PART I Lifestyle Management and Prevention of Cardiovascular Disease

James M. Rippe, MD

Chapter 1 Rationale for Intervention to Reduce the Risk of Coronary Artery Disease 3
James M. Rippe, MD and Theodore J. Angelopoulos, PhD, MPH

Chapter 2 Lifestyle Strategies for Risk Factor Reduction, Prevention, and Treatment of Coronary Artery Disease 19
James M. Rippe, MD and Theodore J. Angelopoulos, PhD, MPH

Chapter 3 Nutrition Interventions for Cardiovascular Disease: Behavioral and Educational Considerations 35
Carol E. O'Neil, PhD, MPH, RD and Theresa A. Nicklas, DrPH

Chapter 4 Physical Activity and Fitness in the Prevention of Cardiovascular Disease 49
Robert F. Zoeller, PhD

Chapter 5 Clinical Strategies for Managing Dyslipidemias 65
Ulf G. Bronas, PhD, ATC, ATR, FSVM and Arthur S. Leon, MD, MS

Chapter 6 Lifestyle Management and Prevention of Hypertension 75
Ulf G. Bronas, PhD, ATC, ATR, FSVM and Arthur S. Leon, MD, MS

Chapter 7 Community Approaches to Reduce the Risks of Cardiovascular Disease 83
Cherise B. Harrington, PhD, MPH, Meridith Eastman, BA, and Laura Linnan, ScD, CHES

PART II Nutritional Aspects of Lifestyle Medicine

Johanna Dwyer, DSc, RD

Chapter 8 Nutrition 101: The Concept of Nutritional Status and Guides for Nutrient Intakes, Eating Patterns, and Nutrition 103
Johanna Dwyer, DSc, RD

Chapter 9 Healthy People 2020: Highlights in the Nutrition and Weight Status Focus Area 119
Pamela Starke-Reed, PhD, Crystal McDade-Ngutter, PhD, and Van S. Hubbard, MD, PhD

Chapter 10 Dietary Guidelines for Americans, 2010: National Nutrition Policy 131
Rachel Hayes Polon, MPH, RD and Eve Essery Stoody, PhD

Chapter 11 Nutritional Considerations for the Active Adolescent 149
Rebecca J. Boulos, MPH and Christina D. Economos, PhD

Chapter 12 Nutrition for the Elite Athlete 163
Ladd Harris, MS, RD and Katherine Beals, PhD, RD, FACSM, CSSD

Chapter 13 Optimal Nutrition Guidance for Older Adults 177
Alice H. Lichtenstein, DSc

Chapter 14 Role of Communication in Changing Nutrition Behaviors to Promote Healthy Lifestyles 185
Jeanne Goldberg, PhD, RD and Lindsay Peterson, MS, MEd

PART III Physical Activity and Fitness
Theodore J. Angelopoulos, PhD, MPH

Chapter 15 Physical Fitness Evaluation 199
Peter F. Kokkinos, PhD and Jonathan Myers, PhD

Chapter 16 Exercise Prescription for Apparently Healthy Individuals and for Special Populations 209
Paul G. Davis, PhD, RCEP

PART IV Behavioral Psychology
Bess Marcus, PhD

Chapter 17 Applying Psychological Theories to Promote Healthy Lifestyles 223
Sarah E. Linke, PhD, MPH and Dori Pekmezi, PhD

Chapter 18 Cognitive and Behavioral Approaches to Enhancing Exercise Participation 233
Barbara A. Stetson, PhD, John M. Cooper, BA, and Patricia M. Dubbert, PhD

Chapter 19 Behavioral Approaches to Enhancing Smoking Cessation 245
Joseph T. Ciccolo, PhD, Ernestine G. Jennings, PhD, and Andrew M. Busch, PhD

Chapter 20 Behavioral Approaches to Enhancing Weight Loss and Maintenance 255
Teresa K. King, PhD, Elizabeth E. Lloyd-Richardson, PhD, and Matthew M. Clark, PhD

PART V Women's Health

Pamela M. Peeke, MD, MPH, FACP

Chapter 21 Women's Health: Challenges and Opportunities 269
Pamela M. Peeke, MD, MPH, FACP

Chapter 22 Menopause 271
Margery Gass, MD, NCMP

Chapter 23 Breast Health: Lifestyle Modification 287
Beth Baughman DuPree, MD, FACS

Chapter 24 Osteoporosis 299
Sobia Khan, MD, NCMP, CCD and Holly Thacker, MD, FACP, NCMP, CCD

Chapter 25 Physical Activity and Health in Women 313
Shari S. Bassuk, ScD and JoAnn E. Manson, MD, DrPH

Chapter 26 Women's Body Composition and Lifestyle 331
Pamela M. Peeke MD, MPH, FACP

Chapter 27 Health and Wellness Coaching Skills for Lasting Change 343
Elizabeth Pegg Frates, MD and Margaret Moore, MBA

PART VI Men's Health

Craig Garfield, MD, MAPP

Chapter 28 Perspectives on Men's Health 363
Craig Garfield, MD, MAPP

Chapter 29 Addressing Men's Mental Health through a Strength-Based Approach 369
Anthony Isacco, PhD, Edvina Talovic, MS, Lindsay C. Chromik, MS, and Nicole K. Yallum, MS

Chapter 30 Promoting Nutrition in Men's Health 383
Brendan Gough, PhD

Chapter 31 Management and Prevention of Urological Diseases in Men 391
Geoffrey R. Nuss, MD and Christopher M. Gonzalez, MD

Chapter 32 Health Promotion and Risk Reduction in Men 405
Lisa Terre, PhD

PART VII Endocrinology and Metabolism

Samuel Crockett, MD

Chapter 33 Lifestyle and Insulin Resistance 421
Samuel Crockett, MD

Chapter 34 Lifestyle Approaches to the Prevention and Treatment of Diabetes 431
Marion J. Franz, MS, RD, CDE

Chapter 35 Lifestyle Medicine and the Treatment of Glucose Intolerance 441
Mary Beth Weber, MPH, PhD, Lisa R. Staimez, MPH, Jennifer Gilligan, MD, PhD, K.M. Venkat Narayan, MD, and Lawrence S. Phillips, MD

Chapter 36 Lifestyle Approaches to the Metabolic Syndrome 455
April J. Stull, PhD, RD, Catherine M. Champagne, PhD, RD, and William T. Cefalu, MD

PART VIII Lifestyle Issues in the Prevention and Treatment of Cancer

Clarence H. Brown, III, MD and Naren Ramakrishna, MD, PhD

Chapter 37 Lifestyle Interventions in the Prevention and Treatment of Cancer 471
Clarence H. Brown, III, MD, Said M. Baidas, MD, Julio J. Hajdenberg, MD, FACP, Omar R. Kayaleh, MD, Gregory K. Pennock, MD, Nikita Shah, MD, and Jennifer E. Tseng, MD

Chapter 38 Obesity and Cancer 483
Clarence H. Brown, III, MD

Chapter 39 The Role of Physical Activity across the Cancer Survivorship Continuum 491
Catherine M. Sabiston, PhD, Jeff K. Vallance, PhD, and Jennifer Brunet, PhD

Chapter 40 Nutrition and Cancer 505
Clarence H. Brown III, MD, Naren Ramakrishna, MD, PhD, Lenore S. Hodges, PhD, RD, CSO, LD/N, and Dawn Napoli, RD, LD/N

PART IX Obesity and Weight Management

John P. Foreyt, PhD

Chapter 41 Epidemiology of Adult Obesity 515
R. Sue Day, PhD, Nattinee Jitnarin, PhD, Austin L. Brown, MPH, and Walker S. Carlos Poston, PhD

Chapter 42 Exercise Management for the Obese Patient 529
John M. Jakicic, PhD, David O. Garcia, MS, and Renee J. Rogers, MS

Chapter 43 Dietary Management of the Overweight and Obese Patient 537
Eileen Stellefson Myers, MPH, RD, LDN, FADA, Raymond A. Plodkowski, MD, Maureen Molini-Blandford, MPH, RD, CSSD, and Sachiko T. St. Jeor, PhD, RD

Chapter 44 Pharmacological Management of the Obese Patient 547
Donald Schumacher, MD and Nikhil Dhurandhar, PhD

Chapter 45 Surgery for Severe Obesity 571
Robert F. Kushner, MD, MS and Lisa M. Neff, MD, MS

Chapter 46 Future Directions in Obesity Research and Treatment 583
Risa J. Stein, PhD, Katie Birkenfeld, and Rachel MacPhee

PART X Immunology and Infectious Disease
David Nieman, DrPH, FACSM

Chapter 47 Exercise, Inflammation, and Respiratory Infection 597
David C. Nieman, DrPH, FACSM

Chapter 48 Chronic Exercise and Immunity: Practical Applications 605
Paul M. Coen, PhD and Michael G. Flynn, PhD

Chapter 49 HIV Infection: Exercise and Immune Function 615
Jason R. Jaggers, MS, PhD and Gregory A. Hand, PhD, MPH

Chapter 50 Exercise, Aging, and Immunity 625
Jeffrey A. Woods, PhD, Brandt D. Pence, PhD, Stephen A. Martin, BS and Marc D. Cook, MS

PART XI Pulmonary Medicine
Nicholas A. Smyrnios, MD

Chapter 51 Respiratory Symptoms 635
Jeremy B. Richards, MD, MA and Richard M. Schwartzstein, MD

Chapter 52 Chronic Obstructive Pulmonary Disease 651
Crescens M. Pellecchia, DO, MS and J. Mark Madison, MD

Chapter 53 Asthma 659
David Ciccolella, MD and Gilbert E. D'Alonzo, DO

Chapter 54 Pulmonary Rehabilitation 677
Emil Lambert G. Tigas, MD

Chapter 55 Food Allergy and Anaphylaxis 689
Michelle E. Conroy, MD

Chapter 56 Influenza 699
Gail Scully, MD, MPH

Chapter 57 Indoor Air Quality 709
Ramesh Donepudi, MD, MRCP and Anthony C. Campagna, MD, FCCP

PART XII Sports Medicine and Orthopedics
Eric McCarty, MD and Sourav K. Poddar, MD

Chapter 58 Sports Supplements 721
Morteza Khodaee, MD, MPH, John Spittler, MD, and Stacy R. Livingwell, MD

Chapter 59 Prevention of Injury 729
Bradley J. Sandella, DO and Eugene Hong, MD, CAQSM, FAAFP

Chapter 60 Female Athlete Triad 739
Stephanie M Chu, DO and Matthew Leiszler, MD

Chapter 61 The Role of Rehabilitation in Injury Management 745
Joy Anderson, PT, ATC, CSCS and Andrea Fetzer, MS, ATC

Chapter 62 Physiology of the Athlete: Bioenergetics, Performance, Physiological Testing, and Monitoring 757
Iñigo San Millán, PhD

Chapter 63 Evaluation of Acute Sports Injuries in the Adult Athlete 773
Rebecca Sjostrom, MD, Eric McCarty, MD, Jennifer FitzPatrick, MD, Amy K. MacDougall, MD, and Lucas Rylander, MD

Chapter 64 Concussion in Sport 789
Kelsey Logan, MD, MPH, FAAPL, FACP and Paul Gubanich, MD, MPH

Chapter 65 Scientific Basis for the Use of Modalities in Sports Medicine 799
Tara Jo Manal, PT, DPT, OCS, SCS, Anna Shovestul, PT, DPT, OCS, Laura A. Schmitt, PT, DPT, OCS, SCS, ATC, DCE, and Lynn Snyder-Mackler, PT, ScD, FAPTA

PART XIII Obstetrics and Gynecology

Hope A. Ricciotti, MD

Chapter 66 Preconception Care 821
Katharyn Meredith Atkins, MD

Chapter 67 Nutrition and Lifestyle for a Healthy Pregnancy 831
Hope A. Ricciotti, MD

Chapter 68 Exercise in Pregnancy 841
Kristin Bixel, MD

Chapter 69 Breast-Feeding 853
Julia Head, MD, Stephanie-Marie L. Jones, MD, and Marcie K. Richardson, MD

Chapter 70 Contraception 867
Sadia Haider, MD, MPH

Chapter 71 Prevention, Screening, and Treatment of Sexually Transmitted Infections 885
Maria Wachendorf Fradinho, MD

Chapter 72 Maintaining a Healthy Pelvic Floor through Childbirth and Menopause 899
Sybil Dessie, MD and Eman Elkadry, MD

Chapter 73 Risk Reduction and Screening for Women's Cancers 911
Jo Marie Tran Janco, MD

Chapter 74 Preventing Medical Errors in Obstetrics and Gynecology 927
Toni Golen, MD

PART XIV Dermatology

Zoe Diana Draelos, MD

Chapter 75 Nutritional Deficiencies, Diseases, and the Skin 939
Christopher Mazur, BS and David H. McDaniel, MD

Chapter 76 Aging and the Skin 953
Omer A. Ibrahim, MD, Diana Bolotin, MD, PhD, and Murad Alam, MD, MSCI

Chapter 77 Sun and the Skin 965
Amy Y.-Y. Chen, MD and Henry W. Lim, MD

Chapter 78 Exercise and the Skin 977
Brian B. Adams, MD, MPH

Chapter 79 Skin Care 991
Zoe Diana Draelos, MD

PART XV Cardiovascular Rehabilitation and Secondary Prevention

Kathy Berra, MSN, NP-C, FAACVPR, FAAN and Barry A. Franklin, PhD, FAHA, FACSM, MAACVPR

Chapter 80 Stress Testing for the Coronary Patient: Beyond ST Segment Depression 1005
Eileen M. Hsich, MD, FACC, Benico Barzilai, MD, and Gordon Blackburn, PhD

Chapter 81 Exercise Prescription for the Coronary Artery Disease Patient 1017
Peter H. Brubaker, PhD and James H. Ross, MS

Chapter 82 Contemporary Guidelines for Cardiac Rehabilitation 1027
Randal J. Thomas, MD, MS

Chapter 83 Benefits and Risks of Exercise for the Coronary Patient 1037
Barry A. Franklin, PhD, FAHA, FACSM, MAACVPR and Kashish Goel, MD

Chapter 84 Psychosocial Considerations in Coronary Heart Disease: Implication for Cardiac Rehabilitation 1053
James A. Blumenthal, PhD and Elizabeth C.D. Gullette, PhD

Chapter 85 Evaluation and Treatment of the Patient with Peripheral Arterial Disease 1067
Kerry J. Stewart, EdD, FAHA, MAACVPR, FACSM

Chapter 86 Impact of Medical Therapy on Cardiovascular Secondary Prevention 1075
Reynaria Nieva, MD, Ahsan Achtchi, DO, Danny J. Eapen, MD, Allen L. Dollar, MD, FACC, FACP, Jefferson Baer, MD, MPH, Kreton Mavromatis, MD, and Laurence S. Sperling, MD, FACC, FACP, FAHA

Chapter 87 Exercise-Based Cardiac Rehabilitation: Outcomes and Expectations 1101
Carl J. Lavie, MD, FACC, FACP, FCCP, Richard V. Milani, MD, FACC, FAHA, and Ross A. Arena, PT, PhD, FAHA

Chapter 88 Future of Cardiovascular Disease Prevention and Rehabilitation 1109
Kathy Berra, MSN, NP-C, FAACVPR, FAAN, Nancy Houston Miller, BSN, FAACVPR, and Shannon Hamilton, BA

Chapter 89 Secondary Prevention: It's a Family Affair 1113
Laura L. Hayman, PhD, MSN, Semira Semino-Asaro, MSN, RN, and Eileen M. Stuart-Shor, PhD, ANP

PART XVI Lifestyle Components of Pediatric Medicine

Thomas W. Rowland, MD

Chapter 90 Pediatric Preventive Medicine: An Introduction 1123
Thomas W. Rowland, MD

Chapter 91 Childhood Obesity and Metabolic Syndrome 1131
Scott Owens, PhD

Chapter 92 Arterial Function in Children: Effect of Exercise and Lifestyle 1141
Bo Fernhall, PhD

Chapter 93 Prevention of Osteoporosis and Bone Fragility: A Pediatric Concern 1155
Saija Kontulainen, BSc, MSc, PhD and Donald Bailey, MA, MSc, PED

Chapter 94 Identification and Management of Children with Elevated Cholesterol Levels 1163
Frank R. Greer, MD and Stephen R. Daniels, MD, PhD

Chapter 95 Cardiovascular Risk Factors and Physical Activity in Children 1171
Lars Bo Andersen, PhD, Dr Med Sci and Robert G. McMurray, PhD, FACSM

Chapter 96 Prenatal Influences on Future Health 1181
Debbie A. Lawlor, MB, ChB, MPH, MSc, PhD, Marie-Jo A. Brion, BA, MSc, PhD, Laura D. Howe, MSc, PhD, and Abigail Fraser, PhD, MPH

PART XVII Family Practice

Charles B. Eaton, MD, MS

Chapter 97 Introduction to Family Medicine Section 1199
Charles B. Eaton, MD, MS

Chapter 98 Office-Based Physical Activity Counseling in Healthy Adults 1201
Charles B. Eaton, MD, MS, Arnold Goldberg, MD, and Emma Simmons, MD, MPH

Chapter 99 Exercise Prescription for Patients with Chronic Health Problems 1209
Carol Ewing Garber, PhD, RCEP, FACSM, FAHA

Chapter 100 Nutrition Counseling in a Busy Office Practice 1215
Kim M. Gans, PhD, MPH, LDN, Kelli Drenner, PhD, and Gemma Gorham, MPH

Chapter 101 e-Health Resources to Support Lifestyle Medicine and Management 1227
David K. Ahern, PhD and Judith M. Phalen, MPH

Chapter 102 Pharmacogenomic Tailored Therapy for Smoking Cessation: The Promise of Personalized Medicine 1235
Aditi Mallick, AB and Sean P. David, MD, SM, DPhil

PART XVIII Lifestyle Medicine in Geriatrics

Charlotte A. Tate, PhD

Chapter 103 Lifestyle Medicine and the Older Population: Introductory Framework 1243
Charlotte A. Tate, PhD

Chapter 104 Aging Successfully: Predictors and Pathways 1247
Debra J. Rose, PhD

Chapter 105 Role of Physical Activity in Successful Aging 1257
Wojtek J. Chodzko-Zajko, PhD and Andiara Schwingel, PhD

PART XIX Epidemiology of Lifestyle-Related Diseases

Alan C. Utter, PhD, MPH, FACSM

Chapter 106 Epidemiology of Child and Adolescent Obesity 1271
Jennifer Utter, PhD, MPH

Chapter 107 Epidemiology and Prevention of Type 2 Diabetes 1281
Edward W. Gregg, PhD

Chapter 108 Physical Activity and Aging 1289
Caroline A. Macera, PhD

Chapter 109 Sex Differences in the Prevention and Treatment of Hypertension: The Physiological Responses to Exercise 1297
Scott R. Collier, PhD, FACSM

PART XX Health Promotion

Kenneth R. Pelletier, PhD, MD

Chapter 110 Health Promotion in the Workplace 1303
Catherine M. Baase, MD and John White, PhD

Chapter 111 Health Promotion in Health Systems 1311
Nicolaas P. Pronk, PhD and Thomas E. Kottke, MD, MSPH

Chapter 112 Financial Impact of Worksite Health Management Programs and Quality of the Evidence 1325
Seth Serxner, PhD, MPH, Daniel Gold, PhD, and Kristin Parker, PhD, MPH

Chapter 113 Future of Health Promotion in the Twenty-First Century 1337
Dee W. Edington, PhD and Alyssa Schultz, PhD

PART XXI Exercise Psychology

Steven J. Petruzzello, PhD

Chapter 114 Taking Stock of Where We Are in Understanding Mind/Body Interactions in the Exercise Domain 1353
Steven J. Petruzzello, PhD, Tina A. Greenlee, MS, Paula Y.S. Poh, MA, and Megan Nickrent, MS

Chapter 115 Genetic Influences on Regular Exercise Behavior 1367
Marleen H.M. de Moor, PhD and Eco J.C. De Geus, PhD

Chapter 116 Influence of Physical Activity on Brain Aging and Cognition: The Role of Cognitive Reserve, Thresholds for Decline, Genetic Influence, and the Investment Hypothesis 1379
Maureen K. Kayes, MS and Bradley D. Hatfield, PhD, FACSM, FNAK

Chapter 117 Physical Activity and Anxiety 1397
Katharina Gaudlitz, MSc, Brigitt-Leila von Lindenberger, MSc, and Andreas Ströhle, MD

Chapter 118 Physical Activity and Depression 1409
Chad D. Rethorst, PhD and Madhukar H. Trivedi, MD

Chapter 119 Redrawing the Model of the Exercising Human in Exercise Prescriptions: From Headless Manikin to a Creature with Feelings 1421
Panteleimon Ekkekakis, PhD, FACSM

Chapter 120 Determinants of Physical Activity: Research to Application 1435
Claudio R. Nigg, PhD, Ryan E. Rhodes, PhD, and Katie R. Amato, BS

PART XXII Injury Prevention

David A. Sleet, PhD, FAAHB

Chapter 121 Injuries and Lifestyle Medicine 1447
David A. Sleet, PhD, FAAHB, Michael F. Ballesteros, PhD, and Grant T. Baldwin, PhD, MPH

Chapter 122 Patient Counseling for Unintentional Injury Prevention 1457
Michael F. Ballesteros, PhD and Andrea Gielen, ScD

Chapter 123 Preventing Traffic Injuries: Strategies That Work 1463
Ann M. Dellinger, MPH, PhD and David A. Sleet, PhD, FAAHB

Chapter 124 Child Injury: The Role of Supervision in Prevention 1473
Barbara A. Morrongiello, PhD and Michael R. Corbett, MA

Chapter 125 Preventing Injuries at Home 1485
Karin A. Mack, PhD and Karen DeSafey Liller, PhD

Chapter 126 Falls and Fall Injuries among Older Adults....1495

Judy A. Stevens, MS, MPH, PhD, Grant T. Baldwin, PhD, MPH, Michael F. Ballesteros, PhD, Rita K. Noonan, PhD, and David A. Sleet, PhD, FAAHB

Chapter 127 Preventing Repeat Intimate Partner Violence 1507

Samantha Illangasekare, PhD, MPH and Andrea Gielen, ScD

Chapter 128 Sports and Recreation-Related Traumatic Brain Injury....1519

Victor G. Coronado, MD, MPH, Lisa C. McGuire, PhD, Michael R. Lionbarger, MPH, Marlena M. Wald, MPH, MLS, Kelly Sarmiento, MPH, and Julie Gilchrist, MD

PART XXIII Public Policy and Environmental Supports for Lifestyle Medicine

Gregory W. Heath, DHSc, MPH, FACSM, FAHA

Chapter 129 Lifestyle Medicine in an Era of Healthcare Reform—2011 1533

Gary B. Wilkerson, EdD, ATC and Gregory W. Heath, DHSc, MPH, FACSM, FAHA

Chapter 130 Policy and Environmental Supports in Promoting Physical Activity and Active Living....1539

Gregory W. Heath, DHSc, MPH, FACSM, FAHA and Paul M. Gordon, PhD, MPH, FACSM, FAHA

Chapter 131 Public Policy and Environmental Supports for Healthy Eating 1545

Zaida Cordero-MacIntyre, PhD, PharmD, MPH, REHS, MS, RD and Alyssa Mompoint, MPH

Chapter 132 Building Strategic Alliances to Promote Healthy Eating and Active Living....1551

Risa Wilkerson, MA, Elizabeth A. Baker, PhD, MPH, and Matt M. Longjohn, MD, MPH

Chapter 133 Obesity and Health 1557

James M. Rippe, MD and Theodore J. Angelopoulos, PhD, MPH

Preface

An overwhelming body of scientific and medical literature supports the concept that daily habits and actions exert an enormous influence on short- and long-term health and quality of life. This influence may be either positive or negative. Hundreds, if not thousands, of studies provide evidence that regular physical activity, maintenance of a healthy weight, not smoking cigarettes, and following sound nutritional and other health-promoting practices all profoundly impact health.

Since the publication of the first edition of *Lifestyle Medicine* (Blackwell Science, 1999), this literature has grown even stronger and more robust. Clearly, the time has come to update and summarize this information in one place and bring it to the attention of physicians and other health care workers with the hope and belief that it will impact on the way they practice medicine. This has been the goal and challenge of the second edition of *Lifestyle Medicine*.

The strength of the literature supporting the health impact of daily habits and actions is underscored by their incorporation into virtually every evidence-based clinical guideline addressing the prevention and treatment of metabolic diseases. For example, the following guidelines and consensus statements from various prestigious medical organizations all provide significant emphasis on lifestyle medicine principles and practices as key components of the prevention and treatment of disease:

- *JNC VII Guidelines for Hypertension, Prevention and Treatment*
- *NCEP (ATP III) Guidelines for Cholesterol Management*
- *Institute of Medicine Guidelines for Obesity Management*
- *Guidelines from the American Heart Association for the Prevention and Management of Coronary Artery Disease*
- *Guidelines from the American Diabetes Association for the Management of Diabetes*
- *Dietary Guidelines for Americans 2010*
- *American Heart Association Nutrition Implementation Guidelines*
- *Guidelines from the American Academy of Pediatrics for the Prevention and Treatment of Childhood Obesity*
- *Guidelines from the American Academy of Pediatrics for Heart Disease Risk Factor Reduction in Children*
- *Guidelines from the American Heart Association and the American Academy of Pediatrics for the Prevention and Treatment of the Metabolic Syndrome*
- *American Heart Association Strategic Plan for 2020*
- *Joint Statement from the American Heart Association and American Cancer Society for the Prevention of Heart Disease and Cancer*

Despite the widespread recognition in evidence-based guidelines of the important role lifestyle measures and practices play in the prevention and treatment of metabolic diseases, little progress has been made in improving the habits and actions of the American population. In some instances, risk factors for chronic diseases have actually gone in the opposite direction and increased over the last decade. Consider the following:

- More than 70% of the adult population in the United States does not get enough physical activity to result in health benefits.
- Over two-thirds of the adult population in the United States are either overweight or obese (a staggering 40% increase over the past 20 years).
- Less than one-third of the adult population gets adequate servings of fruits and vegetables and follows other simple, evidence-based nutritional principles related to good health.
- Of the adult population in the United States, 20.6% still smoke cigarettes.
- The prevalence of diabetes in the United States has doubled in the past 20 years.
- The metabolic syndrome is now thought to be present in 25% to 35% of the adult population in the United States.
- Over one-third of the adult population in the United States has high blood pressure.
- Cardiovascular disease, which remains the leading killer of both men and women in the United States resulting in 37% of all mortality each year, has multiple lifestyle factors as underlying risk factors.
- The choice of an inactive lifestyle increases an individual's risk of developing heart disease as much as smoking a pack of cigarettes per day.
- Obesity is the leading cause of osteoarthritis in women and the second leading cause in men.
- Obesity is the second leading cause of cancer in the United States and is projected to surpass cigarette smoking in the next decade.

