cues, leaves a lasting impression on the family. Sensitivity and kindness of professionals are highly valued by grieving parents.[2] Addressing family members by name personalizes the encounter, and a brief touch or handshake represents an extension of self, a gesture of warmth, concern, and acceptance from professional to parents. An introduction that includes a brief explanation of the professional's role in relation to them and their infant helps orient them: "Good morning, Mr. and Mrs. Black. I'm Sue, your baby's primary nurse. That means that I will be caring for Jason while he is here and working with you." Orientation to the physical surroundings and technical equipment eases the transition to an unfamiliar and often intimidating hospital environment. Providing physical comfort, such as rocking chairs, privacy for interaction, and sleeping facilities for parents, demonstrates the philosophy of the parents' worth and importance to their infant.

Empathy, an emotional understanding of and identification with the plight of another, characterizes a helping relationship. In such a relationship, "How are you?" is asked with the emphasis on *you* and a genuine interest in the answer—unlike a social inquiry in which an automatic "Fine" is expected. Recognition of verbal and nonverbal cues of parental feelings (e.g., "You look tired" or "I hear that you are frustrated") communicates that these emotions are legitimate, understood, and accepted. A willingness to help, listen, console, and give encouragement and positive feedback establishes the professional as a sensitive, responsive person whom parents will trust.[194] Supporting any and all parental involvement, supporting damaged parental egos, and helping parents succeed in the tasks of attachment and detachment are goals of effective intervention.

A qualitative study examining maternal perceptions and experiences showed that mothers had feelings of both empowerment and powerlessness with professional care after the death of their newborns.[119] Feelings of powerlessness occurred when (1) mothers felt disrespected as a person and a mother, (2) good communication between mother and professionals did not exist, and (3) the mother did not feel treated as an individual.[119] Mothers feel empowered (e.g., more confident, able to ask questions, understood, and supported) when they felt that professionals (1) were "near," both psychologically and emotionally; (2) supported their self-esteem and confidence; and (3) provided empathetic, comforting support.[10,72,119]

The nursing staff often determines the tone of in-hospital perinatal settings. Generally, residents, interns, and specialists remain for short periods, and the private physician or permanent medical staff members are not available on a minute-to-minute basis. The development of a safe, trusting environment depends on viewing parents as essential partners in the care of their baby and not as visitors or "disruptors" of the ward routine.[44] Pleasant and relaxed surroundings convey the message of hospitality and "You are welcome here."

Both professional and nonprofessional support systems are available in the crisis of perinatal loss. Yet relating to many people during a crisis is difficult for parents. Primary care (both medical and nursing) uses the same care provider for both the physiologic and psychologic care of the infant and the family. Thus, the family only has to relate to as few professionals as possible. This special caring reassures parents that a few special people love, know, and are invested in their infant. Primary care providers share with the parents the joys of even small gains and the sorrows and tears of complications or death. Professionals and parents benefit from primary care systems in the emotional and psychologic satisfaction of such involvement. Yet this involvement is not without the price of vulnerability to an individual's feelings of loss and grief. Peer support on an individual basis or in a group setting is essential in dealing with the stress of continual attachment and loss.[1,52,54,57] An Australian study of volunteer peer supporters found that most often the callers to the 24-hour telephone support service were bereaved mothers who needed "to talk to someone who understands" in the early weeks and months after perinatal loss.[23]

Normal grief reactions may be facilitated by nursing and medical professionals using other professionals (social workers, chaplains, or counselors)

BOX 30.6 CRITICAL FINDINGS
Indicators of Pathologic Grief [116]

1. Overactivity without a sense of loss
2. Acquisition of symptoms belonging to the last illness of the deceased
3. Psychosomatic conditions
4. Altered relationships to friends and relatives
5. Furious hostility against specific others
6. Formal manner resembling schizophrenia
7. Lasting loss of social interaction patterns
8. Assuming activities detrimental to social and economic existence
9. Agitated depression

when necessary.[15,41,126,146] Interdisciplinary collaboration and consultation helps the staff gain insight into parental and personal behaviors and appropriate intervention strategies.[16,174] The staff also may benefit from the expertise of a trained counselor in dealing with their own feelings of loss and grief.

PATHOLOGIC GRIEF

Maladaptive responses to perinatal loss are indications for referral for specialized care (Box 30.6).[200] Involvement of clergy and religious organizations is often comforting and supportive to the family.[132,145,193,197] Religious rituals (e.g., baptism, prayer service, or anointing) may be advocated by certain denominations and provide a measure of comfort and hope. Often parents in crisis do not think to request infant baptism or to call their priest, minister, or rabbi. Offering to call a clergy member of their choice or the hospital chaplain may be helpful. A national survey of pastoral care providers noted barriers to providing spiritual care: (1) inadequate numbers of pastoral care staff, (2) inability of health care providers to assess spiritual needs, and (3) being called "too late" to give all the care that could have been provided.[68] The use of spiritual activities and coping strategies has been shown to help parents cope with grief and to help mothers to maintain their mental health and experience personal growth after the death of a child.[83] Spiritual and religious coping strategies were most often used by black mothers and Catholic and Protestant parents.[84] Among Iranian families, three spiritual themes have been identified: (1) belief in supernatural power, (2) need for comfort of the soul, and (3) human dignity for the newborn.[162] Negative religious coping (i.e., feeling angry or abandoned by God) is related to poorer family relationships, poorer family cohesion, and the use of denial.[25]

Primary care providers who have shared intimately with the parents the experience of their child's life and death may be invited to attend the funeral or memorial service. For both care providers and parents, this may represent the final act of caring for the infant.[57]

Nonprofessional support systems such as the couple, family, friends, and parent groups are often forgotten as sources of potential help to grieving parents. On the one hand, in our society of isolated, mobile, nuclear families, it may be erroneous to assume that a support system exists. On the other hand, it may be unrecognized because it does not fall into a traditional definition, such as the neighbor or other friend who may be more supportive (and available) than the grandparents. Biologic kinship is not the only valid criterion for a support system; an emotional kinship is the most important factor.

Because professional availability and involvement with the parents is not lasting, the professional has a responsibility to identify, foster, and facilitate a nonprofessional (social) support system. Simply identifying supportive others and expecting them to automatically help in a perinatal loss situation may be unrealistic. Unless those who constitute the support system are as well informed and instructed as the parents about the situation, they will not be able to offer emotional comfort. For example, if the parents wish to talk about their loss but the members of the support system empathically want to spare them by not discussing it, no help will be given or received.

The quality and quantity of ties one has with a social network are associated with improved health status and life satisfaction.[56,197] For parents experiencing a perinatal loss, the quality and quantity of ties with their social network (i.e., extended family, friends, and colleagues) may be profoundly affected. In one study, most families suffered a permanent loss of relationships because others were not sure how to react, avoided talking about the baby, or made comments that diminished the intensity of the loss.[51]

Fathers especially receive little personal attention as friends and colleagues focus their attention on the mother's grief.[51,56] Because grandparents grieve for their grandchild and may feel guilt and

grief for their own child, they may be emotionally unavailable to support the grieving parents. To prevent social network disruption for grieving families, health care providers can (1) share information with families about reactions to expect and reasons for these reactions, (2) support families and enable them to rebuild their networks, and (3) emphasize and support the family's belief in their strengths and capacities.[51,56,146]

Open communication between the parents is essential in preserving and fostering a close relationship by the giving and receiving of mutual support. Sharing the experience presents the couple with the opportunity for personal growth and growth as a couple. Yet the individual experience of grief within the context of a couple is too often fertile ground for misunderstanding and resentment.[156] One study showed that disruption of a couple's sexual relationship occurred after the death of a child.[168] A national study examining parental relationships after live birth, miscarriage, or stillbirth found an increased risk for dissolution of marriage or cohabitation in couples experiencing loss compared with a live birth.[75]

Parental support groups offer their members an opportunity to discuss their feelings with others who have been through similar traumas.[156,190] Knowing how others who have experienced perinatal loss have felt and dealt with similar situations is emotionally comforting and stabilizing to parents experiencing their own loss. Parents provide each other with validation for their feelings and a sense that they are not alone in their pain. Each individual has different needs, different ways of adapting to crisis, and different ways of giving and receiving support. It is essential that professionals use techniques that are real and spontaneous and not adopt words or actions that are foreign to one's own self. Interventions must also be gauged to the parents' needs and pace.

In one study,[188] and as reflected in clinical experience, fathers stated that they received most of their support from their spouse. They reported that little attention is paid to fathers by hospital staff, causing more denial and difficulty expressing their grief. So that the father's grief is not ignored,[128] it is critical for hospital staff to address the father's feelings when addressing parental grief.[163] Suggestions to assist fathers in their grief include implementation of all-male support groups; validation of their feelings; and asking direct, open-ended questions. These may include "What are you feeling right now?" "Tell me how your day is going," and "Tell me about your coping strategies." Health care providers can help a father by reflecting his statements, using his name, and assisting him with expressing his feelings. Fathers should be included and acknowledged in all discussions with staff[189] so that they are not "forgotten mourners."[107] One study documented that family adjustment after the NICU experience improved over time for mothers but deteriorated for fathers, especially if the infant had ongoing health problems.[40] Assessing the family as a unit rather than using the mother as a representative of the entire family, being cognizant of and responsive to gender differences in coping, and being supportive of family strengths and resources are recommendations for clinicians.[49,56]

Information. Information aids in intellectually understanding the crisis, thus facilitating a sense of control over it. Actively seeking and using information enable confrontation and mastery of the crisis. Knowledge about a situation strengthens the ego because it enables "worry work" and psychologic preparation for expected events. Because "the void of the unknown is more frightening than the known; facts are more reassuring than awesome speculations,"[32] a major role of the professional is to provide and clarify facts and information relevant to the perinatal loss situation (Box 30.7).[31,126] In the search for meaning that always accompanies loss, medical facts may help alleviate some parental guilt about causing the tragedy. Repeating to the parents that nothing they did or did not do could have caused this problem is reassuring. Sketchy or no information only serves to contribute to parental denial of the reality or to their fantasies of causation.[164] Confronting the crisis and realizing its real element of danger and trouble starts the process of grief by giving permission for the expression of feelings of fear, sadness, and loss.

Because the family as a unit, composed of the individual members, must deal with perinatal loss, professionals should encourage and support open interfamily communications. Keeping secrets, especially between the parents, should be discouraged because this eventually undermines trust and promotes asynchronous grief work. When parents are given the same information and talk with each other about their loss and their feelings, more

BOX 30.7 PARENT/CAREGIVER TEACHING
GRIEF

1. Grief is a normal reaction and is expected in perinatal situations: pregnancy, abortion, stillbirth, premature birth, when the baby is sick or has an anomaly, death, relinquishment, when the birth process does not meet parental expectations, and when there is postpartal depression.
2. Grief is a staged process that occurs over time and is characterized by stages: shock and disbelief, anger, bargaining, depression and withdrawal, and eventually acceptance.
3. Grief is an individualized process and may be experienced differently by the mother and father.
4. To facilitate grief reactions, the neonatal intensive care unit will provide a safe environment for the expression of feelings; information about the infant and the infant's condition; and supportive, trusting relationships with health care providers.
5. Seeing, touching, and holding the baby are as important to the parents of a sick or dying infant or an infant with an anomaly as they are to the parents of a healthy infant.
6. When an infant dies or is dying, parents and infant(s) have the right to interact with each other, to create memories, to involve extended family and friends, and to engage in specific religious and cultural practices.
7. Parents and families are informed about the grief process, encouraged to support and care for each other, and encouraged to identify and rely on social support systems (e.g., extended family, friends, professional support services).[37]
8. Providing both verbal and written information to parents is essential.[2]

synchronous grief reactions develop.[108] Telling parents together with the infant present prevents misunderstanding, misinterpretations, and "shading" of information to one parent.[145] Informed parents are better able to share their experience with each other and to participate in joint decision making with the professional.[14,28,42,194] A prospective cohort study found that the quality of the mother's relationship with her partner, secure attachment, and social support affect the course of bereavement after perinatal loss.[165]

The questions of when to tell and how much to tell the parents often arise. Parents should be told as soon as possible about perinatal complications or problems.[31,108] Receiving this information at the earliest possible time helps parents establish trust in the care provider, appreciate the reality of the situation, begin the grief process, and mobilize both internal and external support. Information must be given in its entirety because attempts to "spare" parents by staging the truth serve only to undermine their trust in professional credibility. The couple's relationship also may suffer if one parent colludes with the professional in a conspiracy of silence. This is best illustrated by the following incident:

> *To spare a diabetic mother from the truth about her infant's congenitally absent limbs, the physician and the father decided to tell her about his missing legs but not the missing arm. On arriving to transport the baby, the nurse asked if the mother had been told. "Yes" was the response, so she took the infant to the mother's room before transport. As she uncovered the infant, the mother gasped and looked at the physician and the father and said, "You lied to me. You didn't tell me about his arm, too."*

When given the unedited truth, parents can face reality and begin the grief process without fear that there is something else that they are not being told about. The individual's stage of grief influences not when or what will be said but how the information will be given and received. During the initial stage of shock, information, if processed, is processed slowly.[108] Often, events take on a foggy, dreamlike quality so that sensory information remembered is not believed. Yet to give no information only perpetuates this frightening feeling. Communication to those in shock and denial must proceed simply, slowly, and with much repetition and reinforcement. Giving information once does not ensure that it will be retained or understood. Repetition by the professionals is necessary for gradual acceptance of the reality of the situation.[14,28] This may be a nuisance for the professional who has already given the information and wonders why the parents cannot remember it. Parents are so shocked they do not hear what is said, and information must be patiently repeated.[194] Although early contact with parents almost ensures they will be in a state of shock, the tone and content of the first meeting are not forgotten.[31,108] Initial information about the infant and his or her condition may have long-term effects on the parents' ability to attach or detach. In the past, parents were given a pessimistic outlook with the belief that "It will be easier for them. They won't get so involved." Negative descriptions and initial pessimism only increase the amount of grief and detachment while effectively blocking attachment behaviors. If the sick infant or one with an anomaly survives, the parents may have detached to the point of, at least emotionally, burying

him or her. Knowledge of better survival rates and the quality of survival enables a truthfully optimistic outcome for many sick neonates. Therefore, information must be given clearly (not medical jargon), with a minimal focus on possible complications and medical odds.[108,203]

Volunteering information to parents is essential, but encouraging their questions is equally as important. As the normal mechanism for adapting to crisis and gaining mastery over a situation, questions help the professional "start where the parents are" and begin communication with their concerns. Questions and comments unrelated to the discussion may indicate either failure to comprehend or failure to send the information clearly.[203]

Direct questions deserve direct answers because they indicate a readiness and desire for information. Indirect questions or comments by the parents may indicate concern about their own infant that cannot be directly expressed. "Baby Stevie (who died yesterday) had severe respiratory distress syndrome, didn't he?" The parents want to be reassured that their infant will not die, too.

During the crisis of perinatal loss, interpersonal communication is difficult. Therefore, as few professionals as possible should relay information to the parents. Primary care providers (nurse and physician) should coordinate and provide continuity in giving information to parents because individual care providers will supply information about the same topic in different ways.[44,146] The use of varied terms, inflections, and attitudes by a multitude of professionals becomes a monumental source of confusion and anxiety for parents. A trusted relationship[28,31,35] with a primary nurse and physician through whom all communication flows minimizes unnecessary anxiety and concern for parents. It is essential that the nurse (or primary nurse) be present and assists the physician in communication with the parents. Any anxiety-producing information (poor prognosis, complication, or impending death) may not be heard or understood initially by the parents. The nurse must know exactly what information was given to the parents and how this information was delivered. After the physician departs, the nurse must be able to offer clarification, explanation, and support to the distraught parents. Nothing is more distressing than finding a crying, upset mother who is unable to relate what the physician said, why she is upset, or even if she understood what was said.

No family or parent should have to wonder and worry about a dreaded or feared outcome without being given the proper information. If the primary care physician is unavailable to speak with the family, then someone from the health care team must assume this responsibility. No mother whose infant is ill, deformed, or dead should awaken from an anesthetized birth to find her physician absent and the nurses unable to answer "How's my baby?" A plan of action for telling individual parents must be decided and agreed on by all care providers.

Parents are interested in the daily (or hourly) progress of their infant, including both positive and negative developments. It is important for parents to know about a crisis or negative development in an infant's condition as soon as possible. They are then able to participate and care for their infant through the difficulty and to trust professional communication. Parents should have unlimited access to phone or personal contact with the staff in the perinatal care setting. Phone calls to the hospital from concerned parents should be possible any time of the day or night. The knowledge that information about their infant and access to a caring professional are available at any hour often is enough to comfort parents of a critically ill infant.

Lactation suppression for the mother of a dying newborn often has been a forgotten aspect of care.[136] Engorgement creates a feedback mechanism to the maternal brain that leads to the cessation of milk production; however, painful engorgement should be avoided. Using a breast pump to remove enough milk to relieve pressure and discomfort but not enough to empty the breasts will gradually result in a decrease in milk production. If the mother pumps until she is comfortable, gradually prolonging the intervals between pumping and pumping for shorter periods, lactation gradually is suppressed. The use of a well-fitting and supportive bra relieves the discomfort/pain of heavy breasts. A recent study comparing the use of breast binding to a supportive bra found that the breast-binding group had greater breast pain/tenderness, leakage, and use of other pain-relief measures; the study recommendation was to discontinue breast binding for the more comfortable and efficacious supportive bra.[179] Mothers who have pumped and stored breast milk may wish to donate it to a mother's milk bank. A mother also may wish to continue pumping to

be a human milk donor.[40] These options should be sensitively discussed with the mother of the dying infant.

ENCOURAGING EXPRESSION OF EMOTIONS

Because grief is an emotional reaction to loss, expression of these emotions is necessary for grief work to begin and proceed. Verbalizing thoughts and feelings provides an outlet for the intense emotions accompanying grief and signifies to others that emotional support is needed.[31] For some, the open expression of emotions may be difficult because of the influence from their culture, gender-specific roles, and social status. Yet the containment of intense feelings uses a great deal of emotional and physical energy that could be more productively used in moving on with the grief work. Those who are stoic and noncommunicative experience symptoms of grief for a longer period than those who freely express their feelings and emotions.[18]

Experiencing the loss of an infant initiates an "ambivalent transition" into motherhood in a short period.[120] These women often feel totally confused, with broken expectations and elusive grief: "Have I or have I not become a mother?" Supporting families provides them with an opportunity to talk about their infant, confirming the baby's life as important, although short. This process assists parents to attach and subsequently begin the grieving process.[198]

Talking about the loss helps parents validate and assimilate the experience. Timing and events are clarified, including forgotten details, by discussion with each other and with their care providers. Confronting the reality enables them to work through the shock and disbelief, verbalize their fears and disappointments, and begin to cry and grieve. Expression of feelings gradually permits a clarification of the meaning of the loss to the parents. Talking lightens the burden of loss because every time the experience is shared with another, half of the experience and the accompanying emotions are given away. Telling, retelling, reviewing, and reliving the experience are all necessary ways to understand and gain mastery over a frightening and most often unexpected situation.[31,191]

Verbal and nonverbal cues tell professionals where the parents are in their grief process. To elicit feelings, the professional may verbalize his or her own perceptions and observations:

- "Mrs. Green, you sound tense (upset, tired) today."
- "Mr. Brown, you look worried today."
- "I'm sorry that your baby died."

These statements indicate the listening ear and observing eye of one who cares. They set the stage for communication: "It's okay to talk with me about how you are feeling because I acknowledge your pain."

Because they feel scared, alone, and out of control, parents often deny their feelings under direct questioning. Thus, "Do you think you did or didn't do something to cause your baby's problem?" may be answered negatively, despite parents being consumed with guilt. Direct questioning places parents in an awkward and vulnerable position of revealing their most personal doubts and fears. Direct questions may be reworded with safer and more indirect statements:

- "Most parents feel overwhelmed and sad when their baby is sick."
- "Many parents wonder if the cause of their baby's death is something they did or didn't do."
- "It is helpful to many parents to talk about their doubts and fears. These feelings are common and normal in such a difficult situation."

The professional gives information to the parents about the feelings and emotions commonly felt in similar situations. Because there is safety in numbers, if "most" or "many" parents feel this way and it is expected, then it might be safe to share their feelings. Validating parents' reactions as appropriate reassures them that they are not crazy. With this type of invitation, the feelings may be free to come spilling forth, or the parents may need time to establish a relationship with this professional before they are ready to talk about such personal emotions.

Empathetic actions and comments may open communication pathways with parents.[31] A professional presence that is warm and caring may facilitate more communication than any words. Touching or holding grieving parents may help feelings be expressed. Nonverbal cues such as nodding, direct eye contact, uninterrupted attention, and the physical closeness of pulling up a chair and sitting down give positive feedback to verbal communication and indicate active listening by the professional.

Crying is the expression of feelings of sadness, sorrow, and intense longing that accompany the

pain of loss.[116,203] A healthy catharsis, crying should be expected and encouraged in any loss situation. Yet the cultural, gender-specific, and professional taboos against crying have defined it as an unacceptable and inappropriate response and one that should be suppressed. Because tears are healing and therapeutic, professionals must learn to be comfortable with the crying of others. "Don't cry" is often heard from those attempting to comfort grieving parents (or colleagues). This is an admonition against the behavior rather than an empathetic comment. "It's okay to cry" or "Go ahead and cry; let it out" gives permission and acceptance to the behavior and the need for it.

By expecting tears, providing a safe environment for their expression, and encouraging the behavior by words and actions, the professional may facilitate crying in both mothers and fathers. Too often, tears are blocked in a relationship in which one partner (usually the man) is expected to be stoic and in control, whereas the other's (usually the woman's) tears are defined as too upsetting or difficult. Because the ability to cry is a healthy response, the couple must be encouraged to use this outlet together.

In the past, crying in the presence of patients and their families was defined as "unprofessional." Yet the cool, controlled exterior defined as "professional" was seen by others as not caring and not feeling. When the professional cries with the parents, it is an acceptable expression of genuine emotion, a demonstration of empathy, and a role model of the appropriateness of tears given the situation. Parents do not define the tears of care providers as weak or unprofessional. Rather, they feel a special bond of love and care with professionals who have been free enough to share their grief.[9,31,146,156] Instead of relearning that crying is acceptable, many parents and care providers must learn this for the first time.

Talking and crying about the loss are easier to facilitate than the expression of anger.[81] Because of the social expectations of dependency of the patient role and real or imagined consequences of retaliation (against the infant or job status), perinatal care settings are not safe environments for the expression of anger. Parents (and colleagues) will be able to vent anger only in an environment free of punishment or retaliation for their behaviors. It is the responsibility of the professionals to create an environment that allows open expression of negative criticism and anger.

SEEING AND TOUCHING

Seeing and touching are as important to the parents of a sick, deformed, or dead infant as they are to the parents of a normal, healthy one. In the past, fear that seeing a deformed or dead infant would intensify grief and be overly upsetting resulted in a lack of contact between parents and their newborn. Despite the fact that many mothers wished to see their infants, the prevailing practice was to discourage and prevent it. Often no information, including sex or physical characteristics, was given to grieving parents, who were left to fantasize about their newborn's problems or cause of death. Current practice indicates that parental contact with the infant does not cause "unduly upsetting immediate reactions or appear to result in pathologic mourning."[101]

Researchers in the United Kingdom have evaluated mothers and fathers who have seen and held their infants after stillbirth. In several of the studies, researchers correlated posttraumatic stress symptoms in both mothers and fathers[183] and disorganized maternal–infant attachment[184] in subsequent pregnancies to seeing/holding the stillborn infant. Although remarking that seeing/holding the dead infant is culturally entrenched and highly valued by parents, these researchers warn that this practice is associated, in their studies, with psychologic sequelae and based only on clinical impression without empirical evidence of benefit.[14] In a more recent study, most parents chose to see and hold their stillborn infant.[196] Among mothers who chose to see and hold their babies, more intense grief was not equated with poorer mental health, whereas fathers ($n = 9$) reported poorer mental health. The research cited in Table 30.1 shows how this small sample of well-adjusted and low-grieving parents valued holding their infants, being present at the time of death with family/friends, and keeping mementoes and the memory of their child alive.[28] The sequelae of seeing/holding a stillborn and the sequelae of seeing/holding a live infant who has died may not be similar; clearly, more research is necessary.

The British researchers[14] who found psychologic sequelae of parental contact with their stillborn infant state that many parents experience great meaning and treasure the memory of time with their dead infant. They concede that some parents would choose to have contact with their dead infants, regardless of potentially harmful outcomes. They also state that the parental decision to see/

hold the dead infant may be heavily influenced by attending staff who may expose reluctant parents to their dead baby. Clearly, the decision to see and touch their infant is ultimately a parental one.[14,203] Making decisions for parents is not the professional's role; making decisions with parents is the professional's role. The role of the attending professional(s) is to encourage families, provide information for appropriate decision making, and address parental uncertainty and/or apprehension in seeing/holding their baby during the hours after stillbirth because their "opportunity for contact (with their infant) is fleeting and final."[106] Seeing and holding their stillborn baby is associated with better parental psychological health and may be beneficial for their future well-being.[105] Each parent must make the decision for him- or herself; neither may decide for the other. Altruistic others, such as professionals, the spouse, or other family members, must not usurp the right to individual decision making. Often, in an attempt to protect the mother, the father or the professional decides that she should not have contact with her infant. They either actually discourage it or do nothing to facilitate it. Mothers who have not seen their infants always know who prohibited it. The couple's relationship may suffer irreparable damage if one decides for the other, even if the motive is altruistic. The professional's role is to facilitate a healthy decision by each parent so that their individual needs to see or to not see the infant are met.

Parents may not realize that seeing and touching their infant is an option, or they may just be too overwhelmed or afraid to ask if it is possible. Instead of waiting for parents to ask, the professional care provider takes a more active role by offering the possibility to the parents: "Would you like to hold your baby?"

Time is often necessary to make the decision because parents are initially ambivalent about seeing and holding a deformed or dead infant. Most mothers and fathers want to see their child but fear what they might see and how they may feel. The care provider may alleviate the parents' ambivalence by acknowledging that being with the infant will be difficult but that the professional will remain with them unless asked to leave. The emotional support of the physical presence of an empathetic professional may allay the fear of becoming out of control. The professional can reassure the family by explaining what they will see before they hold their infant. Making such a crucial decision in the initial stages of loss is difficult. Giving parents information about the positive aspects of seeing and holding the infant in facilitating their grief process helps make their decision an informed one.[203]

Seeing the infant brings the dreaded impossibility of perinatal loss into stark reality.[203] Parents confirm with their own eyes that the infant is alive or dead or normal or abnormal. Contact enables claiming behaviors and identification of the infant as their own. While holding their infant, parents examine her and begin to recognize familiar family characteristics: "She has my long fingers and her father's red hair." Even small, severely deformed, or macerated infants can be recognized and claimed by the parents as part of their family. What is remembered are the normal, endearing characteristics that identify the child as "mine."