Despite these grim statistics, an impressive body of evidence has also emerged regarding how powerful daily practices, when incorporated into a positive lifestyle, can be in

lowering risk factors and promoting good health. For example, the Nurses' Health Study demonstrated that 80% of all heart disease and over 91% of all diabetes in women could be eliminated if they would adopt a cluster of positive lifestyle practices, including maintenance of a healthy body weight (BMI of 19–25 kg/m^2), regular physical activity (30 min or more on most days), not smoking cigarettes, and following a few simple nutritional practices such as increasing whole grain and consuming more fruits and vegetables. The U.S. Health Professionals Study showed similar dramatic reductions in men from these same positive behaviors. In fact, if individuals adopted only one of these positive behaviors, their risk of developing coronary artery disease would be cut in half.

Furthermore, proper nutrition has been demonstrated to significantly decrease the likelihood of developing diseases—most prominently, obesity, diabetes, and cancer. Physical activity has been repeatedly shown to lower the risk of heart disease and many cancers. Smoking cessation has been clearly associated with increased risk of cancer and chronic obstructive pulmonary disease. The benefits of smoking cessation are profound and occur rapidly.

Even small amounts of weight loss substantially lower the risk of developing chronic disease. For example, in the Diabetes Prevention Program individuals with baseline glucose intolerance, who increased physical activity and lost 5%–7% of their body weight, reduced their risk of developing diabetes by 58%.

In addition to the adverse health consequences of poor lifestyle decisions, these choices also carry a significant economic burden. Each year, the United States spends more than $6700 for every man, woman, and child on what is essentially "sickness" care. In contrast, virtually every other industrial economy spends considerably less. For example, Greece, which ranks as the 16th largest economy in the world, spends less than $600 annually for every man, woman, and child on health care. Yet, Greece achieves superior outcomes on virtually every recognized international standard of health outcomes than does the United States. Every other industrialized economy also spends less money per capita than the United States and often achieves superior health outcomes.

Poor lifestyle choices such as lack of physical activity, poor nutritional choices, smoking cigarettes, and failure to maintain a healthy body weight all represent significant risk factors for such costly diseases as diabetes, coronary artery disease, and cancer. Clearly, until we can make a positive impact on lifestyle measures and practices in modern medical care, we will not solve this enormous financial drain on the American economy as well as the toll of human lives. These facts have been recognized in the recent health care reform debate in the United States and are incorporated into the Accountable Care Organization guidelines.

As the literature relating lifestyle practices and habits has grown deeper and more complex, the challenge for physicians and other health care professionals has become even more daunting to keep abreast of this ever-expanding field and incorporate the findings into the modern medical practice. This challenge is all the more complex since the literature relating to lifestyle and health is spread over a wide variety of disciplines, journals, and textbooks. The need to summarize the evidence behind lifestyle and health into one comprehensive textbook that spans the field of lifestyle medicine has become clearer as the evidence has become deeper and more persuasive. This is what we have attempted to accomplish with the second edition of *Lifestyle Medicine*.

I was proud to serve as the editor of the first edition of *Lifestyle Medicine* that was published in 1999. With this initial comprehensive volume, we coined the term "lifestyle medicine," summarized key findings across multiple disciplines as they existed in the late 1990s, and launched a new emphasis in medicine related to the links between daily behaviors and outcomes. Subsequently, the field of lifestyle medicine has grown dramatically and has matured significantly. There is now an academic, peer-reviewed journal in lifestyle medicine (the *American Journal of Lifestyle Medicine*, SAGE Publications). Physician competencies have been published based on the recommendations from major medical groups, including the American Medical Association, the American College of Physicians, the American Academy of Pediatrics, the American College of Sports Medicine, the American College of Preventive Medicine, and others.

In addition, an academic medical society has been established for physicians and other health care workers (the American College of Lifestyle Medicine) and an educational track in lifestyle medicine is now offered at the American College of Preventive Medicine's annual meeting.

While the field of lifestyle medicine is still in its infancy, there is clearly momentum. It is also clear that the academic discipline relating to short- and long-term health consequences of daily habits and actions will be called lifestyle medicine.

A key consideration for incorporating information and counseling concerning lifestyle and health will be broad acceptance of this imperative in the physician community. While most physicians and other health care professionals support the general concept that physical activity, proper nutrition, weight management, not smoking, and other behaviors profoundly impact on health, incorporation of counseling and information in these areas into the daily practice of medicine has lagged. This is extremely unfortunate since multiple surveys have demonstrated that physician recommendation is the leading reason why individuals change actions and habits. Moreover, 75% of the adult population in the United States sees a primary care physician at least once a year. The opportunity to underscore the links between lifestyle habits and practices and health outcomes is, therefore, extremely large.

So what is "lifestyle medicine"? We defined lifestyle medicine in the first edition of this reference book as "the integration of lifestyle practices into the modern practice of medicine both to lower the risk factors for chronic disease and/or, if disease is already present, serve as an adjunct in its therapy. Lifestyle medicine brings together sound, scientific evidence in diverse health related fields to assist the clinician

in the process of not only treating disease, but also promoting good health." While this definition was put forth over a decade ago, the connections between daily habits and health outlined in this initial formulation remain the fundamental premise behind the field of lifestyle medicine and the organizing principle behind the second edition of our textbook.

With this definition providing the intellectual framework for the textbook, the second edition of *Lifestyle Medicine* is divided into 23 parts based on key disciplines related to lifestyle medicine. The second edition is approximately 20% longer than the first edition. All chapters have been fundamentally rewritten or substantially revised and brought up to date with current understandings and references. Many new chapters and several new parts have been added to reflect the modern understandings and enormous changes that have occurred in lifestyle medicine since the publication of the first edition.

The second edition of *Lifestyle Medicine* opens with Part I on "Lifestyle Management and Prevention of Cardiovascular Disease." We chose to open the second edition with an in-depth exploration concerning lifestyle and cardiovascular disease for several reasons. First, I am a cardiologist, and as such, my initial interest in lifestyle practices and health related specifically to measures designed to lower the risk of cardiovascular disease. Second, the area of cardiovascular medicine has been a leader in identifying linkages between lifestyle-related risk factors and risk of heart disease. Third, despite very significant progress in multiple areas of cardiovascular disease, it remains the leading killer of both men and women in the United States. Finally, it seemed appropriate to open the second edition of *Lifestyle Medicine* with issues in cardiovascular disease, since the American Heart Association has clearly articulated the central role of lifestyle practices and cardiovascular health as a key component in its strategic plan for the year 2020.

Part II on "Nutritional Aspects of Lifestyle Medicine," underscores the key role that nutrition plays in multiple aspects of health and disease. This part contains in-depth analyses of the clinical implications of the Dietary Guidelines for Americans 2010 as well as an extensive discussion of how to evaluate nutritional status and nutrient intakes. Special populations are the focus of several chapters, including nutrition for the active adolescent, nutrition for elite athletes, and nutrition for older adults. An important new chapter relates to how nutrition principles and behaviors can be communicated to patients to help them achieve healthy lifestyles. Part III on "Physical Activity and Fitness" provides clinically important information on how to evaluate physical fitness and prescribe exercise. In addition, since physical activity and exercise are so key to positive lifestyle measures and health, there are individual chapters on these behaviors scattered throughout the book in disease- or condition-specific sections.

Part IV on "Behavioral Psychology" starts from the premise that most of the issues related to lifestyle medicine involve approaches to changing behavior. This part provides an outstanding, clinically relevant framework for how to apply psychological theories to the promotion of healthy lifestyles. These theories have been applied in subsequent chapters within this part to approaches for enhancing adherence to exercise prescription, smoking cessation, and weight loss and maintenance.

Part V on "Women's Health" has been expanded and updated to cover important emerging data in this key area. Chapters on breast health, osteoporosis, and physical activity are complemented by new chapters on menopause, osteoporosis, and wellness coaching for women's lifestyle choices. Part VI on "Men's Health" is an entirely new part that addresses key considerations for this medically underserved population. Mental health issues, nutrition for men's health, and management and prevention of urological diseases as well as health promotion and risk reduction specifically geared toward men are welcome, new, and timely contributions to this important area of the book.

A new part on "Endocrinology and Metabolism" (Part VII) provides in-depth discussions of diabetes, glucose intolerance, and the metabolic syndrome as well as the use of lifestyle measures in their prevention and treatment. Part VIII on "Lifestyle Issues in the Prevention and Treatment of Cancer" is another new part that will be highly relevant to every practicing clinician. Such topics as obesity, physical activity, and nutrition and their role in cancer prevention and treatment are discussed in depth as well as their role in cancer survivorship.

Part IX on "Obesity and Weight Management" remains a key part in our textbook. In a sense, obesity represents the quintessential lifestyle disease since nutrition, exercise, pharmacologic management, and surgery all play significant roles. The linkage between the immune system and infectious disease is also an important and often underappreciated area of both research and clinical application. The role of exercise both in immune function, infections, and aging is ably discussed with current understandings from the research literature in Part X on "Immunology and Infectious Disease."

Part XI on "Pulmonary Medicine" has been totally reworked with updated chapters on asthma and pulmonary rehabilitation and new chapters on indoor air quality and influenza among others. This expanded part will be of great interest to all clinicians.

"Sports Medicine and Orthopedics" (Part XII) occupy prominent places in lifestyle medicine. The greatly expanded part in these areas focuses not only on injury prevention and treatment, but also on rehabilitation and sports supplements. The new chapter on concussions in sports is particularly timely given the recent emphasis on this underdiagnosed condition both in professional and amateur sports.

Part XIII on "Obstetrics and Gynecology" remains a great strength in this textbook with several new chapters and a complete rewriting and updating of all previous chapters. This part adds further depth and clinical relevance to the expanded commitment to women's health issues found in this edition of *Lifestyle Medicine*. Part XIV on "Dermatology" is greatly expanded based on new understandings from research with an emphasis on clinical applications. Particularly important are completely revised

chapters on sun and the skin, exercise and the skin, and overall approaches to skin care for the active individual.

Part XV on "Cardiovascular Rehabilitation and Secondary Prevention" complements the opening part on "Lifestyle Management and Prevention of Cardiovascular Disease." Important advances have occurred both in cardiovascular rehabilitation and the secondary prevention of cardiovascular disease. These topics are admirably discussed with modern evidence-based understandings emphasized.

The power of a positive lifestyle clearly extends into the pediatric population. The modern epidemic of pediatric obesity in the United States and the accompanying dramatic increases in both diabetes and metabolic syndrome in the pediatric population are discussed in detail in the Part XVI on "Lifestyle Components of Pediatric Medicine" as are specific guidelines and recommendations for prescribing pediatric exercise and prevention of osteoporosis. An important new chapter on prenatal influences on future health summarizes modern understandings of an emerging area about how the earliest influences on risk factors may occur in utero. The chapter on cholesterol management in children provides an evidence-based discussion to what has become a controversial topic.

The greatly expanded Part XVII on "Family Practice" provides a comprehensive approach to how busy family practitioners can integrate lifestyle measures and counseling into their daily practice of medicine. Practical advice and recent evidence concerning exercise and nutritional counseling as well as ehealth resources are all discussed in detail. Part XVIII is a new part on "Lifestyle Medicine and Geriatrics" that corrects a significant omission from the first edition of our textbook. The concept of "successful aging" that has gained considerable momentum in the last decade is discussed in detail as are practical strategies for increasing physical activity in the older population.

The greatly expanded Part XIX on "Epidemiology of Lifestyle-Related Diseases" provides a useful framework for the application of epidemiologic principles to both identify and potentially help ameliorate multiple lifestyle-related problems. Part XX on "Health Promotion" has been greatly expanded to include modern understandings of health promotion in the workplace and managed care. This field has grown exponentially in the last 15 years. This part concludes with a provocative chapter on the future of health promotion, taking the reader from current successes in health promotion to an expanded role for corporate health promotion in the future of medicine.

The greatly expanded Part XXI on "Exercise Psychology" moves beyond the part on "Exercise and Sport Psychology," which was contained in the first edition of *Lifestyle Medicine*. New tools and new approaches to understanding mind–body interactions as well as the genetic influences on behavior are discussed in detail. Physical activity and its relationship to anxiety and depression are also thoroughly discussed. A new and important chapter on the impact of physical activity on brain aging and cognitive function is a highlight of this part. A new chapter on how psychological issues help determine the level of physical activity provides new insights for how research can impact on practical application.

Part XXII is a new part on "Injury Prevention" that represents another highlight of the second edition. Injuries are a very significant component of lifestyle medicine and also often underappreciated by practicing clinicians. This part, with an internationally prominent group of contributors, organized by the Division of Unintentional Injury Prevention at the Centers for Disease Control and Prevention, provides a broad approach to research in injury prevention and how it is impacting on the practice of lifestyle medicine.

The final part on "Public Policy and Environmental Supports for Lifestyle Medicine" (Part XXIII) reminds us that we do not practice medicine in a vacuum. Public policy issues concerning health care reform and public and environmental supports for physical activity, healthy eating, and obesity prevention all play important roles in the modern practice of medicine.

The work of generating this comprehensive volume in *Lifestyle Medicine* involved the talent of 25 outstanding part editors who have devoted great energy and talent to the difficult task of organizing and editing parts to be not only scientifically accurate but clinically useful. What has emerged from their efforts and those of the over 200 distinguished contributors is a textbook that I hope and believe will be clinically useful to the practicing health care professional while providing state-of-the-art summaries and practical applications of modern scientific and medical understandings related to the interaction between lifestyle practices, modern medicine, and good health. This dual emphasis can only help all of our patients lead happier, healthier, and more productive lives while lowering their risk of developing the chronic diseases that are so endemic in our society.

Over the last 14 years since the publication of the first edition of *Lifestyle Medicine*, important new information has emerged to provide the scientific links between daily habits and actions and their impact on short- and long-term health and quality of life. The key consideration now will be for those of us in the health care community to apply these understandings to the modern practice of medicine. This is, in my view, the single greatest opportunity that we have to improve health outcomes and lower costs. This is crucial to bringing additional value to the practice of medicine. It is, in essence, both the challenge and opportunity for the future of lifestyle medicine.

James M. Rippe, MD
Boston, Massachusetts

Acknowledgments

Textbook writing and editing are collaborative efforts. Individuals who have contributed to my thinking about the interaction between lifestyle and health over many years are too numerous to acknowledge all by name. I would, however, like to acknowledge a few individuals who have made particularly important contributions to the second edition of *Lifestyle Medicine*.

First, I would like to thank my long-time editorial director, Elizabeth Grady, who plays a critically important role in all of the major writing and editing projects that emerge from my research organization. The second edition of *Lifestyle Medicine* is one of over 40 books that Beth has managed, which have been generated through our organization. In addition, she provides editorial direction to two academic journals that I edit and coordinates a variety of other academic endeavors. Beth's superb organization skills, hard work, and unfailing good humor make these difficult projects possible.

I would also like to thank the 25 section editors who contributed hard work and outstanding editorial skills to ensure scientific accuracy and clinical relevance for each of the sections of this textbook. I am deeply grateful to all of these individuals. A special thanks also to the more than 200 scientists and clinicians who have contributed chapters to this textbook. These individuals, who are experts in the key fields related to lifestyle medicine, have made invaluable contributions to assemble and explain vast amounts of data in this emerging discipline.

I would also like to express appreciation to my office support staff including my executive assistant, Carol Moreau, who seamlessly coordinates my schedule and travel plans to free up the time necessary for such large writing and publishing projects. Our office assistant, Deb Adamonis, assists all of us in multiple daily tasks required to expedite diverse projects in our office, while our chief financial officer, Connie Martell, makes sure that processes are in place for all our projects to move forward smoothly.

The research team at Rippe Lifestyle Institute (RLI) has contributed numerous insights and helped clarify my thinking on a number of aspects of lifestyle medicine. This team is admirably led by Dr. Ted Angelopoulos, who has been a friend and colleague for many years as well as a coauthor and collaborator on multiple papers, books, and other projects. Josh Lowndes directs the day-to-day processes and work flow of the research team, while Amy Stachnik coordinates the day-to-day interactions with multiple research sponsors and the patient population of Rippe Health Evaluation, our executive health program. Noy Supaswud, our research office manager and my executive assistant in Florida, does a superb job in coordinating this large research team and my work schedule when I am at our research facilities in this location.

I would like to thank the superb editorial team at Taylor & Francis Group/CRC Press: Randy Brehm, senior editor, who was an early and key supporter of this project; Jessica Vakili, who coordinated all aspects of the publication process and provided important day-to-day leadership and invaluable assistance on multiple issues related to manuscripts; and Ira Wolinsky, who was an early and strong supporter of this project. We would also like to thank Richard Tressider, project editor at Taylor & Francis Group/CRC Press. who managed every step of the production process with expertise, patience and knowledge. Arun Kumar Aranganathan of SPi Global managed the editing, design, and typesetting of this book with great skill.

Finally, I am grateful to my family including my loving wife, Stephanie Hart Rippe, and our four beautiful daughters, Hart, Jaelin, Devon, and Jamie, who continue to love and support me through the arduous process of editing major textbooks and journals and the other diverse professional responsibilities I juggle along with family life.

If there are errors or omissions in *Lifestyle Medicine*, the responsibility is mine. If there is credit due for this project, it belongs to the numerous people who have made substantial contributions along the way.

James M. Rippe, MD

Editor

James M. Rippe, MD, is a graduate of Harvard College and Harvard Medical School with postgraduate training at Massachusetts General Hospital. He is currently the founder and director of the Rippe Lifestyle Institute (RLI) and professor of biomedical sciences at the University of Central Florida.

Over the past 25 years, Dr. Rippe has established and run RLI, the largest research organization in the world that explores how daily habits and actions impact short- and long-term health and quality of life. RLI has published hundreds of papers that form the scientific basis for the fields of lifestyle medicine and high-performance health. It also conducts numerous studies every year on physical activity, risk factor reduction, nutrition, and healthy weight management.

A lifelong and avid athlete, Dr. Rippe maintains his personal fitness with a regular walk, jog, swim, and weight training program. He holds a black belt in karate and is an avid wind surfer, skier, and tennis player. He lives outside of Boston with his wife, television news anchor Stephanie Hart, and their four children, Hart, Jaelin, Devon, and Jamie.

Northwestern Medical Faculty Foundation
Chicago, Illinois

Paul M. Gordon, Ph.D., MPH, FACSM, FAHA
Associate Professor and Director
Laboratory for Physical Activity and Exercise Intervention Research
University of Michigan
Ann Arbor, Michigan

Gemma Gorham, MPH
Project Director
Institute for Community Health Promotion
Brown University
Providence, Rhode Island

Brendan Gough, PhD
Professor of Social Psychology
Division of Psychology
School of Social Sciences
Nottingham Trent University
Nottingham, United Kingdom

Tina A. Greenlee, MS
Graduate Teaching Assistant
Department of Kinesiology and Community Health
College of Applied Health Sciences
University of Illinois at Urbana–Champaign
Urbana, Illinois

Frank R. Greer, MD
Professor
Department of Pediatrics
School of Medicine and Public Health
University of Wisconsin
and
Wisconsin Perinatal Center
Meriter Hospital
Madison, Wisconsin

Edward W. Gregg, PhD
Chief, Epidemiology and Statistics Branch
Division of Diabetes Translation
Centers for Disease Control and Prevention
Atlanta, Georgia

Paul Gubanich, MD, MPH
Assistant Clinical Professor of Internal Medicine
Department of Internal Medicine, Sports Medicine
OSU Athletics
The Ohio State University
Columbus, Ohio

Elizabeth C.D. Gullette, PhD
Senior Faculty
Center for Creative Leadership
Greensboro, North Carolina

Sadia Haider, MD, MPH
Assistant Professor
Section of Family Planning
Department of Obstetrics and Gynecology
University of Illinois Medical Center
Chicago, Illinois

Julio J. Hajdenberg, MD, FACP
Chairman
Department of Medical Oncology and Hematology
MD Anderson Cancer Center Orlando
Orlando, Florida

Shannon Hamilton, BA
Senior Undergraduate Student
School of Public Health
University of California, Berkeley
Berkeley, California

Gregory A. Hand, PhD, MPH
Professor
Associate Dean for Research and Practice
Arnold School of Public Health
University of South Carolina
Columbia, South Carolina

Cherise B. Harrington, PhD, MPH
Assistant Professor
Department of Prevention and Community Health
School of Public Health and Health Services
The George Washington University
Washington, District of Columbia

Ladd Harris, MS, RD
Athletes' Performance
Phoenix, Arizona

Bradley D. Hatfield, PhD, FACSM, FNAK
Professor and Chair
Neural and Cognitive Sciences Program
Department of Kinesiology
School of Public Health
University of Maryland
College Park, Maryland

Laura L. Hayman, PhD, MSN
Associate Dean for Research
Professor of Nursing
College of Nursing and Health Sciences
and
Associate Vice-Provost for Research
University of Massachusetts Boston
Boston, Massachusetts

Julia Head, MD
Clinical Fellow
Department of Obstetrics and Gynecology, and Reproductive Biology
Beth Israel Deaconess Medical Center
Harvard Medical School
Boston, Massachusetts

Gregory W. Heath, DHSc, MPH, FACSM, FAHA
Assistant Provost for Research and Engagement
Guerry Professor of Health and Human Performance and Professor of Medicine
University of Tennessee at Chattanooga and UT College of Medicine, Chattanooga
Chattanooga, Tennessee

Lenore S. Hodges, PhD, RD, CSO, LD/N
Outpatient Oncology Dietitian
Center for Nutrition Therapy
MD Anderson Cancer Center Orlando
Orlando, Florida

Eugene Hong, MD, CAQSM, FAAFP
Hamot and Sturgis Endowed Chair
Professor
Department of Family, Community and Preventive Medicine
Drexel University College of Medicine
Philadelphia, Pennsylvania

Laura D. Howe, MSc, PhD
Research Fellow
School of Social and Community Medicine
University of Bristol
Bristol, United Kingdom

Eileen M. Hsich, MD, FACC
Director
Heart Failure and Transplantation
Cardiovascular Medicine
Cleveland Clinic
Cleveland, Ohio

Van S. Hubbard, MD, PhD
Director
Division of Nutrition Research Coordination
National Institutes of Health
Bethesda, Maryland

Omer A. Ibrahim, MD
Yale School of Medicine
New Haven, Connecticut

Samantha Illangasekare, PhD, MPH
Postdoctoral Research Fellow
Department of Health, Behavior and Society
Johns Hopkins Bloomberg School of Public Health
Baltimore, Maryland

Anthony Isacco, PhD
Assistant Professor of Counseling Psychology
Chatham University
Pittsburgh, Pennsylvania

Jo Marie Tran Janco, MD
Clinical Fellow
Department of Obstetrics, Gynecology, and Reproductive Biology
Beth Israel Deaconess Medical Center
Harvard Medical School
Boston, Massachusetts

Jason R. Jaggers, MS, PhD
Research Associate
Department of Exercise Science
Arnold School of Public Health
University of South Carolina
Columbia, South Carolina

John M. Jakicic, PhD
Chair and Professor
Department of Health and Physical Activity
and
Director
Physical Activity and Weight Management Research Center
University of Pittsburgh
Pittsburgh, Pennsylvania

Ernestine G. Jennings, PhD
Assistant Professor (Research)
Centers for Behavioral and Preventive Medicine
Alpert Medical School
The Miriam Hospital
Providence, Rhode Island

Nattinee Jitnarin, PhD
Postdoctoral Fellow
National Development and Research Institutes, Inc.
Institute for Biobehavioral Health Research
Leawood, Kansas

Stephanie-Marie L. Jones, MD
Clinical Fellow
Department of Obstetrics, Gynecology and Reproductive Biology
Beth Israel Deaconess Medical Center
Harvard Medical School
Boston, Massachusetts

Omar R. Kayaleh, MD
Section Chief GI Medical Oncology
Department of Internal Medicine
Hematology Oncology Specialty Section
MD Anderson Cancer Center Orlando
Orlando, Florida

Maureen K. Kayes, MS
Doctoral Candidate
Department of Kinesiology
School of Public Health
University of Maryland
College Park, Maryland

Sobia Khan, MD, NCMP, CCD
Women's Health Fellow
Center for Specialized Women's Health
Cleveland Clinic
Cleveland, Ohio

Morteza Khodaee, MD, MPH
Assistant Professor
Department of Family Medicine
University of Colorado School of Medicine
Denver, Colorado

Teresa K. King, PhD
Associate Professor
Department of Psychology
Bridgewater State University
Bridgewater, Massachusetts

Peter F. Kokkinos, PhD
Professor
George Washington University School of Medicine
and
Veterans Affairs Medical Center
Washington, District of Columbia

Lifestyle Management and Prevention of Cardiovascular Disease

James M. Rippe, MD

1 Rationale for Intervention to Reduce the Risk of Coronary Artery Disease

James M. Rippe, MD and Theodore J. Angelopoulos, PhD, MPH

CONTENTS

Introduction 4
Pathophysiology of Atherosclerosis 4
Understanding Risk Factors 5
Concept of Risk Factors 5
Relative Risk versus Absolute Risk 5
Primary versus Secondary Prevention 5
Primordial Prevention and "Ideal" Cardiovascular Health 5
Implementing Risk Factor Reduction Guidelines 6
Scientific Basis for Risk Factor Reduction 6
Modifiable Risk Factors 6
Tobacco Use 6
Dyslipidemias 7
Elevated Low-Density Lipoprotein Cholesterol and Hyperlipidemia 7
Low Levels of HDL Cholesterol 7
Hypertriglyceridemia 7
Hypertension 7
Diabetes and Glucose Intolerance 7
Obesity 8
Inactive Lifestyle 9
Poor Nutritional Habits 10
Non-Modifiable Risk Factors 10
Age 10
Gender 10
Family History 11
Metabolic Syndrome and the Concept of Multiple Risk Factors 11
Emerging Risk Factors 11
High-Sensitivity C-Reactive Protein 11
Other Markers of Inflammation 11
Hemostatic Factors 11
Homocysteine 11
LDL Subclasses and Particle Size 12
Lipoprotein (a) 12
Other Risk Factors 12
Levels of Antioxidants 12
Alcohol 12

INTRODUCTION

Cardiovascular disease remains the leading cause of death for both men and women in the United States each year [1]. Over 37% of all mortality in the United States comes from cardiovascular disease [2]. Although knowledge of many factors contributing to coronary heart disease (CHD) is incomplete, it is clear that many risk factors contribute in significant ways to the ongoing epidemic of cardiovascular disease.