Parental contact confirms the infant's own reality and eliminates the prenatal fantasy of the expected child. For the parents of an infant with an anomaly, grief work about the fantasized perfect child may begin so that the actual child may become the object of love. Early and frequent contact between the parents and the infant encourages a realistic perspective of the infant's problems. A stillborn or aborted fetus may be physically normal rather than the deformed infant imagined by the parents. Seeing the infant allays doubts and fears about the infant's normal state and about the parents' ability to subsequently have a normal child.[164] Seeing and touching enable parents to grieve the infant's reality rather than a feared and dreaded, and thus more frightening, fantasy. It is easier to grieve a real infant than a mystical, dreamlike fantasy of the infant.[108]

Whether the ultimate decision is to see or not to see the infant, the professional must honor and respect that choice.[203] Cultural taboos against viewing dead bodies may preclude some parents from seeing and touching their infant. Yet many such cultures support their members by formalizing the grief process in sanctioned ritual and ceremony. For those parents who decide not to see and touch, the professional should reassure them of their infant's normal condition (e.g., "He had 10 fingers and toes."). The infant should be described in as much detail as necessary to give parents a mental picture. Gender, size, hair color, skin, weight, and distinguishing characteristics should be included. A simple, realistic description of any anomaly is also helpful because the fantasy of the defect is worse than its reality.

Adequate preparation for the first encounter with their infant includes a description of everything parents will see, hear, and feel.[203] Verbal preparation for viewing an infant with a congenital anomaly includes not only a simple description of the abnormality but also the infant's normal characteristics. Seeing a picture of the abnormality first may help parents prepare for seeing their infant. Remaining with the parents at the initial visit, the professional should describe the anomaly and point out normal findings. Focusing by parents on the normal familial characteristics helps in attaching to the less-than-perfect baby. Although parents of a dead, deformed infant view the abnormality, they often focus on the normal traits and remember the infant not as "monstrous" but as beautiful.

For those who have never seen a dead body, the mind may invent frightening images and sensations. Certainly, "dead" is associated with the temperature sensation of cold. However, a newborn who has been placed under a radiant warmer or in an incubator may feel warm rather than cold shortly after death, hence the statement by a mother, "You couldn't be dead. You feel so warm." The professional must touch the infant and prepare the parents for the tactile sensation of warm or cold: "The baby will feel warm to you because she (or he) has been under the radiant warmer."

To prepare parents for seeing their infant, the professional must observe the baby. Color, skin condition, and size must all be described and are not shocking with adequate preparation: maceration, "peeling of the skin"; peripheral shutdown, "the blue-white discoloration"; and the small size, "as long as the length of my hand." Any equipment that must remain on the body should be described and explained before viewing. Even an umbilical cord clamp may cause concern in a parent who has never seen one. The reason for not removing equipment also must be explained. Respectful care[10] of the infant's body after death shows respect for the person of the infant and for the grieving parents. Attention to details, such as wrapping the infant in a blanket rather than a surgical drape or towel, cleaning the infant, and holding the infant in a cuddling position, indicates care and concern.

Parents whose infant has died, has a congenital anomaly, or is ill proceed with attachment behaviors of seeing and touching in the same manner as parents of normal, healthy infants.[108] Touching is important, but the distinction must be made between touching and holding. Cradling one's infant is quite different from merely touching with a hand. Holding the infant, whether healthy, sick, or dead, for the first time is a momentous event. Touching the infant who has died may not be sufficient; parents must be given the opportunity to hold and cuddle the child before, during, and after death. Other parenting behaviors, such as bathing and dressing their infant, also should be offered to parents.[94,99]

Parents of a dead infant may need more than one chance to see and touch the infant. The first time they do so, they attach to the reality of their infant. Subsequent encounters allow a final chance to see and hold their child. Parents have described the initial encounter as saying "Hello" and the subsequent one as saying "Goodbye." Some parents may be able to accomplish closure with one visit, whereas others who might benefit from a final visit may not ask or think to ask. Offering another contact with their infant leaves the decision with the parents.

The emotional effect of seeing the infant requires support, time, and permission to cry. Attaching is a process that occurs over time. Providing parents sufficient time with their infant takes precedence over paperwork, ward routine, or taking the infant to the morgue. Parents have indicated a need to hold their infant for a longer time and not feel pushed by care providers.[94,120] Even infants who have been removed to the morgue may be returned if parents need more time and contact for detachment.[119]

When an infant dies, opportunities for memories are limited. Professionals have the responsibility of helping parents make memories so that they will have a tangible person to mourn. Encouraging parents to name their infant gives the infant a separate identity, which helps facilitate the grieving process. Tangible mementos may include photographs, handprints and footprints, a lock of hair, hand/foot castings,[115,146] measurements of the infant, identification bands, the blanket the infant was wrapped in, a blessing or baptismal certificate, and birth and death certificates. Parents find most beneficial the interventions that acknowledged the infant (e.g., photographs, holding the infant, and receiving personal mementos).* Even when parents say they do not want mementos, the mementos should be kept in hospital files and the parents made aware that they will be available to them in the future if

*References 3, 28, 94, 99, 113, 115, 119, 176.

they want them.[119] Taking pictures of the infant, obtaining other mementos, and telling the parents that such mementos will be available to them on request not only respects their immediate decision to not see or have information on the infant but also provides a mechanism for them to "know" their infant at a later date if they wish to do so.

Before an infant is transported to a newborn special care unit, photographs should be taken and given to the parents to promote bonding. If the infant remains hospitalized for a long time or requires surgery, pictures taken at weekly intervals or before and after surgery can help confirm the reality of the child's condition and progress and assist with bonding, as well as the grief process. Despite the outcome, parents will appreciate some lasting record of their child's life.

The staff members who provide emotional support for parents must also receive support from each other. Expecting staff members to immediately return to work is unrealistic. Such an emotional experience takes time and space for decompression, which is facilitated by the use of exercise, crying, and being alone for quiet time.[57] Interdisciplinary staff often feel inexperienced, anxious, and fearful and experience dread when communicating with families about sensitive end-of-life issues.[5,28,61] Many received inadequate education and support to deal with these families and their own personal pain.[10,41,42,82] Even when providers feel comfortable with end-of-life issues, they often perceive the care given to families as inconsistent and variable.[42] Just as simulation teaches teamwork in clinical psychomotor skills, simulation of "delivering bad news" enables all members of the health care team to enhance their communication skills with families.[10]

OPEN VISITING AND CAREGIVING POLICIES

Perinatal care settings with open visiting and caregiving policies foster a shared family experience and support from others. Regardless of the type of perinatal loss, no mother should experience it alone—a spouse, friend, family member, or identified supportive other should remain with her.[94,189] Members of the mother's support system will also need an outlet for expression of their grief.

Women suffering the grief of perinatal loss should be given a choice about their room assignment. Arbitrary removal from the obstetric unit may deny the mother's maternity: "Am I a mother or not?" It also may escalate her feelings of failure, guilt, and worthlessness as a woman and a mother. Because she did not produce a normal, healthy infant, she may feel punished and banished from the maternity area by isolation on another floor. Her care may be entrusted to those without expertise in the physiologic and psychologic care of the normal postpartum period, much less a postpartum complicated by loss. Placement at the end of the hall far from the nurses' station, with the door closed and no company from staff and family, only increases her feelings of loneliness and isolation. Yet being on a happy maternity floor with normal, healthy infants and their mothers may be an exceedingly difficult and constant reminder of her loss and even complicate her recovery.[101] Information about the advantages and disadvantages of staying or leaving the maternity ward should be given by the professional. The mother, knowing what will be helpful, can then make the decision.[203]

The alternative to maternal hospitalization is discharge as soon as medically possible so that the mother may join her infant when the infant has been transported to another hospital. Early discharge also facilitates an easier mobilization of supportive others in the familiar surroundings of home. Removal from the constant reminder of one's failure (i.e., other healthy infants) may let the grief work begin.[203] Early discharge is not therapeutic when the professional assumes there is a support system to provide care and no one is available. Without a plan for follow-up care and contact, early discharge merely relocates the problem.

Caregiving is as important for the parents of a sick, anomalied, or dead infant as it is for the parents of a normal infant. Open visiting and caregiving policies increase interaction between the parents and their infant by actively involving them in the reality of their child's illness, anomaly, or impending death. Even if the child lives only a short time, parental access to and the ability to take care of the infant complete the attachment process and enable them to begin the detachment of grief work. Even minimal caregiving (i.e., holding, bathing, dressing)[10] helps parents overcome their sense of helplessness and be comforted by the thought that "We did all that we could have done. We cared; we made a difference to our baby." Active parental involvement decreases poor outcomes such as aberrant parenting styles, attachment problems, and unresolved grief.[28,108]

The loneliness and isolation of death are decreased for both parents and infant when they are together at the time of death. Parents often are comforted and relieved that their fantasy of the agony of the death scene is not borne out in the quiet, peaceful reality of death.[108] Having experienced the beginning of life together, parents who are present at the ending of life can feel a sense of closure and completion. Parents who can share even a brief life with their baby and the moment of death can face death's finality knowing they did not abandon their infant but provided him or her love and care.[119] Parents who are not present at death may take care of the infant afterward by seeing and holding him or her.

Parents should be given the opportunity to make final plans for their deceased infant.[146] The planning will help them face the death and facilitate the grief process. For many parents, this is their first experience with death and making final arrangements, and they are not aware of the options. It is helpful to provide the family with detailed, specific verbal and written information about cremation, burial, funeral, or hospital disposal.[34,94,146]

A funeral may be chosen for religious reasons or as a declaration of the fetus or newborn as a person befitting burial rather than disposal. Burial leaves a specific place of remembrance and recognition that this infant lived. Care for the infant after death may include funeral arrangements, such as choosing the clothes or bathing and even dressing the infant. If parents choose not to have a funeral, they may wish to have a memorial service or do something special, such as plant a rose bush or tree, in memory of their infant. Regardless of their decision, the birth and death of their baby constitute a life event for the family, and one must recognize it.

AUTOPSY

For parents who experience a stillbirth, spontaneous abortion, or neonatal death, knowing why the infant was deformed or died eases their recovery from grief.[108] In the search for a cause, many parents blame themselves for doing too much or too little to favorably influence the outcome. Neonatal autopsies reveal important new information and the cause of perinatal loss in only 10% to 40% of the cases.[43,194] Knowing why the infant died or the converse, that not even the "experts" know why the infant died, may help assuage their personal feelings of guilt and failure.

Primary care providers (physician and nurse) must use the utmost tact and show respect for the family's feelings when approaching them for permission to conduct an autopsy. Too often the permission for autopsy is denied because of the way the subject is broached by professionals. Telling the family about their infant's death in one breath and asking for an autopsy with the next is not appropriate. Parents need time to deal with the reality of the death, including seeing and holding their infant and being with each other and supportive others before they are even ready to think about an autopsy. Consideration of the family's feelings and stage of grief greatly enhances communication with the professional.[85] Reasons for the autopsy, including a possible answer to the question of why their infant died or had an anomaly, are important to discuss in a relaxed and unhurried manner.[8] Parents may feel rushed to make a decision without clearly understanding the advantages and disadvantages and resist the emotional topic of a postmortem examination. Time for discussion with an empathetic professional, as well as between themselves, facilitates an informed parental decision; sometimes consultation with a religious leader is necessary.

The professional who receives permission for an autopsy is then obliged to discuss all findings with the parents.[8,101,194] This may entail more than one meeting with the parents because they should be informed of the findings as soon as they are available.[145] Therefore, the professional may meet with them within 24 hours of completing the autopsy to discuss gross and preliminary findings and again 2 to 8 weeks later to discuss microscopic results.[108,130] A major complaint of parents is the "long wait" (i.e., longer than 12 weeks) for autopsy results.[85] Autopsy data may indicate either a condition that has implications for subsequent pregnancies or one that has little chance of recurrence.[8] The need for genetic counseling for future pregnancies may be evident from autopsy results.[43] Discussing the results with the report in hand and offering parents a copy for future reference are also important.

ANTICIPATORY GUIDANCE

Encounters with parents after the death of their infant give professionals the opportunity for anticipatory guidance/information about what to expect from themselves and from others.[94,99] Reactions to perinatal loss differ markedly, so family, friends, and acquaintances may not act as parents might

expect. Some will be supportive and emotionally empathetic, especially if they have suffered a perinatal loss. Others will be uncomfortable and, not knowing what to say or do, may choose to avoid the couple and never mention the loss, even in future conversations. Those who are unaware of the loss may question the newly nonpregnant parents about the new infant. These inquiries are both awkward and painful.

Knowledge of the universal feelings and behaviors associated with grief gives comfort and relief to parents. Knowing what to expect from grief (i.e., how it progresses and how long it takes) is valuable to those who are or will be experiencing it.[72,99,108,146,203] Knowing the stages of grief and that the accompanying behaviors and emotions are normal decreases the feeling of "going crazy." Recovery from the loss takes time and cannot be hurried or ignored. The most difficult time is immediately after birth and the first few months after the loss (2–4 months). The emotions of grief begin to lessen toward the end of the first year.

Parents should be encouraged to support and care for each other in their time of loss. Professionals should advocate mutual support by a free expression of feelings and emotions between the parents. Although parents need each other during grief, they also need an identified support system with whom to talk and cry. Reaching outside of the nuclear family to friends, extended family, and professionals should be encouraged.[28,37,56,146] Professionals have a responsibility to ask to whom parents turn for help and support in a crisis. If there are no identified supportive others, parents must know whom to call for help in the initial bereavement period.

Anticipatory guidance is also essential at the discharge of an infant with an anomaly, a preterm, or a previously ill newborn. Knowing what to expect when going home with an infant with a defect or an infant who has been hospitalized for months makes the transition from hospital to society easier for parents. Evaluation of the grief process, the attachment level of the parents to a less-than-perfect infant, and the presence or potential for postpartum depression (see Chapter 29) is vital.

LONG-TERM FOLLOW-UP CARE

Assessing the health and functioning of parents over the first year after the death of their infant is essential because of the effect of their loss.[201] Follow-up care and contact with professionals assist grieving parents.* A study of bereaved parents highlighted their needs for follow-up: (1) appointments should be scheduled with the neonatologist soon after the baby's death and certainly within 2 months, even if autopsy results are unavailable; (2) appointments should be held in a setting away from the hospital; (3) families value the professionals' efforts to determine how they are coping; (4) families value full, frank, sensitively delivered information and reassurance that enable them to understand what happened and to assess their future risks; and (5) families do not want false reassurances, half truths, and broken promises.[130] Follow-up meetings function as a catharsis for parents, as well as an opportunity for assessment, counseling (psychologic and genetic), and possibly referral. Primary care providers (physicians, nurses, and social workers) from the perinatal care setting may provide follow-up. One study documented a significant decrease in the intensity of a mother's grief after stillbirth when she received one telephone call from the physician.[144] For the family, relating to providers with whom a relationship has been established may be easier than establishing a new relationship with a stranger.[28,35,115,146] However, being with those who are associated with the loss event may be uncomfortable for the parents at the height of their grief. For the professional, the ability to continue to be a source of help and comfort to families with whom they have established a relationship may help complete the family's grief reactions. Maintaining contact with the family may be painful as the professional relives the feelings of grief and loss associated with sharing their tragedy. Although painful, this reexperience of intense feelings gives both parents and professionals another opportunity to work toward grief resolution.

When and where to provide continuing care for families are crucial questions. Contact in the perinatal care setting both at the time of death and daily until discharge provides immediate care. However, when discharged, too often the family returns home alone to face weeks and months of unsupported and lonely grief. Without feedback about their normal reaction and society's expectations that they will shortly be "back to normal," they are abandoned to their emotions. They suffer in silence and often drift apart in their misery. With their support system withdrawn but still feeling overwhelmed with grief, parents describe the period between 2 and 4

*References 28, 56, 94, 145, 146, 201.

months after the loss as the most difficult time.[101] At 2 months after perinatal loss, parents show increased symptoms of anxiety and depression that are reduced by 8 months but still higher than in parents not experiencing perinatal loss.[186] Follow-up care from professionals is most meaningful and needed by parents during this period when they feel deserted by previously supportive others.[94] Parents experience a need for spiritual support weeks and months after the loss. Meeting with families sooner (within weeks of their loss) may alleviate the effect of decreasing support as the months go by. The professional who acknowledges the withdrawal of others but can be relied on to be available provides the parents with the emotional anchor of long-term care and support.

Breaking appointments or continually not being available may be resistance to follow-up contact with the professionals but also represents a reluctance to return to the perinatal care setting with its painful memories. A visit from the professional in the home provides a nonthreatening, familiar environment for follow-up care. The more comfortable home environment enables assessment of family interactions and facilitates communication at the "feeling" level.

Each family member and the family as a unit must be assessed for their place in the grief process as follows:

- In what stage of grief is each family member?
- Is anyone "stuck" in a stage of grief?
- Are behaviors appropriate for normal grief reactions, or do altered behaviors represent pathologic grief reactions?
- Do altered behaviors warrant referral for further treatment and evaluation?
- Do the caregiving and attachment behaviors of the parents reflect resolution of grief over the loss of the perfect child and adoption of the less-than-perfect child as the love object?

Just because everything was progressing normally at previous encounters does not mean that it should be assumed to still be so. As the flood of initial grief subsides, problems and questions that were not considered suddenly become of great concern. For the first time in months, the regressive behavior of siblings not only may be noticed but also may be extremely annoying to parents. The beginning of grief resolution may allow future projections, such as "When can I have another baby?" or the dread of the painful anniversary of the loss.

Referral to public health nurses or visiting nursing services in the community for follow-up care is appropriate. However, a written referral alone is not enough. Involving them in the hospital care and discharge planning is essential for a smooth transition to home care. Having the new professional meet the family in the hospital with the primary care providers facilitates trust transference from the familiar to the unfamiliar. Traditionally, home care providers have been involved in the care of normal mothers and infants in the community. Involvement in perinatal loss situations requires knowledge about the process of grief and willingness to share the grief of the parents. Because these may be new skills for many, continuing education programs that teach the theory and skills of effective intervention help the professional be more comfortable with a perinatal loss situation.[2,82]

Additional expertise may be warranted when the professional recognizes signs and symptoms of pathologic grief, complicated or absent grief, or concurrent multiple stresses or losses. Parents may not be ready for genetic counseling, infant stimulation programs, or financial programs until months later. Between 3 and 6 months after their loss, parents may be ready to reach outside of the nuclear and extended family for help and support for the first time.[156] Suggesting a local hospital support group or the local chapter of a national support organization may at first be met with resistance. Leaving the names and phone numbers of such organizations ensures that the parents have the information at their disposal when they are ready to use it. Until their own support system has withdrawn, parents may not be ready for a support group of other parents.[156]

Throughout this section, examples of what to say and how to say it have been used to illustrate helpful interventions for grieving families. It is essential to state that there are no "scripts." Parents do not say something and the professionals answer with a parroted response. Each encounter is a unique situation consisting of distinct parental and professional personalities. Each situation must be evaluated separately and individual interventions instituted.[94,146] It is recommended that the professional learn by observing an experienced colleague with grieving families and that the professional "practice" with role playing and situation solving before actually attempting to intervene with the parents.[10] The use of formalized education about grief, loss, and bereavement is also recommended for health care providers.*

*References 62, 70, 72, 82, 93, 126, 160.

Innovative bereavement programs have been developed to provide families and staff with support and follow-up care.* Such programs[62,82,94] provide education and assistance to the health care providers who care for the family at the time of their infant's death. There is follow-up care to the family for up to 1 year after the death of their infant.[94] Perinatal bereavement programs may include intergenerational services in which parents, grandparents, and siblings participate together in education and services.[161] Bereavement programs provide the needed support, education, and help to families, as well as to staff. Use of a couples-oriented program enables the following[156]:

- Participation in the group at 3 to 5 months after the loss when most other support systems have ceased
- Ability of partners to share with the group and each other gender-related differences in grief experiences
- Opportunity for men to share and hear about other men's feelings and coping skills
- Opportunity for couples to learn to tolerate their differences in grief processing and to process their grief together
- Enhancement and preservation of the couple's relationship

A study of maternal perceptions of the quality of services they received after a perinatal loss was studied using qualitative analysis. The findings of the study included one major theme: "dissatisfaction with the quality of care received" and six categories: effective communication, expecting responsiveness, expecting to respect the patient's dignity, expecting better care, tension of medical expenses, and insufficient facilities.[170] Having an evaluation tool to assess and continually change and improve the program is essential.[2,94,156]

CHILDREN AND GRIEF

Explaining and helping a surviving child to understand the loss of an infant is an enormous task for parents. Facilitating the child's normal feelings of sadness, worry, and anger after a loss may be difficult for parents who fear being flooded with their own emotions. Unresolved grief from the parents' own childhood may prevent the expression of grief by their children.

To maintain the myth of childhood (innocent happiness), children are often shielded from any knowledge about death, even when it is an inevitable event in their lives. Thus, children are prevented from full realization, validation, and expression of their feelings and emotions. They cannot formalize and express their grief over the loss of a significant person; are at increased risk for the development of complicated grief and emotional and behavioral problems, including psychiatric issues, as children and adults; and are unable to process their grief into reconciling a future life without their sibling.[98,121]

Children are called the "forgotten mourners."[191] Although adults are encouraged to cry, talk, and gradually understand and integrate their feelings of grief, no one helps the child deal with the same frightening feelings. No one discusses the loss with the child, because "He might cry" and because of the adult's inadequacy and lack of understanding of how to respond and what to say. No amount of secrecy or denial of the situation will hide the fact that the child is being excluded from an important family event.

Attempts to protect children from feelings of grief and mourning because of death or other important losses isolate the child. Age and developmentally appropriate explanations include the child in the family's experience, rather than separating and excluding him or her from what is happening. Shielding children from the knowledge of death denies them the reality of life and the opportunity for personal growth and mastery of the experience. Often in America, the subject of death, like that of sex, is taboo for children.

A child's grief and mourning in response to perinatal loss depend on his or her cognitive and developmental level, the extent of prenatal attachment and expectation about the infant, the degree of ambivalent feelings, and the response of the parents to the death. Because the child's understanding of death differs from that of adults, knowledge of the stages of growing awareness is essential for both parents and professionals working with children experiencing grief (Box 30.8).[121,191] Regardless of age or developmental stage, a universal fear of childhood is the fear of separation and abandonment. For a young child (younger than 5 years), the loss of the infant is experienced indirectly through parental grief. A young child reacts to the emotional

*References 62, 82, 94, 115, 156, 161.

BOX 30.8 CRITICAL FINDINGS
A Child's Developing Concept of Death

Age	Cognitive Understanding	How Experienced
Infant (to 12 months)	None	Indirectly through parental grief expressed in: Emotional withdrawal Inability to provide concern and continuity in caregiving behaviors Overconcern for fear of recurrent loss Changes in eating, elimination, and sleep patterns; unresponsive to parental holding and cuddling[121]
Toddler (1-3 years)	Little understanding of cause and effect Death may be confused with sleeping or being away	React to changes in behavior of grieving parents and reflect their feelings and anxiety Changes in sleep and behavior (shy, aggressive, acting out, attention-seeking, angry), regressive behaviors (enuresis, loss of skills), and complaints of headaches and stomachaches[121]
Preschooler (3-6 years)	View death as a temporary state and not an inevitable occurrence Believe that they are the center of the universe and can do anything, and that thinking is doing (thoughts have the power of actions)	Expect the dead to return—ask questions about "when?" Changes in sleep and behaviors (shy, aggressive, acting out, attention-seeking, angry), regressive behaviors (enuresis, loss of skills), and complaints of headaches and stomachaches[121]
School age (6-12 years)	Understand that death is inevitable and irreversible; 6- to 9-years-olds personify death as a separate person (skeleton; bogeyman) About 8 years old: "death phobia," a normal developmental stage characterized by preoccupation with thoughts of own death and that of loved one Reasons concretely, with ability to see cause-and-effect relationships	Realize death occurs in adults, such as parents, and even in children; realize death is permanent, not temporary state May show interest in biologic aspects of death and details of funeral Changes in sleep and behaviors (loneliness, isolation, acting-out, sad, unhappy, depressed, anxious and fearful, aggressive, attention-seeking), difficulties with school work as a result of inability to concentrate, headaches and stomachaches, regressive behaviors (enuresis)[121]
Adolescent (12 years)	Able to think abstractly about death like the adult; philosophic reasoning	Similar to that in adult

Modified from American Academy of Pediatrics, Committee on Psychosocial Aspects of Child and Family Health. The pediatrician and childhood bereavement. *Pediatrics.* 2000;105:445. Reaffirmed in *Pediatrics.* 2013;132(1):e281; Gardner SL, Merenstein GB. Helping families deal with perinatal loss. *Neonatal Netw.* 1986;5(2):17.

withdrawal of grieving parents and fears loss of them (and their love).

Although children at different developmental stages have their own conceptions of death, adults must provide them with the facts about the situation in language that they can understand. They may benefit from guidance by the nurse, social worker, or other health professional about beneficial approaches to facilitate the child's grief work.[151] The professional serves as a resource, role model, and support system to parents and other family members in caring for their surviving children. Printed and videotaped materials are also available to assist parents in helping their other children understand death (see "Resource Materials for Parents" at the end of this chapter). Age-appropriate storybooks concerning death can facilitate grief discussion and elicit questions and feelings from children.

Just as grieving adults need repetition, children need repeated explanations and discussions about the loss. Constantly in a state of developmental flux, the child attempts to view the loss in new ways as a result of increasing maturation. Asking questions (usually at inopportune times) and making comments about the infant are ways the child continues to process the experience, often long after the parents have completed it.

These questions and comments may seem endless and resurrect the parent's own grief. The child's inquiries must be encouraged and supported so that he or she knows that talking about the loss or death is acceptable. Exploring the child's feelings for fears of causation, guilt, or the wonder if "death is catching" enables them to be dealt with appropriately. Truthful discussion with the child dispels the worst fears and fantasies and replaces them with reality that is "not too horrible to discuss" with parents. If the cause of the infant's death is known, it should be explained to the child in simple, direct terms: "Baby Bobby couldn't breathe by himself because his lungs were sick. His sick lungs only happen to little babies."

In one study, bereaved children had more frequent health care contacts for symptoms (e.g., abdominal pain, enuresis, headaches, insomnia) with no organic cause in the year after their loss.[118] Subsequent illness may precipitate worry by the child that he or she, too, will die. Often, this fear is not verbalized but acted out by significant behavioral changes such as withdrawal, clinging, whining, or overactivity that is uncharacteristic for the child. Verbal reassurance that the child will not die and a reminder that "the baby died of a sickness that only little babies get; big boys and girls can't get it" are helpful.

The normal feelings that accompany grief should be acknowledged and explained to the child. "Mommy and Daddy feel sad that Baby Jean died. Sometimes we will cry because we feel sad. It's okay to cry when you feel sad." Permission for the expression of the child's feelings should also be given verbally: "You might feel sad, too. It's okay for you to cry when you're sad. Then we will talk about how you are feeling." Encouraging children to draw or write their feelings is another way of giving them permission to express their grief.

Using words such as "went away," "expired," "lost," or "went to sleep" is dangerous in describing death to children. Because young children are concrete and literal, they think they might die if they "go to sleep" or that anyone who leaves them is in danger of dying. Children also relate current experiences to past ones and interpret "lost" quite literally. In the mind of the child, if the parent only searched well enough, the misplaced (i.e., "lost") child would be found.

Including children at funeral or memorial services facilitates their grief and prevents exclusion from a significant family event.[96,121] Consideration of the family value system, age of the child, and religious customs must enter into the decision to include the child. Adequate preparation includes a discussion of everything the child will see, hear, and feel, including the normal adult emotions of crying and sadness. An adult other than the grieving parents should accompany the child to reiterate what is happening and to meet the child's physical and psychologic needs. Adult support is necessary so that the child can express and deal with his or her feelings.

Helping children with their grief is also therapeutic for parents. Assisting children to master the crisis of loss ultimately augments the parents' self-esteem and restores confidence in their parenting skills.[108] Parents can deal in a healthy way with their own grief when they can facilitate the grief of their other children. Qualitative studies revealed parental spiritual needs and support of siblings after a perinatal loss:[95,132]

- Recognition and acknowledgment of the child's grief, which included listening and answering questions honestly; interpreting and acknowledging the meaning of the child's behaviors; shielding from the insensitivity of others; and knowing when support of the child would be more effectively handled by someone outside the immediate household
- Inclusion of the child in family events, rituals, and practices such as visiting, holding, and touching the baby in the hospital; attending the funeral/memorial service; and visiting the gravesite
- Keeping the baby alive in the family's memory by encouraging questions and comments about the baby; expressing feelings about the loss, including viewing photos and personal items of the baby; and recognizing the deceased infant in birthday/holiday celebrations

PATHOLOGIC GRIEF

The absence of grief when it would be expected is not a healthy sign but, rather, a cause for concern.[101] The emotions of grief and their expression are healing. Early and full expression of grief is associated with an optimal outcome.[101] However, many people in grief-producing situations attempt to avoid the pain of grief and the expression of emotions, the

result of which prolongs mourning, delays a return to the previous lifestyle, prevents the creation of new attachments and relationships, and ultimately results in pathologic grief (see Box 30.6).[101,191]

Not grieving precludes opportunities for growth and change. No new coping styles will be attempted. No novel alternatives to problem solving and adapting to a crisis will be added to the repertoire of behavior for future use. In other words, those who choose not to do grief work say "no" to their own potential and remain frozen in development.[137] Under the stress of not resolving their grief, some may even regress in their development.

Reproductive loss is a blow to self-concept and self-esteem, as well as a loss of the infant. Blocking appropriate feelings of loss, grief, and anger results in a significant decrease in one's sense of self-esteem.[48] After the death of their neonates, 33% of mothers suffered severe and tragic outcomes (including psychoses, phobias, anxiety attacks, and deep depression; see Chapter 29).[108,203] Those who cannot effectively resolve their grief may suffer lifelong emotional damage;[125] however, some empirical research shows that those who suppress feelings of grief may recover with relatively few difficulties.[14]

Not working through grief associated with repetitive contact with perinatal loss also affects the staff. To cope with feelings, they may hide behind a "professional" demeanor characterized by decreased spontaneity and withdrawal. Such a provider defends against the repeated pain of loss by emotional dissociation from the situation. The real self does not respond; instead, the professional stays in the role of the omnipotent, unemotional physician or nurse. The result, self-alienation, eventually desensitizes the professional to the experience and ultimately prevents any empathy with the experience of others.[97] Emotions that cannot be acknowledged or expressed healthily are vented in ways that may be destructive to relationships in personal and professional life.

Unresolved grief does not disappear and is not dissipated. The emotions accompanying grief may never be expressed but are not forgotten by the unconscious mind. Containment of these emotions through repression or suppression takes psychic energy. A conscious, intentional decision to postpone or dismiss grief to meet others' needs or to meet immediate demands of the loss situation (e.g., funeral arrangements/care of a surviving multiple) is called *delayed grief.*[116,125,146] For a period of time (days, weeks, or longer), there is little or no grief response when such a reaction would be expected and appropriate. Delayed grief also may be the result of repression—the unconscious content seems to have a life and energy of its own that become the sources of later emotional conflict.

Grief that is inhibited and never resolved is called *abortive.*[125] Those who have aborted their grief work often live bereft of *joie de vivre,* with no interest, concern, or enthusiasm for life. *Complicated grief,* a failure to transition from acute grief to integrating grief and resuming a fulfilling life, occurs when there is no movement (6 months after the loss) beyond the feelings of acute grief.[138] Inability to function in daily life accompanied by intense longing and yearning for the deceased, failure to accept the reality of the death, overwhelming guilt, and detaching from family and friends characterize complicated grief and must be distinguished from major depression.[104,138] Complicated grief is more common after the loss of a child, including a perinatal loss, and more common among women with preexisting psychological difficulties and/or use of psychopharmacologic therapy.[60,104] One year after a perinatal loss, higher grief levels are associated with (1) being the mother (mothers had more grief than fathers), (2) no previous living children, and (3) a low-level of socioemotional support from the father of the baby's family.[182]Although only 10% to 20% of those experiencing grief and loss have complicated grief, referral for intervention from mental health professionals is required.[138] Studies of internet-based cognitive therapy for perinatal loss showed a significant reduction in grief, PTSD, and depression in the treated group, thus preventing the development of complicated grief.[102,103]

Grief that is not resolved remains buried in the psyche, waiting for an opportunity to "rear its ugly head." A current loss may remind the psyche of the unmourned grief from a previous loss or losses.[63] As the two (or more) losses become intertwined and are experienced as one and the same, repressed emotions of unresolved grief pour forth. Grieving more than one loss or a lifetime of losses is more difficult and emotionally draining than grieving one event at a time.[45] Cumulative grief work also may be occurring when a current loss of seemingly little importance overwhelms the person with intense emotions.[63,125] This flood of emotions seems disproportionate to the current

BOX 30.9 CRITICAL FINDINGS
Symptoms of Unresolved Grief

1. Vivid memory for the details of the perinatal loss event
2. Flashback to the event
3. Anniversary grief (date of birth or expected date of delivery)
4. Emotions of grief (sadness, anger, or crying) when talking about loss
5. Intense emotions with subsequent loss or crisis

loss and is only peripherally related to it. The unconscious, unresolved grief is finally uncovered when the individual is flooded with emotions. Thus, aspects of unresolved grief from the past[190] may influence the emotional components of any grief reaction.

Grief and loss events of the perinatal period have been equated only for a relatively short time (about 30 years).[143] Because loss during the perinatal period is a common experience, many childbearing and older women (and men) have never grieved over their experience of spontaneous abortion, stillbirth, or neonatal death, even 10 to 20 years after its occurrence. Parents (or grandparents) in a current perinatal loss situation also may be dealing with unresolved grief from a previous perinatal loss. Unresolved grief (whether from perinatal or other loss events of life) may become available for resolution in subsequent crisis events. A mother who delivers a normal healthy newborn, yet is depressed in the postpartum period, may not have postpartum depression. Instead, she may be grieving the unresolved loss of a spontaneous abortion, therapeutic abortion, or other perinatal loss. The normal grief reaction accompanying relinquishment may persist and often leads to chronic unresolved grief that may present itself during and after a subsequent pregnancy.[13] Her depressed mood could also be resulting from unresolved grief from the loss of a parent, spouse, or child. Depressed menopausal women may be experiencing the cumulative effects of a lifetime of unresolved grief (Box 30.9).

Recognizing unresolved grief has implications for facilitating grief work in a current loss, episodic care, and health maintenance. The energy to keep unresolved emotions restrained could better be used in personal growth and development, grieving, and maintaining and establishing relationships. The lifelong stress of unresolved grief contributes to both psychologic and physical illness, including increased death rates and an earlier death.[150]

Not grieving a perinatal loss affects the individual involved and the relationships with significant others, including present and future children. Resolution of maternal grief about the infant's prematurity, as well as the quality of maternal interaction, are necessary for secure infant attachment.[172] Asynchronous grief and the absence of grief in one or more family members weaken and strain family relationships.[19,56,108,138] The irritability and preoccupation of normal grief may overly disrupt the family. Differences may be magnified to the extent that major rifts and disruptions in the relationship occur, resulting in an increased incidence of strained marital relationships, separation, and divorce.[19,104,108, 138]

Exclusive dedication to the care of a malformed or ill infant to the detriment of other family relationships is symptomatic of a pathologic grief reaction.[108,175,200] The parent who neglects other children, the couple's relationship, and social outlets is so overwhelmed with guilt about having caused the baby's defect that nothing else in life matters. This guilty attachment and exclusive dedication are ways of avoiding grief work.[175] Other forms of pathologic reactions include parental rejection and intolerance of the deformed or ill infant.[108]

The parent who is emotionally withdrawn and unavailable to the family because of chronic grief and depression cannot attach to and care for present or subsequent children. Aberrant parenting styles (resulting in a vulnerable, battered, or failure-to-thrive child) may be the result of prolonged separation, unresolved grief, or grief that has progressed beyond the anticipatory phase, resulting in the emotional ties with the infant being severed.[108] These difficulties with caring and parenting may affect the deformed or ill child and all the children in the family. In turn, these children may grow up unable to parent subsequent generations because of the type of ineffectual parenting they received. Parents who grieve inappropriately may leave their children a legacy of psychosocial problems, such as difficulty with separation, independence, and control (e.g., school phobia and toilet training); failure to thrive; and sleep disturbances.

Planning for a new pregnancy and another baby should begin after the grief process for the lost infant

is complete (about 6 to 12 months) so that parents are emotionally ready to invest in a relationship with another fetus/newborn.[108] A national survey of U.S. obstetricians found that two-thirds of the respondents endorsed a waiting time of less than 6 months for subsequent pregnancy after stillbirth.[74] The researchers concluded that this was a "provocative" finding because short interpregnancy intervals are associated with increased fetal risks for poorer outcomes.[54] Because the decision to become pregnant is highly personal and individual, many women are pregnant within 6 to 12 months after a perinatal loss.[158] Some women see a subsequent pregnancy as a "cure" for their overwhelming feelings of emptiness and failure,[192] whereas others are averse to a subsequent pregnancy. Pregnancy after a perinatal loss is characterized by (1) increased pregnancy anxiety, a heightened fear, concern, and vigilance about the pregnancy and baby; (2) comparisons of current and previous pregnancies; (3) less attachment to the current versus the previous pregnancy; (4) a desire to see and phone the health care provider more often; (5) a desire for more prenatal testing; and (6) the subsequent pregnancy possibly being the precipitating event for PTSD in both mothers and fathers.[11,20,58,183,190] Having a subsequent child may promote parental resilience and represent positive parental adjustment after a perinatal loss.[100] Mothers appreciate being educated by their health care providers about the benefits and risks of subsequent pregnancies so that they can make an informed choice.[58] Benefits of postponing pregnancy include (1) enabling physiologic recovery from pregnancy before another is attempted; (2) enabling psychologic recovery, progression of grief work, and an optimal state to emotionally invest in a new pregnancy and newborn; (3) avoiding anniversary dates with the second pregnancy/child; and (4) improving the maternal-infant relationship—less anxiety, overprotectiveness, overindulgence, and hypervigilance.[5,190] The time necessary for physical and emotional recovery varies widely, and parents may benefit from interconceptual counseling after a perinatal loss.[105,161]

31 DISCHARGE PLANNING AND FOLLOW-UP OF THE NEONATAL INTENSIVE CARE UNIT INFANT

ANGEL CARTER AND BRIAN S. CARTER

Parents with infants in the neonatal intensive care unit (NICU) have immediate worries about whether their newborn infant will survive but soon thereafter start having concerns about how their child will do through infancy and into adulthood. As the infant's convalescence begins, so does discharge planning; this brings to the forefront questions about outcomes. **Unfortunately, it is almost impossible to know the outcome of any individual infant at the time of discharge from the NICU. Caregivers within the NICU must be knowledgeable of the latest outcomes literature to respond to these questions and to guide parents in the importance of follow-up care.**[159]

Of the many reasons that newborns require neonatal intensive care, the most common one is preterm birth. Numerous publications report the outcomes of very-low-birth-weight (VLBW; birth weight <1500 g) and extremely low-birth-weight (ELBW; birth weight <1000 g) infants.[8,29,105] Many studies have focused on the survival and outcome of even more immature infants with birth weights below 750 g, or on infants born at the limits of viability, 22 to 25 weeks of gestation, often referred to as extremely low gestational age newborns (ELGANs).[29,91] **Late-preterm infants have been a topic of renewed interest because they are at risk for a unique set of problems with adverse outcomes.**[5,60] **Infants with intrauterine growth restriction (IUGR) are also vulnerable to a wide range of complications requiring neonatal intensive care, especially if they are also preterm and experience extrauterine growth failure.**[63,93,123] Full-term infants may also require intensive care because of perinatal or neonatal conditions and are at risk for health and developmental sequelae.[75] Finally, a number of infants with congenital anomalies require surgery and/or neonatal intensive care.

PLANNING FOR DISCHARGE

An organized, well-implemented discharge plan is the beginning of successful follow-up of the NICU graduate. A family-centered multidisciplinary team approach uses the expertise of many disciplines, along with the family, to formulate and implement the discharge and follow-up plan. The team can comprise parents, grandparents, other caregivers, physicians, nurses, case managers, dietitians, therapists, developmental specialists, and social workers.

Integrating family-centered principles into the discharge process, as a continuation of family-centered care practiced throughout the NICU stay, facilitates better parental adaptation to the transition to home.[65] For many infants, the NICU stay has been lengthy and complex, and **families may experience varying degrees of anxiety and stress as they prepare for the infant to come home.** In some cases, a long, complicated medical course may have affected attachment and bonding. **A survey of preterm mothers found that symptoms of psychological distress (fatigue, depressive mood, anxiety, physical symptoms) persisted up to 1 year after the birth of their**

BLUE type highlights content that is particularly applicable to clinical settings.

premature baby.[66] Families may need extra attention paid to these issues before they can successfully attend to the discharge process. A thorough assessment of caregiver needs, environmental issues, and knowledge of their infant's care before discharge is an important part of the planning process. Implementation of a parent educational-behavioral intervention program during the NICU stay may be one mechanism to reduce stress, depression, and anxiety and effect more positive interactions of parents with their infant, and a reduced hospital stay and associated costs.[102]

Considerations Before Discharge

INSURANCE

Many parents may need assistance to enroll their infant in their existing insurance policy or to identify the procedures necessary to apply for medical assistance. This process can take many weeks and must be accomplished before discharge so the parents can select a pediatrician for follow-up care and arrange outpatient subspecialty care as needed. Outpatient physician visits, therapies, medical supplies, medications, and nutritional supplements are often reimbursed differently from inpatient services. Out-of-pocket costs can escalate quickly and add additional challenges for families. Social workers, case managers, and financial counselors are valuable resources to assist families in this process.

IDENTIFYING A FOLLOW-UP PEDIATRIC HEALTH CARE PROFESSIONAL

A pediatric health care professional to follow the infant after discharge, trained in the care of NICU graduates, should be identified before discharge. Ideally, this clinician has been identified early in the admission to facilitate regular communications regarding the infant's medical course. In a 1992 policy statement, the American Academy of Pediatrics (AAP) attempted to define the concept of a medical home for children. Multiple challenges with implementation led to an updated definition with additional designations specific to medical conditions.[9] As defined, a medical home is considered to be the ideal practice for the health care management of children, although challenges remain with resource allocation, role definitions, and implementation.[9,14]

Immediately before discharge, a written summary should be provided to the outpatient primary pediatric health care professional, with follow-up recommendations regarding nutrition and growth, developmental surveillance, and subspecialty referrals, along with verbal notification of the discharge date. Parents should be advised to keep this summary with the infant at all times because this written documentation of the NICU stay is invaluable if the infant needs to be seen on an emergency basis shortly after hospital discharge. Providing families with a "care notebook" containing specialized forms and organizing tools can be a valuable addition to the discharge process, particularly for those with anticipated complex follow-up needs. Information to compile care plans for children with special health care needs can be found on a number of websites, for example, the National Institute for Children's Health Quality Medical Home (www.nichq.org), the AAP Medical Home (www..aap.org/en-us/professional-resources/practice-transformation/medicalhome/Pages/home.aspx), and others.

CAREGIVER EDUCATION

In a family-centered environment, families have been partners in caring for their infant throughout the hospital stay. Discharge teaching then becomes a process of reinforcing and attending to final details. In some instances, however, this teaching may be limited by the inability of the family to be present because of transportation and family or job constraints. In these cases, readiness of the caregivers and home environment should be thoroughly evaluated (Box 31.1). Infants with complex equipment and care needs at the time of discharge may require skilled nursing support in the home to be candidates for discharge from the hospital.

HOME EQUIPMENT

Any necessary durable medical equipment or supplies, such as an apnea monitor, pulse oximeter, feeding pump, ventilator, suction equipment, or oxygen for home use, should be delivered to the hospital before discharge to give parents practice using the equipment. When a home apnea monitor is used, a clear plan outlining the reasons for initiating home monitoring and the indications for discontinuing it should be discussed with the family and the primary care provider before discharge. The company supplying the equipment should provide training in its use and an agreement for maintenance and service support while equipment is being used in the home. NICU nurses or respiratory therapists should verify the parents' understanding of the

BOX 31.1 CAREGIVER EDUCATION

- Every encounter with the parents is a teaching opportunity. Assess each individual family's readiness for discharge.
- Inform parents verbally and in writing about the tests included in the newborn genetic screening and how they will receive the results.
- Teach parents the special nutritional needs of preterm infants after discharge, including nutritional supplementation, lactation support and intervention to promote breastfeeding, and use of alternative feeding methods, if necessary.
- Teach parents the importance of maintaining their infant on home oxygen therapy (e.g., for growth and development, sleep, and feeding) at designated pulse oximetry targets until pulse oximetry studies (e.g., awake, feeding, asleep) document that the infant can tolerate weaning and discontinuing the supplemental oxygen.
- Teach parents to dress their infant appropriately to maintain adequate axillary temperature.
- Teach parents appropriate safety precautions:
  - Proper positioning (supine) for sleep: "Back to Sleep."
  - Proper use of car seats.
  - Importance of a smoke-free environment.
  - *NEVER shake the baby!* Dangers of shaking infants include blindness, brain damage, developmental delays, seizures, paralysis, and death.
  - Information, in writing, about all medications for their infant including name, action, dose, route, side effects, and schedule.
  - Provide parents an opportunity to participate in an infant CPR class.
- Teach parents the importance of follow-up care and appointments:
  - Timely follow-up for infants with ROP provided verbally and in writing.
  - Timely follow-up for hearing screen and referral for rescreening.
  - Need for monthly RSV immunizations throughout the RSV season.
- Give parents the newborn immunization record.
- Teach parents the importance of their own self-care, and assist in identifying resources for support.

CPR, Cardiopulmonary resuscitation; *ROP,* retinopathy of prematurity; *RSV,* respiratory syncytial virus.

purpose of the equipment and its operation and also ensure that home caregivers for the baby have been trained in cardiopulmonary resuscitation (CPR). The family should be provided a clear contact number to the clinician who will be managing the home equipment.

ROOMING-IN

Whether or not an infant is going home with equipment, giving family caregivers the opportunity to provide "independent" care of their infant with professional caregivers nearby for assistance has been shown to increase parental competence and provide confirmation of readiness for independent care at home.[35,115] A recent meta-analysis demonstrated improved outcomes from rooming in for infants with neonatal abstinence syndrome (NAS), including a decreased need for pharmacologic interventions and reduced length of stay.[98]

DISCHARGE CRITERIA

Clearly defined discharge criteria provide both the family and the staff a point of reference from which to judge the infant's progress. Discharge criteria should be reviewed in a multidisciplinary team meeting with the family. Setting goals that the infant, parents, and staff must accomplish before discharge helps keep everyone focused and prevents important components of the discharge process from being overlooked.

For preterm infants, the attainment of a minimum weight is no longer the criterion for discharge. Rather, the ability of a preterm or recovering neonate to maintain physiologic stability and the ability of the family to care for the infant's physiologic and developmental needs dictate the infant's readiness for discharge (Box 31.2). There are significant variations across NICUs for specific discharge criteria, with assessment of apnea and feeding behavior significantly influencing the duration of hospitalization in a healthy preterm infant. The AAP policy statement, "Hospital Discharge of the High-Risk Neonate," provides guidance that should minimize such variations.[9]

TRANSFER

Some infants are not discharged home from the regional or tertiary NICU but, instead, are transferred from a regional referral center to a community unit or facility for the duration of their remaining hospital stay. Transfer to a community hospital may be beneficial to families because they are often closer to the parents' home (especially if the NICU is part of a regional referral center). Possible locations for transfer, as well as the criteria for transfer and financial implications to the family, should be discussed with the parents early in the hospitalization if this is an expected possibility. Communication of a comprehensive discharge plan should

BOX 31.2 SELECTED CRITERIA FOR DISCHARGE OF THE PREMATURE INFANT OR NEONATE WITH SPECIAL NEEDS

Infant

- Demonstrates sustained weight gain of sufficient duration
- Shows adequate maintenance of normal body temperature, clothed in an open bed, at normal room temperature (20°C to 25°C)
- Establishes and maintains competent breastfeeding or bottle feeding without cardiopulmonary problems
- Nutrition assessment and dietary management have been provided as indicated
- Hematologic assessment and management have been provided as indicated
- Physiologically mature and stable cardiopulmonary function of sufficient duration has been documented
- Parents have been given a report of neurodevelopmental and neurobehavioral status
- Metabolic, hearing, and indicated funduscopic screenings have been completed
- Infant has been appropriately immunized, including respiratory syncytial virus prophylaxis and plan for subsequent injections
- Car seat evaluation has been completed
- A review of the hospital course has been completed, pending medical problems have been noted, and follow-up plans have been established
- A home-care plan, individualized to the patient's needs, has been provided by all disciplines

Parents, Family, and Home Environment

- Identify and assess at least two caregivers for home.
- Assess psychosocial and parenting strengths and risks.
- Consider the home environment and on-site visit as indicated.
- Review resource availability (including financial, utilities, and transportation).
- Determine caregiver availability, ability, and commitment to the following:
  - Provide basic infant care: diapering, bathing, dressing, cord and circumcision care.
  - Maintain infant's thermal state: able to take temperature and dress appropriately.
  - Feed infant (breast, bottle, or alternative method—nasogastric tube, gastrostomy, parenteral nutrition), and demonstrate formula preparation if required.
  - Manage home feeding tube, infusion pump, intestinal stoma care, and other devices as indicated.
  - Manage home monitoring, oxygen, and other equipment as indicated; address initial problem solving; demonstrate CPR and initial emergency interventions.
  - Provide a safe environment (car seat, heat, electricity, telephone, transportation, smoke-free, emergency resuscitation).
  - Recognize signs of illness, and identify when to call the primary care provider or emergency services.
  - Have a support system identified to assist in the infant's care.
  - Demonstrate medication administration, and recognize signs of medication adverse effects (e.g., toxicity); understand the importance of follow-up care, and know whom to call for questions or concerns.
  - Obtain influenza vaccine at beginning of influenza season.

CPR, Cardiopulmonary resuscitation.

Modified from American Academy of Pediatrics. Committee on Fetus and Newborn. Hospital discharge of the high-risk neonate. *Pediatrics.* 2008;122(5):1119. Reaffirmed in *Pediatrics.* 2012;129(4):e1103.

take place with the receiving hospital before transfer.[73,91] As the capacity for back-transporting convalescing neonates to community hospitals has increased in the United States over the past 20 years, persistent issues of communication, trust, and psychosocial support remain for parents.[54]

EARLY DISCHARGE

Preterm infants are often discharged between 35 and 37 weeks' chronologic age after demonstrating cardiorespiratory stability, thermal stability, and adequate feeding skills.[9] Parental concerns at the time of discharge may include their own ability to have adequate rest, their readiness to learn and assume self-care and newborn care, their readiness to parent, and availability of support systems. Concerns about the newborn may include transition from the intensive care nursery to the home care environment, ability to feed and hydrate adequately, and the early development and recognition of complications.[135]

Late-preterm infants ($34^{0/7}$ to $36^{6/7}$ weeks' gestational age) are often the size of full-term newborns, but are physiologically and metabolically immature.[66] Timing of discharge of preterm infants should be individualized based on physiologic maturity and feeding competency. Late-preterm infants usually do not meet the necessary competencies for discharge before 48 hours of age.[60] A follow-up visit for medical assessment of these infants is recommended for 24 to 48 hours after discharge.[60]

Screening

GENETIC SCREENING

Initial screening of sick or premature infants is performed as soon as possible after birth, before the administration of blood products. Although it is common for these infants to have some relatively abnormal results—especially for thyroid function or amino acid profiles while on parenteral nutrition—early screening is recommended to identify in a timely manner those infants who may have an inborn metabolic disorder, congenital endocrinopathies, or hemoglobinopathies so that early treatment can be initiated.[16,40,52] **Subsequent screenings should take place according to established guidelines, depending on state requirements.** Recommendations for continued screenings after discharge should be clearly outlined in the discharge summary.