Lifestyle habits and practices constitute a significant contributor to this ongoing epidemic. While progress has been made in some of these areas (e.g., hypertension, total cholesterol, smoking cessation, physical activity), unfortunately, regression has occurred in such areas as obesity and diabetes [3]. The increasing prevalence of these latter two conditions has the potential to wipe out progress made on all the other lifestyle-related risk factors for CHD [3].

In addition to its human cost, CHD also represents an enormous financial drain in the United States. It has been estimated that over $150 billion per year is spent on direct medical expenses and other associated costs related to CHD [4,5].

Lifestyle factors play a particularly prominent role in the development and pathogenesis of CHD. Indeed, five of the major risk factors for developing CHD relate to lifestyle practices: (1) the choice of whether or not to use tobacco products, (2) level of physical activity, (3) control of lipids, (4) diabetes, and (5) obesity. In this chapter, we will focus on the rationale for intervening to reduce risk factors for CHD. The next chapter will discuss applications of lifestyle interventions in clinical practice to reduce the risk of CHD.

Deaths from CHD and stroke have been declining in the United States for the past four decades. For example, between 1963 and 1990 the mortality of CHD fell by more than 50% [6]. Nonetheless, CHD and stroke remain the leading causes of morbidity and mortality in the United States and in most other industrialized countries. The decline in CHD and stroke is a result of not only reduced prevalence of risk factors but also advances in treatment and therapies. Nonetheless, the increased prevalence of diabetes and obesity and an aging population work against reductions in CHD and stroke prevalence and require expanded efforts to reduce lifestyle-related risk factors in order to continue reducing the burden of CHD.

Between 1980 and 2000, the decline in the age-related death for CHD led to an estimated decrease of 341,745 deaths [3]. About half of this decline resulted from improvements and advances in treatment while approximately 44% related to risk factor reduction. An estimated 149,635 fewer deaths from CHD came from improved treatment [3] of some of its risk factors while an estimated 59,370 increase in deaths occurred from the higher rates of obesity and diabetes [3]. As depicted in Figure 1.1, the increasing prevalence of obesity and diabetes has the potential to completely wipe out the advances in the reduction of other risk factors if the trends of these two lifestyle risk factors are not reversed.

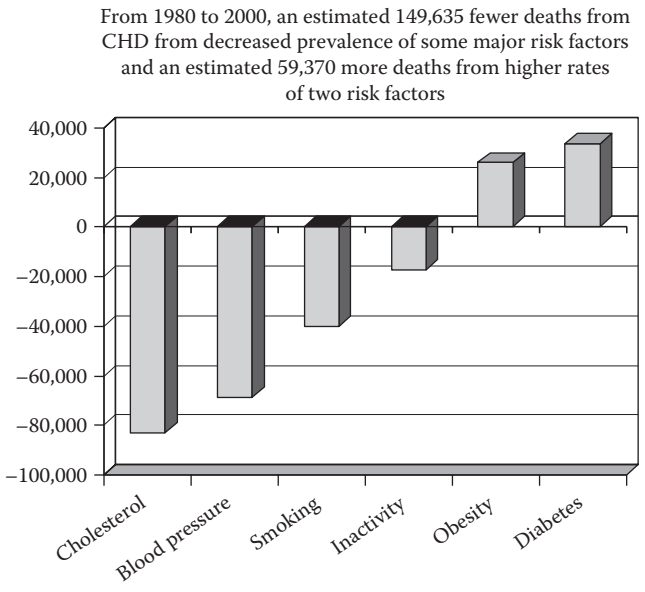

FIGURE 1.1 Impact of lifestyle choices on CVD. (From Ford, E.S. et al., *N. Engl. J. Med*., 256, 2388, 2007.)

Despite advances in reducing certain lifestyle-related risk factors for CHD, these factors remain extremely common. For example, the prevalence of hypertension in the United States has continued to increase with recent data suggesting that more than one-third of American adults have high blood pressure [7]. The Surgeon General's Report on Physical Activity and Health documented that over 70% of the adult population in the United States fail to get enough regular physical activity to lower their risk of CHD [8], despite the fact that the *2008 Physical Activity Guidelines for Americans* demonstrate multiple health benefits for virtually every population group [9]. Overweight and obesity has continued to rise in the United States with over 68% of the population showing one of these two conditions [10].

The epidemic of diabetes in the United States continues to rise with approximately 9% of the adult population currently suffering from this chronic condition—almost double the rate of 20 years ago [11]. After several decades of encouraging declines in cigarette smoking, progress unfortunately appears to have leveled off in this area with about 20% of the overall population in the United States still smoking [12]. Thus, some progress in reducing risk factors has occurred, but enormous challenges and opportunities remain for applying lifestyle measures often, in conjunction with pharmaceutical therapy, to reduce the risk of CHD.

Pathophysiology of Atherosclerosis

As knowledge of the pathophysiology of atherosclerosis has advanced, new understandings have provided crucial linkages to the role of various lifestyle interventions in reduction of risk of CHD. For example, the role of poor

diet (e.g., elevated consumption of saturated fats, etc.) and diminished physical activity have been known for years to contribute to atherogenesis [13,14]. However, only in the past decade has the significant role for inflammation as an initiating event in the process of atherosclerosis begun to be elucidated. Since multiple related entities such as CHD, obesity, diabetes, glucose intolerance, and the metabolic syndrome have significant overlap, it may indeed be a component of systemic inflammation that unites all of these processes.

Fundamental to the understanding of the interplay between lifestyle and atherosclerosis is the evolving concept of the role of various structures and the interaction of components of both normal and diseased arteries (e.g., endothelium, smooth muscle, and intima) as well as how various cells in these structures function both in health and disease [15–17].

The evolving understanding of the biology of atherosclerosis is beyond the scope of the current chapter. The reader is referred to several recent excellent reviews that discuss current understanding of the atherosclerotic process in detail [17,18].

UNDERSTANDING RISK FACTORS

Concept of Risk Factors

The concept of risk factors is relatively new in the history of medicine. In fact, until the initial findings from the Framingham Study were published in the 1960s, the concept of risk factors for CHD did not formally exist [19]. Framingham data showed that factors such as diabetes [20–23], dyslipidemia [24–28], high blood pressure [29–32], and cigarette smoking [33–36] each independently and significantly increased the risk of CHD. Recently, the concept of CHD risk factors has been expanded to include physical inactivity [33,37] and obesity [38]. Other emerging risk factors where lifestyle habits and practices may play a role are under active investigation.

Framingham data also demonstrated that risk factors act synergistically and tend to cluster with each other [39]. Thus, in the presence of two risk factors, an individual quadruples their chance of developing CHD compared to individuals with no risk factors. Individuals with three risk factors increase their risk of developing CHD between 8- and 20-fold compared to individuals with no risk factors [40].

In addition to the lifestyle-related risk factors identified by the Framingham Study and other observational and interventional studies, other risk factors have been determined including age, gender, family history of CHD, elevated C-reactive protein (CRP), hemostatic factors, excessive alcohol consumption, hypertriglyceridemia, elevated homocysteine levels, and perhaps stress and other psychological factors such as depression.

Numerous studies have demonstrated that reducing risk factors for CHD can significantly decrease its likelihood [41–43]. Lifestyle measures are a particularly powerful and effective way of lowering risk factors since these measures are low risk and many of them simultaneously affect multiple risk factors.

Relative Risk versus Absolute Risk

It is important to differentiate between "relative" and "absolute" risk since this distinction underlies treatment strategies for risk factor reduction in CHD. *Relative risk* is a comparison between different risk levels. It compares the likelihood that an individual who possesses a specific risk factor will develop CHD in comparison to an individual without that risk factor. *Absolute risk* represents the likelihood of developing CHD over a specified period of time. Framingham risk scores, for example, typically assess the absolute risk of developing CHD over a 10 year period.

The difference between relative and absolute risk is a critical factor in clinical decision making. For example, a young individual with abnormal lipids would be treated differently than an older individual with a similar lipid profile, all other things being equal; since their increased relative risk may be the same, their absolute risk may be quite different [44–46].

One way of viewing relative risk may be that it provides an indication of how rapidly an individual may move to absolute risk. Thus, a young individual with high relative risk would be at greater risk of ultimately developing high absolute risk and motivates the clinician to devise strategies for lowering risk as a means of slowing the early stages of developing CHD. Such interventions as lifestyle measures which carry multiple benefits and relatively little risk and expense are attractive means for lowering both relative and absolute risk of CHD.

Primary versus Secondary Prevention

It is also important to distinguish between "primary" and "secondary" prevention when approaching risk factor reduction. Primary prevention is based on the goal of preventing or delaying the development of CHD while secondary prevention focuses on interventions designed to reduce the likelihood of repeat cardiovascular events and/or mortality in individuals who already have established CHD. More aggressive measures for risk factor reduction are typically indicated in individuals when they are used in secondary prevention (see Chapters 83 and 88).

Guidelines for risk factor reduction in primary prevention are available from a variety of sources. Perhaps, the most widely used is the Framingham Risk Scoring System [47]. Guidelines for interventions for secondary prevention have also been published by the American Heart Association and are discussed in detail in Chapters 83 and 88.

PRIMORDIAL PREVENTION AND "IDEAL" CARDIOVASCULAR HEALTH

In 2010, the American Heart Association issued a strategic plan through the year 2020 and beyond [48]. New to this plan was a concept of "primordial" prevention. The goal of primordial prevention as articulated by AHA is "that by 2020 to

improve the cardiovascular health of Americans by 20% while reducing deaths from cardiovascular and stroke by 20%." In issuing this statement, the AHA recognized and declared that "Health is a broader, more positive construct than just the absence of clinically evident disease." It defined "primordial" prevention as a process to avoid adverse levels of risk factors in the first place rather than trying to reduce risk factors when they are already present or treating already established disease. This broader risk factor reduction strategy is completely consistent with the goals and vision of lifestyle medicine and will require careful attention to daily lifestyle habits and actions and their impact on risk factors and overall health.

The AHA Strategic Plan [48] also defined a construct of "ideal" cardiovascular health which was defined as the following:

> The simultaneous presence of four favorable health behaviors: absence of smoking within the last year, physical activity at goal, consumption of a "heart healthy" dietary pattern and an ideal body mass index (BMI).
>
> Simultaneous presence of four favorable health factors: absence of smoking for at least one year, untreated cholesterol less than 200 mg/dL, untreated blood pressure less than <120/<80 mm Hg, and the abstinence of diabetes mellitus, absence of clinical cardiovascular disease (including CHD, stroke, heart failure, etc.).

Clearly, this very welcome framework will result in an increased emphasis on physicians treating, and patients following, positive lifestyle behaviors to improve their cardiovascular health.

IMPLEMENTING RISK FACTOR REDUCTION GUIDELINES

Another welcome trend in the area of risk factor reduction comes from the *Dietary Guidelines for Americans 2010* [49], Physical Activity Guidelines for Americans 2008 [9,50], and American Heart Association Scientific Statement on Implementing Pediatric and Adult Nutrition Guidelines [51]. All three of these guidelines have emphasized real world, practical implementation of guidelines. This is an important and new emphasis from these three widely read and influential documents.

SCIENTIFIC BASIS FOR RISK FACTOR REDUCTION

Multiple observational and interventional studies, including the Framingham Study [52], the Nurses Health Trial [53], the U.S. Male Professional Health Trial, and the Women's Health Initiative [54], have all demonstrated the link between risk factors and developing CHD as well as the power of reducing risk factors to reduce the likelihood of developing CHD. Results from these and other studies form the basis for recommendations in the following sections on specific risk factors.

MODIFIABLE RISK FACTORS

This section will focus on risk factor reduction for those risk factors which can be modified, while the next section will focus on those risk factors which cannot be modified. The modifiable risk factors represent a particularly important area for clinical intervention. Numerous studies have demonstrated that lifestyle measures for reducing modifiable risk factors are an effective strategy for reducing the risk of developing CHD.

Tobacco Use

Cigarette smoking is the leading preventable cause of death from all causes in the United States and the single most prevalent modifiable risk factor for the development of CHD [55]. CHD causes 35%–40% of smoking-related deaths and an additional 8% has been attributed to secondhand smoke exposure [56,57].

Unfortunately, following many years of declines in cigarette smoking prevalence in the United States, the percentage of adults who smoke has recently stabilized at about 20% [12]. Rates of tobacco use are actually increasing among adolescents, young adults, and women [12].

The link between cigarette smoking and increased risk of CHD has been established in multiple studies. Individuals who consume 20 or more cigarettes/day have a two- to threefold increase in CHD. Framingham Study data demonstrated that cardiovascular mortality increases 31% in women and 18% in men for each 10 cigarettes smoked per day [58]. Multiple observational studies have also shown that smokeless tobacco and low tar cigarettes do not reduce the risk of CHD.

Numerous studies have demonstrated that smoking cessation improves longevity and reduces the risk of CHD [58]. Thus, stopping cigarette smoking remains the single most important intervention in preventive cardiology and lifestyle medicine. Smoking cessation yields significant benefits in a relatively short period of time [59]. In one study comparing 1282 cigarette smokers to 2068 controls, the risk of developing CHD among those individuals stopping cigarette smoking approached the level of never smokers within 3 years [60]. In addition to contributing greatly to the risk of CHD, cigarette smoking also significantly increases the likelihood of developing lung cancer and chronic obstructive pulmonary disease.

Despite the important and powerful health benefits of cigarette smoking cessation, the medical community has not been active enough in this area. The Centers for Disease Control and Prevention (CDC) estimates that only slightly more than half of smokers who had at least one physician visit in the previous year reported were advised to quit smoking cigarettes [61]. The impact of spouse, friends and families on cigarette smoking cessation is also significant. Recent studies suggest that smoking cessation by a spouse decreases an individual's chance of smoking by 67% while smoking cessation by a coworker, sibling, or friend contributes to a person's decrease in likelihood of smoking by 25%–36% [62].

Dyslipidemias

Numerous trials have demonstrated that a variety of dyslipidemias or combination of dyslipidemias increase the risk of CHD [42,63–73].

Elevated Low-Density Lipoprotein Cholesterol and Hyperlipidemia

Hypercholesterolemia has been clearly associated with increased risk of CHD. In particular, increased plasma levels of low-density lipoprotein (LDL) have been associated with increased incidence of CHD. Based on these data, the Nutrition Cholesterol Education Program Adult Treatment Panel Guidelines (ATP III) established LDL as the primary target for intervention [74]. Numerous observational trials including the Framingham Study, MRFIT, the Nurses Health Study, and the U.S. Male Health Professional follow-up study have all demonstrated an association between elevated blood cholesterol and increased risk of CHD. Numerous interventional studies have also established that elevated blood cholesterol, and in particular elevated LDL, is associated with increased incidence of CHD [63–73]. These studies have become particularly robust since the development of hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins). These agents lower LDL cholesterol much more efficiently than previously available drugs. Numerous, large clinical trials where statins have been utilized to lower LDH cholesterol by 20%–60% reduced coronary events by up to one-third over a 5 year period without evidence of increased nonvascular mortality [41].

Low Levels of HDL Cholesterol

A number of prospective cohort studies have also demonstrated an inverse relationship between high-density lipoprotein (HDL) cholesterol and risk of CHD. Conversely, low HDL increases the risk of CHD [42]. Each increase in HDL cholesterol by 1 mg/dL is associated with a 2%–3% decrease in risk of total cardiovascular disease [41]. Low HDL cholesterol has been defined as an HDL lower than 40 mg/dL. Levels lower than this are defined as an independent risk factor for CHD in the most recent National Cholesterol Education Program Guidelines. Moreover, the NCEP Adult Treatment Panel (ATP III) Guidelines support an HDL level of >60 mg/dL as a negative risk factor for CHD [74]. It should be noted that several recent trials of novel pharmaceutical agents designed to raise HDL have been somewhat disappointing and have resulted in untoward side effects such as hypertension.

Hypertriglyceridemia

An association between elevated triglyceride levels and cardiovascular disease has been known for many years [75,76]. However, the evidence supporting a direct linkage is less robust than that for elevated LDL or low HDL and CHD. Recent attention has been focused on elevated triglycerides as a risk for heart disease, given its association with obesity, insulin resistance, and diabetes. Recently released statements from the American Heart Association on Childhood and Adolescent Obesity and on Triglycerides and Cardiovascular Health emphasize the importance of lowering triglycerides through lifestyle measures as a means of lowering risk of CHD [77]. Current designations for triglyceride levels are as follows: 150–199 mg/dL borderline high, 200–499 mg/dL high, and >500 mg/dL very high. Overall, 31% of the adult population in the United States has a triglyceride level ≥150 mg/dL [42].

Hypertension

High blood pressure constitutes a significant increased risk of CHD. The prevalence of hypertension has increased steadily in the United States over the past 10 years [78]. According to the report of the most recent Joint National Committee on Prevention, Evaluation and Treatment of High Blood Pressure (JNC VII), one out of every three adults suffers from high blood pressure [78]. This means that more than 50 million individuals have high blood pressure [78]. A subsequent report based on data from the most recent National Health and Nutrition Evaluation Survey (NHANES III) places the number even higher at 38% of the population (65 million individuals) [79]. Even individuals who have normal blood pressure at the age of 55 years have a 90% lifetime risk of developing hypertension during their lifetime according to recent data from the Framingham Heart Study [80].

The relationship between blood pressure and the risk of CHD events is independent of other risk factors for CHD. For every 10 mm Hg rise in diastolic blood pressure or 20 mm Hg rise in systolic blood pressure above 115/75 mm Hg, the increase in risk of CHD doubles [78].

The JNC VII guidelines create a lower than previously established guideline for normal blood pressure (below 120/80 mm Hg) and create a new category of "prehypertension" to replace the old category of "high normal." The JNC VII classification for blood pressure in adults is found in Table 1.1 [78].

High blood pressure is also frequently found coexisting with other risk factors for CHD. For example, individuals with high blood pressure have a greater than 40% chance of having elevated blood cholesterol [81–83]. This is particularly important since over half of heart disease occurs in individuals with two or more risk factors. JNC VII guidelines recommend a 6 month trial of lifestyle-related measures such as weight loss, smoking cessation, regular exercise, and improved nutrition for individuals with stage 1 hypertension before starting pharmacologic therapy [78].

Diabetes and Glucose Intolerance

The incidence of type 2 diabetes, which represents a major risk factor for CHD, has increased dramatically in both men and women in the United States over the past 20 years.

TABLE 1.1
Classification and Management of Blood Pressure for Adults Aged 18 Years or Older

				Management[a]		
					Initial Drug Therapy	
BP Classification	Systolic BP (mm Hg)[a]		Diastolic BP (mm Hg)[a]	Lifestyle Modification	Without Compelling Indication	With Compelling Indication
Normal	<120	and	<80	Encourage		
Prehypertension	120–139	or	80–89	Yes	No antihypertensive drug indicated	Drug(s) for the compelling indications[b]
Stage 1 hypertension	140–159	or	90–99	Yes	Thiazide-type diuretics for most and may consider ACE inhibitor, ARB, β-blocker, CCB, or combination	Drug(s) for the compelling indications Other antihypertensive drugs (diuretics, ACE inhibitor, ARB, β-blocker, CCB) as needed
Stage 2 hypertension	≥160	or	≥100	Yes	2-Drug combination for most and ACE inhibitor or ARB or β-blocker or CCB[c]	Drug(s) for the compelling indications Other antihypertensive drugs (diuretics, ACE inhibitor, ARB, β-blocker, CCB) as needed

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; BP, blood pressure; CCB, calcium channel blocker.

[a] Treatment determined by highest BP category.

[b] Treat patients with chronic kidney disease or diabetes to BP goal of less than 130/80 mm Hg.

[c] Initial combined therapy should be used cautiously in those at risk for orthostatic hypotension.

Diabetes now affects over 8% of adults [11]. Perhaps of even greater importance is that an estimated 35%–40% of adults have impaired glucose tolerance or impaired fasting glucose levels [81]. Diabetes represents a significant risk factor for CHD. Individuals with diabetes have between two and eight times higher rates of cardiovascular events, compared to nondiabetic controls [82]. This risk factor is particularly potent in women with diabetes who increase their risk of developing CHD by three- to sevenfold compared to two- to threefold increased risk in men. The increase in diabetes parallels the increase of obesity in the United States [83]. It has been estimated that individuals born in the United States in the year 2000 will have a 36% chance of developing diabetes in their lifetime [84].

For all of these reasons, prevention, early detection, and treatment of diabetes assume great importance as a modality for reducing risk of CHD. Typical treatment involves multiple components of lifestyle measures such as weight loss for individuals who are overweight or obese and regular physical activity.

Obesity

The prevalence of overweight and obesity has increased significantly in the United States and other developed countries over the past 30 years. It is estimated that over two-thirds of the adult population in the United States are now overweight or obese [10]. Increases have been particularly prominent in the area of stage 1 obesity and severe obesity. Between 1980 and 2004, the prevalence of obesity among adults in the United States doubled. In 2006, it was estimated that 35% women and 33% of men in the United States were obese [85]. Numerous studies have demonstrated that obesity constitutes a strong and independent risk factor for CHD in addition to its association with other risk factors such as dyslipidemia, diabetes, and hypertension. The American Heart Association classifies obesity as a major risk factor for CHD because of these associations.

The most practical and recognized way of assessing obesity in clinical practice is to determine an individual's body mass index (BMI). BMI has also been shown in numerous studies to correlate with health risk. BMI classifications, according to the Institute of Medicine [86], are listed in Table 1.2.

The linkages between obesity and CHD are not completely understood although they are probably mediated not only by direct effects on the cardiovascular system (a hyperdynamic state and increased blood flow) but also through systemic inflammation. Adipocytes used to be considered relatively inactive storage depots; however, recent studies have shown that, in fact, adipocytes are very metabolically active and generate a variety of inflammatory markers such as interleukin-6 (IL-6), tumor necrosis factor α (TNF-α), and CRP [87–90]. Excess weight is also associated with a variety of novel risk factors including an atherogenic dyslipidemia (low HDL cholesterol, elevated triglycerides, elevated apoprotein B, and elevated LDL). In addition, obesity is associated with elevations in thrombotic factors such as plasminogen activator inhibitor I (PAI-1) and increased levels of fibrinogen [91,92].

Distribution of body fat is also strongly and independently associated with CHD over and above increased body weight. In particular, increased abdominal obesity

TABLE 1.2
Classification of Overweight and Obesity as Recommended by the National Heart, Lung, and Blood Institute Guidelines

Disease Risk[a] Relative to Normal Weight and Waist Circumference

			Waist Circumference	
	BMI (kg/m²)	Obesity Class	<102 cm (Men) <88 cm (Women)	>102 cm (Men) >88 cm (Women)
Underweight	<18.5		—	—
Normal[b]	18.5–24.9		—	—
Overweight	25.0–29.9		Increased	High
Obesity	30.0–34.9	1	High	Very high
	35.0–39.9	2	Very high	Very high
Extreme obesity	≥40.0	3	Extremely high	Extremely high

BMI, body mass index.

[a] Disease risk for type 2 diabetes, hypertension, and cardiovascular disease.

[b] Increased waist can also be a marker for increased risk in normal weight individuals.

has been demonstrated to increase risk of CHD [93,94]. A practical way of estimating abdominal obesity is to measure waist circumference. A waist circumference of ≥40 in. in men and ≥35 in. in women confers a significantly increased risk of CHD compared to lower levels of abdominal fat.

Adult weight gain also confers additional risk of CHD. According to the Nurses' Health Study [95] and U.S. Men's Health Professional Study [96], individuals who gained 20 lb or more during their adult life significantly increased their risk of type 2 diabetes and CHD.