HEARING

All infants should be screened for hearing loss using otoacoustic emissions or automated auditory brainstem response testing before discharge from the nursery.[112] This initial screening should be performed once the infant is medically stable, and **if there are any concerns that warrant a secondary screen, rescreening should occur before 1 month of age.** Infants who do not pass (are "referred" after secondary screening) should have a full-scale auditory diagnostic evaluation by 3 months of age. **Infants with confirmed hearing loss should receive intervention by 6 months of age from an infant hearing specialist.**[15,18] Those infants with an increased risk for hearing impairment should be assessed by a pediatric audiologist with a follow-up schedule outlined for the parents (Box 31.3). **The goal of early detection and intervention is to maximize language, cognition, literacy, and social development of the hearing-impaired infant.**[137]

VISION

Development of severe retinopathy of prematurity (ROP) may still be a concern at the time of NICU discharge for infants born prematurely. Infants born at less than 30 weeks of gestation or less than 1500 g birth weight, and selected infants with a birth weight between 1500 and 2000 g or gestational age greater than 30 weeks with an unstable clinical course, should have a retinal screening examination with pupillary dilation.[17] Published tables make recommendations for timing of the initial examination dependent on postmenstrual age and chronologic (postnatal) age.[17] Timing of follow-up examinations should be according to the ophthalmologist's recommendations based on retinal findings. **Arrangements for follow-up examinations should be made before discharge.** Ophthalmologic follow-up for infants with any stage of ROP (whether they required treatment or not) is recommended at 4 to 6 months after hospital discharge.[17] **Current research indicates that the risk to visual development in preterm infants does not end when the risk for ROP has passed. All infants born prematurely, whether or not they develop ROP, are at increased risk for amblyopia/strabismus and refractive errors.**[117]

CRITICAL CONGENITAL HEART DISEASE

With as many as 30% to 50% of critical congenital heart disease (CCHD) cases diagnosed after discharge, pulse oximetry screening before discharge was recognized in the United States

BOX 31.3 CONDITIONS ASSOCIATED WITH INCREASED RISK FOR HEARING LOSS

- Neonatal intensive care unit admission for more than 5 days or any of the following regardless of length of stay: extracorporeal membrane oxygenation, assisted ventilation, exposure to ototoxic medications (gentamicin and tobramycin) or loop diuretics (furosemide [Lasix]), hyperbilirubinemia requiring exchange transfusion
- Syndromes associated with hearing loss such as neurofibromatosis, osteopetrosis, and Usher syndrome
- Family history of hereditary childhood hearing loss
- Craniofacial abnormalities
- Congenital infections such as cytomegalovirus, toxoplasmosis, bacterial meningitis, syphilis, herpes, and rubella
- Physical findings (white forelock) associated with syndromes known to include hearing loss
- Neurodegenerative disorders (e.g., Hunter syndrome) or sensory motor neuropathies (e.g., Friedreich ataxia and Charcot-Marie-Tooth syndrome)
- Culture-positive postnatal infections such as bacterial and viral (especially herpes and varicella) meningitis
- Chemotherapy
- Caregiver concerns regarding hearing, speech, language, or developmental delay

Modified from American Academy of Pediatrics and Joint Committee on Infant Hearing. Year 2007 Position Statement. Principles and guidelines for early hearing detection and intervention programs. *Pediatrics.* 2007;120(4):898.

as a critical component to discharge planning of the neonate.[139] Guidelines for this screening were developed and published in 2011 and recommend screening within 24 hours of life, or close to discharge, and should include preductal and postductal oxygen saturation with a "failure" receiving further evaluation by echocardiography and a pediatric cardiologist.[87]

IMAGING

Premature infants are at increased risk for injuries to the brain, potentially causing permanent damage. The most common form of damage and the leading cause of chronic neurologic morbidity is periventricular white matter injury.[20] Imaging techniques for routine screening for white matter injury has traditionally been cranial ultrasonography because of its availability and tolerance by the infant, though studies have shown magnetic resonance imaging (MRI) and advanced MRI to be superior at term equivalent age.[110,121] Woodward et al.[161] reported that **abnormal findings of MRI at term equivalent age in very preterm infants strongly predict adverse neurodevelopmental outcomes at 2 years of age.**[161] However an evaluation of the prognostic value of head ultrasonography versus MRI found that conventional near-term MRI did not substantially enhance the prediction of severe early school-age outcomes.[78] Another recent study of the effect of MRI on preterm infants and their families predicted moderate or severe motor impairment at 20 months of life only slightly better than ultrasonography, while also increasing costs.[58]

A review of MRI screening to identify risks of suboptimal neurologic outcomes suggests the following be considered as indications for screening by MRI at approximately 36 weeks' or greater postmenstrual age:[76]

- Grade III to IV intraventricular hemorrhage (IVH)
- Periventricular hemorrhagic infarction
- Cystic periventricular white matter injury
- Cerebellar hemorrhage or other abnormalities on ultrasonography
- Suspected white matter abnormalities on ultrasonography (echodensities/echolucencies)
- Posthemorrhagic hydrocephalus
- Abnormal neurologic examination
- Other conditions warranting detailed neuroimaging (metabolic disorders or suspected congenital structural abnormality)

Preventive Care

IMMUNIZATIONS

Infant immunizations are recommended for all NICU infants, according to the guidelines issued by the Centers for Disease Control and Prevention (CDC) and approved by the AAP.[41] **Immunizations administered in the NICU should appear in the discharge summary.** When immunizations have been declined by parents, this should be clearly indicated in the discharge summary, along with follow-up recommendations.

RESPIRATORY SYNCYTIAL VIRUS INFECTION PROPHYLAXIS

Respiratory syncytial virus (RSV) infection poses a risk for serious morbidity or even death of infants who were born prematurely, especially those with chronic heart or lung disease. In a study of 702 infants who were admitted for RSV infection, 42% were admitted to the NICU, with 20% requiring mechanical ventilation and the frequency intensifying with earlier gestational age and younger chronologic age.[25]

For qualifying infants, RSV prophylaxis should be initiated with intramuscular palivizumab before discharge into the community setting during RSV season. RSV infection prophylaxis should be coordinated with the follow-up pediatric care provider for subsequent monthly injections. Recommendations for qualifications have not changed since 2014 and include, but are not limited to those listed in Box 31.4.

BOX 31.4 RECOMMENDATIONS FOR PALIVIZUMAB PROPHYLAXIS[20,107]

- Infants born before $29^{0/7}$ weeks of gestation, given in their first year of life
- Infants born before $32^{0/7}$ weeks of gestation with chronic lung disease (oxygen requirement >21% beyond first 28 days), given in their first year of life
- Infants who qualified in their first year of life with continued need for respiratory medical intervention in their second year of life
- Other infants with compromised cardiopulmonary, neuromuscular, or respiratory systems

Assessments

CAR SAFETY

All 50 states require infants to be restrained in a safety seat while riding in a motor vehicle, although laws vary from state to state. Discharge of smaller infants from an NICU results in the use of car seat restraint devices that were designed for 7- to 8-pound term infants. **In these devices, preterm infants may experience oxygen desaturations and apnea and bradycardia caused by head slouching and airway obstruction.**[51] Infant car seats (rear facing) are now available for infants as small as 5 pounds, should be reclined to 45 degrees, and often come with tested and approved inserts for head or body support. **Supportive inserts that come with the infant car seats are preferable to the use of rolled diapers, blankets, or after-market inserts to support upright posture, prevent slouching, and enable the preterm infant to maintain stability while in the car seat.** In addition, infants with certain conditions (e.g., Down syndrome, osteogenesis imperfecta, myelomeningocele, Pierre Robin syndrome, cerebral palsy [CP]) may benefit from special-needs car restraints.[95] In 2018, the AAP published a technical report addressing the use of an algorithm to assist pediatricians and families in optimizing infant car seat safety.[57]

A car seat tolerance screening (CSTS) before discharge is recommended for all infants born before 37 weeks of gestation; this includes late-preterm infants (i.e., 34 to $36^{6/7}$ weeks) who are cared for and discharged from level I/normal newborn nurseries.[11,12] Although the CSTS has not been standardized, certain components are common: (1) using the car seat purchased by the parents, (2) positioning the infant in the car seat immediately before discharge while on cardiorespiratory and pulse oximetry monitoring, (3) using the car seat for a prescribed period (e.g., 30 to 90 minutes), and (4) recording respiratory/heart rates, oxygen saturations, and apnea/bradycardia events. Although this is a recommended practice, limitations have been identified. **First, little objective evidence supports the ability of this challenge to absolutely confirm safe travel for an infant.** Recent studies of CSTS failure have identified an association with being a full-term LBW infant,[49] and for preterm and late-preterm infants, an association with concurrent caffeine use, antacid use, and history of failure of a trial without respiratory support.[84] Failure of the initial CSTS is associated with a longer length of stay of 3.1 days but not with hospital readmission or 30-day mortality.[141]

NUTRITION AND GROWTH

Before discharge, safe oral feedings should be established, along with guidelines for advancing and monitoring growth, calorie, and nutrient supplementation. In studies of infants who experienced extrauterine growth restriction (EUGR), commonly defined as weight less than the 10th percentile for corrected gestational age (CGA) at discharge, the period from discharge to 30 months has been shown to be a critical period for growth.[134] **Nutritional intake at this time sets the trajectory for growth and neurodevelopment in childhood and adolescence.** VLBW children who have low weight gain in early years of life have a higher probability of cognitive deficits; conversely, those with excessive weight gain have a higher likelihood of obesity, cardiovascular disease, and diabetes.[39]

NEURODEVELOPMENT

Some premature infants may have recognized risks to their later development evident at discharge. **Identification of infants at high risk for poorer outcomes related to brain injury allows for timely referrals to early intervention therapies,** which improve cognitive outcomes into preschool age.[148] **Early intervention has been shown to improve neurobehavioral development with improved cognitive outcomes and parent-child interactions.**[31]

Technology-Dependent Infants

Infants who rely on long-term technologic support are being discharged home in increasing numbers.[153] In the past, children who were ventilator dependent; who had tracheostomies, gastrostomies, or jejunostomies; and even those who required long-term intravenous (IV) access for medications or parenteral nutrition would remain hospitalized, separated from their families and susceptible to other morbidities associated with long hospital stays (e.g., infection, delayed development, impaired mental health). **With this increase of technology-dependent children discharged into the community comes a greater need for support services for the parents, providers, and the infants themselves.**[34] Numerous investigators

have undertaken projects to understand the impact that caring for these children has on the individual child and the family as a whole. Toly et al. described the experiences of well siblings of technology-dependent infants, as told by their mothers.[152] Three themes were identified including (1) well sibling adjustment to a "new normal;" (2) upside experiences described as increasing empathy and compassion; and (3) downside experiences including anxiety/worry and feelings of resentment/jealousy. The implications illuminated are **the potential positive impact of whole-family intervention programs, including siblings, before discharge encompassing relationships and tips for managing everyday life.**[152]

Thorough assessment of families' understanding of their infant and caregiving requirements, extensive education of family caregivers, and early, clear, and consistent information addressing the skills, psychosocial impact, and identified supports are essential for successful discharge.[34] A discharge framework for these infants has been identified that addresses three areas of focus including (1) parental involvement in the early and ongoing care; (2) rooming-in experiences with customized education and frequency; and (3) outpatient care coordination with collaborating subspecialists and coordination of appointments.[34] **Rooming-in with their infant for one or more nights provides an important opportunity to evaluate their abilities and confidence in caring for their child.**

NEURODEVELOPMENTAL FOLLOW-UP OF HIGH-RISK INFANTS

Ideally, parents of all NICU infants would be offered comprehensive, coordinated, developmentally based, family-centered follow-up for their child through infancy and childhood (Fig. 31.1). Each infant is unique, as is each infant's family. **The following are the primary objectives of follow-up care:**

- **To counsel the family about their child's development so that they are empowered to optimize the child's health, growth, and development**
- **To recognize and diagnose (early) significant health conditions and neurodevelopmental disabilities to facilitate appropriate referrals for community services**
- **To anticipate future difficulties and needs so that optimal development is promoted and secondary complications are avoided or minimized**

The ultimate goal is to promote the child's integration into the family, school, and community.

In the current health care environment, follow-up resources are generally limited, and both public and private health insurance plans determine how children will access care. Consequently, criteria for developmental follow-up of NICU infants vary widely. Some high-risk infants are routinely referred to early intervention programs for developmental care, but implementation of these programs varies among states. **The dynamics of development are such that periodic assessments of the child's health and developmental progress are needed to determine whether current interventions are effective and sufficient.** Parents often need guidance to better understand what to expect from their child, how to interpret their own observations of their child, and how health care and community services can support their child's development. The AAP has emphasized that each child have a "medical home," especially the child with complex health and developmental needs, and has a policy statement regarding the recommended components of developmental surveillance.[8,12,14] **Unfortunately, the care of these children often is fragmented among numerous subspecialists and therapists.**[13] Well-organized NICU follow-up clinics can facilitate developmental and health care of the NICU infant in coordination with the primary care provider and the family.

Developmental Milestone Attainment

In developmentally based follow-up, much of the information about the child's development comes from a careful interview of the parent about the child's health status and developmental milestone attainment. **Noting the age of acquisition of the gross-motor, fine-motor, language, and adaptive-behavioral milestones helps determine a possible developmental delay.** Parents are very good historians of their child's current functioning and recent accomplishments, which is why eliciting a history of milestone attainment during serial clinic

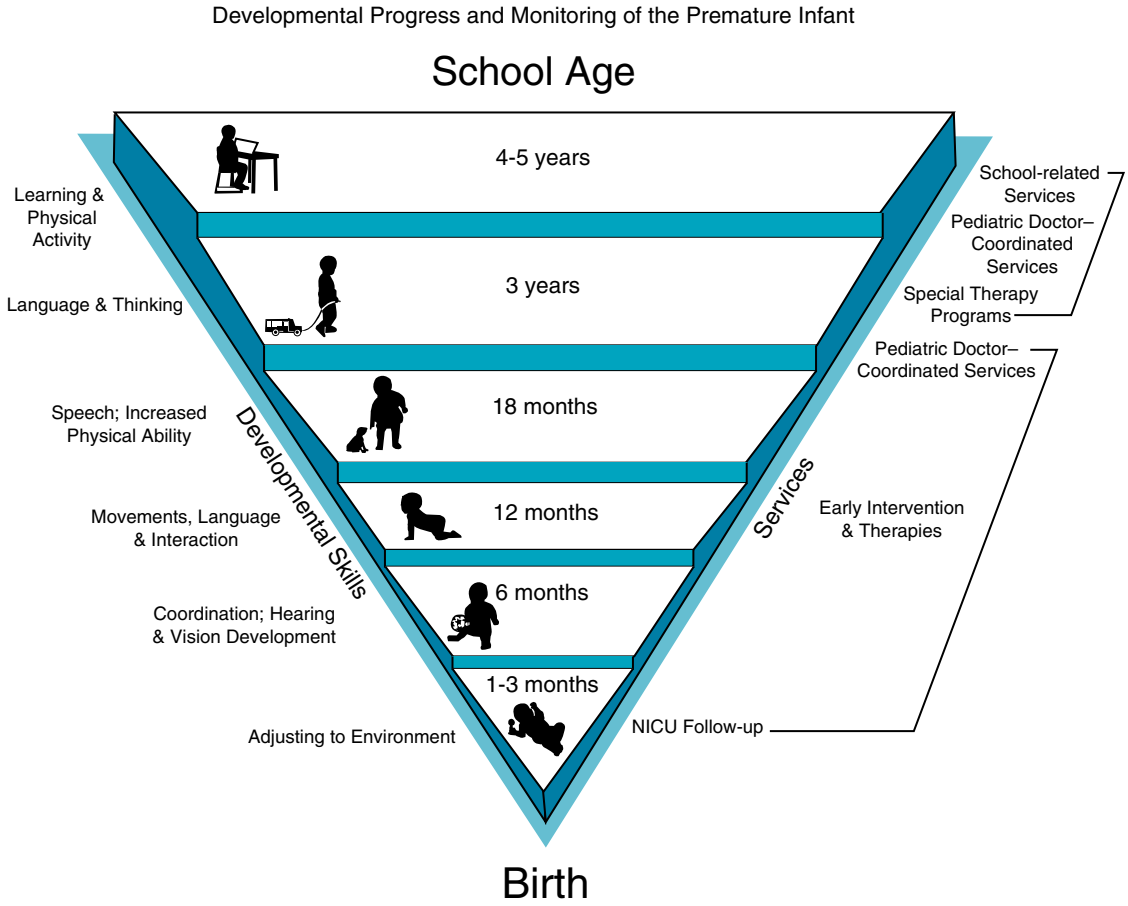

FIGURE 31.1 Developmental progress and monitoring of the premature infant. (Courtesy Angel Carter, Brian S. Carter, and Donna K. Daily. Vanderbilt University Medical Center, 2010.)

visits is so useful in assessing a child's rate of development. Sometimes additional explanation may be needed to clearly determine the age of acquisition, especially language milestones.

A number of accurate screening tools are available to monitor general developmental progress or domain-specific evaluation.[56] Early delay in language and self-help milestones raises concerns about cognitive development, language disorder, or hearing impairment.[2] Many NICU developmental follow-up clinics rely on **pediatric clinical psychologists to formally evaluate the cognition of high-risk infants, preferably with sequential assessments but sometimes with one assessment at a specific age (e.g., at 18 to 24 months' corrected age).** For infants, the *Bayley Scales of Infant and Toddler Development,* third edition, is the most commonly used assessment tool in NICU follow-up programs in the United States.[30] For preschool-age and school-age children, several cognitive tests are available, including the Wechsler Preschool and Primary Scale of Intelligence (WPPSI), the Stanford-Binet Intelligence Scales, and the Kaufman Assessment Battery for Children (K-ABC II).[86,132,160]

Adjustment for Degree of Prematurity

One controversy that arises in monitoring developmental scores of preterm infants is whether to adjust for degree of prematurity (i.e., whether to use the child's chronologic age, calculated from birth,

or to use adjusted age for degree of prematurity). **The best evidence supports adjusting for degree of prematurity**, but whether it is best to adjust throughout infancy is controversial, and **there is no agreement as to when one should stop adjusting for degree of prematurity.**[45] **By convention, most practitioners adjust through 2 years of age.** It is necessary to be very cautious when interpreting adjusted age scores at 12 months or less for ELBW infants. Parental understanding may lead to an overly optimistic outlook that will not be supported by testing at a later date.

Neurodevelopmental Examination

For high-risk infants, the standard pediatric neurologic examination is expanded to include a detailed assessment of posture, muscle tone, movements, reflexes, postural reactions, and functional abilities. Interpretation of the examination requires a thorough understanding of the normal pattern of development over time, the examiner's skill at assessing the infant's performance, recognizing deviations from the norm, and determining the significance of these findings.[2] An alternative to the standardized examination, the General Movements Assessment, has been found to have the best predictive accuracy for CP and, in one study, showed a positive predictive value of 87% to 100% for later spastic CP.[32] **Abnormalities of posture, muscle tone, movements, and reflexes are common in preterm and other high-risk NICU infants during the first year.** These abnormalities include asymmetries of movement, marked extensor tone through the neck and trunk with significant shoulder retraction or elevation, hypotonia, and lower extremity hypertonia and hyperreflexia. CP should be considered in infants with persistent abnormalities in tone, posture, movement, and motor delay. Mild delay and neuromotor tone variation suggest transient neuromotor abnormalities.

NICU Follow-Up Guidelines

The issue of how to do NICU developmental follow-up and how to conduct follow-up studies for high-risk infants has been complex. The methodology can lead to inadequate interpretation of published studies. The National Institute of Child Health and Human Development (NICHD), the National Institute of Neurologic Disorders and Stroke, and the CDC convened a workshop in 2002 to address these issues. Their purpose was to provide standardized guidelines for follow-up care, especially for tertiary care centers with neonatal fellowship training programs in the United States. The results of that workshop have been published and address topics such as risk factors that affect outcome, appropriate assessments, correction for prematurity, assessment tools, and research-related subjects.[14]

Again, these criteria may not fit the need or focus of every program. The resources available across states, within communities, and in individual hospitals and the commitment within the NICU strongly drive follow-up programs in different communities. Programs that wish to have developmental follow-up for quality care surveillance and to provide families with information about their high-risk infant can be resourceful in developing partnerships with local early intervention programs and community physicians. Programs that address scientific questions generally need a focused approach or a research network to approach the study.[156]

Survival to the end of the NICU stay is a very short-term outcome. Ideally, infants would be followed up to, and including, the beginning of school to best identify true developmental outcomes, but most programs do not have the resources to do this. Furthermore, it has become apparent that the effects of prematurity may extend throughout the life span. This is important to know but clearly goes beyond the capability of most NICU follow-up programs.

COMPLEX DISORDERS OF BRAIN DEVELOPMENT

Complex disorders of brain development are a group of chronic, nonprogressive disorders of central nervous system (CNS) function that occur as a result of a primary malformation or insult to the developing brain.[2] **There is a spectrum of neurodevelopmental impairments, from major disabilities (CP, seizures) and severe cognitive impairments (formerly referred to as *mental retardation*) to sensory impairments and other complex disorders of brain development** (Box 31.5).

BOX 31.5 COMPLEX DISORDERS OF BRAIN DEVELOPMENT

Neurodevelopmental Impairment
Major disability
Cerebral palsy
Global developmental delay and severe cognitive impairment

Sensory Impairment
Hearing impairment
Visual impairment

Other Complex Disorders of Brain Development
Language delay or disorder
  Expressive language delay
  Receptive and expressive language delay
Developmental coordination disorder
  Fine-motor incoordination
  Sensorimotor integration problems
Learning disability
  Variable cognitive abilities
  Visual-perceptual problems
Behavior disorders
  Attention-deficit/hyperactivity disorder
  Autism spectrum disorders

Modified from Accardo PJ, ed. *Capute and Accardo's Neurodevelopmental Disabilities in Infancy and Childhood.* 3rd ed. Baltimore, MD: Paul H. Brookes Publishing Co; 2008; Wolraich ML, ed. *Disorders of Development and Learning.* 3rd ed. Hamilton, ON: B.C. Decker; 2003.

Neurodevelopmental Impairment

Preterm infants are at an increased risk for major disabilities and also for other cognitive and behavioral concerns. Both may have a long-term impact on their life.[7,100] **The World Health Organization (WHO) has categorized disability, impairment, and handicap in the *International Classification of Functioning, Disability and Health* (ICF) and places emphasis on the interaction of functioning and disability, health condition of the individual, and factors of the environment.**[136,162] The ICF is structured around the following components: (1) body functions and structure, (2) activities and participation, and (3) additional information on severity and environmental factors.[162] This view has aided our thinking not only of the specific disability but also how it affects a child's ability to function physically and socially within his or her home and community.

Cerebral Palsy

CP is "a disorder of the development of movement and posture, causing activity limitations attributed to nonprogressive disturbances of the fetal or infant brain that may also affect sensation, perception, cognition, communication, and behavior."[130] **Important to this current definition is the recognition of the accompanying disturbances of secondary musculoskeletal problems and epilepsy.** CP is the most disabling motor impairment found in preterm infants and should be diagnosed as early as possible. A recent systematic review found that infants exhibit early signs and symptoms of CP before 2 years of age.[114] Early diagnosis includes a thorough medical history, neuroimaging (i.e., MRI), and standardized neurologic and motor assessments. Early diagnosis prompts referral for early intervention, with a goal of optimizing infant motor and cognitive plasticity, preventing and minimizing secondary complications, and optimizing caregiver well-being.[37,114]

CP has traditionally been classified by physiologic type (tone abnormality), topography (i.e., muscle groups involved), and severity.[2] Again, the most recent recommendation for definition and classification has been expanded and relates to the WHO ICF.[162] Components of the **currently recommended classification stress motor abnormalities, accompanying impairments, anatomic and neuroimaging findings, and causation and timing.** Because consensus has not been clear on the definition of level of severity, the Gross Motor Function Classification System is now commonly used to address motor function, and scales are being developed to more reliably measure other important areas of functioning, such as hand control, speech, and swallowing.[119,130] **Persistently increased muscle tone and increased deep tendon reflexes with persistence of pathologic reflexes (e.g., Babinski) are early signs of spasticity. Variable tone with persistent primitive reflexes, often with involuntary movements, is a sign of extrapyramidal CP.** The child may be 2 to 3 years of age before involuntary movements are seen. **Children who manifest signs of both spasticity and extrapyramidal CP have mixed CP.** Extrapyramidal CP is generalized, but spasticity should be further typed according to which limbs are most significantly involved.

Spastic diplegia, the most common form of CP in preterm infants, is characterized by spasticity in both lower extremities, with mild or minimal involvement of the upper extremities.[2] *Spastic hemiplegia* is characterized by involvement of one side of the body, with the upper extremity more involved than the lower. Because intrauterine and perinatal strokes are usually unilateral, children who had strokes often demonstrate spastic hemiplegia. *Quadriplegia* is the most severe form of spastic CP, with involvement of both upper and lower extremities and the lower more severely affected than the upper. Children with neonatal encephalopathy (whether caused by hypoxia/ischemia, metabolic disorders, or other causes) who develop CP are most likely to have spastic quadriplegia or severe mixed CP.[2]

Global Developmental Delay and Cognitive Impairments

Developmental delay is used to describe a deficit in any of the five developmental domains (cognition, motor, language, adaptive, social-emotional skills). *Global developmental delay* is used to define deficits in two or more areas of development with scores more than 2 standard deviations below norm referenced standards.[143] Currently in the United States, a child may receive services through his or her local school district special education program with a diagnosis of developmental delay until almost 8 years of age before the definition may be switched to severe cognitive impairment, again based on standardized testing. Standardized tests such as the Bayley scales have score groupings and definitions to match, such as *low average* and *borderline,* for each domain.[30] Early detection enables early intervention services for the high-risk infant because the early developing brain is most likely able to adapt or circumvent areas of injury.[31,56,118]

Severe cognitive impairment is a global impairment of cognitive functioning resulting from injury to or malformation of the developing brain that impairs the child's ability to adapt and function in society.[2,7,100] It frequently manifests with an early delay in language and problem-solving abilities. A diagnosis of severe cognitive impairment requires a comprehensive evaluation of the child, with neuropsychological testing of intelligence and assessment of adaptive (functional) abilities, which can be reliably done only at school age.

Neuropsychological testing includes an assessment of a child's intelligence quotient (IQ). Intelligence is not one entity but, rather, many different abilities, including auditory and visual memory, visual-perceptual abilities, and understanding complex language concepts. The older the child is, the greater the number of functions that can be tested and therefore the more accurate the tests are in assessing intelligence. Intelligence and functional ability tests for school-age children and adults consist of a variety of subtests. Most children with severe cognitive impairment have lower abilities for age across all domains of development, so the severity of cognitive impairment is easily classified. Many preterm children have a significant variability in cognitive functions, with high scores on some subtests and low scores on others, which makes them more difficult to classify and appropriate educational services more difficult to determine.

Cognitive impairment is classified in terms of severity, from profound (IQ below 20), severe (IQ 20 to 34), moderate (IQ 35 to 49), to mild (IQ 50 to 70).[2] Children with an IQ of 70 to 85 have borderline intelligence, not severe cognitive impairment. They are capable of academic learning but may have trouble keeping up with their class. The most important characteristics of children with cognitive impairments that enhance adult functioning are interpersonal skills and the ability to communicate and relate to other people.

Sensory Impairments

An NICU admission increases the risk of hearing loss. Most states require hearing screening for all newborns using a two-step process: initial screening with otoacoustic emissions, followed by auditory brainstem responses if the first test is failed.[15] Because of the risk for progressive hearing impairment, infants with congenital cytomegalovirus (CMV) infection, primary pulmonary hypertension, congenital diaphragmatic hernia, and infants treated with extracorporeal membrane oxygenation (ECMO) should have serial hearing evaluations during infancy and early childhood, as should infants with recurrent ear infections.[15,19]

Neonates demonstrate hearing thresholds similar to those of older children and adults. Even preterm infants as early as 24 to 25 weeks' gestational age demonstrate an immature brainstem waveform in response to sound stimuli, although the pattern of the waveform matures to a normal waveform as the infant reaches near-term equivalence. **Infants hear and process language throughout their first year, beginning at birth.**

ROP results from injury to the very immature developing retina caused by abnormal proliferation of retinal blood vessels. Severe ROP, which tends to occur in the most immature and sickest preterm infants, is usually treated with laser photocoagulation to try to prevent retinal detachment and blindness. Recent data indicate that intravitreal bevacizumab monotherapy in infants with stage 3+ ROP can significantly benefit zone I disease, but not zone II disease, compared with conventional laser therapy.[17] Preterm infants may develop medically related eye complications (retinal detachment, cataract, glaucoma) and are at increased risk for refractive errors, strabismus, and amblyopia.[116] Infants who have structurally normal eyes, no refractive error, and a history of no or low-level regressed ROP may be dismissed by the ophthalmologist after 12 to 18 months of age but should continue to receive routine childcare eye screening based on the AAP recommendations for routine preventive care.[117] Late-preterm and term infants with other neonatal complications and neurodevelopmental sequelae may also have visual impairments and need ongoing ophthalmologic follow-up.

Infants with congenital infections should be examined by ophthalmologists for chorioretinitis. Neonates symptomatic of congenital infection (e.g., TORCHES, HIV, West Nile and Zika viruses) have a high risk of visual and/or hearing impairment (see Chapter 22).[88] Preterm infants in the NICU with varying types of postnatal sepsis syndromes have also been identified as having an increased risk for neurodevelopmental impairment.[124] If infants with neonatal encephalopathy develop disability, they tend to have severe multiple disabilities, including cortical visual impairment or processing and hearing impairment.[129]

OTHER COMPLEX DISORDERS OF BRAIN DEVELOPMENT

Even if the NICU graduate does not develop major disability or sensory impairment, he or she remains at increased risk for disorders of higher cortical function (see Box 31.5). These disorders may be less evident in infancy and may be associated, initially, with only nonspecific symptoms (e.g., irritability, posturing, feeding problems). Diagnostic criteria, and even nomenclature, for these disorders vary widely, and few reports of preschool and school-age outcome studies have a comparison group evaluated in the identical manner.

***Language delay* may manifest as early as 6 to 12 months of age as a delay or deviance (i.e., nonsequential) in language milestone acquisition.[2]** Expressive language delay, either alone or in combination with receptive language delay, is common in preterm and other NICU infants. **Every child who manifests with delayed language should have a hearing test and neuropsychological testing to distinguish between language disorder, hearing impairment, and cognitive impairment.**

Developmental coordination disorder (DCD), also referred to as *minor neuromotor dysfunction,* **presents as mild delay or deviant motor milestone acquisition in conjunction with mild or transient neuromotor abnormalities.[50]** These children sit by 1 year of age and walk by 2 years, although they may have an atypical pattern to their motor progress (e.g., transient low or high tone, toe-walking, persistent wide-based gait). These **children generally have typical functioning by 3 to 5 years of age, although they may continue to have some balance or motor planning problems.** Fine-motor incoordination, visual-perceptual deficits, and sensorimotor inefficiencies may accompany DCD, but they may not be recognized until preschool or school age.[27] ***Visual-perceptual deficits,* often in combination with fine-motor incoordination, manifest as an inability to recognize and copy figures, letters, and numbers;** complete puzzles and mazes; or copy block designs; or as some level of difficulty with these tasks. ***Fine-motor incoordination* makes it difficult to button, zip, cut with scissors, draw, and write. *Sensorimotor inefficiencies* are characterized by difficulty following directions that include demonstrating an action (e.g., tying shoelaces) and tolerating motion through space (e.g., swinging on a swing) or different tactile sensations (e.g., clothing or food textures).** For children with DCD, fine-motor incoordination or sensorimotor inefficiencies and failures in school and on the playground erode self-esteem and peer relationships.

Language disorder, visual-perceptual problems, DCD, transient neuromotor dysfunction, and variable cognitive disabilities are associated with learning disability and other school problems.[2,27] Learning disability means difficulty learning one or more academic subjects (reading, writing, arithmetic) in children with normal intelligence who have had adequate exposure to school. Some children have more of a learning inefficiency, in that they do well in the early grades of school but have a relative inefficiency in reading or writing that causes them trouble as the work becomes more complex. **Their intelligence and resiliency help them make adaptations in learning, but they become overwhelmed in situations in which speed and accuracy are viewed as important.**

Behavior disorders are more common in preterm infants, late-preterm infants, and other children who were in the NICU as neonates.[1,85,122,149] **Some children have attention-deficit/hyperactivity disorder (ADHD), characterized by marked distractibility, short attention span, and impulsivity.**[82] ADHD can occur with or without hyperactivity; the child may be restless, always on the move, or constantly busy or may just demonstrate difficulty paying attention and impulsiveness. One must recognize these more subtle concerns as soon as possible. **Counseling parents and teachers can prevent the devastating effect these "mild" disabilities have on self-esteem, peer relationships, and performance in school and at home.**

Autism Spectrum Disorders

Expanding research indicates that the causes of autism spectrum disorders (ASDs) are multifactorial and include genetic, environmental, and epigenetic factors.[97,145] Risk factors for the development of ASD include advanced parental age, preterm birth, prenatal exposure to air pollution, and short intervals between pregnancies; more research into prenatal nutrients, metabolic conditions, and exposure to endocrine-disrupting chemicals is necessary.[97] In an effort to confirm prevalence rates, researchers followed a group of premature infants for 21 years and found the **risk to be five times greater for those infants born less than 2000 g compared with the general population.**[106] A more recent meta-analysis of 18 studies also found the prevalence of ASD to be significantly higher in children born preterm.[4]

The association between brain injury and the risk of ASD continues to be explored. Following 1105 LBW infants, Movsas et al.[106] **found strong evidence linking the occurrence of ventricular enlargement in the neonatal period with diagnosed ASD in those children by adolescence or early adulthood. Although any white matter injury significantly increased the risk for a positive screen for ASD, ventricular enlargement increased that risk sevenfold** with no associated increase with isolated germinal matrix or IVH.[106]

As research continues to explore potential explanations for causality, counseling for families and caregivers concerning the risks and prevalence is warranted. **Early attention to these risks, and potential, may provide earlier screenings, diagnoses, access to services, and behavioral interventions to the benefit of the child and family.**

Diagnosis of Disability

Major disabilities may be recognized and diagnosed in the first 2 years after birth. The more severe the disability, the sooner it may be recognized and diagnosed. Occasionally a child may have significant motor delay initially but seems to "catch up" by 1 to 2 years of age, with concomitant improvement in neuromotor abnormalities. These are often children with ongoing health problems (e.g., bronchopulmonary dysplasia [BPD]/chronic lung disease [CLD]) and are diagnosed with DCD **but have a high risk for learning disability at school age. Language disorders, visual-perceptual difficulties, and fine-motor incoordination are generally recognized and diagnosed during the preschool years (3 to 5 years of age). Specific learning disabilities and attention difficulties cannot be diagnosed until school age, usually around 7 to 8 years of age.** Mild learning disabilities or learning inefficiencies may **not be recognized until middle school or high school.**

Because there is so much overlap among the neurodevelopmental disabilities, whenever an abnormality in one area is detected, the child should have a comprehensive, multidisciplinary evaluation of all of his or her abilities. Services are now available to all children through the Individuals with Disabilities Education Act (IDEA 2004).[81] **Children from birth to 3 years**

of age receive services through their early intervention program, and after 36 months of age they receive services through their local public school's special education program.

PERINATAL RISK FACTORS FOR NEURODEVELOPMENTAL IMPAIRMENTS

Many conditions that require neonatal intensive care also increase the risk for neurodevelopmental disability. Perinatal risk factors can be used to identify NICU infants with a high risk for neurodevelopmental disability so they can be followed closely and referred for comprehensive evaluations and early intervention programs when appropriate (Box 31.6). **Broad categories of risk include the following:**

- Prematurity
- Maternal complications (chorioamnionitis, placental abnormalities)
- Birth complications (asphyxia, need for resuscitation)
- Infant conditions (IUGR, macrosomia, congenital anomalies)
- Neonatal illness (necrotizing enterocolitis [NEC], respiratory conditions, infection)
- CNS-associated conditions (brain hemorrhage, periventricular leukomalacia [PVL], stroke, structural defects)

Multiple risk factors increase an infant's risk for neurodevelopmental impairment, and the effects may be more than additive. As a group, preterm infants or full-term infants with IUGR tend to have a lower mean IQ than full-term appropriate-for-gestational-age (AGA) infants.[90,133,158] Infants with both prematurity and IUGR are vulnerable to the complications of each condition.

BOX 31.6 PERINATAL RISK FACTORS FOR NEURODEVELOPMENTAL DISABILITIES

- Maternal characteristics
  - Socioeconomic status
  - Education
  - Race/ethnicity
  - Obstetric/prenatal complications
- Maternal illness
  - Chorioamnionitis
  - Maternal ingestions (alcohol, drugs, medications)
  - Congenital infection
  - Multiple gestation
  - Labor or delivery complications
  - Placental abnormalities
- Physical characteristics
  - Prematurity
  - Postmaturity
  - Intrauterine growth restriction
  - Small for gestational age
  - Macrosomia
  - Gender
  - Microcephaly
  - Congenital anomalies
  - Dysmorphic features
- Condition at birth
  - Apgar scores
  - Cord pH
  - Meconium staining
  - Need for and response to resuscitation
- Neonatal complications
  - Hypoxia
  - Acidosis
  - Hypotension/shock
  - Apnea and bradycardia
  - CLD
  - Sepsis
  - Meningitis
  - Seizures
  - Hypoxic-ischemic encephalopathy
- CNS structure and function
  - IVH
  - Intraparenchymal hemorrhage or infarction
  - Ventricular dilation
  - Cortical atrophy
  - PVL
  - Burst-suppression pattern on EEG
  - Abnormal neurologic examination

SPECIFIC NEURODEVELOPMENTAL OUTCOMES

This section summarizes reported neurodevelopmental outcomes for some of the most frequently encountered conditions in the NICU. **A systematic approach (see Box 31.6) allows the clinician to assess the risk factors that may affect developmental outcome.** Preterm infants and their medical sequelae are most commonly encountered in neonatal intensive care. However, term infants with pulmonary disease, encephalopathy, or congenital defects also may require intensive care and have significant sequelae. Finally, although we have focused our attention in recent years on smaller and smaller babies in tertiary care centers, **it has become apparent that we have often neglected issues for larger "late-preterm" infants (see Chapter 5).** These infants are more typically followed in level II or transitional nurseries but are not without risk. It is beyond the scope of this chapter to cover **congenital malformations or genetic conditions (see Chapter 27), but it is well known that these infants often require complex multidisciplinary care,** and the principles of follow-up outlined earlier apply to them as well.

Prematurity

For more than 50 years, the medical literature has described the neurodevelopmental outcome of preterm VLBW infants (birth weight <1500 g). With the beginning of modern neonatal intensive care in the mid-1960s, tertiary care NICUs began reporting the incidence or prevalence of major disability—in survivors.

In a review of outcomes studies conducted from 2000 to 2013, Vohr[155] reported that, at 18 to 30 months' follow-up, cognitive impairment (scores >2 standard deviations below the mean) is the most common impairment of preterm infants, with incidences as high as 61% in the smallest survivors.[155] A more recent study also showed that parent-reported behavior problems were related to cognitive, language, and motor development in toddlers (22 to 26 months' corrected age) who were born extremely preterm.[96] By school age, 50% to 70% of VLBW children exhibit learning difficulties related to executive function, visual-motor skills, and memory, resulting in failed grades and special education requirements.

In ELBW children, a meta-analysis of the outcomes of infants delivered at 22 to 25 weeks of gestation reports that when followed at 4 to 8 years of age, all survivors had a likelihood of moderate to severe impairment, with decreasing severity rates in the higher gestational ages.[105] These authors report this to be a unique analysis of data from nine prospective cohort studies published after 2004 in that it is one of the first meta-analyses of studies reporting impairments from school-age children, rather than in the young toddler, where, because of still developing skills and adaptations, rates of impairment may be overestimated.

More recently, researchers suggest that the impact from prematurity extends beyond "merely" neurodevelopmental impairment, with a more broadly felt effect on long-term outcomes.[89,151] Areas of concern include (1) learning and cognition, (2) mental health, (3) physical health, and (4) quality of life.[55] Although 20% to 25% of extremely premature infants do experience moderate to severe neurodevelopmental impairment on evaluations at 2 years of age,[131] long-term outcomes in each of these four domains may be equally important and, perhaps, less considered in outcomes measurements.[77]

Although many challenges are possible for the infant born prematurely, particularly the smallest and youngest, the potential also exists to overcome or adapt to limitations. **Early intervention services, supportive home environments, and access to resources for the families can all help eliminate or mitigate many of the potential negative outcomes.**

Late-Preterm and Early Term Infants

Late-preterm and *early term infants* are defined as infants born between $34^{0/7}$ and $36^{6/7}$ and $37^{0/7}$ and $38^{6/7}$ completed weeks, respectively (see Chapter 5). **These infants are physiologically and metabolically immature, which places them at risk for medical complications and resulting adverse neurodevelopmental sequelae.**[61] Studies have identified **this group of infants to be at a higher risk for poor neurodevelopmental outcomes, which predisposes them to problems with school performance. Learning and behavioral problems, including ADHD and learning disabilities, occur at a higher rate than in term infants.**[74,122,149,154]

Short-term complications, such as fever, glucose instability, apnea, jaundice, and poor feeding, also occur in late-preterm infants at a higher rate than in term infants during the first few days of life.[60,68] Despite their increased morbidity, early discharge of late-preterm infants remains a practice in many centers.[68] Discharge should be individualized and carefully planned with parental input and education. **Long-term outcomes in late-preterm infants related to growth, higher use of health care resources, and developmental delay are outlined in Box 5.3.**

Maternal Complications

Maternal complications increase the risk for conditions associated with problematic birth, but also for long-term adverse outcomes for the infant. Placental abruption causes immediate threat of decreased oxygen supply to the fetus, potentially resulting in neurodevelopmental impairment.[128] Chorioamnionitis may result in adverse short-term outcomes including sepsis, IVH, need for ventilation, and others.[26] **Long-term outcomes associated with exposure to chorioamnionitis include cognitive impairment and death.**[120] Finally, other maternal conditions such as infection, preexisting health conditions, mother's weight, age, use of tobacco or other substances, and prior pregnancy and contraceptive history may increase the risk of prematurity or infant compromise (see Chapter 2). Infant outcomes related to prematurity or birth compromise are detailed throughout this chapter.

Birth Conditions

NEONATAL ENCEPHALOPATHY

The extent and nature of an initial hypoxic-ischemic event cannot be easily determined for many individual infants, leading clinicians to rely on recognizable signs and symptoms of neonatal encephalopathy to predict outcome. These signs and symptoms include the following:

- Poor feeding
- Hypotonia or extensor hypertonia
- Lethargy or hyperexcitability
- Apnea
- Seizures
- Abnormalities on neuroimaging studies, which are far more predictive than low Apgar scores
- The need for positive-pressure ventilation or CPR at birth
- Initial response to resuscitation

Many infants with congenital brain malformations or prenatal brain injury may present with perinatal cardiorespiratory depression. They do not breathe normally at birth and may require positive-pressure ventilation or further resuscitation. It is very difficult to distinguish these infants from those with encephalopathy caused by hypoxia or ischemia. Metabolic problems or neonatal sepsis may also present with these signs. **Therefore the term *neonatal encephalopathy* is preferred over the term *hypoxic-ischemic encephalopathy (HIE),* because etiology cannot always be determined with certainty.** However, the clinician must evaluate the history and relevant factors of each infant to address the etiology of his or her encephalopathy.[21] The etiology may be important in decisions about treatment, prognosis, follow-up, and family planning.

In the absence of a confirmed specific etiology, the stages of encephalopathy described in 1976 by Sarnat and Sarnat remain highly predictive of outcome.[137] Infants with *stage 3 (severe) encephalopathy* and coma, severe hypotonia or increased extensor tone, intermittent decerebration, decreased or absent reflexes, variable pupil reactivity, and abnormal electroencephalogram (EEG) **generally will die or have multiple severe disabilities. Only 20% to 30% of infants** with *stage 2 (moderate) encephalopathy* with lethargy or coma, mild hypotonia, overactive reflexes, seizures, abnormal EEG, and generalized parasympathetic function (constricted pupils, bradycardia, profuse secretions, and diarrhea) **will have multiple severe disabilities.** The remainder of newborns with stage 2 encephalopathy have lower scores on tests of cognition, vocabulary, reading, spelling, and arithmetic than children with *stage 1 (mild) encephalopathy* (hyperalert state, jitteriness, overactivity and easily elicited reflexes, increased sympathetic function, dilated pupils, and decreased gastrointestinal motility) or healthy control children. **Infants with neonatal encephalopathy should be evaluated with both EEGs and neuroimaging studies.** Very-low-voltage EEG patterns (signifying little brain activity) and burst-suppression EEG patterns carry an extremely poor prognosis, as does diffuse encephalomalacia detected by MRI.[42,129,146] **Infants with moderate encephalopathy may benefit from therapeutic hypothermia, commonly called *cooling,* leading to increased survival without disability (see Chapter 26).** The results from all published trials in North America and Europe

are most promising for encephalopathies of less than a severe nature, and cooling is considered to be a standard of care in many countries for infants meeting cooling criteria.[28,71,125,140] **Follow-up of infants receiving cooling therapy supports the therapeutic value of hypothermia.**[70,92,111,125,126] Mild encephalopathy with only a subarachnoid hemorrhage carries a favorable prognosis, although these children should be monitored for later learning difficulties.

Infant Conditions

INTRAUTERINE GROWTH RESTRICTION

Prenatal and postnatal growth can seriously affect neurodevelopmental outcomes of high-risk infants. The neurodevelopmental outcome of IUGR infants is strongly associated with the cause of IUGR; with the timing, severity, and duration of the insult; and with perinatal complications the IUGR infant encounters (see Box 31.6). Early severe IUGR often reflects a chromosomal anomaly, another severe genetic disorder, or a congenital infection that occurred early to cause organ malformation or significant injury. **Some causes of IUGR result in death** (e.g., trisomy 18) or severe disability. **Some carry a high risk for neurodevelopmental disability** (e.g., fetal alcohol syndrome). Others are associated with only mild disability (e.g., an increased incidence of attention and behavior problems in infants born to mothers who took narcotics or cocaine during pregnancy).

One of the most common causes of IUGR is uteroplacental insufficiency, generally a diagnosis of exclusion. **The fetus responds in many adaptive ways when the supply of nutrients or oxygen is limited.**[23,24] **There is first a decrease in subcutaneous tissue, resulting in lower birth weight, and then a decrease in length, before head and brain growth are affected (symmetric growth restriction).** Nevertheless, the problem may be severe enough to overwhelm these adaptations and lead to brain injury. In addition, a chronically compromised fetus, with decreased glycogen and nutrient stores, has more difficulty with the stresses of labor and delivery, leading to perinatal depression, cold stress, hypoglycemia, and hypocalcemia. Polycythemia may result from chronic intrauterine hypoxia but may result in the complications of hyperviscosity.[133]

Prospective studies of full-term IUGR school-age children compared with full-term AGA children showed that more IUGR children had language problems, learning disability, minor neuromotor dysfunction, hyperactivity, and attention and behavior problems. Postnatal growth may also be affected, but this will largely depend on whether the infant has symmetric or asymmetric IUGR. **Preterm IUGR children demonstrate the disadvantages of both prematurity and IUGR, but which is more important in determining outcomes is not clear.** The degree of IUGR may influence early delivery, either spontaneous or induced, because of concerns of fetal well-being. **The most striking findings in studies of preterm IUGR children and preterm AGA controls are the high rates of major disability (7% to 23%) and learning disability (36% to 50%).**[93,144]

CONGENITAL ANOMALIES

Cardiac. The presence of congenital heart disease (CHD) places children at an increased risk for developmental delays and neurodevelopmental impairment related to cyanosis, cardiac surgery itself, and more specifically cardiac surgery with cardiopulmonary bypass, or comorbid conditions such as prematurity.* Accumulated evidence for these risks led to the collaboration between the American Heart Association and the American Academy of Pediatrics to issue policy guidelines for the surveillance, identification, and interventions for these children.[22]

Early assessments of children with CHD show motor deficits as most common with language and cognitive deficits appearing later.[108] The most common indicator of later neurodevelopmental deficit was the failure to achieve full oral feedings without supplemental tube feedings; the presence of comorbidities and poor growth were the next most commonly identified risk factors.[108]

Periodic, longitudinal screening is indicated for children with CHD because evidence shows increased risk for motor, language, and cognitive effects. The American Heart Association developed a management algorithm to be used by the primary care provider, within the child's medical home. This algorithm assists with identification, evaluation, and management of potential neurodevelopmental challenges and allows for earlier access

*References 39, 45, 100, 109, 114, 149.

to potential intervention services for the child and family.[22]

Congenital Diaphragmatic Hernia. Congenital diaphragmatic hernia (CDH) increases the risk for poor neurodevelopmental outcomes, likely affected by the severity of CDH and associated hypoxemia (e.g., need for ECMO, prolonged ventilation). Most commonly reported deficits are neuromotor abnormalities (i.e., hypertonicity, hypotonicity motor performance) and neurocognitive dysfunction (i.e., language, cognition).[46–48]

CENTRAL NERVOUS SYSTEM INJURY

Infants with ischemic perinatal stroke are another group of infants with brain injury who are at risk for long-term developmental sequelae. This entity is generally distinctly different from the diffuse ischemia seen in the so-called "watershed" injury of perinatal HIE. Timing of the event may also be less easily determined, but the infant may present with focal or generalized seizures or less-defined clinical signs such as poor perfusion ("dusky" or "gray" spells), respiratory distress or apnea, poor feeding, or low neuromotor tone in the first few days of life. MRI is the most reliable method of diagnostic detection in the newborn period if timed appropriately. Neurologic deficits (i.e., cognitive, behavioral, motor, and language) have been reported in 50% to 75% of survivors, and hemiplegic CP is most commonly found.[94] Later difficulties with sensory impairment or learning difficulties also occur, thus requiring long-term follow-up.[127]

HEMORRHAGE

Although intracranial hemorrhage most commonly occurs in the preterm infant, it may also occur in the term infant, and any concerns need to be carefully investigated with infant outcomes closely monitored.[72] Subdural hemorrhage is the most common type in the term infant, with 44.4% of infants in a recent study having poor outcomes.[79] Impact of intracranial hemorrhage ranges from short-term feeding or state disruptions to severe disability and death (see Chapter 26 for the physiology of these hemorrhages). Attempts to associate the injury with disability have identified that ventricular dilation, as well as grade and laterality, can be predictive of the severity of any deficits, with bilateral grade IV IVH having the poorest outcomes.[43,67,83,103] Infants may experience cognitive and/or motor disability from the brain injury and the combined effects from risks associated with prematurity, comorbid medical conditions, or illnesses.

ILLNESS

Respiratory. Persistent pulmonary hypertension of the newborn (PPHN) and meconium aspiration syndrome (MAS) often overlap clinically, and many of these infants require neonatal intensive care technologies such as inhaled nitric oxide, high-frequency ventilation, and ECMO (see Chapter 23). Full-term survivors have an increased risk for major disability, neuromotor dysfunction, borderline intelligence, language delay, and attention problems.[80] Although the risk of acute neurologic morbidities is present with the use of ECMO for any population, neonates are the most affected, with neurologic morbidity rates of 20% to 50%.[101] Infants who experienced seizures while on ECMO were found to have a lower IQ score at school age and were at higher risk for CP and developmental delay.[101]

Bronchopulmonary Dysplasia/Chronic Lung Disease. BPD/CLD is the most common morbidity in surviving preterm infants.[64] The etiology of neonatal lung injury has changed over time and is now recognized to be an "arrest of lung development" rather than solely injury.[53] Complications of BPD/CLD are listed in Box 23.14.

Necrotizing Enterocolitis. NEC, with or without intestinal perforation, carries with it a high rate of neurodevelopmental impairments, especially in those preterm infants requiring surgery.[6] One study reported an incidence of neurodevelopmental impairments at 82% in infants requiring surgery.[157] Impairments include cognitive deficits, CP, nutritional compromise, and severe visual impairment, with rates significantly higher for those infants requiring surgery.[3,138]

Infection (Sepsis, Meningitis, and Other Non-NEC Related). The impact on neurodevelopmental outcomes from neonatal infection has primarily been studied by individual insult. A 2012 systematic review, however, attempted to define the global

burden of "intrauterine and neonatal insults" with individual sequelae identified per insult.[109] *Sepsis* was identified in five studies reviewed, with 40% of the infants affected (N = 977). The most commonly identified sequelae were cognitive, general developmental delay, or learning difficulties in 74% of the infants. *Meningitis* was identified in 11 studies, with 42% of the infants affected (N = 209) and 100% reporting cognitive deficits as the sequelae. *Cytomegalovirus* identified 377 infants with deafness or hearing loss (67%) and cognitive deficits (66%) as the identified sequelae. *Herpes* affected 116 infants, with 94% of them experiencing cognitive sequelae, and *rubella* was a cause of sequelae in 720 infants, with deafness or hearing loss reported as the most common impairment (80%).[109]

These data support the need for high surveillance, primary prevention, and close monitoring of follow-up for infants born with or acquiring infection in the neonatal period.