Inactive Lifestyle

Physical activity carries multiple health benefits [50]. Unfortunately, the population in the United States (both children and adults) has become increasingly inactive. Numerous studies have demonstrated that an inactive lifestyle significantly increases the risk of CHD. In one recent study, fitness level was more strongly associated with heart disease than any other risk factor, including cigarette smoking and hypertension [97]. The recently released Physical Activity Guidelines for Americans 2008 lists multiple significant benefits for increased physical activity as demonstrated in Table 1.3.

There is strong evidence that regular physical activity lowers the risk of high blood pressure, adverse lipid profiles, type 2 diabetes, the metabolic syndrome, and weight gain. In addition, regular physical activity also overall risk for CHD, risk for stroke, and all-cause mortality.

TABLE 1.3
From 2008 Physical Activity Guidelines for Americans

Health Benefits Associated with Regular Physical Activity—Children and Adolescents

Strong evidence

- Improved cardiorespiratory and muscular fitness
- Improved bone health
- Improved cardiovascular and metabolic health biomarkers
- Favorable body composition

Moderate evidence

- Reduced symptoms of depression

Adults and Older Adults

Strong evidence

- Lower risk of early death
- Lower risk of coronary heart disease
- Lower risk of stroke
- Lower risk of high blood pressure
- Lower risk of adverse blood lipid profile
- Lower risk of type 2 diabetes
- Lower risk of metabolic syndrome
- Lower risk of colon cancer
- Lower risk of breast cancer
- Prevention of weight gain
- Weight loss, particularly when combined with reduced calorie intake
- Improved cardiorespiratory and muscular fitness
- Prevention of falls
- Reduced depression
- Better cognitive function (for older adults)

Moderate to strong evidence

- Better functional health (for older adults)
- Reduced abdominal obesity

Moderate evidence

- Lower risk of hip fracture
- Lower risk of lung cancer
- Lower risk of endometrial cancer
- Weight maintenance after weight loss
- Increased bone density
- Improved sleep quality

The Healthy People 2010 Initiative recommends the goal that at least 30% of the population over the age of 6 years should engage in light to moderate physical activity of at least 30 min/day. This goal has been repeated in the Healthy People 2020 guidelines. Clearly, we are falling far short of these goals. The Surgeon General's Report on Physical Activity documented that 24% of individuals report no recent physical activity, 54% are active but fall short of the recommendations from Healthy People 2010 while only 22% of adults achieve this level of activity [8].

Numerous guidelines including those from the American Heart Association, the American College of Sports Medicine [98], the Centers for Disease Control, and most recently the Physical Activity Guidelines for Americans 2008 [50] all consistently recommend that adults accumulate at least 30 min of moderate intensity physical activity on most, if not

TABLE 1.4
From 2008 Physical Activity Guidelines for Americans

Classification of Total Weekly Amounts of Aerobic Physical Activity into Four Category Levels of Physical Activity	Range of Moderate Intensity	Summary of Overall Health Benefits	Comment
Inactive	No activity beyond baseline	None	Being inactive is unhealthy
Low	Activity beyond baseline but fewer than 150 min/week	Some	Low levels of activity are clearly preferable to an inactive lifestyle
Medium	150 to 300 min/week	Substantial	Activity at the high end of this range has additional and more extensive health benefits than activity at the low end
High	More than 300 min/week	Additional	Current science does not allow researchers to identify an upper limit of activity above which there are no additional health benefits

all, days. The Physical Activity Guidelines for Americans 2008 provides an alternative of 75 min/week of vigorous intensity physical activity [50]. Definitions of low, medium, and high physical activity are found in Table 1.4.

Numerous studies have shown that physician recommendation is a powerful motivator to change lifestyle habits including level of physical activity. Moreover, several studies support the finding that if the physicians themselves are physically active they are more likely to recommend physical activity to their patients [99,100]. The most common form of physical activity recommended by physicians (first choice of over 90% of physicians) is walking [101].

Poor Nutritional Habits

A large body of research supports a linkage between nutritional habits and risk of CHD. The American Heart Association Guidelines for Pediatric and Adult Nutrition [102], the *Dietary Guidelines for Americans 2010* [49], and the American Heart Association's Strategic Impact Goal Plan through 2020 and Beyond all recommend nutrition intervention to lower the risk of CHD. These guidelines are consistent in recommending lower fat, higher fiber, increased consumption of fruits and vegetables, and control of calories to maintain a healthy body weight [103].

The AHA Strategic Plan for 2020 [48] establishes the following metric for nutrition goals to lower the risk of CHD and states "in the context of diet that is appropriate in energy balance pursing an overall dietary pattern that is consistent with a DASH (Dietary approaches to Systolic Hypertension] type eating plan including, but not limited to:

- Fruits and vegetables: five of more cups per day
- Fish: two or more 3.5 servings per week" (preferably oily fish)
- Fiber rich whole grains: 1.1 g or more of fiber per 10 g of carbohydrate (three or more 1 oz equivalent servings per day)
- Sodium: <1500 mg/day
- Sugar sweetened beverages: ≤450 kcal (36 oz)/week

While these recommendations do not cover all aspects of a heart healthy diet, they represent a good starting point for physicians counseling patients about improved nutritional practices to lower the risk of CHD.

NON-MODIFIABLE RISK FACTORS

The risk factors described in the previous section can all be reduced through appropriate lifestyle practices and habits in patient's daily lives. There are also a number of non-modifiable risk factors for CHD which will be discussed in this section.

Although this second group of risk factors cannot be altered through lifestyle habits, they play an important role as part of the overall patient risk factor profile. Specifically, individuals who have significant non-modifiable risk factors should be even more strongly counseled to make appropriate lifestyle changes to alter those risk factors which are modifiable.

Age

Strong and consistent evidence associates increased age with increased risk of CHD. Approximately 80% of all fatal myocardial infarctions occur in individuals over the age of 65 [104]. Thus, in the elderly population control of modifiable risk factors assumes increasing importance. Regular physical activity, weight management, control of lipids, and blood pressure are all important areas for physicians to counsel patients over the age of 65.

Gender

More women die each year than men of heart disease, although CHD typically occurs at a younger age in men than in women [105]. Framingham Study data demonstrate that men typically display the onset of symptoms of CHD 10 years younger than women [105]. It is important to note that symptoms of CHD may present differently in women than in men. The American Heart Association "Wear Red" program has provided an important emphasis on reducing risk factors for heart disease in women [106].

Family History

A positive family history CHD before the age of 65 in a first-degree relative constitutes an independent risk factor for CHD [104]. Why CHD tends to aggregate in some families is not completely understood although it may be mediated through genetics or through risk factors that relate to lifestyle components, such as levels of physical activity, nutritional habits, dyslipidemia, or weight.

METABOLIC SYNDROME AND THE CONCEPT OF MULTIPLE RISK FACTORS

Framingham data clearly support that clustering of risk factors is common [39]. One type of clustering of risk factors has been referred to the "metabolic syndrome." While there is ongoing debate about the criteria for the metabolic syndrome [107], and numerous different definitions exist, the one most commonly employed (such as in the National Cholesterol Education Program ATP III Guidelines) [74] includes the following criteria:

- Waist circumference: >40 in.
- Blood pressure: >135/85 mm Hg
- Fasting blood glucose: >110 mg/dL
- HDL cholesterol: <40 mg/dL
- Fasting triglycerides: >150 mg/dL

According to the ATP III Guidelines if an individual has three or more of these five criteria, he or she is considered to have the metabolic syndrome.

Individuals with metabolic syndrome are at significantly higher risk for both CHD and diabetes than the general population. The ATP III Guidelines recommend that an individual with the metabolic syndrome should be treated as though they already have CHD. Data from the Framingham Study demonstrate that 60% of CHD is found in individuals who possess two or more risk factors.

Debate is ongoing about the exact mechanism through which metabolic syndrome increases the risk of CHD. Some investigators maintain that the mechanism is through insulin resistance [108]. Others have emphasized underlying inflammatory processes as part of the metabolic syndrome which link to increased risk of CHD [109]. While the metabolic syndrome and obesity are not synonymous, they are strongly linked to each other. According to Framingham Study data, obese individuals have approximately a 50% chance of having at least two other risk factors for CHD [40].

The increased prevalence of obesity in children has drawn attention to its linkage to the increasing prevalence of both diabetes and the metabolic syndrome in children [110]. While considerable controversy exists about the criteria for the metabolic syndrome in children, the American Heart Association has recommended careful exploration for other risk factors for CHD in children who are obese.

It should also be noted that recent data support that metabolic syndrome also results in a proinflammatory state. This is recognized by the most recent definition of the metabolic syndrome by the National Heart, Lung, and Blood Institute [111]. This observation is important since a proinflammatory state also occurs in diabetes, hypertension, and obesity.

EMERGING RISK FACTORS

Recent research has identified a variety of other risk factors which are associated to a greater or lesser degree with CHD. These risk factors are discussed in this section.

High-Sensitivity C-Reactive Protein

Inflammation has been identified as a key component of atherosclerothrombosis and provides an important link between plaque formation and acute rupture [112]. CRP, which is a marker of inflammation, has been identified as a significant cardiovascular CHD risk marker [113]. Numerous prospective studies have demonstrated that high-sensitivity CRP (hs-CRP) independently predicts the risk of CHD [114–119]. These data also apply not only to individuals with existing CHD but also to healthy individuals including both men and women at all age levels. Elevated hs-CRP is not only associated with obesity and diabetes but also found in increased prevalence in individuals who lead sedentary lifestyles or are cigarette smokers [113]. These findings carry significant practical implications for counseling individuals concerning a variety of lifestyle measures.

Several of the statin medications have been demonstrated to lower CRP in addition to lowering LDL cholesterol, which carries significant implications for combining pharmaceutical therapies along with lifestyle measures [120,121].

Other Markers of Inflammation

The relationship between CHD and inflammation is an area of active research. A variety of other markers of inflammation in addition to CRP have emerged as potential risk factors for CHD. Most prominently, TNF-α and IL-6 have been associated with increased risk of CHD but the data supporting these relationships are not as advanced as with CRP [41].

Hemostatic Factors

Factors that may contribute to thrombogenesis have also been associated with increased risk of CHD. Factors currently under investigation that may contribute to thrombogenesis include PAI-1, fibrinogen [122,123], and coagulation factor VII.

Homocysteine

Elevated levels of homocysteine, an amino acid derived from the degradation of methionine, have been associated with increased risk of CHD. While laboratory tests are available to assess homocysteine, studies attempting to reduce the risk

of CHD by reducing homocystine levels have not yielded promising results [124,125]. Thus, homocystine is not currently included as part of a risk factor profile.

LDL Subclasses and Particle Size

Laboratory tests are available to determine the amount of cholesterol carried by individual lipoprotein particles which are characterized by their particle size. Some studies have suggested that small, dense LDL particles may be more atherogenic than larger LDL particles [126,127]. Of note, small, dense LDL particles have been associated more frequently in obese individuals and individuals with abdominal obesity than normal weight individuals. The data have not established the association between LDL particles size and CHD risk at a level that is useful for risk factor reduction strategies.

Lipoprotein (a)

Lipoprotein (a) (Lp (a)) is an LDL particle linked to a protein by a disulfide bridge. A number of studies have supported the role for LP (a) as a determinant vascular risk [128]. However, it remains uncertain that LP (a) contributes further sensitivity or specificity to standard risk factor reduction strategies [129].

OTHER RISK FACTORS

A variety of other risk factors for CHD have been either identified or postulated to potentially influence the likelihood of its development.

Levels of Antioxidants

Initial observational studies including the Health Professional Follow-up Study [130] and the Nurses Health Trial [131] showed an association between high levels of vitamin E and other antioxidants and reduced risk of CHD. Subsequent interventional trials, however, have not corroborated these findings [132]. The American Heart Association does not currently advocate antioxidant supplementation as a means of reducing CHD risk.

Alcohol

Alcohol consumption exerts a variety of effects on the overall cardiovascular system. A number of studies have demonstrated that moderate alcohol consumption reduces the overall risk of CHD [133]. "Moderate" alcohol consumption is typically defined as no more than one to two beers, one to two glasses of wine, or one to two "shots" of distilled spirits daily. Men are typically able to drink higher amounts of alcohol within the moderate range than women because of higher levels of alcohol dehydrogenase—the enzyme in the liver that breaks down alcohol. The mechanism by which moderate alcohol consumption may reduce the risk of CHD is attributed either to increasing HDL or decreasing platelet aggregation [134]. In contrast, alcohol consumption of three alcoholic drinks per day or more has been associated with increased risk of hypertension, overall risk of heart disease, congestive heart failure, a variety of gastrointestinal cancers, and motor vehicle accidents.

Stress and Type A Personality

Some studies have supported the concept that personality type may contribute to the risk of CHD; however, these data remain controversial and inconclusive [135,136]. In particular, the anger element of Type A personality (a Type A personality is often found in individuals who are highly competitive and ambitious and perceive a constant struggle with their environment) may increase the risk of CHD. The mechanism by which stress may lead to increased risk of vascular disease is not completely understood but is possibly related to platelet and endothelial dysfunction as well as the induction of ventricular arrhythmias.

Depression

Depression has been demonstrated in a number of studies to predict CHD [137,138]. This association appears to be an independent one although depression is also associated with lack of physical activity, hypertension, and smoking [137,138]. The mechanism through which depression may increase the risk of CHD includes elevated levels of hs-CRP, increased platelet activation, and decreased heart rate variability. Depression occurs in one out of three patients with heart failure and one out of five patients with CHD. Whether therapy for depression lowers risk for CHD is uncertain.

FUTURE TRENDS IN RISK FACTOR ASSESSMENT

Some technological enhancements, both in imaging techniques and genomics, have provided opportunities which may yield more precise and individualized characterizations of atherosclerotic plaque and risk of CHD.

Direct Plaque Imaging

High-speed computed tomography (CT scanning) of the coronary arteries has been demonstrated in several studies to detect preclinical atherosclerosis [139]. Advances such as volume CT scanning (VCT) may further enhance precision and predictive value of these technologies. At the current time, these technologies remain investigational. Concern has also been raised about the potential to over interpret predictive values from imaging techniques such as coronary calcium scoring. In one study, 41% of all future vascular events occurred in individuals with a coronary calcium score lower than 100 and 17% occurred with a coronary calcium score of zero [140]. In this study, individuals with high risk scores by Framingham criteria but low coronary calcium scores still remained at high risk of CHD.

Genomic Approaches

Advances continue to be made in genetic determinants of atherothrombosis. Although this field remains in its early stages of development, progress continues to be made [141–143]. Challenges exist because of multiple gene–environment interactions. Although this remains an area of active research, no genetic markers for atherothrombosis have yet achieved clinical utility.

New Risk Factor Scoring Systems

The Framingham Risk Scoring System has contributed in substantial ways to the ability to predict the risk of CHD; however, it is limited but does not incorporate such risk factors as level of physical activity and obesity. One particularly attractive system has emerged from the New Zealand Guidelines Group which provides useful information on 5 and 10 year risk of atherosclerosis. This area remains one of active research.

Implementation of Risk Factor Reduction Strategies

One encouraging trend in risk factor reduction is an increased emphasis on more sophisticated and comprehensive approaches to implementation of currently existing risk factor reduction guidelines [49,51,102]. Both the *Dietary Guidelines for Americans 2010* [49] and the Nutrition Guidelines from the American Heart Association [51] make a substantial effort to focus on strategies for implementing existing guidelines.

CONCLUSIONS

The identification of risk factors for CHD continues to evolve and is an area of great practical relevance to clinicians. Particularly given the high level of modifiable risk factors for CHD, an enormous opportunity exists for physicians and other health care workers to counsel patients on lifestyle medicine concepts to lower their risk of CHD. Specific concepts for how to integrate lifestyle measures into clinical practice will be the topic of the next chapter.

Coronary heart disease (CHD) remains the leading killer of men and women in the United States [1]. CHD also represents one of the quintessential lifestyle-related diseases since many of the risk factors for it, including cigarette smoking [2], elevated cholesterol [3], high blood pressure [4], obesity [5], and an inactive lifestyle [6], have significant lifestyle-related components.

Lifestyle strategies can play a significant role in the reduction of risk factors for CHD as well as its prevention and effective treatment. In Chapter 1, we focused on the rationale for employing lifestyle strategies for risk factor reduction. The current chapter provides practical strategies for employing these modalities in clinical practice for the prevention and treatment of CHD.

Lifestyle interventions also represent an important strategy for physicians and other health care workers to assist patients in lowering their risk factors as well as preventing CHD and treating individuals with established CHD. These lifestyle-related strategies are particularly valuable since they carry very little risk and may simultaneously reduce multiple risk factors for CHD. Furthermore, the American Heart Association has articulated a vision to pursue "primordial" risk factors meaning the prevention of risk factors in the first place. Lifestyle measures will be key components of this strategy [7].

Furthermore, lifestyle measures are already incorporated as key recommended early intervention steps in most of the major, evidence-based guidelines either prior to or in conjunction with pharmaceutical therapy to help patients lower the risk of CHD [3,4,8–15]. Unfortunately, many health care workers still do not properly emphasize these measures in their daily clinical practices. In addition, reimbursement models currently provide disincentives for using these strategies since lifestyle interventions are typically not covered by health insurance plans. It is hoped that with aspects of the Health Care Reform Act [16], particularly the Accountable Care Organizations provision, financial models will be developed to encourage these low cost, potentially high-yield lifestyle measures.

In addition to the financial disincentives, lack of time may also represent another hurdle. Delivery of those measures related to prevention of CHD recommended by the

TABLE 2.1
Evidence-Based Guidelines That Employ Lifestyle Measures to Reduce the Risk of CHD and Other Metabolic Conditions

- American Heart Association Nutrition Implementation Guidelines
- Guidelines from the American Academy of Pediatrics for the Prevention and Treatment of Childhood Obesity
- Guidelines from the American Academy of Pediatrics for Heart Disease Risk Factor Reduction in Children
- Guidelines from the American Heart Association and American Academy of Pediatrics for the Prevention and Treatment of Metabolic Syndrome
- Joint statement from the American Heart Association and American Cancer Society on the Prevention of Heart Disease and Cancer

U.S. Preventive Health Services Task Force has been estimated to take the typical clinician a minimum of 1.5 h/day in non-reimbursable time [17]. Thus, it will be important in clinical practice to find ways to deliver proven lifestyle interventions with efficient strategies that are time sensitive.

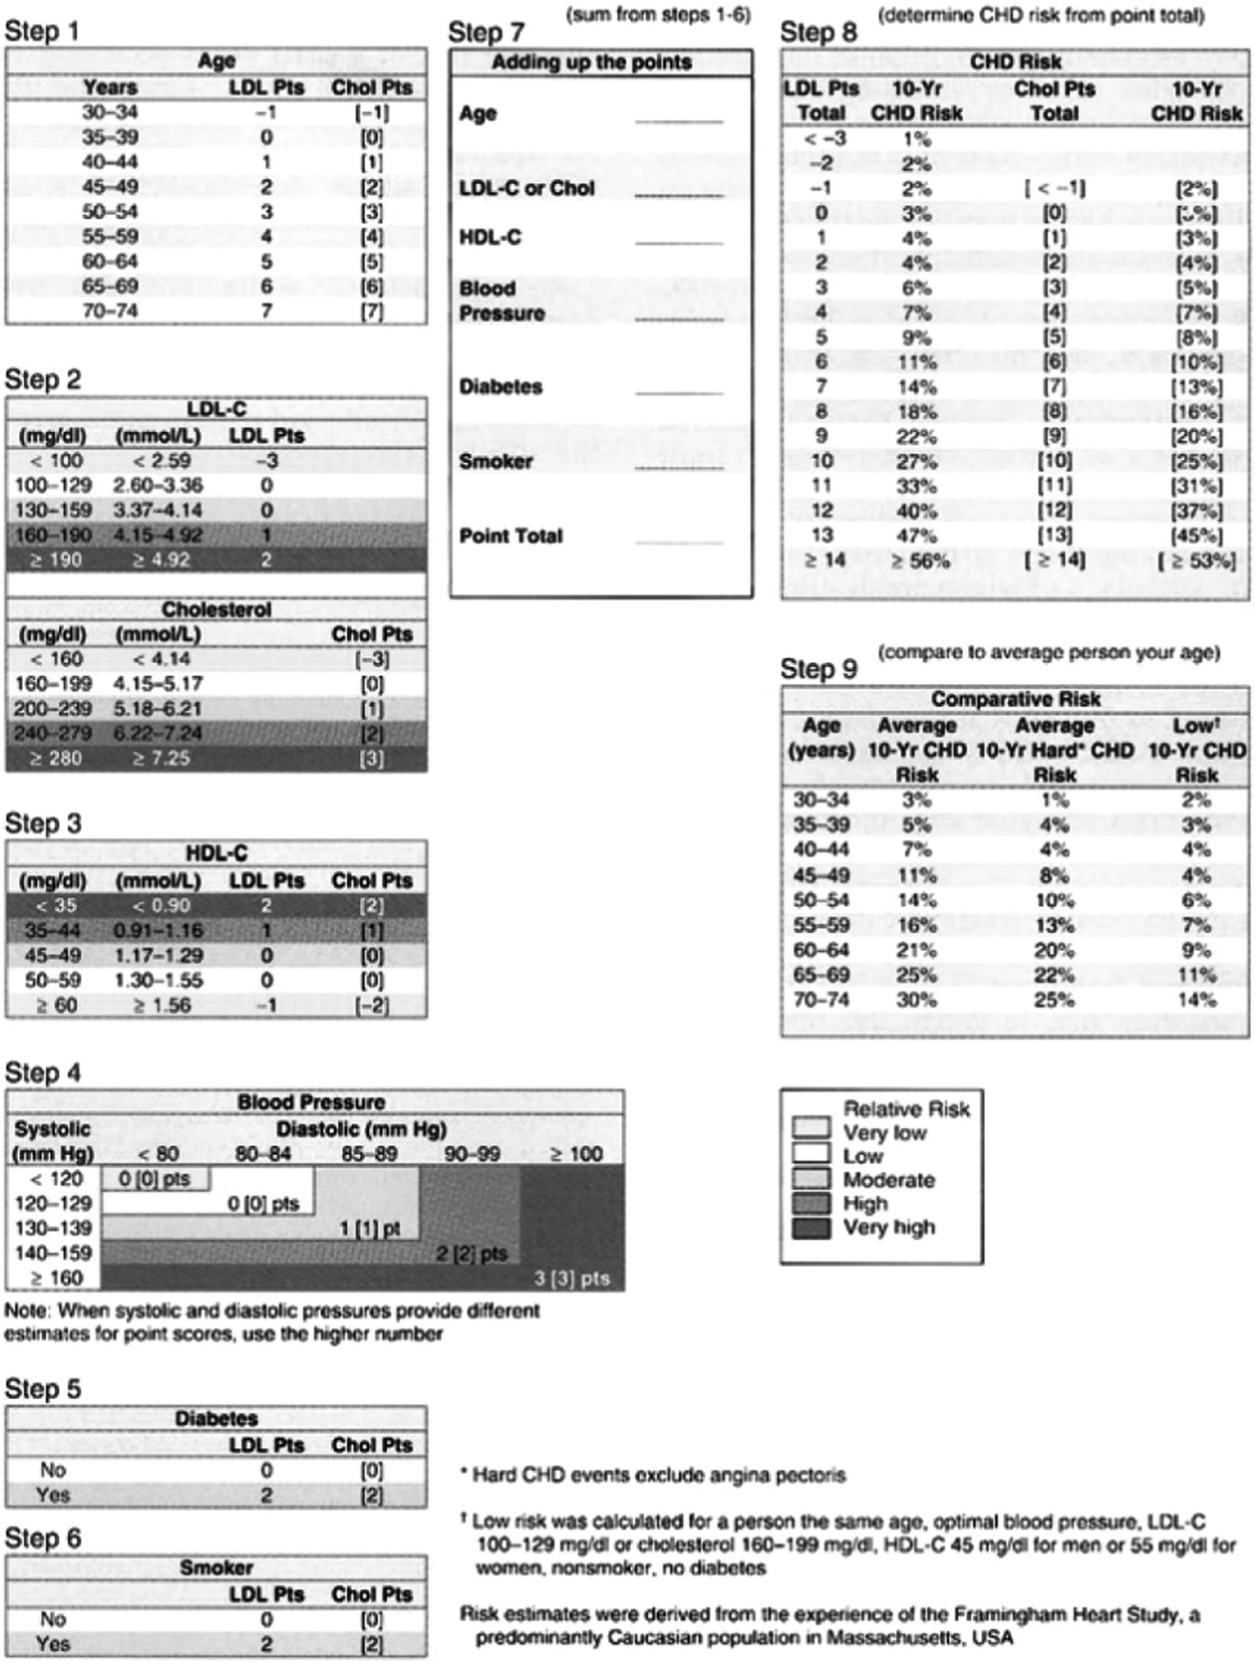
A representative listing of national guidelines that incorporates lifestyle medicine emphasis in the treatment of CHD or as a strategy for lowering risk factors for related metabolic conditions are found in Table 2.1.

Health care professionals can be enormously influential in helping patients take positive lifestyle actions to lower their risk of CHD. Health care providers' recommendations to make changes in behaviors such as cigarette smoking cessation, weight loss, or improved nutrition have all been demonstrated to play important roles in lowering risk factors for CHD. Numerous studies have shown that the public perceives medical professionals as a reliable and credible source of information concerning health-related behaviors [18–24]. Often, however, health care workers underestimate how powerful their role as health counselors can be. For example, <50% of smokers report receiving advice to quit from their physician [25] and <40% of obese individuals report receiving advice about weight loss. This is unfortunate since the average adult in the United States visits a physician's office more than five times per year and it has been estimated that physicians come in contact with over 75% of adults in the United States in any given year [26]. In addition to physicians, nutritionists, nurses with an interest and background in preventive cardiology or diabetes education, and other health care professionals can play critically important roles in counseling patients on positive lifestyle behaviors to lower their risk of CHD.