TRACKING HEALTH OUTCOMES: THE PRIMARY CARE PROVIDER

Primary Care Follow-Up

At the time of discharge, the NICU staff must provide the primary care provider and the parents with a complete and accurate history of the child's NICU course, including recommendations for ongoing care (Box 31.7). Special health concerns that are specific to the premature infant should be closely monitored, and surveillance of these should supplement the AAP guidelines for preventive, "well-child" care.[33] These additional areas of special concern for the premature infant include the following:

- Neurodevelopmental follow-up
- Visual and hearing outcomes
- Growth, nutrition, and feeding issues
- Osteopenia of prematurity
- Dental enamel defects
- Sequelae related to issues during hospitalization, including pulmonary, gastrointestinal, hematologic, and surgical conditions

Along with subspecialty medical follow-up, the primary care provider will also need to coordinate other supportive services such as early intervention programs and developmental follow-up through an NICU follow-up program, if available.[36] Recommendations for specialized follow-up of the late-preterm infant have also been proposed with the focus on feeding, sleeping, temperature regulation, jaundice, and infection in an effort to reduce postdischarge morbidities and rehospitalization of these infants.[60]

BOX 31.7 POSTDISCHARGE CARE NEEDS FOR NICU GRADUATES

Central nervous system: IVH/PVL imaging before discharge; consider value of MRI instead of, or in addition to, ultrasonography for predicting developmental challenges; plan for ongoing developmental assessment.

Vision: Complete ROP monitoring and treatment in a timely fashion as indicated; visual acuity evaluation between 6 and 12 months of age.

Hearing: Universal screening and recurring screening for high-risk groups (CMV, PPHN, HFV, ECMO, CDH); specific evaluation and augmentation, if indicated, by 6 months of age.

Cardiac: Pulse oximetry screening to rule out critical ductal-dependent cardiac lesions (usually completed in first 1 to 2 days of hospital admission) completed before discharge. Outpatient follow-up of cardiac issues identified during hospitalization (other structural defects, PPHN, or other functional problems).

Pulmonary: Evaluation of BPD classification at 36 weeks' corrected age; outpatient management of BPD, management of oxygen and monitoring of needs; management of additional support, including tracheostomy and ventilators as needed in select patients.

Gastrointestinal: Management of feeding regimens and close attention to growth; management of enteral feeding needs if oral intake is inadequate. Referrals for evaluation and management of oral eating problems.

Development: Early referrals for therapies as indicated for speech, motor, and cognitive development.

BPD, Bronchopulmonary dysplasia; *CDH,* congenital diaphragmatic hernia; *CMV,* cytomegalovirus; *ECMO,* extracorporeal membrane oxygenation; *HFV,* high-frequency ventilation; *IVH/PVL,* intraventricular hemorrhage/periventricular leukomalacia; *MRI,* magnetic resonance imaging; *PPHN,* persistent pulmonary hypertension of the newborn; *ROP,* retinopathy of prematurity.

Growth, Nutrition, and Feeding

Premature infants are at increased risk for growth deficits after discharge; many are discharged below the body weight of their healthy term counterparts. The failure to achieve adequate growth is known as *extrauterine growth restriction (EUGR)*

and is defined by weight less than the 10th percentile for CGA at the time of discharge.[134] **EUGR also occurs commonly in ill preterm newborns.**[39,135] **In the NICU, infants with lower somatic growth who did not also experience a preservation of head growth (head sparing) had a higher incidence of neurodevelopmental impairment** at 18 to 22 months' follow-up in the NICHD Neonatal Research Network.[59,104]

Postdischarge growth failure for preterm infants is also a common problem, especially in those with associated BPD/CLD. Transitional formulas, occasionally with enhanced caloric concentration, may be needed to optimize growth and subsequent development.[69] Recommendations from the European Society for Paediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) Committee on Nutrition support breastfeeding of AGA infants or formula with long-chain polyunsaturated fatty acids for formula-fed, appropriately grown infants.[62] **For those infants with evidence of growth deficits present at discharge (EUGR), breast milk should be supplemented with a human milk fortifier. Formula-fed infants should receive a special postdischarge formula, with increased protein, minerals, and long-chain polyunsaturated fatty acids, for at least the first 9 months.**[10] Serial measurements of head circumference, weight, length, and weight/length ratio should be closely monitored.[150]

Some infants do not achieve full breastfeeding before discharge. It is essential, therefore, to provide **clear verbal and written instruction to the breastfeeding mother about how to assess her infant's hydration status if the transition from partial to full breastfeeding is to occur at home, along with ensuring that the mother has access to medically sound breastfeeding support from the child's pediatrician or a qualified lactation consultant.**

Although premature infants are at an increased risk for childhood obesity and the metabolic syndrome associated with excess weight gain, this risk is thought to be small compared with the risk for growth failure and should be considered with other risk factors such as parental size, adolescent weight, and lifestyle factors.[69] Nutritional status should be monitored closely to intervene for either deficient or excessive weight variations.

Gastroesophageal reflux (GER) is a frequent complication of the VLBW infant postdischarge, and it can affect growth and increase family stressors.[142] Management of these symptoms is often variable and may include medications, formula changes or thickening, and further assessments of potential allergies, insensitivities, and oral feeding skills. Delays in diagnosis and management often lead to caregiver frustration and may negatively affect the infant and development.[142] The use of a screening algorithm has been suggested as a way to more effectively assess and manage these symptoms and reduce caregiver stressors.[142]

Medically Fragile and Chronically Ill Infants

Increasing survival of infants with post-NICU morbidities, including those associated with CDH, short bowel syndrome, and others, has increased the need for detailed parent training, home health care arrangements, and comprehensive, coordinated, multidisciplinary follow-up. The AAP has issued extensive follow-up guidelines for infants with CDH, including monitoring neurodevelopment, managing pulmonary morbidities such as pulmonary hypertension and CLD, assessing hearing function at regular intervals, providing early therapies for feeding difficulties such as oral aversion and gastroesophageal reflux, and monitoring for hernia recurrence, which has been reported in 8% to 50% of CDH infants.[19] Brodsky and Ouellette[36] recommend close monitoring of infants with a history of NEC and/or short bowel syndrome, including neurodevelopmental delays; growth, nutrition, and feeding concerns; dehydration and electrolyte imbalances; and signs of associated complications such as infection, late strictures, and cholestatic liver disease.

LONG-TERM NEURODEVELOPMENTAL FOLLOW-UP

During hospitalization, parents may ask questions about outcome that simply cannot be answered. **Although the infant's risk for cognitive and motor impairment should be discussed, parents must understand that the certain diagnosis of developmental delay or disability cannot be made before 12 to 24 months of age. This need to "wait and see" creates an additional burden**

for families that the NICU staff should help the family anticipate. Referral to a multidisciplinary developmental follow-up clinic should provide the family with ongoing information about their child's progress and give parents the opportunity to speak with professionals about their concerns. **These clinics often provide families with concrete, focused tasks to undertake with their child that may optimize infant development and help parents feel they are contributing to their child's success.**

An additional concern that has more recently surfaced is even longer-term outcome issues for high-risk children. Because many children may be seen once for a multidisciplinary evaluation (18 to 24 months' corrected age) or may not be followed beyond 3 to 5 years of age in the NICU follow-up clinic, it is important that **parents be informed before release from specialty follow-up care about longer-term concerns regarding health and development, especially possible challenges with academics and social-emotional issues.**[7,100]

Pediatric health care professionals need to be aware also that recent reports delineate some more lifelong effects on the former NICU patient's quality of life as a child and adolescent, daily personal and social functions, and overall experiences with health and disease. Although much of this information may be speculative and studies remain ongoing, it is nonetheless important to inform the family that their child's long-term health and quality-of-life issues may relate to their child with a history of prematurity, regardless of the developmental status of the child when seen in the first few years of life.

32 ETHICS, VALUES, AND PALLIATIVE CARE IN NEONATAL INTENSIVE CARE

JULIE R. SWANEY, NANCY K. ENGLISH, AND BRIAN S. CARTER

Clinical decision making is influenced by the values of the individuals involved. In the neonatal intensive care unit (NICU), these values include preserving life, decreasing morbidity, relieving pain and suffering, and, at times, end-of-life care. Sound clinical skills and judgment, combined with ethical reasoning and supportive palliative care, result in the art of care in the neonatal intensive care setting. Technologic advances in medicine have benefited many patients. We are better able to prolong life; at the same time, we are more often in a position to make deliberate decisions about when and how death will occur. Concomitantly, it has become necessary for society to reassess whether the value of prolonging life conflicts with other values, such as relieving pain and suffering and enhancing end-of-life care. In such cases, values of society, the family, and the health care professional necessarily enter into and influence the decision-making process.

Ethical reasoning and palliative care insist that we understand the role of values, as well as medical data, in making decisions.

HISTORICAL OVERVIEW

Historically, ethical concerns in neonatal care focused on the risks and benefits of available technology (Table 32.1). An example is oxygen therapy with the offsetting dilemma that treatment could cause degrees of blindness or residual lung damage, whereas nontreatment might result in death or brain damage (1960s). Treatment of premature infants and those with birth defects became technically possible in the 1950s with development of infant incubators, ventilators, and refined surgical techniques. Because these new technologies not only failed to eliminate all bad outcomes but also added new problems, controversies developed over when and how much to use them. Care of newborns with spinal cord defects is illustrative.

Zachary[114] and Shurtleff[97] advocated aggressive management, which increased survival rates but offered questionable quality of life for those more severely affected. Lorber[72,73] was less optimistic about the effects of aggressive management of infants with meningomyelocele and is recognized for his selective nontreatment of some of these infants. Today, open neural tube defects are routinely closed in the immediate neonatal period, and research is ongoing to assess the potential for fetal surgery to close these defects to mitigate long-term morbidity in what is clearly acknowledged as a nonlethal condition.[10,29]

Discussion of treatment of seriously ill newborns was stimulated by the 1973 publication of Duff and Campbell.[36] Their seminal article described the selective nontreatment or withdrawal of treatment for 43 seriously ill newborns at Yale–New Haven Hospital (between 1970 and 1972) whose "prognosis for meaningful life was extremely poor or hopeless." According to Duff and Campbell[36]:

> *Both treatment and nontreatment constitute unsatisfactory dilemmas for everyone. When maximum treatment was viewed as unacceptable by families and physicians in our unit, there was a growing tendency to seek early death as a management option,[20] to avoid that cruel choice of gradual, often slow, but progressive deterioration of the child.*

They recognized that most survivors of NICUs are healthy; however, they also recognized that some infants remain severely disabled by congenital

BLUE type highlights content that is particularly applicable to clinical settings.

TABLE 32.1 SELECTED ISSUES IN PERINATAL/NEONATAL HISTORY OF ETHICAL IMPORT

TIME	FETAL DIAGNOSIS	FETAL THERAPY	NEONATAL THERAPY
1900s (early)			Temperature regulation, nutrition; limited survival in low-birth-weight and anomalous infants Recognition of congenital rubella syndrome Cardiovascular surgery in the newborn period Modern incubator developed Oxygen therapy for respiratory distress
1950s		Tocolysis (EtOH)	EBF (Rh) incompatibility recognized Oxygen toxicity recognized: retrolental fibroplasia/blindness in treated infants; cerebral palsy and death in those untreated Other iatrogenic diseases Antibiotic usage broadens
1960s	Placentocentesis Early ultrasonography Fetal heart rate monitoring Fetal scalp pH assessment Amniocentesis Chromosomal analysis	Intraperitoneal blood transfusion for EBF	Birth of "modern" neonatal intensive care units Field of teratology develops after thalidomide disaster Improved outcome for infants <2500 g Surgical management of meningomyelocele becomes an issue
1970s	Fetoscopy Real-time ultrasonography Improved structural, chromosomal, and metabolic diagnostics	Intravascular blood transfusion for EBF Beta-adrenergic agonists for tocolysis Corticosteroids for lung maturation Legalization of abortion	Continuous positive airway pressure, modern neonatal ventilator Improved outcome for infants <1500 g Bronchopulmonary dysplasia recognized Problems of the very-low-birth-weight infant: intraventricular hemorrhage, bronchopulmonary dysplasia, necrotizing enterocolitis TPN/HAL becomes available Improved pediatric surgery Newborn metabolic screening
1980s	Chorionic villus sampling Cordocentesis Doppler flow studies of placenta and umbilical vessels New reproductive technology Alpha-fetoprotein monitoring	Fetal surgery Prophylactic penicillin for group B streptococcus infection Treatment of fetal dysrhythmias via maternal medications	High-frequency ventilation Surfactant replacement therapy Improved survival in infants <1000 g Extracorporeal membrane oxygenation Intravenous immunoglobulin
1990s	Fetal cell isolation in maternal blood Polymerase chain reaction and genetic amplification	Treatment of twin-to-twin transfusion syndrome	Liquid ventilation Recombinant erythropoietin Nitric oxide therapy
2000–2010	First-trimester high-resolution ultrasonography	Further advances in fetal surgery (including that for nonlethal anomalies)	Head cooling; total-body therapeutic hypothermia to mitigate HIE

TABLE 32.1 SELECTED ISSUES IN PERINATAL/NEONATAL HISTORY OF ETHICAL IMPORT—CONT'D

TIME	FETAL DIAGNOSIS	FETAL THERAPY	NEONATAL THERAPY
2010–2019	Ever-expanding genetic testing (including noninvasive fetal testing from maternal blood) Expanded perinatal, genetic, and metabolic screening	Potential genetic treatments	Prostanoids, endothelin-receptor antagonists, and phosphodiesterase inhibitors for pulmonary hypertension Orphan drug approval for some rare metabolic conditions Erythropoietin to mitigate HIE Rapid genomic testing: facilitation and influence on parental decision making, especially during the acute distress of their infant's diagnosis; justification of cost and resource allocation.[13,49]

EBF, Erythroblastosis fetalis; *EtOH,* ethyl alcohol; *HIE,* hypoxic-ischemic encephalopathy; *TPN/HAL,* total parenteral nutrition/hyperalimentation.

malformations that, until recently, would have resulted in premature death. They were legitimately concerned about the quality of life for these infants and their families.

The majority of newborns treated in NICUs do grow up to lead active, productive lives, but not all fare well with even the most aggressive treatments.[42,43] Consequently, there is increasing concern over what is "appropriate" treatment of newborns, particularly seriously ill or disabled ones. Recognizing the risks and benefits of technology over 40 years ago, Eisenberg[38] stated, "At long last, we are beginning to ask, not *can* it be done, but *should* it be done."

Baby Doe (1982) and Baby Jane Doe (1983) became the focus of controversy over the issue of withholding treatment and nutrition from handicapped infants.[9,23,83,105] Today, new issues require our attention. Advances in fetal surgery continue to raise the question of whether interventions for nonlethal conditions warrant the attendant risks of preterm birth and treatment postnatally in the NICU.[10,29] Further, assisted reproductive technologies (ARTs) contribute to increasingly greater numbers of very-low-birth-weight (VLBW) infants born as multiples (twins, triplets, and higher-order multifetal gestations) in NICUs. At what point these well-intended services should be restrained or curtailed to prevent prematurity and its associated morbidities continues to pose new ethical questions.

Throughout this short but focused "history" of ethical issues in neonatal care, it has become increasingly apparent that there are significant issues about appropriate treatment and the limits of treatment.[47,84] The role of palliative care has become increasingly recognized. Diagnosis, prognosis, and the meaning of palliative care to families are important factors in clinical decision making. Not only numerous issues but also many individuals are involved in the decision-making process about treatment and nontreatment options. More people become involved as technologic advances increase treatment options. Parents have always been presumed to be the best decision makers on their child's behalf. Health care providers also have been committed to providing what is in the best interest of their patients. Historically, decisions were made privately between parents and their physician. In the modern NICU, treatment goals and decisions are made in the context of a health care team composed of professionals from various moral communities who offer specialized input into the care of the neonate and the family. Parents must be included in the team, because their values are of paramount importance in establishing goals and making decisions about their infant's care. Societal concerns generally have focused on protecting infants against decisions that are detrimental to their best interest by statutes on child abuse and neglect. Professional groups such as the American Academy of Pediatrics (AAP),[4,16,73] the American College of Obstetricians and Gynecologists (ACOG),[7] and the Canadian Pediatric Society (CPS)[68] have now addressed these concerns in published guidelines for care of critically ill infants. The National Association of Neonatal Nurses (NANN) has published guidelines on neonatal palliative care.[27] Community groups[35,37,110] are addressing limitations of interventions for critically ill infants as well. Clinical decision making is affected by parents, the health care team, professional groups,

and society. Bioethics and palliative care advocate a shared decision making model in which parents and clinicians decide together, seeking to balance the appropriateness of interventions and the protection of children against harm.

DEFINITION OF BIOETHICS

Ethics is the study of rational processes for determining the most morally desirable course of action in view of conflicting value choices. Ethics is a branch of philosophy that considers competing values to obtain the best possible outcome to a given situation. When values conflict and each value is morally justifiable, an ethical dilemma exists. For an ethical dilemma to exist, a real choice between possible courses of action must exist.

Bioethics seeks to determine the most morally desirable course of action in health care given the conflicting values inherent in varying treatment options.[8] Most often, when a conflict of values does not exist, moral conflict does not exist. That is, when the health care providers and parents all agree that it is most beneficial to an infant to not treat the infant aggressively and to allow the infant to die, no dilemma or conflict between them exists. Of course, that they agree does not mean that conflict does not exist with moral views of outside parties or principles. Regardless, the goal is to determine the most morally desirable course of action under a given set of circumstances.

THEORIES OF ETHICS

An ethical theory provides a basis for making morally appropriate decisions. There are many theories or approaches to ethics to consider. *Principle-based ethics* identifies fundamental principles that form the foundation of ethical deliberation. This approach emphasizes the centrality of principles and rules to determine moral duty. Principles commonly recognized are autonomy, beneficence, nonmaleficence, and justice.[17] *Virtue ethics* is character based, and as such, identifies the virtues of the moral agents involved, rather than the applied principles, as essential to ethical outcome. Various views of the moral life emphasize different virtues as more primary than others. In modern bioethics, primary virtues include respect, fidelity, honesty, and benevolence. *Casuistry* is *case-based ethics* in which the claims, grounds, and warrants of a particular case are compared with similar cases. The basic question for moral casuistry is how a general moral precept is to be understood in similar sets of circumstances. *Narrative ethics* is story based, in which the narrative itself is a method of ethical reasoning. Every case has different "narratives" to consider, such as medical knowledge, personal identity, patient experience, and the doctor-patient relationship. Although the medical model may focus on disease, psychopathology, objectivity, and diagnosis, the narrative model may focus correspondingly on illness, "the person," subjective experience, and caring. *Feminist ethics* is relationship based and considers primarily the ethics of care. All of these approaches are important to consider. Deciding which moral theory is operative is important to proceeding.

CLINICAL DILEMMAS IN THE NEONATAL INTENSIVE CARE UNIT

Personhood

Decision making in the NICU often revolves around the concept of personhood. When is one a person? Determining what this means depends on which moral community is consulted. Designation of personhood is morally significant because it determines whether and what duties and obligations are owed to a particular newborn.

Some communities believe personhood is present at the moment of conception; they equate "human" with "person." Shelp[96] refers to this as the "genetic theory of personhood." Others believe personhood depends on the presence or absence of certain basic human qualities. Shelp calls this moral theory "property based." Although with the latter theory there is agreement that the concept of personhood is nongenetic, there are differences about which qualities qualify for "person" status.

Fletcher[46] and Engelhardt[39] support the "property-based" stance. They believe that there are human lives that are "subpersonal." Fletcher states, "It is not what is natural but what is personal which has the first-order value in ethics."[46] Both researchers believe that neocortical function is necessary for personhood. Engelhardt[39] relates qualities such as self-consciousness, rationality, and self-determination

to personhood. He distinguishes between persons in a moral sense and persons in a social sense. Infants are deemed persons only in a social sense, not a strict sense by which societal rights are obligatory. The rights of the infant, according to Engelhardt, are held in trust by his or her parents; therefore "decision(s) about treatment belong properly to the parents because the child belongs to them in a sense that it does not belong to anyone else, even to itself."[39]

Tooley[104] suggested that "The ability to see oneself as existing over time is a necessary condition for the possession of a right to life."[62] If Tooley's reasoning is correct, no infant has a right to life, at least not for some time. Although the "pro-life" moral community assigns person status to all with potential life, Tooley denied that potential has anything to do with a right to life. He advocated a quality-of-life standard. When a life is full of intractable pain and suffering, death is seen as a morally acceptable option. In fact, it is sometimes considered a relatively more favorable outcome than continuing life.

Ramsey[91] and Robertson[95] hold a contrasting view. For them, death is never better than life; quality-of-life assessments are not part of their moral reasoning. Life is considered sacred, an absolute good. Both the fetus and newborn are considered persons with a right to live. Therefore "death must always be imposed nonhumanly by God or nature or some other cosmic arbiter."[46] This "pro-life" position supports the moral right of all fetuses and newborns to the same care, implying that abortion and infanticide are morally reprehensible.

If one is deemed a "person," society owes one certain obligations and expects certain duties. If one is not deemed a "person," it is morally reasonable for societal benefits to be withheld or withdrawn. Whatever justification is needed for a particular moral dilemma in the NICU extends from this beginning. Clearly, there is no final definition of personhood, and differing definitions must be considered.

Patienthood

A primary problem confronting a perinatal clinician is this fundamental question: Who is the patient? The adult patient is generally competent and worthy of respect as a moral agent. However, in the case of a newborn, the newborn, the family, and, in some circumstances, society have been variously considered the "patient." The accordance of rights to the newborn as an independent agent is a relatively recent occurrence. Neonatal cases are inextricably bound in the context of varying definitions of personhood and of complicated family and societal situations. This fundamental question remains: To whom is the moral duty owed? To the infant? To the family as "patient"? To society? If there are competing moral obligations, it is essential to determine to whom the primary moral duty is owed.

Professional-Patient Relationship

The importance of the professional-patient relationship cannot be overestimated, because this is the human context in which decision making occurs. With neonates, this includes a relationship between parents as surrogates and the health care team. This is especially recognized in bioethics and palliative care.

When the four major bioethics principles—autonomy, beneficence, nonmaleficence, and justice—are applied to health care relationships, several moral rules can be derived. These moral rules include fidelity, truth telling, and confidentiality. The professional-patient relationship is considerably affected by the meaning and extent of these rules.

Fidelity, or promise keeping, may be derived from the principle of autonomy. The duty to keep promises may promote the greatest good (utilitarian) or be seen as an obligation (formalist). Many relationships between professionals and patients (or surrogates) involve promises or contracts, whether implicitly or explicitly made. For example, once professionals have established a relationship with a patient, their duty of fidelity includes not abandoning or neglecting that patient. An obvious problem in dealing with surrogates may be conflicting duties to the surrogates and the patient. Promises made by professionals are binding except when they are superseded by stronger obligations.

Truth telling, like fidelity, can be derived from the principle of autonomy or respect for persons. It assumes an implicit contract between parties that the truth will be told. At the heart of truth telling is trust, which gives professional-patient relationships their integrity. Lying violates implicit contracts, respect for persons, and trust. It also impedes informed consent.

Utilitarians and formalists may agree on the duty to tell the truth, although they may disagree on the duty not to deceive. Cases have been made for "benevolent deception," when intentional deception is morally justifiable if its primary intent is for

the benefit of the patient. In such cases, telling the truth may be a violation of *beneficence and nonmaleficence.* Others argue that deception, benevolent or not, is morally wrong, because it violates respect for persons and trust. Ultimately, the professional-patient relationship erodes. Respect for persons involves acknowledging patient autonomy to know or not to know the truth of his or her particular situation. It is important to ask individuals how much they want to know.

It is generally agreed that *confidentiality* should prevail in professional-patient relationships. With minors, confidentiality extends to the parents or legal guardians. Part of the implied contract is that information gained by both parties will be kept confidential. From the earliest days of medicine, protecting the patient's privacy has been a fundamental tenet of clinical practice. There are, of course, instances in which confidentiality is justifiably breached. It is at this point that many ethical dilemmas arise.

Breach of confidentiality may be morally and legally justified to protect the life of a patient or the lives of others who may be endangered. The value of human life overrides the relationship, but the professional should be able to demonstrate clear danger before violating a patient's privacy. This also may be seen as a violation of autonomy. "The health care professional's breach of confidentiality thus cannot be justified unless it is necessary to meet a strong conflicting duty."[17]

Obviously, health care professionals can be torn between conflicting moral obligations, such as between the patient and society. Such instances in which a breach may be justified include child abuse and neglect and certain communicable diseases. However, there is strong justification among both utilitarians and formalists for maintaining the privacy and confidentiality of patient information. Most important, the genuine integrity of the professional-patient relationship will be enhanced and preserved when confidentiality, like fidelity and truth telling, is respected and upheld. This integrity of relationship then becomes the basis of the decision-making process.

Informed Consent

The issue of valid informed consent is repeatedly raised in the environment of the NICU. All relevant information for a decision must be given. Voluntary consent, free of coercion, by competent persons must be obtained. Information given to parents may be poorly understood for many reasons, including the complex nature of the information; the emotional or physical state of the parents after the birth of a sick, premature, or anomalous infant; physical separation of the parents from their newborn; and feelings of bewilderment and intimidation leading to uncontested paternalism. Indeed, there are indications that valid informed consent is an ideal toward which we work but one that, within the realities of practice, may rarely be obtained. Consent should be sought, however, and open lines of communication and parental education established to facilitate some level of understanding and enable more than token participation in decision making by the parents.[80,109]

One standard that has been put forth in an effort to accomplish informed consent is the "reasonable person standard." It asks, "What would a reasonable person want in this circumstance?"

Both bioethics and palliative care may enact the *reasonable person standard* in multiple ways in the NICU, thus ensuring that more valid informed consent is obtained. First, early contact should be made with the parents or family about the expected prognosis, interventions, and potential meaning of the prognosis. This consultation may be initiated even before delivery. Advanced care birth planning is recognized as vital to delivery room decision making for the at-risk infant. Second, information should be provided by the clinical staff in a factual, compassionate manner. Parents may need continued orientation or reorientation to the NICU environment. This may be necessary, especially for parents who are geographically separated from their infant. Third, phone calls and photographs are important means for parents to maintain emotional involvement with their baby. Fourth, social workers, chaplains, or other support resources should be contacted and used early to manage emotional distress and facilitate communication. Fifth, regular patient care conferences with the parents should be scheduled. This will keep parents apprised of the newborn's status and will keep the staff informed about the parents' level of understanding, perspectives, and values. Additional efforts to communicate must be made at the time of special procedures, tests, or therapies to enhance everybody's understanding and the informed consent process.

An integral part of the informed consent process and one that directly affects decision making is the

principle of fidelity, commonly called *truth telling,* as discussed earlier. Issues of what to tell, how and when to tell, and whom to tell become a daily part of the staff's interaction with each other and the families of affected newborns.

In practice, the issue of truth telling is considered an essential component of the professional-patient relationship. Information should be shared among staff members and presented to the family truthfully, compassionately, and without bias. However, it is often best for a single voice (e.g., the attending neonatologist, neonatal nurse practitioner, or primary care clinician) consistently to relate information and interpret facts for families to minimize confusion or misinformation.

Double Effect

The principle of "double effect" asserts that an action may be considered good if the intent of the action is a positive value, even if the secondary effects of the action might be considered harmful if undertaken as the primary goal; further, the good effect should be commensurate with the harm. Double effect is used frequently in the NICU. An example is the use of opioids (morphine or fentanyl) in a newborn for whom there has been a compassionate life-support withdrawal from assisted ventilation; the positive goal is reduction of air hunger and suffering, even at an acknowledged low risk for causing some degree of respiratory depression.

Problems of Uncertainty

A major difficulty in ethical decision making and palliative care is the uncertainty that exists around medical and prognostic outcomes. Supportive palliative care should always be provided. It is difficult to determine what may be in the best interest of the child when the prognosis remains unclear. Even when the prognosis may seem clear, there are always those children who confound science, whose developmental outcomes are far from expected.

Some of the most frequent problems in working with perinatal cases arise as a result of this uncertainty. Parents always ask, "Will my baby be okay when he (or she) grows up?" Answers are often unsatisfying or incomprehensible. In most cases with premature infants, truth telling may compel an answer that, when reduced to its simplest form, says, "I don't know." A statistical approach to answering the question may be "Most babies like yours grow up to be normal" or "Some babies like yours have serious problems." These answers are often followed by a litany of statistical probabilities of each morbidity. Neither approach answers the parents' question of what their particular baby will be like. Such approaches serve to complicate the clinician's relationship with parents over issues such as expertise, veracity, and disclosure. The statistical approach may answer the NICU staff's question of quality of care, but few parents understand such statistics or are willing to apply them to a loved one. Nonetheless, uncertainty is a way of life in many perinatal cases, and this observation significantly compromises the resolution of ethical problems in the NICU. This uncertainty should be incorporated in a holistic palliative care approach.

In considering medical uncertainty, it may be helpful to recognize two general classes of perinatal cases. NICU patients can be generally classified as either premature infants without known anomalies or near-term infants with major anomalies, either syndromic or nonsyndromic. Neonatal deaths, by definition occurring in the first 28 days of postnatal life, are principally associated with prematurity or anomalies and account for about two-thirds of all infant mortality cases (death before the first birthday). For infants with known syndromes or major anomalies, prognoses from the literature are describable with reasonable accuracy. This assists with some certainty.

A detailed review of neonatal outcome is beyond the scope of this chapter, but several conclusions appear justified. First, the infant mortality rate has declined rapidly since the establishment of NICUs, and the major mortality groups are in lower weight and younger gestational age groups.★ Second, coincident with the decline in mortality rate have come improvements in neonatal morbidity (both neurodevelopmental and pulmonary).† Third, the absolute number of normal premature survivors has increased dramatically, and the absolute number of moderately and severely affected survivors appears to have increased as well.‡

Despite this, "extreme prematurity, on the other hand, is characterized by an enormous uncertainty. In these cases, predictions of outcome at birth

★References 14, 33, 40, 58, 87, 93, 99.
†References 3, 34, 67, 82, 90, 100, 113.
‡References 1, 2, 11, 52, 56, 60, 75, 79, 92, 99, 101.

are probabilistic at best."[94] Accordingly, attempts have been made to establish guidelines for treatment of extremely low-birth-weight (ELBW) infants.[7,21,35,37,110] The morbidities in premature survivors are variable in nature, but central nervous system morbidities generally include visual impairment and blindness, speech and hearing impairment, neuromuscular impairment, and serious cognitive impairment.[101] Few premature survivors require long-term institutional care. The combined risk for one or more of these disabilities is in the range of 15% to 20%.[32,50,51,111] Most people agree that these are indeed serious disabilities, with major effect on the patient and family. However, do they justify withholding or withdrawing treatment? If so, under what circumstances?

For perinatal clinicians for whom quality of life is a major consideration, it remains an exceedingly difficult practical problem to predict which particular child will be significantly impaired and in what manner. The predictive value of postnatal evaluations in estimating long-term disability is low.

The intent of raising these questions is to underscore the complexity of ethical discussions as particularly applied to problems in the modern NICU. This in no way reduces the enormity of such problems for the patient, family, health care providers, or society. Technologic advances may resolve old uncertainties but often seem to carry new uncertainties that are equally perplexing. Supportive palliative care should continue to be provided to incorporate these uncertainties and to coordinate care.

Setting Goals

Clinicians should discuss diagnosis, prognosis, and the meaning of the prognosis of the newborn as early as possible for parents to consider their goals for their baby. Parents should be involved, not just informed, in determining the overall goals of treatment based on their values for their child. Treatment goals should be established so that incremental decisions can be made. Decisions toward that end then can be made. Goals expressed by parents may be living a "normal" life, living with a debilitating outcome but without persistent pain or suffering, existence without any notable "quality of life," and so on. Accordingly, treatment goals may be to improve an infant's health, help the infant to maintain the current state of health, or help the infant die with supportive palliative care. Too frequently, decisions are made before the treatment goal is established. The parents and health care team members may be working toward different goals. The physician, health care team, and parents all should be guided by established goals so that beneficial treatment can be offered. There should be a model of shared decision making. The AAP Committee on Fetus and Newborn has stated that although the role of parents in goal setting and decision making must be respected:[7]

> *The physician is not obligated to provide inappropriate treatment or to withhold beneficial treatment at the request of the parents. Treatment that is harmful, of no benefit, or futile and merely prolonging dying should be considered inappropriate. The physician must ensure that the chosen treatment, in his or her best medical judgment, is consistent with the best interest of the infant.*

Treatment and Nontreatment

For parents to be involved in determining overall treatment goals and the decision-making process, they must be fully informed to consent to or refuse treatment for their child. Infants should be treated humanely and with respect in an environment that is conducive to maximum comfort and healing. Humane judgments should be made in determining how infants can most benefit from treatment in any given situation. Palliative care should be provided to all infants at all times.[18] As noted in Chapter 12, sufficient analgesic should be administered to infants having surgery because they can indeed experience physical and psychological pain. Staff and parents should maximize the development of premature infants and offer every possible benefit to them. The nursery environment should be as free from excessive overstimulation as possible (see Chapter 13).

Other perplexing ethical questions arise when the benefit of treatment is unclear. Even the most perfunctory of decisions should be based on the patient's best interest, yet "best interest" is often difficult to determine. Should a baby born with anencephaly be resuscitated or receive life-sustaining interventions solely for the purpose of organ transplantation? Should an ELBW infant receive aggressive ventilatory therapy? Should an infant with trisomy 18 be treated with aggressive life support or surgery? Medical and ethical decisions involve considering not only what kind

of treatment serves the patient's best interest but also whether the treatment is appropriate at all. Limited or nontreatment decisions are agonizing and regularly result in ethical and palliative care discussions. A nontreatment decision is sometimes incorrectly called withholding or withdrawing *care*. Only *treatment* may be withheld or withdrawn. *Care* always should be provided, whether curative or palliative.

"Nonbeneficial" Treatment

The concept of "nonbeneficial" (or futile) medical treatment may be as perplexing as the concept of benefit. It does, however, deserve attention, because there are increasing circumstances in which treatment may be considered to be nonbeneficial and thus withheld or withdrawn. There is no ethical obligation to offer nonbeneficial treatment, yet there is no one definition of "nonbeneficial."

Most often, judgments about benefit are based on medical or physiologic data. It may be medically nonbeneficial to resuscitate an infant under certain conditions, because the treatment cannot alter the course of the illness or problem, yet there are psychological, social, and religious reasons that such treatment might be offered. If, because of the treatment, the family has time to hold the infant and say goodbye, the resuscitation may not be considered by them to have been nonbeneficial. Of course, the opposite is also true; that is, what may not be physiologically nonbeneficial may be considered to be nonbeneficial by the family or surrogates based on religious or other reasons. Again, there is no ethical obligation to offer nonbeneficial treatment. It is possible to get a medical effect but not a medical benefit. The distinction can be significant. Determination of the appropriateness of treatment should be based on medical benefit as determined by family goals for the patient, which include physiologic, psychological, social, and religious data.[65] By attending to all of these aspects of care, which include staff and family input alike, a determination of what is nonbeneficial therapy and thus what is beneficial therapy can be made.

Research Ethics

A persistent and controversial issue in neonatal care has been the introduction of new therapies or procedural interventions into the NICU without appropriate research into their safety, efficacy, net benefit, and long-term outcomes for those critically ill infants who receive them. Appropriate studies in animal models ideally are followed by randomized, controlled clinical trials in human newborns (see Chapter 1). Extracorporeal membrane oxygenation, high-frequency ventilation, and recombinant erythropoietin all have been examples of interventions that crept into neonatal care before controlled trials were conducted. In recent years, the use of glucocorticoids either to enhance fetal lung maturity antenatally or to prevent or treat bronchopulmonary dysplasia postnatally is an example worth evaluating.

Although the benefits of a two-dose regimen of antenatal steroids was demonstrated in 1972,[71] the development of recent practice patterns in which multiple doses of steroids were used over successive weeks of pregnancy was unsubstantiated by randomized clinical trials designed to address the efficacy or safety of such practices. Subsequently, the National Institutes of Health held a Consensus Development Conference and published a statement advising that repeat courses of steroids not be used routinely.[84] Research conducted after these practice patterns were established demonstrated increased maternal infection and suppression of the normal hypothalamic-pituitary-adrenal axis and both fetal and neonatal decreased somatic and brain growth, adrenal suppression, neonatal sepsis, chronic lung disease, and increased mortality rate. In addition, neurodevelopmental outcome studies suggested an increase in psychomotor delay and behavioral problems.

The acute, seemingly beneficial effects of administering systemic steroids to newborns with lung disease, however, were not met with significantly improved mortality rate or long-term outcome. It is also associated with a number of acute side effects (e.g., gastrointestinal perforation, hypertension, hyperglycemia) and possible long-term harmful consequences on lung and central nervous system function (see Box 23.13). Studies that caution about the poor postnatal brain growth among some ELBW NICU survivors raise additional concerns about the wisdom of adding risks associated with steroid treatment to an already at-risk newborn. Research into the future use of steroids in premature infants should be well designed and adequately powered to provide answers and should include an evaluation of long-term neurodevelopmental outcome.[44]

Recent concerns have been publicly aired in the lay and professional media over the conduct of neonatal research, the adequacy of the informed consent process for parents of newborns, and the overall safety and conduct of neonatal research.[53] As stated by Lantos, "the clinical judgment of conscientious and knowledgeable physicians is only as good as the evidence on which it is based."[63] This matter is clear, and the requisite evidence-based practices we all seek require carefully acquired evidence from well-conducted and safe studies (see Chapter 1). But there are other lessons in the SUPPORT legacy, not the least of which is the need for transparency and honest communication of what we *do not* know—hence the difficulty in explaining to parents and colleagues alike that the involvement in clinical research may or may not affect the risk of bad outcomes—or good! And that is why the research is being done.[64] Parents are vulnerable, their babies are critically ill, and everyone in the NICU—including clinicians—is hopeful. But these truths can make the informed consent process, and the conduct of research, challenging in seemingly unapparent ways.[78,80,109] If parents of critically ill children respond to the challenges present in decision making for clinical care by wrestling with multiple influences beyond any simple explanation or exchange of clinical information and attendant risk/benefit analysis, they likely are no less inclined to do the same in the context of clinical research.[23]

DECISION MAKING IN THE NEONATAL INTENSIVE CARE UNIT

In the NICU, decisions of serious proportion are encountered regularly, based on medical facts and nonmedical values.[85] Both bioethics and palliative care advocate for a model of shared decision making aligning values with the expected outcome for the infant. From the moment of birth, and in some cases even earlier during the antenatal period, a foremost issue is that of determining the appropriate level of intervention treatment of sick or anomalous newborns. Entire texts have been devoted to this issue.[62,108] Primary concerns are when to treat, when and how to intervene, when to limit intervention, and who should be involved in the decision-making process.[74]

A frequently encountered treatment problem requiring attention, other than the much-publicized anomalous infant, is the extremely premature or VLBW infant whose course is marked by slow or absent progress despite appropriate and seemingly heroic intervention. Together, these may portend a guarded or very poor prognosis.

These cases may prompt "quality of life" and "ordinary versus extraordinary treatment" discussions. The President's Commission[88] noted that "there is no basis for holding that whether a treatment is common or unusual, or whether it is simple or complex, is in itself significant to a moral analysis of whether treatment is warranted or obligatory"—a view that had been voiced previously by moral philosophers. The AAP has published a strategy for the initiation and withdrawal of treatment for high-risk newborns.[4,6] General recommendations include the importance of ongoing evaluation, parental participation, establishing the goals of humane care, and upholding the best interest standard seeking to benefit the infant: "It is inappropriate for life-prolonging treatment to be continued when the condition is incompatible with life or when the treatment is judged to be futile."[4,6] The AAP Committee on Bioethics further "supports individualized decision making about life-sustaining medical treatment for all children, regardless of age. These decisions should be jointly made by physicians and parents."[4,6] If we are honest about our professions, we must realize that "quality of life" is what we are all about. Health care professionals are entrusted by society to advance the health and well-being of the mind and body of all persons so that they can lead their lives and function as part of the human family, individually or collectively. No individual is capable of establishing what is an acceptable "quality of life" for all persons in all circumstances. Each case requires our collective efforts to facilitate the best decision for that particular patient.

Steps in Ethical Decision Making

The approach to decision making should follow a method that clearly demonstrates the practice of applied clinical ethics and supportive palliative care. Palliative care also includes the principles of ethical decision making in supporting decision makers as they make informed decisions regarding the care that the infant receives. The goal of both applied ethics and palliative care is to make the best decisions

BOX 32.1 APPROACH TO ETHICAL DILEMMAS IN NEONATAL CARE

1. Consider who is involved in making and implementing the decision (family, guardians, clinicians, society).
2. Decide who will make the final decision. Is referral to an ethics committee indicated?
3. Clarify all medical facts within the case; consider indications, alternatives, and consequences of each action or inaction.
4. Understand significant human factors and values (for patient, family, and health care team).
5. Identify the ethical dilemma or conflict.
6. Make a decision:
   a. List options as solutions to the problem.
   b. Weigh and prioritize values.
   c. Make a decision.
7. Check for moral and rational defensibility.

Data from Brody H. *Ethical Decisions in Medicine.* Boston, MA: Little, Brown; 1981; Francoeur RT. From then to now. In: Harris CC, Snowden F, eds. *Bioethical Frontiers in Perinatal Intensive Care.* Natchitoches, LA: Northwestern State University Press; 1985.

for and with a particular patient. Such a decision requires first that a decision maker be determined. The decision maker, whether a parent, health care provider, or other, must understand his or her own (1) relationship to the patient (or family), (2) interpretation of ethical principles and values, (3) theoretical basis of ethics used (e.g., utilitarian, deontologic), (4) source from which morality is derived, and (5) palliative care goals.

Ethical decision making involves identifying and working through substantive issues based on values and goals, resulting in a decision.[103] Implementing decisions requires determining who will decide, by what criteria they will be allowed to do so, and subsequently how the decisions or actions are to be implemented.

Box 32.1 presents the essential steps to decision making in neonatal cases in which a dilemma exists. Consider all involved values and possible solutions to the problem, realizing that alternative solutions may uphold different principles and result in different (positive or negative) consequences. Options that may appear acceptable to the family may be unacceptable to the health care team, or vice versa. There may be societal (legal) constraints on certain actions. In some instances, only one option will be consistent with the rules and principles to which the decision maker subscribes. Other options may present apparent conflicts between competing values or result in unacceptable consequences. In a decision, there will probably be some give and take. A shared decision-making model embraces all parties and viewpoints. Some priority must be assigned to a certain set of values, rules, principles, or resultant effects of any action or inaction. A decision should be made in light of these issues. This process need not always be invoked in full. Often, when the case is carefully dissected and medical facts, values, treatment alternatives, and expected prognoses are revealed, issues that at first seemed in question are clarified, and it becomes apparent that no real dilemma exists.

Good ethics, then, starts with good facts and effective communication. A viable patient-professional relationship that clarifies facts (taking into account uncertainties and the difficulties of prognosticating), human values and feelings, and the interests of all relevant parties is essential to ethical decision making. Decisions made should reflect a moral choice that is beneficial to the newborn as determined by the established, informed decision makers.

Although it may be arguable whether the patient is the neonate, family, or another societal group, it is prudent to develop a consensus wherever possible and thus minimize conflict among the interested parties. Efforts should be made by interdisciplinary team members to involve the parents and family early in the care of their child and listen carefully to their values, goals, and dreams. Clinical information should be presented sensitively and thoroughly. These efforts may help minimize the stresses on the parents and prepare them to participate in decision making about the care of their child. These efforts will also assist staff as they participate with the parents in the decision-making process. With careful attention to the needs of patients, families, and staff, many conflicts can be resolved at an early stage before positions are hardened and emotional investment is high.

In most cases, consensus is reached. In a minority of cases, conflict is unavoidable. In some cases, medical care raises issues that are highly controversial either within the group of clinicians providing care or in the broader context of societal problems. In many cases, the family is far from homogeneous in its expression of wishes. Many parents are young and in the process of achieving independent adulthood with well-developed values. Single-parent families are not uncommon. The birth of a critically

ill infant may serve as a focus to crystallize disagreements between spouses or may aggravate conflicts between the parent (or parents) and the extended family. In such cases, a more formal process, such as a formal family care conference, appeal to an ethics committee, or even involvement of the legal system, may help resolve or minimize conflicts of values. It is preferable, however, that decisions be made by involved parties as close to the bedside as possible.[98]

Proxy Decision Makers

In dealing with newborns who are, by their very nature, incompetent and cannot make decisions for themselves, value conflicts must be resolved with the input of a proxy or surrogate decision maker acting on the infant's behalf. This may be the parents, a family member, a friend, a guardian ad litem, or the physician. To be considered a valid surrogate, the person should be competent, knowledgeable of integral values of the patient or family, free from conflicting interests, and without serious emotional conflicts in dealing with the case.

Society has for many reasons allocated to the parents the primary authority role in collaboration with health care providers in making decisions about their newborn's care. In most instances, the parents are best suited for deciding such matters and have the infant's best interest in mind. They are usually present when possible, are concerned for their infant's well-being, and are willing to hear the facts of their infant's condition and learn about needed therapies. Of all people, they also know best the values of the family culture or environment in which the infant will be raised.

Yet parents may be less understandably overwhelmed at times, both physically and emotionally exhausted, and baffled or intimidated by the high-technology environment of the NICU and the complexities of their infant's care. Amid feelings of grief, fear, anxiety, and wonderment over their premature or anomalous infant, they may be uncertain of their proper role and responsibilities as parents. Some parents show signs of acute stress disorder and posttraumatic stress disorder. Health care providers should give daily updates on the infant's condition and anticipated course. Parents' needs for emotional support and avenues to both vent their frustrations and explore their concerns over economic, marital, family or sibling, and career effects of their predicament make resources such as nurses, social workers, and chaplains essential in providing assistance to allow them to participate in goal setting and difficult decision making. Occasionally it will be necessary to assess the level of parental competency in assuming the role of surrogate, recognizing when additional help or support for them is needed to fulfill this role.

Reliance on clinicians as decision makers is yet another option. Clinicians know and understand the complexities of the medical condition and treatment more than parents do. They may be more objective about individual cases and are not emotionally overwhelmed, as the parents might be. Also, based on experience, they offer a perspective of effectiveness of treatments and can be consistent in treating similar cases.

However, clinicians also may encounter problems when they act as the principal decision makers. Although their knowledge of medical facts is the most complete of all persons, it is at the same time, unfortunately, incomplete. Accurate diagnoses and certainty in prognoses are elusive at times. Medical knowledge does have limits. Statistics are helpful for groups of similarly affected patients, but individual outcomes are difficult to predict. Further, although physicians have an advanced degree of specialized information and knowledge, they do not necessarily possess any more moral expertise than that of parents or others.

Treatment versus nontreatment decisions are ultimately moral, not simply medical, decisions. These decisions are weightier than most clinical decisions that clinicians make. More is involved than a rote, rational process employed in isolation from the family or health care team. The clinician must contend with his or her own values and emotions, as well as the medical facts, in each individual case. He or she must facilitate parental and health care team communication and interaction and ultimately order the level of intervention.

Fortunately, physicians and nurse practitioners do not work in isolation from the health care team when making decisions about patients. Nurses, child life workers, social workers, and chaplains are vital members of the decision-making team. A potential problem with each of these clinicians as surrogates is that a conflict of interest may exist between them and the infants for whom they are deciding. Members of the health care team may be biased toward the prolongation of life, have preconceived and strong biases about euthanasia, or be influenced by issues unrelated to the infant, including

advancement of care, financial issues, or societal issues. Hence they may not fully consider the best interest of the patient or the values of the involved family. In contrast with parents, they do not live with the results of their decisions and actions. Also, consistency in their application of principles to similar cases may be lacking, and they may give in to strong pressures (real or perceived) exerted by the law or very assertive parents.

Various factors should contribute to minimizing the potential problems in parents and health care professionals reaching morally defensible decisions in the best interest of the premature or anomalous infant. The professionalism of health care team members who are committed to serving the health and interests of their patients is a foremost consideration that serves this purpose. A sense of duty leads these professionals to assist families in achieving their life goals through facilitating open communication and discussion of their varied concerns. A great sense of personal and professional satisfaction may be derived by helping families accept and deal with their emotions, questions, and concerns for their infant and their own circumstances.

For many years, hospital ethics committees have facilitated ethical decision making for sick neonates. Generally, their roles are to provide education, policy interpretation, and clinical consultation. Clinically, ethics consultants function to clarify the ethical dimensions of various treatment options and serve in an advisory capacity only. They do not make clinical decisions. Clinical decisions are best made at the bedside by parties who are involved with the sick infant. At times, however, clinicians and parents need clarification and support. Ideally, ethics committees facilitate the resolution of any conflicts between parents and clinicians in matters of treatment. They help work through ethical aspects of treatment decisions. One important role they play is to improve effective communication between staff and families. Finally, they may prove to be a safeguard for infants for whom parents and professionals are working toward an end that may be perceived as contrary to the infant's best interest.

Surely, much reflective thinking should be invested in our decisions, as individuals, parents, or members of a committee. However, a small number of cases will proceed beyond institutional review to a court. Every effort should be pursued before going to court. Courts may employ many of the criteria for being proxies. They can ensure that all relevant facts are presented and considered, and judges are capable of exercising unmatched control of data collection, investigation, questioning of experts, and seeking of alternative solutions. A judge also can appoint a guardian ad litem to be the patient's advocate when necessary.

There are at least a few weaknesses in courts as proxies. They are removed from the NICU and have no contact with the case, patient, staff, or family whose problem they are deciding; hence they are more remote than other possible proxy decision makers. Working through cases may be time-consuming, which may result in additional problems, changes in pertinent facts, or prolongation of suffering. Sometimes the consequences of court proxies are that they become the decision maker for the infant instead of the parents and/or clinicians. Although the best interest of the infant may override the rights of the parents, this can result in the rights of the state's legal system overriding the rights of the parents and even the best interest of the infant.

Standard of Best Interest

The best-interest standard has been advocated by the President's Commission and others seeking to accomplish valid moral decision making in difficult neonatal cases.[68,81,88,91] We are obliged "to try to evaluate benefits and burdens from the infant's own perspective."[68] This standard requires a balance of beneficence, nonmaleficence, and justice. It is accepted in the case of newborns over "substituted judgment." Because newborns are, by definition, never competent, substituted judgment can only be applied hypothetically. The best-interest standard is accepted as the best method available for parents and clinicians to decide on behalf of newborns.

The potential for self-seeking by the decision maker is easy to understand and has been recognized. The interests of parents, siblings, clinicians, hospital staff or administration, and society may all seem to compete with those of the newborn. But the interests of others—be they emotional, economic, or otherwise problematic—cannot justifiably override those of the patient[12,61] based on the actual or potential personhood of the critically ill neonate. Individual or societal problems or perceived burdens generally are not viewed on the same moral plane as a person's claim to life.

Certainly some cases stretch the best-interest standard to its limits. Cases of protracted treatment

with uncertain prognoses beg the question of quality of existence (in which nonmaleficence is the principle of concern) and require consideration of more than mere suffering and pain.[61] Indeed, in the words of Arras,[12] "Sometimes circumstances may be so extreme and the consequences so dreadful that the priority of justice can no longer be maintained." In this sense, we have to find the best balance of beneficence, nonmaleficence, and justice.

We also must consider other morally relevant concerns of neonates who may be doomed to brief lives with less than recognizably "human" existence. Human capacities (e.g., ability to think, be aware of self, relate to other people) may be different from biologic human life. The preservation of biologic human life bereft of the benefit of distinctly human capacities is controversial and has been challenged in quality-of-life decisions.[12,36,62,72,108] Walters[107] has written of the "proximate personhood" model. Arras[12] suggested the "relational potential standard" (Does this child have the ability, or potential, to relate to physical space and time and to communicate to others?) as a means to address these concerns more aptly than the "misapplied best interest standard," calling on society itself to inquire "into the conditions of valuable human life."