It should also be noted that the majority of patients who make lifestyle behavior changes do this without formal participation in an organized program. For example, over 90% of individuals who have stopped smoking have done this without formal smoking cessation programs [27]. Furthermore, the majority of patients who lose weight also do this on their own. Nonetheless, health care professional recommendations and support can be very valuable to motivate patients to start and maintain the process of behavioral change.

It is particularly important that physicians play a proactive role in this area. At the current time, physician office visits represent a missed opportunity to promote behavioral changes. It is hoped that the advent of such organizations as the American College of Lifestyle Medicine [28] and the lifestyle medicine track in the American College of Preventive Medicine [29] will help physicians build the knowledge, basic skills, and confidence needed to make these recommendations. A recent "blue ribbon" panel of physicians representing most major medical organizations has urged physicians to become involved in lifestyle medicine and outlined a series of competencies in this area [30]. Furthermore, the Health Care Reform Act [16] including the Accountable Care Provision will increasingly mandate that physicians become active in this area.

PREDICTING RISK



A key first step prior to using lifestyle measures to lower risk factors for CHD involves predicting risk. Risk prediction involves understanding the type and strength of evidence underlying risk factor assessment strategies as well as clearly understanding the difference between relative risk and absolute risk (see Chapter 1).

Most currently employed, evidence-based frameworks for lowering risk factors for CHD involve assessing absolute risk. For example, lowering absolute risk underlies the strategies for the National Cholesterol Education Program ATP-III Guidelines [3], the American Diabetes Association Guide of Managing Diabetes [9], and the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) [4].

ASSESSING RISK

Multiple frameworks are available for assessing risk of CHD. The most widely used and the one recommended by the American Heart Association is the framework developed by the Framingham Heart Study investigators [31]. This is found in Figures 2.1 and 2.2. Figure 2.1 is used to assess risk for men and Figure 2.2 is used to assess risk for women. The Framingham framework is based on estimating an individual's 10 year risk of developing CHD. The higher the 10 year risk, the more intensity of intervention is warranted.

It should be noted that there are alternatives to the Framingham score. For example, the Reynolds Risk Score provides a variation to the Framingham Score by incorporating whether a parent suffered myocardial infarction (MI) before the age of 60 years as well as high-sensitivity CRP (hs-CRP) level [32,33]. The Reynolds Score appears to be a better predictor of individuals in the middle risk category and is comparable to the Framingham Risk Score for individuals with low or high risk.

Step 1

Age		
Years	LDL Pts	Chol Pts
30–34	−1	[−1]
35–39	0	[0]
40–44	1	[1]
45–49	2	[2]
50–54	3	[3]
55–59	4	[4]
60–64	5	[5]
65–69	6	[6]
70–74	7	[7]

Step 2

LDL-C		
(mg/dl)	(mmol/L)	LDL Pts
< 100	< 2.59	−3
100–129	2.60–3.36	0
130–159	3.37–4.14	0
160–190	4.15–4.92	1
≥ 190	≥ 4.92	2

Cholesterol		
(mg/dl)	(mmol/L)	Chol Pts
< 160	< 4.14	[−3]
160–199	4.15–5.17	[0]
200–239	5.18–6.21	[1]
240–279	6.22–7.24	[2]
≥ 280	≥ 7.25	[3]

Step 3

HDL-C			
(mg/dl)	(mmol/L)	LDL Pts	Chol Pts
< 35	< 0.90	2	[2]
35–44	0.91–1.16	1	[1]
45–49	1.17–1.29	0	[0]
50–59	1.30–1.55	0	[0]
≥ 60	≥ 1.56	−1	[−2]

Step 4

Blood Pressure					
Systolic (mm Hg)	Diastolic (mm Hg) < 80	80–84	85–89	90–99	≥ 100
< 120	0 [0] pts				
120–129		0 [0] pts			
130–139			1 [1] pt		
140–159				2 [2] pts	
≥ 160					3 [3] pts

Note: When systolic and diastolic pressures provide different estimates for point scores, use the higher number

* Hard CHD events exclude angina pectoris

† Low risk was calculated for a person the same age, optimal blood pressure, LDL-C 100–129 mg/dl or cholesterol 160–199 mg/dl, HDL-C 45 mg/dl for men or 55 mg/dl for women, nonsmoker, no diabetes

Risk estimates were derived from the experience of the Framingham Heart Study, a predominantly Caucasian population in Massachusetts, USA

FIGURE 2.2 Score sheet for women based on Framingham experience in women 20–74 years of age at baseline. Average risk estimates are based on typical Framingham subjects, and estimates of idealized risk are based on optimal blood pressure, total cholesterol (TC) of 160–199 mg/dL (or low-density lipoprotein cholesterol [LDL-C] of 100–129 mg/dL), high-density lipoprotein cholesterol (HDL-C) of 55 mg/dL, no diabetes, and no smoking. Use of the LDL-C categories is appropriate when fasting LDL-C measurements are available. Pts, points. (From Wilson, P.W. et al., *Circulation*, 97, 1837, 1998.)

Other available risk scores include Systematic Coronary Risk Evaluation Project (SCORE) developed by the European Joint Task Force utilizing studies in 12 European countries involving 250,000 individuals [34]. A more recent set of guidelines was developed by the New Zealand Guidelines Committee which assesses absolute cardiovascular risk during 5 years instead of 10 years [35].

CLASSIFYING INTERVENTIONS FOR MODIFIABLE RISK FACTORS

As outlined in Chapter 1, risk factors for CHD can be conveniently divided into "modifiable" and "non-modifiable." This framework also carries practical implications and is a commonly employed classification strategy [36]. In addition, classifications employed by the American College of Cardiology and the American Heart Association divide risk factors into four categories based on the level of evidence that modifying a particular risk factor will result in lower risk of CHD. The following four classifications are typically employed:

- *Class 1 Interventions*: These interventions involve risk factor reduction strategies that have been proven to reduce risk when used.
- *Class 2 Interventions*: This classification includes risk factors where interventions are likely to lower the incidence of events but proof is less strong than Class 1 interventions.
- *Class 3 Interventions*: This classification includes risk factors that have been clearly associated with increased risk of CHD which, if modified, might lower the likelihood of a coronary event.
- *Class 4 Interventions*: This classification includes risk factors which have been associated with increased risk of CHD which, if modified, are not likely to decrease the risk of CHD or cannot be modified.

The framework for classifications is summarized in Table 2.2.

TABLE 2.2
Framework for Risk Factor Reduction Interventions (See Text for Details)

Class 1 Interventions
- Cigarette smoking cessation
- Management of dyslipidemias
- Management of hypertension
- Pharmaceutical measures for cardiac protection

Class 2 Interventions
- Obesity prevention and management
- Diabetes/glucose intolerance management
- Physical inactivity

Class 3 Interventions
- Nutritional counseling
- Psychological risk factors/counseling
- No alcohol consumption

Class 4 Interventions
- Age
- Male gender
- Low socioeconomic status
- Family history of early onset CVD

CLASS 1 INTERVENTIONS

Lifestyle Approach to Cigarette Smoking Cessation

Cigarette smoking is the leading cause of preventable death in the United States each year resulting in an estimated 440,000 deaths [37]. More than 40% of deaths from cigarette smoking result from cardiovascular disease [38]. The 1989 Surgeon General's Report showed that smoking doubles the risk of CHD and increases CHD mortality by 50% [39]. Both of these risks increase with age and the number of cigarette smoked. Worldwide, >1 million more deaths were attributable to tobacco in the year 2000 than in 1990 [40]. Worldwide, tobacco use is estimated to be responsible for 5 million deaths per year [41]. In the United States, cigarette smoking peaked in 1955 reaching 55% of men who were smokers. The peak for women came 10 years later with >33% smoking. Since that time, cigarette smoking has substantially declined; however, the rate of decline has slowed substantially in the past decade.

Currently in the United States, 21% of adults smoke [42]. Slightly more of these individuals are men than women. Eighteen percent of women over the age of 18 years smoke and approximately 23% of men over the age of 18 years old smoke [42]. If individuals do not smoke cigarettes by the time they graduate from high school, it is highly unlikely that they will adopt this habit as adults. Smoking rates among high school seniors are slightly above 30% with more female smokers slightly higher than males [43]. Smoking also tracks with socioeconomic status. Thirty-two percent of individuals living below the Federal poverty line are smokers.

The U.S. Public Health Service has published clinical practice guidelines classifying tobacco dependency as a chronic condition requiring repeated intervention [44]. These guidelines recommend that health care professionals ask every patient about tobacco use at every clinic visit [45]. Counseling and behavior therapies are based on the following:

1. Securing social support
2. Providing problem-solving skills
3. Social support outside treatment

According to the U.S. Public Health Service Guidelines, which support a combination of counseling and pharmaceutical therapy, seven pharmacotherapies reliably increase long-term smoking abstinence including bupropion hydrochloride [46], darenicline, and five nicotine replacement therapies (nasal spray, gum, patch, inhaler, and lozenges) [47]. The efficacy of smoking cessation programs ranges from 6% 1 year success with physician counseling alone to 18% with self-help programs and 20%–40% with counseling plus pharmacological intervention [48]. All individuals who smoke should, of course, be counseled

to cease this potentially deadly habit. A particularly appropriate time to encourage patients to make this effort is after a cardiac event or discovery of existing cardiovascular disease.

Lifestyle Approach to Management of Dyslipidemias

Average cholesterol levels among adult men and women in the United States have decreased to some degree since the 1960s. Currently, approximately 45% of all American adults still have cholesterol levels greater than 200 mg/dL and 16% have levels higher than 240 mg/dL [49]. In addition, both depressed HDL cholesterol levels and elevated triglyceride levels often occur together and result from different metabolic pathways than are typically involved in elevated LDL. These latter two lipid abnormalities are particularly associated with the metabolic syndrome.

Various organizations have listed somewhat different recommendations for cholesterol screenings. There is wide agreement that all patients with currently existing CVD should be periodically screened for serum cholesterol levels. The NCEP ATP-III Guidelines recommend that all adults older than 20 years should be routinely screened for serum cholesterol [3]. The American College of Physicians (ACP) provides less aggressive screening recommendations with advice that men between the ages of 35 and 65 be screened and women between the ages of 45 and 65 be screened [50]. The U.S. Preventive Services Task Force advocates screening women over the age of 45 and men over the age of 35 [45].

It is important to understand that all of the earlier referenced guidelines advocate treatment based on assessment of the patient's overall risk. The ATP-III Guidelines not only utilize LDL level but also recommend calculations based on the Framingham Risk Score (see Figures 2.1 and 2.2). A guideline algorithm presented by the ATP-III Guidelines is presented in Figure 2.3. New guidelines from the NCEP (ATP-IV) are anticipated to be published in 2012.

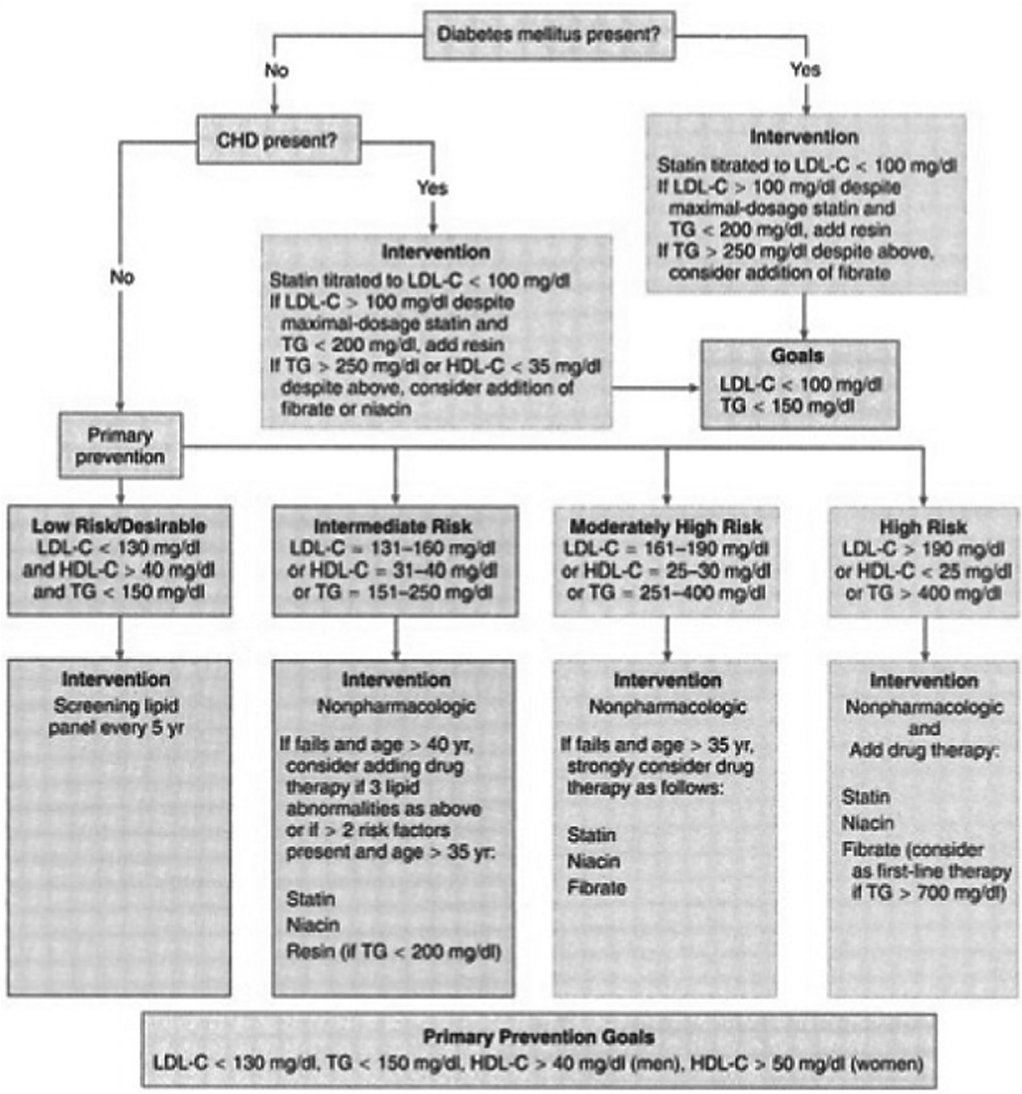

FIGURE 2.3 Algorithm for lipid-lowering therapy based on findings from intervention trials. CHD, Coronary heart disease; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; TG, triglycerides. (From the Third Report of the National Cholesterol Education Program (NCEP), *Circulation*, 106, 3143, 2002.)

New guidelines from the NCEP (ATP-IV) are anticipated to be published in 2012. A variety of lifestyle recommendations are incorporated as recommended first-line treatment in the NCEP ATP-III Guidelines. Nutritional intervention is recommended including maintaining calories from fat between 25% and 35%, saturated fat counting for <7% with cholesterol level intake limited to <200 mg/day. Complex carbohydrates are recommended at 50%–60% of calories and protein at 15%. NCEP ATP-III Guidelines recommend consumption of 20–30 g of dietary fiber daily—an amount far more than the average American adult currently consumes [3].

In 2006, American College of Cardiology and American Heart Association updated their secondary prevention guidelines for lipid management including most of the provisions of the NCEP guidelines but also strengthening them for individuals with established CHD. The AHA/ACC Guidelines extend the option of levels of <70 mg/dL for LDL for all patients with CHD not just those at very high risk [51]. The guidelines also recommend that patients with triglyceride levels of 200–499 mg/dL should have non-HDL cholesterol level of <130 mg/dL and potentially further reduction to <100 mg/dL. Also in 2006, the AHA listed its nutritional and lifestyle recommendations [52]. A summary of these recommendations and their lifestyle interventions is found in Table 2.3. Within a clinical setting, it may be valuable for patients to receive the services of a registered dietitian to help them adhere to nutritional guidelines recommended by the AHA and NCEP ATP-III.

A variety of pharmaceutical agents have been demonstrated to lower both total and LDL cholesterol as well as reduce morbidity and mortality from CHD. Most prominent among these medicines are the statins. While statins vary according to potency, they appear to be equally efficacious. Adherence is the key issue. Other agents available include niacin, fibrates, bile acid sequestrants, and cholesterol absorption inhibitors. A complete review of pharmaceutical therapies for the management of dyslipidemia is beyond the scope of this chapter and has been well treated in a variety of other publications. All the major cholesterol management guidelines advocate that lifestyle measures be combined if pharmaceutical agents are employed to produce the most favorable outcome.

TABLE 2.3
AHA 2008 Diet and Lifestyle Recommendations for Cardiovascular Disease Risk Reduction

1. Balance caloric intake and physical activity to achieve or maintain a healthy body weight
2. Eat a diet rich in vegetables and fruits
3. Choose and prepare foods with little or no salt
4. Minimize your intake of beverages and foods with added sugars
5. Consume oily fish at least twice a week
6. Limit your intake of saturated fat to <7% of energy, *trans* fat to <1% of energy, and cholesterol to <300 mg/day by choosing lean meats and vegetable alternatives; selecting fat-free (skim), 1% fat, and low-fat dairy products and minimizing intake of partially hydrogenated fats
7. Choose whole grain, high fiber foods in your diet
8. If you consume alcohol, consume in moderation
9. When you eat food that is prepared outside of your home, follow the AHA Diet and Lifestyle Recommendations

Lifestyle Management of Hypertension

According to the JNC 7 Report, one out of every three American adults has high blood pressure, which represents >50 million Americans [4]. Another 25% fall into the "prehypertensive" category, which represents another 45 million Americans. The JNC 7 blood pressure classification is found in Table 2.4.

According to data from the Framingham Heart Study, individuals who have a normal blood pressure at the age of 85 years still have a 90% chance of developing hypertension in their lifetime [53]. Control of high blood pressure in the United States remains abysmally low with over two-thirds of individuals with hypertension not adequately controlled [54].

A number of lifestyle measures are recommended by JNC 7 and can play significant roles in either reducing the likelihood of developing hypertension or treating it if it currently exists. These lifestyle measures include weight management, regular physical activity, proper nutrition, cessation of cigarette smoking, and moderation of alcohol—all of which represent first-line lifestyle-related measures in the treatment of high blood pressure within the JNC 7 framework [4].

Increased body weight has clearly been associated with increased risk of high blood pressure [55]. Conversely, weight reduction in overweight or obese individuals represents a highly reliable way of lowering blood pressure. In most studies, individuals who are overweight or obese can anticipate losing 1 mm Hg both systolic and diastolic blood pressure for every 2 lb of weight loss [56]. The mechanism of blood pressure lowering resulting from weight loss is not completely understood. It may represent a decrease in blood volume, an initial diuresis, or reduction in systemic vascular resistance [57,58].

Proper nutrition can also play a significant role in blood pressure control. Both the JNC 7 Guidelines [4] and the AHA Nutrition Guidelines [52] recommend that individuals with hypertension should consume a diet with no more than 2300 g of sodium per day. Recently released Dietary Guidelines for Americans 2010 [59] recommends an even lower sodium consumption of 1500 mg/day for individuals at increased risk for cardiovascular disease and all individuals over the age of 50.

Practical ways to lower salt consumption include removal of the salt shaker from the table, reduction of salt in cooking, careful label reading of processed foods (a significant and often underrecognized source of sodium), and increased consumption of whole grains and fruits and vegetables. The Dietary Approaches to Stop Hypertension (DASH) diet which emphasizes whole grains, fruits and vegetables, and low-fat dairy products has been shown to reliably lower high

TABLE 2.4
Classification and Management of Blood Pressure for Adults Aged 18 Years or Older

BP Classification	Systolic BP, mm Hg[a]		Diastolic BP, mm Hg[a]	Management[a]		
					Initial Drug Therapy	
				Lifestyle Modification	Without Compelling Indication	With Compelling Indications[b]
Normal	<120	and	<80	Encourage		
Prehypertension	120–139	or	80–89	Yes	No antihypertensive drug indicated	Drug(s) for the compelling indications[c]
Stage 1 hypertension	140–159	or	90–99	Yes	Thiazide-type diuretics for most; may consider ACE inhibitor, ARB, β-blocker, CCB, or combination	Drug(s) for the compelling indications Other antihypertensive drugs (diuretics, ACE inhibitor, ARB, β-blocker, CCB) as needed
Stage 2 hypertension	≥160	or	≥100	Yes	Two-drug combination for most (usually thiazide-type diuretic and ACE inhibitor or ARB or β-blocker or CCB)[d]	Drug(s) for the compelling indications Other antihypertensive drugs (diuretics, ACE inhibitor, ARB, β-blocker, CCB) as needed

ACE, Angiotensin-converting enzyme; ARB, angiotensin receptor blocker; BP, blood pressure; CCB, calcium channel blocker.

[a] Treatment determined by highest BP category.

[b] See Table 6.

[c] Treat patients with chronic kidney disease or diabetes to BP goal of <130/80 mm Hg.

[d] Initial combined therapy should be used cautiously in those at risk for orthostatic hypotension.

blood pressure [60]. An addition of further sodium restriction to the DASH diet results in further reduction in blood pressure. Unfortunately, <20% of individuals with established high blood pressure are following a DASH type diet [61].

Regular physical activity also helps prevent high blood pressure and lowers blood pressure in individuals with currently existing hypertension. Physically active individuals reduce their risk of hypertension between 20% and 50% [62]. Individuals with established hypertension who start a physical activity program (emphasizing aerobic activities such as walking) may lower both systolic and diastolic blood pressure by 5–10 mm Hg by participating in such moderate-intensity physical activity [62].

Excessive alcohol consumption is a risk factor for hypertension [63]. Moderation of this habit can also contribute significantly to controlling blood pressure. Cigarette smoking and use of other tobacco products have been repeatedly shown to raise blood pressure [64,65]. Cessation of this deadly habit should be recommended for multiple reasons. Some evidence supports stress reduction as playing a role in lowering blood pressure although this effect seems to be less prominent than the other lifestyle measures already discussed [66]. A beneficial aspect of lifestyle measures in relationship to blood pressure control is that they often act synergistically with each other. It should be noted that positive lifestyle measures when practiced simultaneously appear to have additive benefits. The PREMIER trial showed that a combination of weight loss, sodium restriction, increased physical activity, and limited alcohol consumption when practiced together resulted in substantial blood pressure reductions in individuals with above optimal blood pressure, including Stage 1 hypertension (120–159 mm Hg systolic and 80–95 mm Hg diastolic) and who were not taking antihypertensive medications [67]. Further benefits were achieved by individuals who implemented a DASH diet in addition to these other lifestyle modifications.

Pharmaceutical Measures for Cardiac Protection

A detailed review of pharmacological interventions to lower the risk of heart disease is beyond the scope of this chapter. However, it is important to recognize that certain pharmacological interventions have been demonstrated to be effective in either primary or secondary prevention of cardiovascular disease.

Aspirin has been demonstrated to lower the risk of subsequent events in individuals with existing CHD, where aspirin reduces the risk of subsequent events by 25% [68]. The AHA/ACC recently lowered the recommended prophylaxic dose of aspirin in individuals with existing CHD from 75 to 325 mg/day to 75 to 162 mg/day since antiplatelet trials had showed no difference in the reduction benefit and reduced risk of bleeding at this lower dosage range [51]. Other antiplatelet agents do not offer significant benefit over aspirin. These agents such as clopidogrel should be limited to patients with aspirin allergy or intolerance [69].

The picture of aspirin usage in primary prevention is less clear [70]. The AHA guidelines issued in 2007 for women recommend aspirin for high risk women whose 10 years of a coronary event, based on Framingham criteria, exceeds 20% and for all women over the age of 65 in whom blood

pressure is controlled and the potential benefit for preventing MI or ischemic stroke outweighs the risk of bleeding or hemorrhagic stroke. The U.S. Preventative Health Services Task Force (USPHSTF) recommends aspirin for men 45–79 years of age and women 55–79 years of age for benefit in reduction of risk of MI in men and ischemic stroke in women if these benefits outweigh the risk of gastrointestinal bleeding [71].

Other potentially beneficial pharmaceutical agents include statins, β-adrenergic receptor blockers after MI, and angiotensin-converting enzyme inhibitors in individuals at high risk for CHD events. Extensive reviews of all these medications may be found elsewhere.

CLASS 2 INTERVENTIONS

Obesity Prevention and Management

Obesity [72], adult weight gain [73], and increased abdominal fat [74] are all independently associated with increased risk for CHD [75–78]. Obesity also contributes to a variety of other risk factors for CHD including hypertension, Type 2 diabetes, and dyslipidemia. The American Heart Association recognizes obesity as an independent risk factor over and above its association with other risk factors for CHD [79].

Over the last 40 years, the percentage of the U.S. population considered to be overweight (BMI ≥ 25 ≤ 29.9) and obese (BMI ≥ 30.0) has risen steadily and substantially. As depicted in Figure 2.4, over two-thirds of the adult population in the United States are now considered overweight or obese [80,81]. The prevalence of obesity has risen particularly sharply, with the most dramatic increase in individuals who are extremely obese (BMI ≥ 40.0).

The same trends have occurred in children [82] as depicted in Figure 2.5. The prevalence of overweight has more than tripled among children in the United States in the past 40 years ("overweight" in children is defined by CDC criteria as ≥95th percentile weight for height based on CDC 2000 tables) [83]. Some criteria such as those from the American Medical Association also include a description of ≥85th percentile weight for height as "overweight" and ≥95th percentile of weight for height as an appropriate definition for "obese" in children [84].

Obese individuals are particularly likely to demonstrate clustering of risk factors [85]. Framingham data have demonstrated that over two-thirds of CHD is found in individuals with two or more risk factors [86]. Moreover, obesity is the major driver of the metabolic syndrome which afflicts between 25% and 35% of the adult population in the United States and represents a potent risk factor for both CHD and diabetes [87].

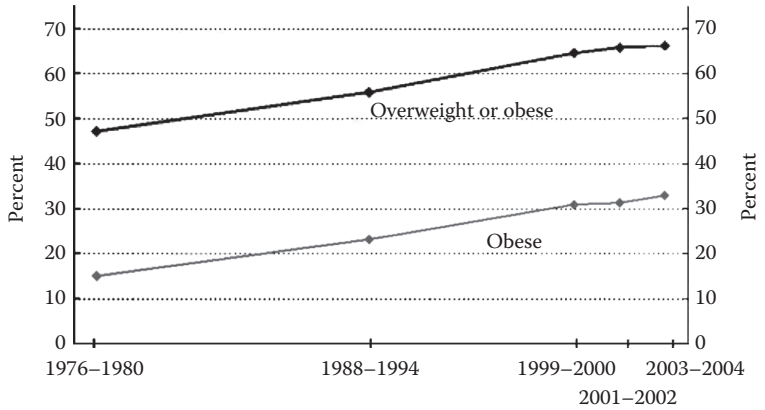

FIGURE 2.4 Trends in adult overweight and obesity ages 20–74 years. (From National Center for Health Statistics, Health, United States 1987, USDHHS Pub. No. 88-1232, U.S. Department of Health and Human Services, Public Health Service, Washington, DC, 1988.)

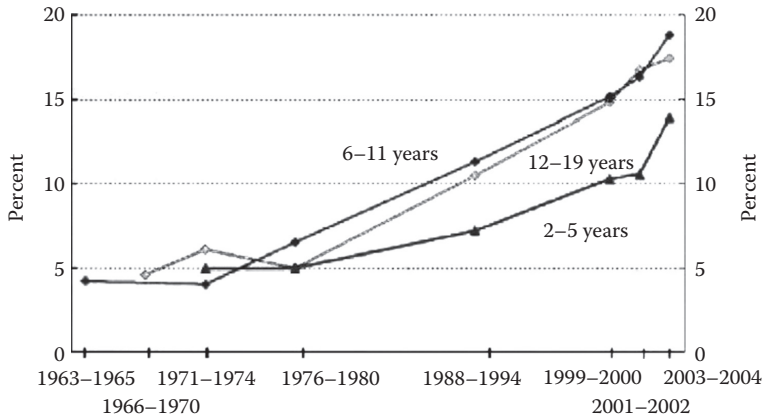

FIGURE 2.5 Trends in childhood overweight. (From National Center for Health Statistics, Health, United States 1987, USDHHS Pub. No. 88-1232, U.S. Department of Health and Human Services, Public Health Service, Washington, DC, 1988.)

Although the association between obesity and increased risk of CHD is well established, no large scale, randomized trials of weight reduction as an intervention to lower risk of CHD are available to estimate the benefits of weight loss. A number of trials, however, have shown that weight loss in obese individuals reduces risk factors for CHD and a variety of other chronic conditions. For example in the Diabetes Prevention Program, individuals who were overweight who lost 5%–7% of their body weight and adopted a program of regular physical activity reduced their risk of developing diabetes by 58% [88]. Nutritional strategies, with a particular emphasis on matching calorie intake to calorie output, have demonstrated effectiveness for weight loss. The *Dietary Guidelines for Americans 2010* [59] list overconsumption of calories and overweight/obesity as the leading nutritional problems in the United States.

In addition, regular physical activity in conjunction with attention on caloric consumption has been found in numerous studies to help in the maintenance of long-term weight loss [89,90]. The preferred form of physical activity for most overweight or obese individuals is walking. Some studies have recommended 30–60 min of moderate-intensity walking per day as a reasonable goal for individuals as a component of an effective and safe weight loss program [90]. The *Dietary Guidelines for Americans 2010* recommend 60 min or more of moderate physical activity as a component of weight management [59].

Behavioral strategies and social support are also important as components of an overall strategy for long-term weight loss [91]. Support from an individual's family and friends or from groups (e.g., from an organization such as Weight Watchers International) has been demonstrated to be helpful in long-term maintenance of weight loss [92].

Few pharmaceutical therapies are currently available for weight loss. The only agents approved in the United States at the current time are Phentermine and Orlistat. A number of other agents are in various stages of development.

It has been regularly shown that physician involvement in recommendations for weight loss represents an important predictor of both initial weight loss and maintenance of weight loss. A detailed description of available programs and therapies for weight loss is beyond the scope of the current chapter. The authors have, however, coedited a textbook on this topic and the reader is referred to this textbook for more detailed information in this area [93].

Diabetes/Glucose Intolerance

The prevalence of diabetes in the United States has grown significantly over the past decade which appears to reflect corresponding increases in the prevalence of overweight and obesity [94]. Currently, approximately 8% of the adult population in the United States—nearly 24 million people—has diabetes mellitus. The vast majority of these individuals (>90%) have Type 2 diabetes [94]. Unfortunately, approximately one-fourth of individuals with diabetes are not aware they have this condition. Another significant problem is the recent increase in Type 2 diabetes in children. It is now estimated that more new cases of Type 2 diabetes are found in children each year than Type 1 diabetes [82].

Diabetes represents a significant risk factor for CHD and is the leading cause of death for both men and women with diabetes resulting in 75% of all mortality [95,96]. A variety of lifestyle measures such as weight loss in overweight or obese individuals and regular physical activity play important roles in the management of diabetes [97,98]. These modalities are particularly important for blood sugar control in individuals with Type 2 diabetes.

Because patients with diabetes often have other risk factors for CHD, aggressive treatment of these other risk factors is imperative. For example, guidelines from the American Diabetes Association for treating high blood pressure in individuals with diabetes recommend a target of blood pressure ≤130/80 mm Hg for individuals with diabetes [99]. NCEP ATP-III Guidelines treat diabetes as a CHD equivalent and recommend reduction of LDL cholesterol in diabetic individuals to a goal of <100 mg/dL [3].

Impaired glucose tolerance often proceeds overt diabetes and is particularly common in obese individuals. Recent CDC data indicate that 35%–40% of the adult population in the United States has glucose intolerance [100]. Recent studies have shown that overweight individuals with impaired glucose tolerance who lose weight, reduce total fat intake, and increase physical activity significantly decrease their risk of developing diabetes [88,101]. Thus, lifestyle measures are highly appropriate in both diabetic and prediabetic patients.

Few data are available to address appropriate strategies for long-term reduction in CHD mortality among patients with Type 2 diabetes. It is hoped that the Look AHEAD (Action for Health in Diabetes) trial should provide some important information in this area. Initial data from this study are anticipated in 2012 [102].

Physical Inactivity

The U.S. population has become increasingly sedentary. Both the U.S. Surgeon General's Report on Physical Activity and Health [103] and data from the Behavior Risk Factor Surveillance System (BRFSS) [104] have suggested that >70% of the adult population in the United States does not achieve 30 min of moderate-intensity physical activity on most, if not all, days. Multiple studies have demonstrated that an active lifestyle substantially decreases the risk of CHD. The American Heart Association has listed the lack of physical activity as a major risk factor for CHD [105].

The recently released *Physical Activity Guidelines for Americans 2008* provides a listing of known or anticipated health benefits from increased physical activity [106]. A listing of these known benefits and the strength of the evidence supporting these relationships are found in Table 2.5. As can be seen from this table, many of the

TABLE 2.5
Health Benefits Associated with Regular Physical Activity

Children and adolescents

Strong evidence

- Improved cardiorespiratory and muscular fitness
- Improved bone health
- Improved cardiovascular and metabolic health biomarkers
- Favorable body composition

Moderate evidence

- Reduced symptoms of depression

Adults and older adults

Strong evidence

- Lower risk of early death
- Lower risk of CHD
- Lower risk of stroke
- Lower risk of high blood pressure
- Lower risk of adverse blood lipid profile
- Lower risk of Type 2 diabetes
- Lower risk of metabolic syndrome
- Lower risk of colon cancer
- Lower risk of breast cancer
- Prevention of weight gain
- Weight loss, particularly when combined with reduced
- Improved cardiorespiratory and muscular fitness
- Prevention of falls
- Reduced depression
- Better cognitive function (for older adults)

Moderate to strong evidence

- Better functional health (for older adults)
- Reduced abdominal obesity

Moderate evidence

- Lower risk of hip fracture
- Lower risk of lung cancer
- Lower risk of endometrial cancer
- Weight maintenance after weight loss
- Increased bone density
- Improved sleep quality

Source: From U.S. Department of Health & Human Services, *2008 Physical Activity Guidelines for Americans*, http://www.health.gov/PAguidelines, accessed: August 29, 2011.

known benefits from physical activity involve reduction of risk of CHD.

The *Physical Activity Guidelines for Americans 2008* recommend that individuals try to accumulate 150 min of moderate-intensity activity or 75 min of vigorous activity on a weekly basis. Moderate-intensity activities include such forms of physical activity as walking, jogging, cycling, or swimming at moderate intensity. A listing of *Physical Activity Guidelines* is beyond the scope of this chapter. The reader is referred to the *Physical Activity Guidelines for Americans 2008* for an excellent compendium of literature in this area [106].

Moderate Alcohol Consumption

A number of studies have demonstrated that moderate alcohol consumption decreases the risk of vascular diseases such as heart attack, peripheral vascular disease, and sudden cardiac death [107]. It should be noted that these studies have also demonstrated that excessive alcohol consumption increases both all-cause mortality and cardiovascular disease mortality [108]. The most reasonable course in a clinical setting is to assess risks and benefits of alcohol consumption on a case-by-case basis with each patient.

CLASS 3 INTERVENTIONS

Nutritional Counseling

Numerous studies have demonstrated that diet has an impact on CHD risk [109–112]. The U.S. Preventive Services Task Force listed nutritional counseling as having "moderate" evidence supporting its role in lowering the risk of CHD. Recent Scientific Statements from the American Heart Association [52] as well as the *Dietary Guidelines for Americans 2010* [59] both emphasize the important role of nutritional counseling to lower the risk of CHD. In particular, improved nutritional practices may help improve blood lipids, and strategies such as the DASH diet [60,113] have been demonstrated to help control high blood pressure.

Guidelines and resource materials are available in this area from the American Heart Association [114] as well as the American Dietetic Association [115] and the Preventive Cardiology Nurses Association [116] to assist patients in making nutritional choices to lower their risk of CHD. Numerous guidelines are available from various professional societies providing key components of overall health and nutritional patterns. The guidelines are all very consistent with each other, so the individual health care professional is able to choose whichever one fits most conveniently into his/her practice [117].

Psychological Risk Factors/Counseling

A number of psychological factors including depression, chronic hostility, social isolation, and lack of social support have been linked to increased risk of CHD [118]. Some studies have suggested that improved psychological support systems may improve outcome following MI. For example, one meta-analysis of 37 smaller studies showed that stress management and health education in individuals with CHD reduced recurrent MI by 29% and cardiac mortality by 34% [118]. Office visits following MI clearly represent an excellent opportunity to assess levels of depression and social isolation in individuals who have suffered recent cardiac events.

POSTMENOPAUSAL ESTROGEN THERAPY

It is well established that the risk of CHD in women increases significantly following menopause. Relatively, few women experience CHD at younger than 45 years of age in the

United States [119]. However, by the age of 60 years, CHD is the leading cause of death among women.

Multiple factors may explain the increased risk of CHD after menopause. For many years, the increase in CHD after menopause was attributed to the decline in endogenous estrogen that accompanies menopause [118]. However, the Women's Health Initiative findings did not support this concept [120–122]. For this reason, hormone therapy is no longer recommended as an approach to prevention of CVD for the USPHSTF, the American Heart Association, or other scientific organizations [121].

DETERMINANTS OF BEHAVIORAL CHANGE

The belief that it is possible to change patient's behavior provides the fundamental underpinnings to the concept of utilizing lifestyle measures to help patients adopt positive lifestyle behaviors to lower the risk of CHD or as an adjunct to the treatment of established CHD. A detailed review of the literature in this area is beyond the scope of the current chapter. However, this literature has been very well summarized in a variety of other publications [123,124].

A variety of theoretical constructs provide the foundation for behavioral therapy [125]. These include

- Cognitive behavioral therapy (which assumes that behavior is learned and can, therefore, be unlearned through cognitive and behavioral strategies)
- Social cognitive theory (this is based on the assumption that behavior is the result of interaction of personal and behavior factors as well as environmental influences)
- Transtheoretical theory (stages of change; based on accurately placing an individual along the path of various stages of change) [124]

Familiarity with these theoretical constructs, as well as technique of motivational interviewing, provides useful underpinnings and a practical framework for incorporating lifestyle change messages in clinical practice.

ESTABLISHING A LIFESTYLE MEDICINE EMPHASIS IN CLINICAL PRACTICE

As already indicated, physicians can play a particularly powerful role by recommending and monitoring lifestyle-related changes for reduction in the risk of CHD. While challenges remain including lack of time and inadequate reimbursement models, it is clear that health care professionals need to move in this direction.

The evidence supporting lifestyle therapies for reduction of risk of CHD is diverse and powerful. Moreover, an emphasis on the linkages between daily lifestyle habits and practices and the risk of CHD is incorporated in virtually all of the evidence-based guidelines for treating CHD and its risk factors as well as reducing the risk of other metabolic diseases [3–15]. The American Heart Association has also included positive lifestyle measures as a fundamental component of its strategic plan for 2020 for improving the cardiovascular health of the nation [7]. Finally, the Accountable Care Organization provision of the recent Affordable Health Care Act suggests that health care organizations and individual providers will be mandated to increase involvement in this area [126]. The recently released *Physical Activity Guidelines for Americans 2008* [106] as well as the *Dietary Guidelines for American 2010* [59] provide fundamental, evidence-based approaches to lifestyle-related issues and should be the foundation for health care workers' increasing emphasis on these strategies in their daily practice.

SUMMARY

An extensive body of scientific literature supports the concept that positive lifestyle measures are highly effective in lowering multiple risk factors for CHD as well as serving as components of therapy for individuals who already have established CHD. These interventions carry the substantial advantages of being low cost, carrying virtually no adverse side effects, and often simultaneously ameliorating multiple risk factors for CHD. The key imperative for physicians and other health care workers is to commit to learning how to incorporate counseling concerning these lifestyle measures in clinical practice and establishing strategies to bring this valuable body of information to their patients.

CARDIOVASCULAR DISEASES AND LIFESTYLE

Death rates from cardiovascular diseases (CVD), including coronary heart disease (CHD), stroke, and heart failure, have declined; however, they remain the major cause of mortality in the United States. In 2007, CHD caused 1 in 6 deaths in the United States; stroke accounted for 1 in 18 deaths; and 1 in 9 death certificates mentioned heart failure. Traditional risk factors for CVD remain prevalent. Approximately 76,400,000 (33.5%) of the U.S. adult population had hypertension (HTN); 23.1% of men and 18.3% of women smoked cigarettes, approximately 33,600,000 (15%) adults had total serum cholesterol levels ≥240 mg/dL; 18,300,000 (8%) adults had diagnosed diabetes; and approximately 149,300,000 (67.3%) were overweight or obese [1].

In the United States, there are ethnic disparities in the prevalence of CHD and HTN. Blacks (6.7%) had the highest prevalence of CHD, followed by Whites (6.4%), Latinos (5.8%), American Indians or Alaska Natives (4.1%—figure considered unreliable), and Asians (3.9%). Blacks also had the highest prevalence of HTN (32.3%), followed by Whites (23.0%), American Indians or Alaska Natives (21.8%), and Asians (19.4%) [1]. Older and lower socioeconomic status individuals also have an increased prevalence of CVD and they are more likely to have risk factors associated with CVD, including sedentary behavior, overweight, and unhealthy dietary habits [2].

The American Heart Association has projected that direct and indirect costs of CVD in the United States will increase from $252.5 and $171.7 billion dollars in 2010 to $818.1 and $275.8 billion in 2030, respectively. These cost estimates do not include all costs related to obesity, diabetes mellitus, and tobacco use [3]—all major risk factors for CVD.

Although death rates from CVD have fallen, the prevalence and severity of risk factors associated with these diseases has increased [4]. Thus, reduction of incident cases of CVD is a primary public health goal. "To improve cardiovascular health and quality of life through prevention, detection, and treatment of risk factors for heart attack and stroke; early identification and treatment of heart attacks and strokes; and prevention of repeat cardiovascular events" is a goal for Healthy People 2020 (HP 2020) [5]. To meet this goal, HP 2020 has 24 specific objectives related to increasing the overall cardiovascular health in the U.S. population. These objectives include those related to lifestyle changes, including Heart Disease & Stroke goal (HDS-10): (Developmental): "Increase the proportion of adults with hypertension who meet the recommended guidelines" which includes reducing saturated fatty acid (SFA) and sodium intake, and moderating alcohol intake. Another goal related to reducing CVD using lifestyle changes is HDS-13 goal: (Developmental) "Increase the proportion of adults with elevated low-density lipoprotein cholesterol (LDL-C) who have been advised by a health care provider regarding cholesterol lowering management including lifestyle changes and, if indicated, medication." Components of this goal include lowering serum cholesterol levels and weight control through diet.

The potential impact of diet and other lifestyle factors on the risk of CHD was shown by Ancel Keys in the Seven Countries study [6] and by a study that looked at heart disease in Japanese men living in Japan, Hawaii, and California [7]. Although these studies are older, and have been criticized for design and analyses issues, they provide an historical basis for the link between diet and CHD.

Modifiable risk factors for CVD accounted for 90% and 94% of the Population Attributable Risk (PAR) factors in males and females, respectively. Smoking and abnormal lipids were shown to be the most important risk factors, accounting for approximately two-thirds of the PAR of an acute myocardial infarction. These were followed by psychosocial factors, abdominal obesity, diabetes, and HTN [8]. The severity of dyslipidemia, abdominal obesity, diabetes, and HTN can be modified by lifestyle changes, including diet.

RECOMMENDATIONS FOR "HEART HEALTHY DIETS"

Overall nutrient and food consumption patterns play a central role in the prevention of CHD in individuals and population [9,10]. A meta-analysis of dietary trials showed that lowering of serum cholesterol levels by diet produced as much CHD risk reduction as did lipid-lowering drugs—corresponding to their respective degree of cholesterol lowering [11]. Diets, and other lifestyle measures, designed for primary or secondary prevention of CHD, should be designed not only to reduce serum total cholesterol, LDL-C, and triglycerides in those individuals with dyslipidemia and to increase high-density lipoprotein cholesterol (HDL-C) but also to control other risk factors for CHD, including overweight/obesity, blood pressure, and blood glucose levels.

Dietary and physical activity recommendations for prevention and treatment of CHD, as well as other chronic diseases, including HTN, stroke, type 2 diabetes, cancer, are remarkably consistent [12–18]. Recommendations are for total healthy diet patterns, which are generally rich in whole grains, fruit and vegetables, low-fat dairy, and lean proteins; some agencies also recommend consumption of nuts. Nutrient recommendations include high intakes of poly-UFA (PUFA) and mono-unsaturated fatty acids (MUFA) and potassium, and low intakes of added sugars, SFA, *trans*-fats, and sodium.

It is also important that individuals balance energy intake with physical activity to maintain a healthy weight [16]. The Department of Health and Human Services recommends specifically that adults (18–64 years of age) should do 150 min of moderate-intensity weekly, or 75 min of vigorous-intensity, aerobic physical activity weekly, or an equivalent combination of moderate- and vigorous-intensity aerobic physical activity. Aerobic activity should be performed in episodes of at least 10 min, preferably spread throughout the week. Additional health benefits are seen from increasing physical activity to 300 min/week. Adults should also do muscle-strengthening activities that involve all major muscle groups performed on 2 or more days per week. Adults older than 64 years should follow these recommendations unless limited by chronic conditions, and if present, individuals should be as physically active as they can. Few Americans meet the recommendations for either diet or physical activity [18].

The U.S. Preventive Services Task Force (USPSTF) recommends intensive behavioral dietary counseling for adult patients with hyperlipidemia and other known risk factors for CVD and diet-related chronic disease [19]. Such secondary prevention of CVD can be conducted by a physician or a Registered Dietitian (RD) via nutrition education or counseling. The USPSTF, however, failed to find sufficient evidence to recommend for or against behavioral counseling for primary prevention of CVD in unselected patients [19]. A Cochrane Review found that education or counseling in the general population did lower risk factors modestly, but did not lower CHD events or total or CHD mortality and were not recommended. It did find that high risk patients could, however, benefit from these efforts [20].

Dietary recommendations for secondary prevention of CHD or HTN are similar to those for the general public, although they are somewhat more restrictive [11,21] (Table 3.1). For example, population-wide recommendations for SFA are <10% of energy, whereas the recommendation for those with dyslipidemia or who have had a coronary event is <7% of energy from SFA [11]. Dietary changes are recommended as the first-line treatment for mild to moderate dyslipidemia [22]. The principal goal of the National Cholesterol Education Program's Adult Treatment Panel III's goal is to lower serum LDL-C levels [11]. With the reduction in serum LDL-C levels comes a concomitant decrease in CHD mortality [23]. Dietary changes can reduce serum cholesterol levels by up to 30% [24]; however, in practice, reductions of 5%–15% are more common [25]. The principal dietary modifications to reduce serum LDL-C levels are to reduce the intake of SFA and increase the intake of PUFA and MUFA.

TABLE 3.1
Nutrient Recommendations for Primary and Secondary Prevention of CVD

	Primary Prevention			Secondary Prevention	
	IOM[a]	2010 DGA	AHA	ATP III	DASH
Energy	Energy intake should be balanced with energy expenditure to achieve and maintain an appropriate weight				
Protein	10%–35% of energy	N/A	N/A	~15% of energy	18% of energy
Carbohydrates	45%–65% of energy	N/A	N/A	50%–60% of energy	55% of energy
Refined grains	N/A	No more than 3 oz eq[b]	"Choose whole grain foods"	N/A	N/A
Added sugar	<25% of energy[c]	Reduce Intake	<10% of energy	N/A	N/A
Fiber	38–21 g/day[d]	14 g/1000 kcal	N/A	20–30 g/day; 10–25 g/day viscous fiber	30 g/day
Total fat	20%–35% of energy	20%–35% of energy	25%–35% of energy	25%–35% of energy	27% of energy
SFA[e]	As low as possible	<10% of energy	<7% of energy	<7% of energy	6% of energy
trans-fat	As low as possible	As low as possible	<1% of energy	"Low intake"	N/A
Solid fat	N/A	Reduce intake	Minimize	N/A	N/A
MUFA	N/A	N/A	N/A	Up to 20% of energy	N/A
PUFA	N/A[f]	N/A	N/A	Up to 10% of energy	N/A
Cholesterol	As low as possible	<300 mg/day	<300 mg/day	<200 mg/day	150 mg/day
Potassium	4700 mg	4700 mg	N/A	90 mmol[g]	4700 mg
Sodium	19–50 years 1500 mg; 51–70 years 1300 mg; >70 years 1200 mg	<2300 mg[h]	Moderation	2400 mg[g]	2300 mg[g]
Magnesium	Males: 19–30 years 330 mg; ≥31 years 350 mg Females >19 years 265 mg	N/A	N/A	Enough for good health[g]	500 mg
Calcium	Males: 19–70 years 800 mg; ≥71 years 1000 mg Females: 19–50 years 800 mg; ≥51 years 1000 mg	N/A	N/A	Enough for good health[g]	1250 mg
Alcohol[i]	N/A	1 drink/day females; 2 drinks/day males	Moderation		Limit

N/A, no specific recommendation; however, this will revert to the DGA or the IOM's DRI values. American Heart Association (AHA): Lichtenstein, A.H. et al., *Arterioscler. Thromb. Vasc. Biol*., 26, 2186, 2006; the AHA added sugars recommendation is from Van Horn, L. et al., *Circulation*, 122, 2470, 2010.

[a] Unless otherwise noted, recommendations are for adults 19+ years; pregnant and lactating females excluded. Institute of Medicine (IOM) acceptable macronutrient distribution ranges are presented for protein, carbohydrates, and total fat.

[b] Based on a 2000 kcal diet.

[c] Acceptable macronutrient distribution range, not the recommended intake.

[d] Fiber recommendations are age- and gender-dependent: males 19–50 years 38 g/day, 51+ years 30 g/day; females 19–50 years 25 g/day, 51+ years 21 g/day.

[e] Saturated fatty acids (SFA) in the diet should be replaced by monounsaturated fatty acids (MUFA) and polyunsaturated fatty acids (PUFA).

[f] IOM acceptable macronutrient distribution range for *n*-6 polyunsaturated fatty acids (linoleic acid) is 5%–10% of energy and for *n*-3 polyunsaturated fatty acids (α-linolenic acid) is 0.6%–1.2% of energy.

[g] Referenced from JNC VI.

[h] Intake should be reduced to 1500 mg among 51+ years, African Americans, or individuals with hypertension, diabetes, or chronic kidney disease.

[i] If alcohol is consumed, intake should be moderate, as defined earlier; this is not a specific recommendation for alcohol consumption.

When counseling patients to reduce SFA intake, it is important to consider this reduction in the context of the macronutrients that replace it. Replacement of SFA with PUFA or MUFA has shown to reduce both LDL-C and HDL-C and may lessen CHD risk. Generally, MUFA has a slight positive effect on HDL and LDL levels and improves insulin sensitivity [26,27]. Olive oil, a MUFA, has also been shown to have a positive effect on lipid levels, but it is unclear if this is due to the fatty acid profile or to the polyphenolic content of the oil [28]. However, if the energy from SFA is replaced by carbohydrates, particularly refined

carbohydrates, this can increase triglycerides and small LDL-C particles, as well as reduce HDL-C. Other dietary interventions, as described later, can reduce the risk of CVD.