Priority should be given to attempts at effecting a cure in these ill infants. Whether or not a cure can be achieved, patient comfort should be sought. Some maintain that life itself may not always be an absolute good; thus it may be morally justifiable to withhold or withdraw futile treatment associated with inhumane risks or harms that would prolong dying. Mitchell, while a member of the American Nurses Association Committee on Ethics, has stated[83]:

> *Some infants are so premature and underweight, so profoundly impaired, so hopelessly diseased, or so severely asphyxiated that their foreshortened lives are full of misery for them and those around them. For infants who are so impaired that medical therapies are futile or would only prolong suffering, invasive medical procedures and surgery are morally, as well as medically inappropriate.*

She calls on nurses to shift their focus in such cases to "seek primarily to provide comfort, relieve suffering and help a grieving family."

Creating an Ethical Environment

Ethical decisions do not happen in a vacuum. Environments should exist that promote ethical behavior and deliberation and include integrated palliative care. Such environments should be institutional (the NICU, the hospital, the community, social and political structures) and attitudinal. In effect, these environments portray an ethical culture of the institution. Attitudes include those in which families and staff are empowered to express their opinions and engage in the decision-making process, all voices are valued, information is openly and honestly shared (including uncertainties), respect for all individuals is upheld, and the predominant concern is to benefit the patient, whether that be minimizing overstimulation of patients, administering the appropriate analgesic, or providing appropriate palliative care. Routine ethics rounds or ethics committee and palliative care consultations, along with family care conferences and generally good family communication, are recognized means of enhancing such an environment in the NICU. Yet none of these replace the responsibility of all staff members consistently to promote an overall ethical milieu in the NICU in which ethical practice and integrated palliative care are the standards of care.

Recent literature has focused on the concept of moral distress, particularly among nursing staff. Moral distress occurs when conflict exists between personal values and treatment being given. The most commonly reported cause of distress is following orders to support patients at end of life with advanced technology when palliative or comfort care would be, from the perspective of the caregivers, more humane.[42] A more recent study among clinicians in NICUs and PICUs found that moral distress was positively associated with burnout and uncertainty.[66] Among the clinicians surveyed, nurses reported higher moral distress intensity than physicians. Only in nurses was moral distress positively associated with more years of ICU experience and uncertainty about whether their care benefited the child.[66]

Some clinical settings hold weekly staff conferences for education, clarification, and open and informed communication among staff members. Information can be clarified, and family care conferences can be arranged. When the NICU staff enter into these dialogues with parents or when an ethics consultant joins in, it enhances the ability to clarify the goals of care and understand the present condition of the patient and potential future concerns of all parties as they view the patient.

ETHICS COMMITTEE OR PALLIATIVE CARE CONSULTATION?

Generally in practice, it is preferable to keep the shared decision-making responsibility within the professional-patient relationship. In the vast majority of cases, members of the health care team and the parents do have the infant's best interest in mind. Yet in view of the vast dimension and difficulties of some of the required decisions, many clinicians will consult with a hospital ethics committee (HEC), infant bioethics committee (IBC), or palliative care team (PCT). Some institutions have all three of these committees—the IBC falling under the HEC—but many do not have an IBC, PCT, or palliative care consultant. For those who have both ethics and palliative care consultation available, it is reasonable to question whom to call, and when, for consultation. These intersecting processes enhance clinical care. When there is agreement about a treatment plan, both the ethics committee and palliative care might be consulted for confirmation of that plan. When there is a dispute about a proposed course of treatment, the HEC (and/or IBC) may be consulted for clarification of ethical principles, values, and various treatment options that would be consistent with ethical and legal standards.[59] The PCT or consultant may also be used for consultation on goals clarification and the development of a comprehensive palliative treatment plan to include comfort measures, specific symptom management, and support to the infant, family, and caregivers. Palliative care provides comprehensive management of physical, psychosocial, spiritual, and existential needs of patients and families facing life-limiting illness.[6]

The stimulus to the establishment of IBCs in the United States was the controversy over and death of Baby Doe in Bloomington, Indiana, when society (and government) became acutely aware of the moral issues surrounding what many perceived to be wrongful nontreatment of a handicapped newborn.[86] Resulting government regulations, along with AAP policies, have focused on the importance of ethics consultation to promote quality decisions about treatment of ill newborns. HECs, composed of members from different disciplines, are a resource for consultation and advice. They are not a decision-making body, although some groups are moving toward a consensus model. Different committees have different procedures.[45,68,81] Ethics consultation should be sought for values clarification and decision making. Committee functions and responsibilities may include (1) offering counsel and ethical review, (2) educating hospital personnel, (3) retrospectively and prospectively reviewing pertinent government guidelines, and (4) developing appropriate institutional policies. In most institutions, *anyone* involved in a particular case may request a consultation from the HEC.

Palliative care is both a philosophy and an approach to care delivery.[6] It focuses on comprehensive, compassionate comfort and support. Many domains of palliative care are appropriate for all patients. Palliative care may, however, be especially important—and become the predominant paradigm of care—when an infant is on the threshold of viability, is gravely ill or has an uncertain outcome, or is dying despite appropriately applied intensive care measures.[18] Many clinicians are comfortable and skilled at providing palliative care to their patients and families, and others prefer consultation with a palliative care specialist. Palliative care consultation should be considered (1) any time there is a question about comfort or support, (2) any time there is a question about pain and symptom management specific to the realm of comfort and end-of-life, and (3) when an infant has a life-threatening condition or is dying despite life-sustaining interventions. Palliative care services generally work collaboratively with HEC members and the clinical team to ensure maximum comfort and minimal suffering for newborns whether their conditions are improving or worsening. Such consultations, along with good family communication, enhance patient care and the ethical environment of the NICU.

COMMUNICATING WITH FAMILIES

The most important element in communicating with families is listening to them. Indeed, consistent, sensitive, and thorough communication of clinicians with families is essential to good patient care. Active listening, clarifying treatment goals, and addressing emotional stress of parents and families are import tasks at the heart of palliative care and bioethics. The more complex the medical situation, the more crucial it is that parents receive consistent information. This requires concentrated efforts among staff to clearly communicate the care plan within the

interdisciplinary team to facilitate clear, consistent communication with the parents. Parents often are confused by the various prognostications offered by multiple subspecialists and cannot synthesize the data into a "larger picture" of what is happening to their baby. Yet in the urgency to communicate information, clinicians sometimes forget to listen to the grief, fears, and concerns of parents for their child (see Chapters 29 and 30.) These feelings can profoundly influence decisions that are made and how they are made. Ethics and palliative care must also consider the range of human emotions involved in life-and-death issues, not just clinical information. What parents would not be distraught over the premature birth of their infant? Overwhelmed by their severely disabled infant? The prospect of lifetime rehabilitation? The reality or prospect of suffering? The prospect of death of their newborn?

Clear, consistent communication with parents is essential, because parents play a vital role in the decision-making process. They, along with the infant, are the most affected.[19] No matter what their religious or sociocultural background, almost all parents experience shock and grief over their infant's need for intensive care (see Chapters 29 and 30). They deal with this in better and worse ways. For many parents, the ability to participate in ethical decision making is impaired while they are in such an acute stage of shock. Usually, prenatal diagnosis of anomalies gives parents time to adjust to their baby's condition before birth or before decisions have to be made. This adjustment time can be most valuable. To participate in shared decision making, particularly decisions about withholding or withdrawing treatment, parents must have achieved some degree of emotional reorganization and acceptance. Interdisciplinary team assistance in helping them move from emotional disorganization to reorganization is crucial to further decisions that should be made. At this point, parents may be better able to absorb medical data, ethical values, and principles. Although a theoretical difference may not exist between withholding withdrawing treatment, there is a large emotional difference. The sound clinician, as well as the ethicist and palliative care provider, must be sensitive to this distinction.

Choices about treatment and nontreatment do affect the grieving process. Questions such as "Am I just prolonging suffering by keeping her alive?" are countered by "Am I not giving her a chance and playing God by allowing her to die?" Duff and Campbell[34] report that families experienced "a normal mourning for their losses" after allowing their seriously ill infants to die. What remains for many parents are doubts that their choice was correct. For some, decisions based on certain religious principles or other value criteria offer moral justification of behavior that assists in the mourning process. For others, the justification may be logically but not emotionally clear. In these instances, grieving can become more complex and difficult.

A valuable role of an ethics committee and/or ethics consultant may be to offer input into, if not confirmation of, the parents' decision in a way that helps allay guilt that can interrupt normal grieving. Ethics, although at once highly theoretical and intellectual, must consider that the situations with which it most intimately deals are highly emotional. For parents, the psychological trauma will affect their ethical considerations, and ethical decisions will have further psychological effect. A valuable role of the palliative care provider may be to assist parents and families in their bereavement and other dimensions of emotional strain.

A real value of an interdisciplinary health care team is the particular attention paid to the many complex aspects of a patient's living and dying. When parents are facing the death of their baby and the goals of care become more palliative than curative, the entire team may be involved in providing palliative care to assist them. Nurses and physicians, social workers, chaplains, and psychologists may all be intimately involved with monitoring the patient's comfort level and deteriorating course and with comforting grieving parents. Baptisms (when appropriate) and especially funerals are important ritualistic ways of organizing the meaning of the traumatic event. The entire staff should encourage parents to offer all that they can to their dying infant. They should provide active palliative care—maximum comfort for the patient and maximum support to the family. Helping patients and families cope with death is a privilege. It can be personally and professionally satisfying, and ultimately immeasurably helpful to everyone involved, to enter emotionally into this process. Often care of the living means care of the dying.

Good communication among staff members is also important. The effect on the health care team members of helping an infant die also should be recognized because their concern and involvement with the infant usually are significant. Helping someone

through the dying process can be a difficult, though rewarding, experience. In such instances, professionals may agree with the decision (preferably the parents') to withhold or withdraw treatment. Professionals may also disagree with the decision but may place a higher value on the parents' autonomy to decide than on the decision itself. Respecting this, they may abide by the parents' wishes for their infant. No one should be forced to compromise personal or professional integrity, however, and in cases in which one's ethics or integrity is being violated, the case may be transferred. Staff support is essential to address bereavement and to alleviate any more distress that may be occurring. Preferably, professionals can learn about the range of ethically defensible options and can support the parents in choices different from their own.

How does the clinician discuss such sensitive issues, especially dying, with parents? In many ways. First and foremost, listen to their thoughts, feelings, and concerns as they express them. Clinicians should consider the vulnerability of parents who are frequently overwhelmed by the delivery, their baby's condition, and other related stressors. Clinicians should be compassionate not only in their listening but also in their communication to parents. What are they feeling, perceiving, wondering about, fearing, hoping for? Box 32.2 suggests some questions to engage in empathic conversation. Such questions are relevant to the parents of the infant whose condition is improving, the infant whose future is uncertain, the infant for whom parents must make agonizing decisions, and the infant who is clearly dying. Empathic communication with families is a critical component of good palliative care and the ethical environment of the NICU.

BOX 32.2 SUGGESTED QUESTIONS TO ENGAGE EMPATHIC CONVERSATION

- What do you understand is going on with your baby?
- Who is your main doctor? What has he or she told you?
- Do you have the medical information you need, or do you want more?
- What kind of information would help you the most right now?
- What are you expecting for your baby?
- What do you think your baby feels?
- What do you see your baby doing?
- Who is your very best support person right now?
- Is he or she available?
- What is your greatest concern about your baby?
- What would give you a sense of peace or comfort in the midst of this, if that is possible?
- What is happening at home?
- Faith and beliefs can be very important in the grief and healing process. Is there anything about your faith or beliefs that we should know to be able to take care of you and your baby?
- Who or what is helping you get through this?
- This may be or is the best condition your baby will ever be in. When this is the case, we usually focus on keeping him or her warm and comfortable until he or she dies rather than on curing. How do you feel about this for your baby?
- Our goals in health care are to (1) improve health, (2) maintain health, and (3) help someone die.
- How can we ease this experience for you?

SOCIAL ETHICS

Social ethics reflects on the sociocultural aspects of human life. It considers how individuals as moral agents are accountable for their behavior in social structures and public policy issues. It also can refer to shared patterns of moral judgment. Moreover, it focuses on how social contexts influence individual moral behavior and the range of moral responsibility.

In a pluralistic society like the United States, there is no one social ethic. Some believe in rugged individualism; others believe in equality of opportunity, worth, and treatment; still others believe that we bear mutual responsibility for one another. An underlying concern of most socioethical systems is concern for both the individual and the common good.

In NICUs, bioethics and social ethics converge. Treatment decisions have social implications; societal values influence treatment decisions. As described, government regulations highlight the paradox of societal values about the treatment of disabled infants. These federal guidelines advocate the use of "reasonable medical judgment" in treating disabled infants, yet their effect may be seen as increasing the perceived obligation to treat—to the point of "unreasonable." Through government, society expresses the determination to treat, yet societal commitment to the long-term care of special-needs NICU graduates and families is wholly insufficient. Public funds for such care have been reduced while the expressed urgency for treatment of all babies has increased.

The values inherent in our public policy decisions about initial and long-term treatment are curiously disparate.

After comparing the health care and social policies of the United States with the seemingly more equitable policies of Great Britain and Sweden, Young[112] concluded, "We need to strive for a better balance between aggressive treatment in the neonatal intensive care units initially, and the resources currently allocated for the long-term care of the disabled." Such a balance might include being more selective about aggressive treatment and learning more about prematurity and trying to prevent it. Young continued, "To the extent that society fails to ensure that seriously ill newborns have the opportunity for an adequate level of continuing care, its moral authority, to intervene on behalf of a newborn whose life is in jeopardy, is compromised."[112]

Recognizing this disparity, various community groups have attempted to establish guidelines for standards of care that are fiscally, morally, and medically responsible to guide parents and clinicians in goal setting and decision making. They have recognized the high cost, in every respect, of neonatal and pediatric intensive care. Their impetus has been to determine community "agreed-on" values for treatment and nontreatment of disabled infants to effect a standard of care for the extreme premature, severely disabled, and critically ill infant. Managed care organizations are also assessing the ethics of reasonable care and the limits of treatment to be offered. Although not wholly able to determine "agreed-on" values for treatment and nontreatment standards of care, these community and professional groups have offered important social voices to the complexity of neonatal care.

INTEGRATING PALLIATIVE CARE IN THE NEONATAL INTENSIVE CARE SETTING

The majority of newborns admitted to the NICU are in critical condition and need life-supporting interventions. Parents anxiously wait for any news concerning the life of their newborn infant. Could palliative care be included in the life-supporting care for the newborn? Would parents benefit from the additional support that palliative care offers during this critical time and for the days and weeks that follow? When palliative care is offered concurrently with life-sustaining cure-oriented care and continues throughout the infant's intensive care stay, it is referred to as an *integrated* or *mixed model of care delivery.*[6,28,55]

BOX 32.3 GOALS OF PALLIATIVE CARE PROGRAMS[54]

- Improve quality of life and prognostic understanding of problems/conditions.
- Relieve pain, distress, and uncertainty.
- Help clarify and address patient and family goals and associated treatment preferences.
- Strengthen communication, decision making, and family satisfaction/well-being.
- Coordinate medical and practical needs across settings.
- Reduce resource utilization and costs by matching treatment to patient and family goals.

Palliative care for infants and children emerged from the adult palliative care model and is defined as an interdisciplinary team approach to care for all seriously ill patients and their families. The goals of care are focused on quality of life and the relief of suffering (Box 32.3). By offering an integrated model of neonatal care, parents and clinicians will begin to dispel the prevailing myth in health care and in the public that palliative care can only be offered when death is certain.[28] Palliative care focuses on the needs of the infant and family rather than the prognosis of an infant's condition.

THE UNMET NEEDS OF INFANTS/PARENTS IN THE NICU

In 2003, the Institute of Medicine (IOM) assessed the care received by seriously ill and medically fragile infants and children.[43] Approximately 400,000 infants and children were living with unmet needs related to the conditions, which in the majority of cases, were first identified at birth (neurologic trauma, extreme prematurity, congenital or chromosomal abnormalities). Many of these children spent months in the confines of the NICU receiving the most modern technologically advanced treatment in neonatal care. However, parents and caregivers reported that they received little, if any, support from the pediatric health care community; they

felt abandoned and struggled alone to manage the complex needs of their child. Additionally, the IOM report acknowledged the high incidence of infant death in the NICU as 34% of all childhood deaths occur in the first 28 days of life.[25,43]

After the IOM report, a majority of neonatal peer-reviewed literature focused on improving end-of-life care for neonates and their families.[48,70] Pioneering efforts in neonatal palliative care recognized and attended to the reality that the death of an infant leaves a profound lifelong imprint and trauma on parents, siblings, extended family, and the community. However, these early efforts did not encompass the spectrum of care management that is needed for support of parents and coordination of care from the intensive care setting to the home setting. Confusion continues to exist in the literature and in practice as to which newborns are critical enough to receive palliative care and when is the right time to include palliative care in the infant/family care plan.[20,48,76,102] Often which infant receives palliative care is dependent on the attitude and awareness of the neonatal team.

Currently little evidence suggests a standard of care or established protocol for an integrated model of care delivery in the NICU.[15,30,89] Among 17 articles reviewed, only one reported on an integrated model of care for all neonates admitted at 28 weeks or less of gestation.[89] The integrated model uses a clinical algorithm that clearly integrates palliative and cure-oriented approaches in care.[30] This algorithm was initiated when the newborn was admitted and continued until discharge or death.

Another integrated model of neonatal care includes all newborns at risk for neurologic trauma or birth malformations.[69] This model outlines areas in which palliative and neonatal care interventions overlap in providing comfort and bonding for the newborn and parents, such as swaddling, non-nutritive sucking, light reduction, and minimal stimulation. The addition of palliative care expertise in symptom management, navigating prognostic uncertainty, communication with families, and shared decision making is a more comprehensive approach to caring for neurologically challenged infants, children, and parents.

Recent articles enumerate the goals of neonatal and palliative care from a historical and value-based perspective.[25,57,77] From this perspective, the future of palliative and family-centered care can merge to offer neonates and families the comprehensive support that is needed for families of the medically fragile newborn and continue postdischarge from the NICU. The delivery of palliative care in four US NICUs has been described and is seen by the neonatologists as an intricate and necessary part of the care offered in the NICU, in outpatient clinics, and in the home.[26] Three NICUs initiate the integrated care model on admission to the NICU and continue after discharge. The palliative care team consults and advises the primary neonatal care team. When an infant requires extensive care coordination and community services after discharge or is expected to die, a referral to the palliative care team is made by the primary neonatal team, usually the attending neonatologist. At Children's Mercy Hospital, palliative care clinicians (i.e., nurse practitioner or physician) are part of the neonatal care team, make rounds daily with the intensive care team, and are always available to staff. Coordination of the infants care on discharge from the intensive care setting to the community is facilitated by the palliative care team.

MANDATED PALLIATIVE CARE EDUCATION FOR ALL HEALTH CARE PROVIDERS

In 2015, the IOM published another study that found that the majority of seriously ill children (and adults) were not referred to a palliative or hospice care and most primary care providers were ignorant about the benefits and services offered by palliative care. The IOM report encourages healthcare educators to include palliative care knowledge and skills in basic education of all health care providers. Clinicians and educators are also encouraged to begin the process of integrating palliative care skills into clinic settings where death occurs frequently (i.e., intensive care settings) and for patients with chronic, complex conditions.[55]

NECESSARY SKILLS TO INTEGRATE PALLIATIVE CARE INTO NEONATAL PRACTICE

Box 32.4 lists the requisite attitudes, knowledge, and skills to integrate palliative care into neonatal practice. An integrated model of care delivery also includes a palliative care team specialist (clinicians

who have advanced education and experience in palliative care) who is available to the primary care team as an advisor.[24] In the NICU, the primary neonatal integrated team can seek the advice and consultation from a specialist on the palliative care team for complex symptom management, complicated family situations, or when coordination of care after discharge is required. The specialist team is available to the neonatal staff in a similar fashion as the ethics consultation team.

NICU professionals must evaluate their current practice and make adjustments that include palliative care in the model of care delivery. Most importantly, neonatal clinicians and educators must gather evidence on what works and what does not work with an integrated model of neonatal care, so that each setting can adjust the model for their specific needs. Although an overall shift in how neonatal care providers view palliative care takes time, resources, and often-moral courage, a few committed and dedicated clinicians and educators can create a climate of change that would benefit all infants and their families. A step-by-step process is needed to begin the integration of palliative care in the neonatal intensive care setting (Table 32.2).

BOX 32.4 REQUISITE ATTITUDES, KNOWLEDGE, AND SKILLS FOR INTEGRATING PALLIATIVE CARE INTO NEONATAL PRACTICE

- Advanced communication skills
- Shared decision making
- Awareness of variables pertaining to cultural/religious sensitivity
- Coordinating care across settings and in the community
- Additional pain and symptom management skills

THE COMMUNITY PALLIATIVE CARE SPECIALIST

The integrated model continues after discharge in outpatient clinics and at home. The care coordinator (nurse, social worker, or case manager) is a bridge between the inpatient setting and community pediatric primary providers. Care coordinators support parents in adapting to their role of primary care provider, while ensuring that care continues as prescribed on discharge from the inpatient setting.

Offering palliative care concurrently with life-supporting care to all newborns on admission to the NICU promotes continuity of care from diagnosis to discharge or the death of the newborn. Integrated care acknowledges the family's decisions about care, even when it means that the child is

TABLE 32.2 STEPS IN IMPLEMENTING AN INTEGRATED MODEL OF NEONATAL CARE[55]

STEPS FOR IMPLEMENTATION	COMMENTS
Step 1: Identify champions (Neonatal Palliative Care Champions)	Neonatal educators and clinicians committed to the goal of integrating palliative care into neonatal care-delivery model. Begin by exploring domains of care delivery:[55] 1. Patient care 2. Organizational concerns—legal, economic 3. Education 4. Research
Step 2: Create a mission statement	Mission statement communicates the goals of an integrated model of care that are specific to the setting. Mission statements are usually written in terms of the philosophy and values of the parent organization. Encourage all neonatal care providers to become involved in focus groups that explore knowledge, attitudes, and priorities of staff toward creating an integrated model of care.[106]
Step 3: Examine how to disseminate knowledge, skills, and attitude	Develop concrete and sustainable change in how palliative care is integrated in caring for infants/parents. How can the knowledge, skills, and change of attitudes begin to take shape for neonatal clinicians in the setting?

indefinitely dependent on life-prolonging interventions. An integrated model of neonatal care recognizes the profound and long-term emotional impact that a child's complex condition and/or death has on a family unit and a community.

NEWBORN METRIC CONVERSION TABLES (CONT'D)

Length

INCHES TO CENTIMETERS

1-inch increments Example: To obtain centimeters equivalent to 22 inches, read "20" on top scale, "2" on side scale; equivalent is 55.9 centimeters.

INCHES	0	10	20	30	40
0	0	25.4	50.8	76.2	101.6
1	2.5	27.9	53.3	78.7	104.1
2	5.1	30.5	55.9	81.3	106.7
3	7.6	33.0	58.4	83.8	109.2
4	10.2	35.6	61.0	86.4	111.8
5	12.7	38.1	63.5	88.9	114.3
6	15.2	40.6	66.0	91.4	116.8
7	17.8	43.2	68.6	94.0	119.4
8	20.3	45.7	71.1	96.5	121.9
9	22.9	48.3	73.7	99.1	124.5

One-quarter (¼) inch increments Example: To obtain centimeters equivalent to 14¾ inches, read "14" on top scale, "¾" on side scale; equivalent is 37.5 centimeters.

	10–15 INCHES					
	10	11	12	13	14	15
0	25.4	27.9	30.5	33.0	35.6	38.1
¼	26.0	28.6	31.1	33.7	36.2	38.7
½	26.7	29.2	31.8	34.3	36.8	39.4
¾	27.3	29.8	32.4	34.9	37.5	40.0

	16–21 INCHES					
	16	17	18	19	20	21
0	40.6	43.2	45.7	48.3	50.8	53.3
¼	41.3	43.8	46.4	48.9	51.4	54.0
½	41.9	44.5	47.0	49.5	52.1	54.6
¾	42.5	45.1	47.6	50.2	52.7	55.2

NOTE: 1 inch = 2.540 centimeters. Centimeter equivalents rounded one decimal place by adding 0.1 when second decimal place is 5 or greater; for example, 33.48 becomes 33.5.

Weight (Mass)

POUNDS AND OUNCES TO GRAMS

Example: To obtain grams equivalent to 6 pounds, 8 ounces, read "6" on top scale, "8" on side scale; equivalent is 2948 grams.

	POUNDS														
OUNCES	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14
0	0	454	907	1361	1814	2268	2722	3175	3629	4082	4536	4990	5443	5897	6350
1	28	482	936	1389	1843	2296	2750	3203	3657	4111	4564	5018	5471	5925	6379
2	57	510	964	1417	1871	2325	2778	3232	3685	4139	4593	5046	5500	5953	6407
3	85	539	992	1446	1899	2353	2807	3260	3714	4167	4621	5075	5528	5982	6435
4	113	567	1021	1474	1928	2381	2835	3289	3742	4196	4649	5103	5557	6010	6464
5	142	595	1049	1503	1956	2410	2863	3317	3770	4224	4678	5131	5585	6038	6492
6	170	624	1077	1531	1984	2438	2892	3345	3799	4252	4706	5160	5613	6067	6520
7	198	652	1106	1559	2013	2466	2920	3374	3827	4281	4734	5188	5642	6095	6549
8	227	680	1134	1588	2041	2495	2948	3402	3856	4309	4763	5216	5670	6123	6577
9	255	709	1162	1616	2070	2523	2977	3430	3884	4337	4791	5245	5698	6152	6605
10	283	737	1191	1644	2098	2551	3005	3459	3912	4366	4819	5273	5727	6180	6634
11	312	765	1219	1673	2126	2580	3033	3487	3941	4394	4848	5301	5755	6209	6662
12	340	794	1247	1701	2155	2608	3062	3515	3969	4423	4876	5330	5783	6237	6690
13	369	822	1276	1729	2183	2637	3090	3544	3997	4451	4904	5358	5812	6265	6719
14	397	850	1304	1758	2211	2665	3118	3572	4026	4479	4933	5386	5840	6294	6747
15	425	879	1332	1786	2240	2693	3147	3600	4054	4508	4961	5415	5868	6322	6776

NOTE: 1 pound = 453.59237 grams; 1 ounce = 28.349523 grams; 1000 grams = 1 kilogram. Gram equivalents have been rounded to whole numbers by adding 1 when the decimal place is 5 or greater.