Nutrient recommendations may be difficult for the public to follow, so either the recommendations need to be in food, as they have been for MyPlate [29], the interpretation of the DGA for the consumer, or the DASH diet [21]. These are recommendations for whole diets rather than individual foods or nutrients. Health providers, including RDs, can help individuals make appropriate food and diet choices to reduce CVD risk (Table 3.2). Consumption of fruit and vegetables may lead to a reduced intake of SFA and dietary cholesterol. These foods also contribute dietary fiber, antioxidant vitamins, potassium, magnesium, and phytochemicals to the diet that may be cardioprotective [30]. Adults that consume fruit and vegetables tend to have a lower body weight than those that do not, although the association was weak [31]. Whole grains contribute dietary fiber, vitamin E, B vitamins, folate, and magnesium and may enhance satiety and displace refined carbohydrates in the body. Nuts provide unsaturated fatty acids (some [walnuts] are high in omega-3 fatty acids), phosphorus, magnesium, and phytochemicals; nut consumers also have lower body weights than nonconsumers. Fish, especially fatty fish, provide omega-3 fatty acids, selenium, magnesium, and vitamin D. Moderate alcohol intake is associated with some cardioprotective factors, notably elevating HDL-C levels, reducing systemic inflammation, and improving insulin resistance. Heavy habitual alcohol intake, on the other hand, is associated with ventricular dysfunction and a higher risk of atrial fibrillation [30].

Additional therapeutic dietary options for individuals with dyslipidemia that cannot meet LDL-C goals, with or without lipid-lowering medication, include plant stanols/sterols (2 g/day) [11,32] and increased viscous (soluble) fiber (10–25 g/day) [11]. Other lifestyle variables that can be modified by behavioral interventions are increasing physical activity and smoking cessation. However, the efficacy and availability of statins and other cholesterol-lowering drugs has reduced enthusiasm for behavioral modifications.

ENVIRONMENTAL AND INTERNAL FACTORS INFLUENCING FOOD BEHAVIORS

Despite the consistency of dietary recommendations across agencies and across time, the majority of Americans do not meet them [33]. On average, adults consume 11% of energy from SFA, 12%–13% of energy from MUFA, and 6%–8% of energy from PUFA [34]. Intake of whole grain [35], fruit and vegetables [36,37], and low-fat dairy [38] is also well below current recommendations.

Dietary behaviors are complex issues, and for interventions to be effective, they must not only be based on sound

TABLE 3.2
Food Recommendations (2000 kcal Diet) for Primary (MyPlate) and Secondary (DASH) Prevention of Cardiovascular Disease

	MyPlate	DASH Diet	Components that Reduce CVD Risk Factors
Total grain/whole grain	6/3 oz	6–8 servings	Whole grains contribute dietary fiber, vitamin E, B vitamins, folate, and magnesium and may enhance satiety and displace refined carbohydrates in the body. Whole grains are generally low in total fat and saturated fatty acids and sodium; no cholesterol
Fruit	2 cups	4–5 servings	High in dietary fiber, antioxidant vitamins, potassium, magnesium, and phytochemicals; low in total fat and saturated fatty acids and sodium; no cholesterol
Vegetables	2.5 cups	4–5 servings	High in dietary fiber, antioxidant vitamins, potassium, magnesium, and phytochemicals; low in total fat and saturated fatty acids and sodium; no cholesterol
Low-fat dairy	3 cups	2–3 cups	High in vitamin D, calcium, and potassium; low in total and saturated fatty acids
Lean protein[a]	5.5 oz	≤6 oz	Low in total and saturated fatty acids; fatty fish are high in omega-3 fatty acids, selenium, magnesium, and vitamin D
Nuts, seeds, legumes[b]	N/A	4–5/week	Nuts and seeds provide unsaturated fatty acids (some [walnuts] are high in omega-3 fatty acids), phosphorus, magnesium, and phytochemicals; low in sodium. Legumes are high in dietary fiber, low in total fat and saturated fatty acids and sodium; no cholesterol
Oils	6 t	2–3 servings	High in monounsaturated fatty acids

Sources: United States Department of Agriculture, MyPlate, http://www.choosemyplate.gov, accessed August 10, 2011; National Institutes of Health, National Heart, Lung, and Blood Institute, *Your Guide to Lowering Your Blood Pressure with DASH*, http://www.nhlbi.nih.gov/health/public/heart/hbp/dash/new_dash.pdf, accessed August 10, 2011.

All recommendations are per day except as noted. DASH servings of grain: 1 slice of bread, ½ cup cooked cereal, pasta, or rice, 1 oz ready-to-eat cereal; fruit: 1 piece of fruit, ½ cup cut fruit, ¼ cup dried, ½ cup juice; vegetables: 1 cup leafy green, ½ cup cooked; nuts: 1½ oz, 2 T peanut butter, ½ oz seeds, ½ cup legumes; oils: 1 t soft margarine, 1 t vegetable oil, 1 T mayonnaise, 2 T salad dressing. Sugars should be limited in both eating plans.

[a] Protein foods should be prepared using methods that minimize addition of added fats: baking, broiling, and grilling are recommended.

[b] MyPlate does not have a specific recommendation for nuts, seeds, or legumes; however, these are included in the category of protein foods.

theoretical theories and learning principles but be individualized to patients' specific environmental and behavioral factors influencing their food behaviors and food choices. Taste, cost, nutrition, convenience, and weight control have been shown to be the most important factors influencing food choice. Other contributing factors are socioeconomic status and level of education, interpersonal and cultural influences, and family influences.

Although it is assumed that individuals have the freedom to choose a healthy lifestyle, food choices are often constrained by economic factors which can lead to unhealthy dietary practices [39,40]. Grains, oils, and sugar have been shown to be cheaper than vegetables and fruit [41,42]. Overall, the cost of nutritious diets was higher than less nutritious diets [43]; cost or the perceived cost of healthy foods may limit individuals' ability to consume these foods [44]. Often the cheapest easiest to prepare "convenience" foods are high in SFA, added sugars, and sodium, which are nutrients to limit in a healthy diet [45]. Supermarket availability [45], food accessibility [45], and lack of nutrition knowledge and food preparation skills [44] also affect the ability of individuals to consume a healthful diet.

Nutrition knowledge, especially as it relates to diet–disease relationships, can help promote more healthful dietary choices. Declarative and procedural knowledge are both necessary components of a nutrition intervention program [46], but neither is sufficient without the motivation and support to elicit a behavioral change. An example of declarative knowledge would be knowing the number of grams of SFA in butter or olive oil, but not knowing how to incorporate olive oil (or other oils high in MUFA) into the diet. Procedural knowledge is needed to transform declarative knowledge into behavior. Important knowledge for individuals seeking to change dietary behaviors includes shopping skills, reading nutrition labels, and food preparation skills. Knowledge of food and food sources of nutrients is also needed [47] to help improve the diet.

Nutrition labels have been referred to as "a cost-effective population-level intervention with unparalleled reach." However, it is important to ensure that the information presented is accessible and understandable to all population. Although controversial [48], front of package labels may help those individuals with time constraints [49].

Other than understanding the potential link with dietary SFA and CVD, consumers appear confused about dietary fat and the health implications of consuming dietary fats [50,51]. Consumer education has been shown to increase the knowledge of some types of fat that may increase the risk of CVD; however, knowledge of food sources remained low [52]. The SFA and *trans*-fat content of foods are provided on the Nutrition Facts label and it is important for health professionals to help individuals understand how to read these labels and to know that foods low in these fats are not necessarily healthy foods. In a survey, American consumers were asked "which types of the following specific information that relate to heart health do you look for on food or beverage labels or packages?" Responses were sodium (60%), total fat (58%), cholesterol (54%), *trans*-fat (53%), SFA (50%), and statements about heart health benefits (41%). These findings did not always translate into heart healthy behaviors; for example, only 37% of individuals surveyed used more healthful fats than *trans*-fats and only 27% reviewed information on *trans*-fats and SFA together before purchasing the product. Some consumers also substituted tropical oils for products with *trans*-fats or SFA [52].

Nutrition education has been shown to improve knowledge of the food label in a variety of populations [53,54]. Individuals with type 2 diabetes, hypertension, or hyperlipidemia who read food labels consumed less sugar and more fiber than those who did not. Also, individuals with these health problems read food labels more frequently than those without them [55]. Additional education is needed to help the general consumer and those with chronic nutrition-related diseases to read Nutrition Facts labels.

Meal structure and patterning is changing with more convenience and prepared foods consumed and fewer fresh foods used in meals. Although lack of time has been cited as a principal reason for this, use of convenience foods also depends on economic and social factors and lack of self-efficacy [47,56]. A lack of cooking or food preparation skills has also been associated with consumption of pre-prepared foods [57] where an individual has no control over the sodium content or the type or amount of fat used. Food preparation has been associated with a better diet quality and less frequent fast food intake; those who prepared food frequently were more likely to meet dietary recommendations for fat, calcium, fruit, vegetables, and whole grains than those who did not [58].

Dietary modifications for CVD can include highly restrictive and highly supervised programs, like the Pritikin Program or the Ornish Lifestyle Heart Diet or be those that are behaviorally driven, including meal replacement plans, and nutrition education, or counseling.

THE PRITIKIN PROGRAM AND THE ORNISH LIFESTYLE HEART DIET

Making successful small, stepwise changes to improve diet and physical activity can increase the confidence and motivation of most individuals. Other individuals become frustrated and lose motivation if the results of their changes are minimal. The alternative for them may be to begin with a highly restrictive diet, such as the Pritikin Program [59,60] or the Ornish Lifestyle Heart Diet [23]. The Pritikin Program is provided in a physician's office and incorporates diet (10%–15% of energy from fat, 15%–20% from protein, 65%–75% from carbohydrates), exercise, and counseling lasting 21–26 days; there is an optional residential component available for participants. The Ornish lifestyle change approach incorporates comprehensive lifestyle modifications, including exercise, a very low-fat diet (10% energy from fat), smoking cessation, stress management, and group support which is available at several centers in the United States. The Ornish Program has been demonstrated to reverse coronary atherosclerosis and reduce the number of coronary events when compared with more traditional diets [23].

Diets that focus on macronutrient content, such as the Pritikin and Ornish diets, may be deficient in micronutrients and it is important that counselors also focus on helping individuals obtain nutrient adequacy. A recent study showed that after 8 weeks on the Ornish diet, intakes of >25% of females were below the Estimated Average Requirement for vitamins A, E, and B12, magnesium, and zinc [60].

In August 2010, the Centers for Medicare and Medicaid Services approved both programs for inclusion in the list of approved intensive cardiac rehabilitation programs for Medicaid and Medicare reimbursement. To qualify for reimbursement, these programs had to demonstrate through peer-reviewed, published research that they improved patients' CVD through specific outcomes and that they significantly influenced one or more of these elements: (1) positively affected the progression of CHD, (2) reduced the need for coronary bypass surgery, and (3) reduced the need for percutaneous coronary interventions. Finally, the programs had to demonstrate significant reductions (from baseline) in five or more of the following measures: (1) LDL-C, (2) triglycerides, (3) body mass index (BMI), (4) systolic blood pressure, (5) diastolic blood pressure, and (6) the need for cholesterol, blood pressure, and diabetes medications. Intensive cardiac rehabilitation sessions are limited to 72 one hour sessions, up to 6 sessions/day, over a period of up to 18 weeks [61]. It should be noted that, per patient, the Ornish Program costs four times as much as some traditional cardiac rehabilitation programs [62], thus may not be a suitable option for all patients.

MEAL REPLACEMENT OR STRUCTURED MEAL PLANS

These are considered as nutrition counseling strategies since meal replacements help participants control food portions while attempting to modify their eating patterns. Meal replacements include over-the-counter shakes, bars, or portion-controlled frozen meals; they can be purchased in a supermarket or can be ordered by mail. They have the advantage of simplifying food choice, reducing the time planning or preparing food, reducing the temptation to overeat, and controlling portion sizes [63]. The disadvantage is that using them does not teach the patient/client meal planning or food selection or preparation skills.

Meal replacements are most commonly used for weight loss, blood sugar control in conjunction with weight loss in individuals with diabetes, or reducing dietary fat. Short-term studies have shown that prepared meal plans have shown improved cardiovascular risk factors, quality of life, dietary compliance, and nutritional adequacy [64]. One study that compared meal replacements with a self-selected diet accompanied by nutrition education information and the ability of participants to follow the National Cholesterol Education Step Diets showed a higher prevalence of those receiving meal replacements were able to meet recommendations for both Step 1 and Step 2 diets* [65].

BEHAVIORAL CHANGE THEORIES

It is important to consider the personal and environmental factors that affect consumer choices; however, these factors do not explain how patients make decisions to change behaviors. Behavioral change is based on the assumption that behavior is learned, and can be unlearned and replaced by other behaviors. Behavioral change theories and models have been proposed that account for how individuals make decisions and should be used when designing and implementing nutrition counseling programs. Three variables have been identified as key determinants of behavior [66–68]: (1) the person has committed to performing the behavior; (2) there are no environmental constraints making it impossible for the behavioral change to occur; and (3) the person has the necessary skills to make the behavioral change. These variables are common to behavioral change theories. Other factors that influence the strength and direction of the intention of the behavior include the person's attitude that the advantages of performing the behavior outweigh the disadvantages and that the person believes that he or she has the capability to perform the behavior under a variety of circumstances (self-efficacy).

Interventions that are based on a behavioral theory are more likely to be successful than those that are not and strategies that combine multiple theories are more likely to have a larger effect [2,69]. The three principal behavioral change theories used in nutritional counseling are the cognitive behavioral theory (CBT) [70–72], the transtheoretical theory [73], and the social cognitive theory (SCT) [74].

Cognitive Behavioral Theory

This theory assumes that behavior is learned and can, therefore, be unlearned through cognitive and behavioral strategies taught to patients. The CBT focuses on external factors (environmental and reinforcement) and internal factors (thoughts) [63]. The CBT uses strategies to promote dietary change that may include goal setting, self-monitoring, problem solving, cognitive restructuring, social support, relapse prevention, and contingency management [75].

Social Cognitive Theory

The basis of the SCT is that behavior is the result of the complex interaction of personal and behavioral factors, and environmental influences; the theory also acknowledges

* Step diets were the previously recommended dietary programs to reduce serum LDL-C levels and reduce the risk of CHD. They have been replaced by the Therapeutic Lifestyle Change (TLC) diet recommended by the Adult Treatment Panel III. Step 2 diets were more restrictive than Step 1 diets and were employed if patients were unable to meet their LDL-C goals on a Step 1 diet.

the ability of the individuals to alter and construct their environments to fit their needs [69]. A basic premise of SCT is that people learn not only through their own experiences but also by observing the actions of others and the results of those actions [74]. Key constructs of SCT that are relevant to health behavioral change interventions include observational learning (acquiring behaviors by watching others), reinforcement (responses to the behavior that can increase or decrease the likelihood of repeating the behavior), self-control (personal regulation of behavior), and self-efficacy (the personal confidence in the ability to perform a behavior and overcome barriers to that behavior under any circumstance) [69].

Self-efficacy can facilitate or hinder behavioral change since individuals are more likely to engage in behaviors they believe they can successfully perform and avoid behaviors in which they believe that they will be unsuccessful. Nutrition counseling strategies can strengthen patient's self-efficacy by setting goals, using demonstrations and modeling, developing skills, and providing social support and reinforcements—including self-monitoring records [63,69]. Because of its broad appeal, the concept of self-efficacy has been incorporated in several other behavioral change models, including health belief model, theory of planned behavior, and transtheoretical model [76].

Transtheoretical Theory (Stages of Change)

Introduced in 1981 to explain smoking cessation behaviors, the transtheoretical model of health behavioral change has also been used to guide a wide variety of health behavioral changes, including dietary changes. The model's core concept includes five stages of change that people pass through over time with change most likely to occur when individuals engage in the right activities for the right stage [77]. The early stages of behavioral change are precontemplation (unaware a change is needed or not planning to make any changes) and contemplation (thinking about making a change within the next 6 months). In preparation, individuals are planning to take action in the near future (within 30 days) and are taking steps to change behaviors. In the action stage, individuals have made overt change and in maintenance (usually defined as 6 months), the behavior is sustained. Individuals usually do not progress linearly through these changes of change and relapses are common depending on the motivation and self-efficacy of the patient.

It is important that clinicians working with patients tailor their message to the specific stage [78], since determining the readiness to change is a key element of effecting dietary change. This should be a standard element of nutritional counseling [78,79]; unfortunately, few clinicians do this. Patients can be categorized into a specific stage by asking questions and listening to the replies. Statements in pre-contemplation that a patient may make could include "I don't need to change the way I eat" or "I tried eating more fruit and vegetables, but I just can't." In contemplation, they might say "I've been thinking about eating healthy for awhile now." In preparation, the statement might be "I bought a new cookbook on low-fat cooking." In action, "I'm using my new cookbook and including more fruit and vegetables in the family's meals. It wasn't as hard as I thought it would be." For the patient to be in maintenance, they would need to say something like "I've been eating healthy for about 6 months, and it's become my standard now." Understanding a patient's stage of change can also help to understand barriers and enablers to dietary change.

Health Belief Model

This model is widely used in nutrition education and counseling. This model is based on the theory that patients have choices and can make appropriate decisions regarding health behaviors. In the health belief model, patients must perceive themselves as susceptible to a health threat or disease that has the potential to impact them or their lifestyle. They must also perceive that the benefits to making changes outweigh the effort of making behavioral changes. Internal and external cues motivate patients to take action and patients have the self-efficacy to accomplish these actions [80].

COMPONENTS OF SUCCESSFUL BEHAVIORAL CHANGE

Many of the behavioral theories outlined earlier have common components including goal setting, problem solving, self-monitoring, and feedback.

Goal Setting

Goal setting is appropriate for patients ready to make a change or in action or maintenance stages. Measurable goals that focus on a behavior (e.g., increasing fruit and vegetable intake) rather than a physiological target (e.g., improving LDL-C levels) are preferable since behaviors, not outcomes, are under an individual's control [2]. Setting a challenging goal, but one that can be achieved, is better than setting one that cannot be reached or is so easy that it does not provide a sense of accomplishment when it is achieved [2]. Goals should be defined in terms of a measureable outcome. Goal setting will only work if the person accepts the challenge and has the experience, self-efficacy, and necessary feedback to accomplish the behavioral changes [81]. One to three goals, depending on the needs and skills of the patient, should be set, so as not to overwhelm an individual [80]. Ideally, goals should be established jointly by the health care provider and patient; however, goals set by either can elicit the desired outcomes [2].

Common to the success of any intervention is setting reasonable and achievable specific goals rather than having either vague goals or no goals at all. An example of an appropriate goal for the end result of lowering serum cholesterol levels would be: eat oatmeal for breakfast three times a week, not increase dietary fiber [80]. As much as possible, approach

goal setting as what the client can have, not what they cannot have. Regular feedback on goal attainment is important to reinforce self-efficacy. The need for feedback typically diminishes as the patient's skills improve.

Problem Solving

Problem-solving skills provided to and practiced by the patient should address specific barriers to behavioral change related to chronic illness. It is especially important part of self-management for patients with diabetes. Glasgow et al. [82] described a specific technique for analyzing problems and developing solutions: "S—specify the problem; T—think of options; O—opt for the best solution; and P—put the solution into action." It is also suggested that patients look beyond the obvious solution and brainstorm to find multiple solutions to barriers to behavioral change [75].

Self-Monitoring

Self-monitoring is associated with improved treatment outcomes. It increases awareness of behaviors and helps to identify barriers to change; self-monitoring also identifies behavioral patterns and facilitates recognition of program progress made toward achieving a goal [2]. This entails keeping a detailed record of behaviors that influence diet or physical activity. The record may include what foods were eaten and where they were eaten; frequency, duration, and intensity of physical activity; any physical measurements, for example glucose levels; and thoughts associated with the behavior. Self-monitoring strategies can reflect the patient's self-response or external prompts, such as e-mail reminders or personal digital assistant programs can be used to help motivate patients.

Feedback

Feedback is effective in reinforcing positive behavioral changes and increasing self-efficacy [80]. Those at high risk for CVD are more likely to respond to feedback than those not receiving it [83].

MOTIVATIONAL INTERVIEWING

Lack of motivation is a major reason for backsliding on the readiness to change continuum outlined earlier in the transtheoretical model and can result in a lack of long-term behavioral change. Motivational interviewing was shown to be a highly effective strategy, especially when coupled with CBT. Goal setting, problem solving, and self-monitoring were effective strategies in helping individuals maintain behavioral changes. Motivational interviewing is a technique used by counselors to help individuals build motivation. It has been described as "a client-centered, directive method for enhancing intrinsic motivation to change by exploring and resolving ambivalence" [84]. Motivational interviewing is used to identify and resolve discrepancies between desired and actual behaviors and to increase the motivation to change behaviors. It is client-centered and adheres to the concept that behavioral change is a shared responsibility of the client and practitioner and practitioners can enhance motivation to change or contribute to resistance [85].

The principles of motivational interviewing include expressing empathy, which suggests an acceptance and understanding of the client's perspective and situation; developing discrepancy, which emphasizes the discrepancy between present behavior and goals can facilitate change; avoiding escalating resistance from the client and, if present, changing strategies to assist change; rolling with resistance or provide a comfortable atmosphere for change; and supporting self-efficacy since confidence in the ability to make changes or achieve goals is a powerful motivator [80,84].

Motivational interviewing is an evidence-based counseling strategy that builds on several behavioral theory models, including the transtheoretical model of change, and is best applied to individuals who are not ready to change behaviors (pre-contemplation, contemplation, or preparation) or are unwilling or are ambivalent about changing diet or lifestyle. Reflective listening, eliciting self-motivational statements, and asking open-ended questions to elicit self-motivational statements are specific strategies that can be used [80]. Although developed originally for individuals with substance abuse, motivational interviewing has been used effectively to reduce energy [86] and sodium [87] intake and to increase intake of fruit and vegetables [88]—all of which would be important in counseling patients with CVD. It is less clear if behavioral changes can be sustained over time and what the overall effect on health is. Motivational interviewing and health-promoting behaviors have been recently reviewed [89].

MULTICULTURAL COUNSELING

The majority of conventional theories that guide behavioral change strategies were developed by white males of European descent; they may have gender and cultural limitations and may not consider the influence the family has on the patient. Although all counseling occurs in a cultural context, counseling is only considered multicultural or cross-cultural when the counselor is of a different racial/ethnic group than the individual receiving the counseling. Effective multicultural counseling requires flexible techniques and training in cultural sensitivity and cultural norms [80]. This issue becomes more complex when individuals indentify with more than one culture. As the United States moves to a racial/ethnic plurality, it is critical that more individuals be competent in cross-cultural counseling and that more individuals from different races/ethnicities become health professionals.

It is vital to develop cultural strategies to address the needs of specific groups. It is also important to consider all patients as individuals. For example, Latinos in the United States come primarily from Mexico, but they also come from all Central and South American countries and the countries of the Caribbean. Knowledge, attitudes, and beliefs, as well

as food, the role of the family in food and health norms, and languages spoken and understood may be different. The level of literacy, including health literacy, and acculturation, or the process by which immigrants adopt the attitudes, beliefs, and dietary practices of the host country, must be considered and how complete any acculturation is [90].

Latinos are the largest ethnic minority in the United States; they are at high risk for developing diet-related chronic diseases, including CVD. A recent review suggested that there was no relationship between intake of dietary fat and percent energy from fat and that less acculturated individuals consumed more fruit, rice, beans, and whole milk and less sugar, sugar-sweetened beverages, snacks, and added fats [91]. Dietary acculturation may have a negative effect on the diet and health of immigrants and places them at higher risk for developing diet-related chronic diseases [90–92]. Although it is important for counselors to develop cultural sensitivity, this was not sufficient for a successful intervention and it needed to be combined with behavioral change strategies and awareness of the individuals' socioeconomic status [90].

ROLE OF HEALTH CARE PROVIDERS IN DIETARY INTERVENTIONS

The majority of individuals seeking to change dietary behaviors to reduce the risk of CVD do not choose either highly restrictive programs or meal replacement programs. Many of those interested in dietary change rely on group or individual education or counseling by health professionals, including physicians and RDs.

Healthy People 2020 [5] has as a goal to "Increase the proportion of physician office visits made by patients with a diagnosis of cardiovascular disease, diabetes, or hyperlipidemia that include counseling or education related to diet and nutrition" from 20.8% to 22.9% (+10%). Physician advice is highly valued by patients [93], presenting an ideal opportunity to provide counseling to patients about reducing risk factors of CVD. Those receiving advice about dietary change from a physician were more likely to report a healthy diet than those not receiving this advice [94].

Family physicians and general internal medicine physicians screen for CVD risk factors and may provide initial advice on lifestyle changes to patients who present with risk factors, such as high LDL-C or low HDL-C levels. Sixty-one percent of individuals surveyed by the Academy of Nutrition and Dietetics (AND) [95] cited physicians as very credible sources on nutrition. Paradoxically, the same survey showed that only 10% of respondents used physicians as a source of nutrition information—physicians ranked lower on this question than the Internet (~25%) or family and friends (~20%).

The link between nutrition and chronic disease is widely understood by physicians and they can be effective counselors for patients with CVD [96]. However, many physicians do not feel prepared to do nutrition counseling with their patients [97] or do not believe that nutrition counseling is one of their responsibilities [98]. Most physicians have not been trained in nutrition counseling, and barriers to physician counseling for CVD and CVD risk factors include lack of time and compensation [98], nutrition knowledge [97,98], low self-efficacy [97], lack of knowledge of the guidelines [99], ineffective communication between doctors and patients [99], and "clinical inertia" [100].

During an office visit, a patient spends only about 10 min with a physician [101], suggesting that time is a principal barrier to effective nutrition counseling. Referral of patients with dyslipidemia, CHD, or hypertension to an RD can expand the time available for a counselor to spend with a patient. Implementing the nutrition care process [102], the RD can provide quality theory-driven interventions and provide patients with effective nutrition interventions to reduce CVD risk [103]. Overall, however, providing nutrition information is a shared responsibility among physicians, RDs, and other health professionals [11].

EFFECTIVENESS OF NUTRITION INTERVENTIONS: THE EVIDENCE

The AND's Evidence Analysis Library (EAL) Nutrition Counseling Workgroup recently conducted a systematic review of the literature related to behavioral change theories and strategies used in nutrition counseling [63]. They found that there was strong evidence to support the use of a combination of behavioral theory and CBT in facilitating behavioral change targeted to dietary habits, weight, and cardiovascular risk factors. The evidence was fair that problem-solving strategies were effective for diet management and weight loss, but the EAL noted that the studies available were small and limited to women. The effectiveness of client self-selected behavioral goal setting and goal attainment intervention was also validated. There was little evidence that cognitive restructuring was effective in patients without eating disorders and there was no evidence that stress management or stimulus control were effective strategies in eliciting behavioral change. The EAL also found that the evidence was fair that group counseling was more effective than individual counseling and that short-term CBT (less than 6 months) could result in long-term behavioral changes.

Nutrition Care Process

In 2003, the AND published the Nutrition Care Process, which they termed "a road map to quality care and outcomes management" [102]. The four steps of the nutrition care process are (1) nutrition assessment, (2) nutrition diagnosis, (3) nutrition intervention, and (4) nutrition monitoring and evaluation. Nutrition assessment has five domains: food/nutrition-related history; anthropometric measurements; biochemical data, medical testing, and procedures; nutrition-focused physical findings; and client history. It is essential that a counselor understands these components for effective counseling and to be able to help the client/patient be able to set the behavior goals that will help

them meet the ultimate health outcome goals, such as weight loss or lowering LDL-C levels. Nutrition diagnosis has three domains within which the problems fall: intake, clinical, and behavioral/environmental. From the standpoint of behavioral counseling, understanding behavioral/environmental aspects of the client, their family, and their living situation will help the client address potential barriers and find unique solutions to these barriers. There are four domains of nutrition intervention: food or nutrient delivery, nutrition education, nutrition counseling, and the coordination of nutrition care. Nutrition monitoring and evaluation terms are coupled with the first four domains of nutrition assessment [102,104].

The nutrition education domain is further divided into content with instruction intended to lead to nutrition knowledge, and application, with "training intended to lead to nutrition-related result interpretation or skills." Nutrition counseling, on the other hand, is defined as "a supportive process, characterized by a collaborative counselor-patient/client relationship, to set priorities, establish goals, and create individualized action plans that acknowledge and foster responsibility for self-care to treat an existing condition and promote health." This domain is divided into a theoretical basis approach and strategies [104]. Nutrition education or counseling is critical to elicit long-term dietary change.

Client/Patient and Health care Professional Contact

Nutrition counseling can be provided to individuals or groups and in single or multiple sessions. The advantage to group counseling is that individuals can learn from each other and provide support to group members. The disadvantage is that less time is available to address individual problems. Group counseling tends to be more effective than individual counseling [63].

Multiple sessions tend to be more effective than single sessions since frequent contact helps to establish trust between the patient and provider, which is especially important among racial/ethnic minorities. Continued contact can also help patients progress through stages of change, provide patients with multiple skills, and allow for follow-up that can reinforce positive behavioral change. Ongoing contact can be face-to-face, via the telephone, e-mail, or the Internet. As contact decreases, new behaviors may wane and actually cease if contact stops. The majority of interventions that induce long-term behavioral changes involved multiple contacts [2].

Long-Term Dietary Change

Despite consistent health messages, the general public may not make dietary changes to improve their health; thus, nutrition interventions are critical, especially for those with chronic disease or risk factors for chronic disease [105]. To be effective in reducing CVD risk factors, nutrition interventions need to influence behaviors that are sustainable. When patients and health professionals are setting goals, it is important to consider short-term, as well as long-term goals. For most patients that follow a diet to reduce CVD risk factors, significant reductions have been shown within 4–6 weeks and cholesterol reduction goals can be met within 3 to 6 months [106]. With a well-designed intervention, highly motivated individuals can sustain reduced fat intake and increased intake of fruit, vegetables, and fiber for 12 months, but for most, sustaining changes over longer periods was less successful [105].

It is clear, however, that long-term dietary changes to reduce CVD risk factors can be made by population and by individuals. Perhaps the most dramatic example of a population change was the 80% decline in coronary mortality in Finland. This reflects principally the "great" reduction in risk factors, including declines in serum cholesterol levels, blood pressure, and smoking prevalence. The greatest change in health behaviors was diet—including the type and amount of fat consumed and the intake of fresh fruit and vegetables. These changes were associated with long-term chronic disease prevention and health promotion interventions. It is unclear why the change in risk factors among the Finns is so much better than in other population, although it may be related to the collaboration among health services, nongovernmental organizations, and industry [107].

CONCLUSION

Facilitating dietary changes that reduce the risk of CVD can reduce the disease and cost burden to the United States. Dietary changes should be theory driven and individuals should be provided with the knowledge and skills to facilitate and maintain these changes. Self-efficacy and sustained motivation must compliment the knowledge and skills provided to the patient.

Cardiovascular disease (CVD), as defined by the Centers for Disease Control and Prevention (CDC), encompasses coronary heart disease (CHD), stroke, hypertension, and heart failure (HF).[1] Nearly 2400 Americans die from some manifestation of CVD every day; approximately one in every 37s.[1] CVD has been the leading cause of death since 1900 and remains so despite a decade-long decline in CVD mortality.[1]

Data from the National Heart, Lung, and Blood Institute predict that some 785,000 Americans will experience a first myocardial infarction this year and approximately 470,000 will be the victim of a reinfarction.[1] Of these, it is estimated that 21% will be "silent" with no symptoms or symptoms other than angina which are missed or ignored.[1] The relative risk of CHD attributable to physical inactivity ranges from 1.5 to 2.4, an increase in risk similar to that estimated for high cholesterol, hypertension, or cigarette smoking.[1] Given that more than half of all Americans do not engage in regular physical activity of even moderate intensity with nearly 1 in 4 reporting no leisure-time physical activity (LTPA)[2] and that the greatest reduction in risk for CHD appears to be for those engaging in even modest amounts of physical activity compared with the most physically inactive,[3] even relatively small increases in physical activity could potentially result in a significant decrease in CHD for a large portion of the American population. For example, epidemiological data suggest that the estimated 2.3% decline in physical inactivity between 1980 and 2000 prevented or at least postponed 17,445 deaths due to CHD in the United States.[4]

In spite of the overwhelming evidence implicating physical inactivity as an important and significant risk factor for CHD, fewer than half of adults meet even the minimum recommendation for aerobic exercise.[5] Statistics for young people are even more alarming with fewer than 20% of adolescents performing the recommended ≥60 min of daily physical activity.[6]

Despite the documented lack of physical activity in the United States, and the well-established benefits of regular exercise, many physicians are not encouraging their patients to exercise and lose weight.[7–9] Of equal importance, they do not appear to be adequately prepared to provide recommendations for exercise and physical activity. For example, a survey of 175 primary care physicians revealed that only 12% were aware of the recommendations of the American College of Sports Medicine (ACSM) for physical activity.[9] An evaluation of 51 internal medicine residents reported that while 88% were confident in their knowledge of the benefits of exercise, only about 25% demonstrated adequate knowledge useful for patient counseling.[10]

Health care professionals need to promote physical activity with all of their patients. In that regard, an understanding of the health benefits associated with physical fitness and regular physical activity is fundamental. This chapter reviews the evidence linking greater physical activity and fitness with primary prevention of cardiovascular and metabolic disease through effective risk factor management. Recommendations for exercise are also provided both in general terms and for specific conditions.

PHYSICAL FITNESS VERSUS PHYSICAL ACTIVITY

Physical fitness, specifically cardiorespiratory fitness, is defined here as the ability to deliver and utilize oxygen during sustained activity and typically quantified as maximal oxygen uptake (VO_{2max}). When respiratory gases are measured with a metabolic cart during a maximal graded exercise test, VO_{2max} is valid and reliable. However, submaximal tests or those relying on indirect measures such as time to exhaustion are subject to considerable error. Measures of physical activity, on the other hand, usually rely on retrospective self-reported data (i.e., physical activity questionnaires). Nonvocational or LTPA is most commonly assessed. Vocational physical activity, household chores, and biking or walking to work are also sometimes quantified but less often. The definitions of physical activity vary greatly from study to study and the components of physical activity or exercise such as intensity, duration, and frequency are often not reported or inadequately assessed.

The categorization of physical activity (i.e., low, moderate, or high) also varies from study to study. Many studies use different criteria for moderate- and vigorous-intensity exercise or activity. ACSM defines moderate physical activity as any activity requiring 50%–70% of VO_{2max} or maximal heart rate.[11] Vigorous physical activity is anything greater than 70% VO_{2max} or maximal heart rate.[11] Walking or brisk walking is generally recommended as the type of exercise that meets the criteria for moderate physical activity. However, it is important to understand that the intensity of walking, or any exercise for that matter, is relative to an individual's age, physical condition, and fitness level. For example, based on the ACSM Guidelines for Exercise Testing and Prescription,[11] even brisk walking may not be of sufficient intensity to meet the minimum criteria for moderate physical activity in a normal, healthy individual of college age. Conversely, brisk walking might be considered vigorous activity for someone over the age of 65 years. As such, any exercise recommendations should be applied relative to the individual's capabilities and limitations.

Surprisingly, physical fitness has been shown to be only modestly correlated with physical activity with correlations ranging from 0.09[12] to 0.60.[13] In a meta-analysis of 7 physical fitness and 16 physical activity cohorts cited in the 1996 Surgeon General's Report,[14] Williams[3] found that the risk of CHD or CVD decreased linearly with increasing percentiles of physical activity. He also found that the reduction in risk for CHD or CVD associated with increasing percentiles of physical fitness demonstrated a precipitous decrease occurring just before the 25th percentile of the physical fitness distribution. Further, at all ≥25th percentiles, the reduction in risk for CHD and CVD was significantly greater for physical fitness compared to physical activity (Figure 4.1).

These findings are supported in a more recent comparison of fitness versus physical activity in predicting all-cause mortality in a cohort of 842 men referred for exercise testing.[12] While both physical activity and fitness were strong predictors of all-cause mortality, physical fitness was a stronger predictor of mortality than activity level. A 1000 kcal/week increase in physical activity was found to be similar to a 1 MET (metabolic equivalent; oxygen uptake of 3.5 mL/kg/min) improvement in fitness with both conferring a 15%–20% reduction in mortality. Of equal, if not greater, interest, these data also demonstrated that 40% of the reduction in mortality occurred between the least active or fit and the next least fit or active groups suggesting that even modest increases in physical activity or fitness, especially in those who are inactive, may result in a significant reduction in mortality.

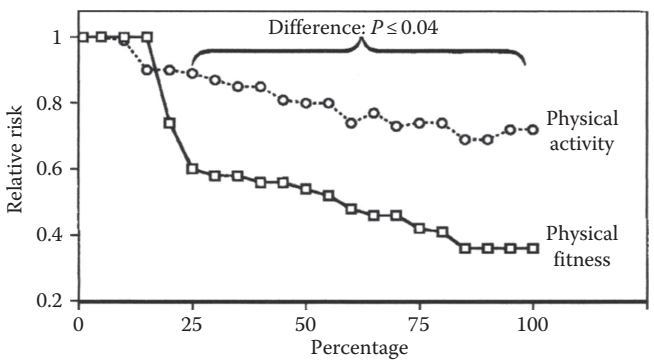

FIGURE 4.1 Estimated dose–response curve for the relative risk of either CHD or CVD by sample percentages of fitness and physical activity. Studies weighted by person-years of experience.

GENERAL RECOMMENDATIONS FOR PHYSICAL ACTIVITY

In 1996, the Surgeon General's Report on Physical Activity and Health recommended "people of all ages to include a minimum of 30 min of physical activity of moderate intensity (such as brisk walking) on most, if not all, days of the week. It is also acknowledged that for most people, greater health benefits can be obtained by engaging in physical activity of more vigorous intensity or of longer duration."[14] More recently, the 2008 Physical Activity Guidelines for Americans[15] provide updated and more specific recommendations for different age groups and some clinical population. Following is a very brief summary of their recommendations:

Adults

- All adults should avoid inactivity. Some physical activity is better than none, and adults who participate in any amount of physical activity gain some health benefits.
- For substantial health benefits, adults should do at least 150 min/week of moderate-intensity, or 75 min/week of vigorous-intensity, aerobic physical activity, or an equivalent combination of moderate- and vigorous-intensity aerobic activity.
- Adults should also do muscle-strengthening activities that are moderate or high intensity and involve all major muscle groups on ≥2 days a week, as these activities provide additional health benefits.

Children and Adolescents

- Children and adolescents should do 60 min (1 h) or more of physical activity daily.
- *Aerobic*: Most of the ≥60 min a day should be either moderate- or vigorous-intensity aerobic physical activity and should include vigorous-intensity physical activity at least 3 days a week.
- It is important to encourage young people to participate in physical activities that are appropriate for their age, that are enjoyable, and that offer variety.

Older Adults

- When older adults cannot do 150 min of moderate-intensity aerobic activity a week because of chronic conditions, they should be as physically active as their abilities and conditions allow.
- Older adults should do exercises that maintain or improve balance if they are at risk of falling.
- Older adults should determine their level of effort for physical activity relative to their level of fitness.
- Older adults with chronic conditions should understand whether and how their conditions affect their ability to do regular physical activity safely.

WOMEN AND CHD

About 8.4 million women in the United States have a history of heart attack, angina pectoris, or both. Of these, 3.5 million have a history of myocardial infarction.[1] Each year over 350,000 women will have a new or recurrent MI.[1] Twenty-three percent of women age 40 and older die within a year after their first MI compared with 18% of men.[1] Because women typically have heart attacks at older ages than men do, they are more likely to die from them within a few weeks.[1]

Despite these overwhelming statistics, surveys indicate that some 43% of women still do not know that CHD is by far the number one killer of women in the United States.[1] And while regular physical activity has been demonstrated to significantly reduce the risk of CVD in women, they are on average less physically active than men with only 53.1% of women compared with 60.3% of men engaging in moderate to vigorous activity ≥3 days/week.[5]

Although a greater exercise volume and/or intensity appears to produce greater health benefits for most people, the literature examining the relationship between exercise intensity and risk for CHD is not unequivocal.[3] A meta-analysis of 16 gender-specific physical activity cohorts found that the risk for CHD decreased linearly with increasing percentiles of physical activity but examination of the individual cohorts revealed considerable variation in the outcomes.[3] This inconsistency in findings has been observed elsewhere[17] and may reflect real differences in study cohorts differing in age, gender, level of fitness, and other important factors but has also been ascribed to differences in study design. For example, in the 16 studies he examined, Williams[3] found that the intervals (tertiles, quartiles, etc.) reported, differed greatly with nine studies using three levels, six using four levels, and one study using six levels.

Despite issues related to study design, there is evidence to suggest that the dose–response relationship between exercise intensity and risk for CHD or mortality may differ between men and women.[16–20] For example, based on data from the Nurses Health Study, a cohort of 72,488 female nurses 40–65 years old, Manson et al.[17] concluded that "the reduction in risk for CHD for women who walked at a brisk pace ≥3 h/week was similar to those women who engaged in regular vigorous (≥6 MET) exercise." Data from the Women's Health Study[16] showed that walking 1–1.5 h/week was associated with a 51% reduction in risk for CHD but walking ≥2 h/week conferred no greater reduction in risk. More vigorous activity was not associated with a lower risk for CHD, comparing highest with lowest. Similarly, the relationship between walking pace and risk for CHD did not demonstrate a linear trend.

Other studies have not demonstrated an association between physical activity/inactivity and CHD and/or mortality in women with one review reporting no relationship between physical inactivity and CHD in 10 of 14 studies.[18] More recently, Blair et al.[19] found that all-cause mortality rates in women did not differ across the range of physical activity levels. The Framingham

Study also found no association between physical activity level and mortality in women.[20]

Therefore, it would seem that the risk reduction associated with physical activity is variable, depending on the study population. As such, the apparent gender differences in the response to physical activity may be mediated by the physical activity levels of the study participants. As an example, the most active 20% of women in the Women's Health Study expended ≥1500 kcal/week in LTPA whereas men in highest quintile of physical activity in the Harvard Alumni Health Study reported expending ≥3129 kcal/week in LTPA.[3]

The relatively limited data on the relation between physical fitness, and risk for CVD and/or mortality in women suggests a greater similarity with studies of men, when compared with studies of physical activity. For example, data from the St. James Women Take Heart Project demonstrated a 17% reduction in mortality for every 1 MET increase in exercise capacity.[21] As such, it would appear that women who engage in exercise vigorous enough to improve aerobic fitness gain health benefits comparable to their male counterparts.

STROKE

While the incidence of stroke has been declining, it is estimated that 795,000 people in the United States experience a new (~610,000) or recurrent (~185,000) stroke each year.[1] Of these, the large majority are ischemic (~87%) with the remainder being hemorrhagic in nature.[1] The risk of a stroke for African Americans is nearly double that for Caucasians and tends to occur at a younger age.[1] Hispanics, particularly Mexican Americans, have significantly higher rates of ischemic stroke and at a younger age.[1] Annually, 55,000 more women than men have a stroke with the incidence in women aged 45–54 years especially high.[1]

Some 200,000–500,000 transient ischemic attacks (TIAs) are estimated to occur in the United States each year and the incidence is higher in men, African and Mexican Americans.[1] The occurrence of a TIA increases the risk of a stroke both short term and long term.[1] Approximately 15% of all strokes are preceded by a TIA and about 12%–13% of individuals will die within a year of a TIA.[1]

The most important risk factors for stroke include history of TIA, preexisting CHD, age, hypertension, diabetes mellitus (DM), cigarette smoking, and atrial fibrillation.[1] Physical inactivity has also been shown to increase the risk of a stroke and stroke mortality but its relationship to cerebral events is less well understood than that for CHD.[1] Meta-analyses have shown that the reduction in risk for stroke associated with aerobic exercise/activity ranges between 20% and 40% depending on the type of stroke and study design.[22,23] The benefit for women is less clear and may not be as great as that for men.[22] It remains unresolved as to whether or not a dose–response relationship exists between level of physical activity and stroke risk. While those studies that looked at different levels of physical activity generally found a greater benefit for higher levels of physical activity, there was a real lack of consistency in their findings.[22] In addition, the criteria for different levels of physical activity are not uniform, varying from study to study and often poorly quantified. As such, an exercise prescription to optimize the reduction in risk for stroke remains undetermined. Currently, the American Heart Association (AHA) recommends moderately intense aerobic physical activity for *at least* 30 min/day to reduce the risk of ischemic stroke.[24] While there is evidence that greater muscular strength in youth is associated with a modestly reduced risk (~5%–10%) for stroke later in life,[25] the relationship between muscular strength, strength training, and stroke risk remains virtually unexplored.

HYPERTENSION

Based on data from the National Health and Nutrition Examination Survey (NHANES), the AHA estimates that over 76 million adults or almost 1 in 3 American adults suffer from hypertension (systolic blood pressure [SBP] ≥140 mm Hg and/or diastolic blood pressure [DBP] ≥90 mm Hg).[1] Approximately 69% of individuals who have a first myocardial infarction, 77% of those who suffer a first stroke, and 74% of those who have HF are hypertensive.[1] A meta-analysis of 61 studies involving more than 1 million individuals demonstrated that mortality associated with both ischemic heart disease (IHD) and stroke increases linearly from levels as low as 115 mm Hg SBP and 75 mm Hg DBP.[26] For every 20 mm Hg SBP or 10 mm Hg DBP increase in blood pressure, there is a doubling of mortality from both IHD and stroke.[26] Those with hypertension have a shorter life expectancy, shorter life expectancy free of CVD, and can expect to live more years with CVD compared with those who are normotensive.[1]

Regular physical activity has been shown to be an effective way to lower blood pressure in 75% of persons with hypertension.[27,28] Compared with sedentary adults, those who are physically active have a lower incidence of hypertension,[29–31] with blood pressures that average 5 mm Hg lower.[32] Higher levels of occupational and/or LTPA are associated with lower BP.[27,31,33] These data have led to recommendations for regular physical activity as lifestyle therapy for the prevention and management of hypertension.

The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VII)[33] recommends regular aerobic physical activity such as brisk walking at least 30 min/day, most days of the week for the prevention and management of hypertension. In a meta-analysis of 44 trials of at least 4 weeks duration and after controlling for other factors, increased physical activity was associated with a small but significant decrease of 3/2 mm Hg in normotensive subjects and 7/6 mm Hg in hypertensive subjects.[34] The training intensity in these studies averaged 65% of heart rate or VO_2 reserve. However, the characteristics of the training programs (intensity, duration, and frequency) explained less than 5% of variance in blood pressure response. Weekly energy expenditure was not significantly related to the changes in SBP or DBP. Vigorous exercise was not found to be different from moderate-intensity exercise in its ability

to reduce blood pressure, with some studies showing that exercise at 40% of VO_2 reserve to produce a greater reduction in SBP than exercise at 65%–75% of VO_2 reserve.[35,36] As such, and per JNC VII, regular moderate-intensity exercise is recommended for the prevention and management of hypertension.

Resistance Exercise Training and Blood Pressure

Resistance training is generally recommended as an adjunct to aerobic activity. On average, studies have reported 3 mm Hg reductions in resting SBP and DBP following progressive weight-lifting programs.[30,37–39] Although this decrease may seem small, a 3 mm Hg reduction lowers the risk of CHD, stroke, and all-cause mortality.[30] Two to three days per week of total body resistance training is generally recommended.[16,40–42] However, as with aerobic exercise, the "optimal" exercise prescription for strength training is not known. More specifically, low- to moderate-intensity strength training (30%–40% of a 1 repetition maximum [1RM] for upper body exercises, and 50%–60% 1RM for lower body exercises) is currently recommended by some for the prevention and management of high blood pressure.[27,42] Rezk et al.[43] showed that both single bouts of high- or low-intensity resistance exercise lower SBP, but only low-intensity training lowered DBP. Other studies reported that high-intensity resistance training reduced neither SBP nor DBP, and actually raised SBP in some individuals.[44]

The currently recommended strength training program to optimize BP reduction is 1–3 sets of 10–15 repetitions for each of the major muscle groups (thighs [hamstrings and quadriceps], hips, back, chest, arms, and abdominals), 2–3 days/week.[30,42]

HEART FAILURE

It is estimated that some 5 million Americans suffer from HF (also known as congestive heart failure).[1] The risk of developing HF increases with age; by the age of 40 years, both men and women have a one in five risk of developing HF some time in their lives.[1] Both the incidence and prevalence of HF are particularly high in minorities, especially African Americans.[1] HF occurs earlier and mortality is higher in African Americans, compared to Caucasians.[1]

Surprisingly, few studies have examined the relationship between physical activity and primary prevention of HF. Two large longitudinal studies exploring this association found that compared to sedentary individuals, those who engaged in regular vigorous exercise had a 15%–35% lower risk for developing HF.[45,46] Vigorous activity was defined as activities "vigorous enough to work up a sweat"[45] such as running, jogging, swimming, heavy gardening, or competitive sports.[46] The reduction in risk was correlated with the frequency of vigorous exercise in a dose–response manner.[45] Activity of a moderate intensity, defined as >4 h/week of walking, cycling, or light gardening was associated with ~15% reduction in risk.

DIABETES

The latest available data from NHANES estimates that 12.9% of Americans over the age of 19 years have DM, of which >90% are classified as Type II (T2DM).[47] Insulin resistance (IR) often precedes the onset of T2DMM and is prevalent in the prediabetic states of impaired fasting glucose (IFG) and impaired glucose tolerance (IGT). Nearly 30% of Americans are classified as prediabetic with IFG and/or IGT.[47] This means that more than 40% of all adults have some degree of abnormal glycoregulation.[47] The prevalence of CHD has been estimated to be as high as 55% in adult diabetics and T2DM is an independent risk factor for myocardial infarction and CVD in both men and women.[48,49] T2DM is a predictor of ischemic stroke and HF, and DM increases the overall CV risk in patients with preexisting HF.[50,51] Compared to nondiabetics, mortality from CHD has been reported to be twice as great in diabetic men and four to five times greater in diabetic women.[52] CVD is responsible for at least two-thirds of deaths in adults with DM.[52]

Metabolic Syndrome, CVD, and T2DM

The clustering of risk factors known as the metabolic syndrome (see section later for definition and more information) is predictive of both T2DM and CVD. It is associated with a twofold increase in the risk for cardiovascular events and a fourfold increase in the development of T2DM.[53] Abdominal obesity in particular is an independent risk factor for IR[54,55] and T2DM.[56] Much of the increased risk of CHD and CVD associated with T2DM can be attributed to the presence of the metabolic syndrome.[57] One study reported 10 year cardiovascular mortality to be 3.55 times greater in men with metabolic syndrome compared to those without the condition.[58]

Numerous studies have demonstrated an inverse relationship between physical activity and/or fitness and the risk for developing T2DM.[59–67] Men of low fitness have a two to three times greater risk of developing T2DM compared to those in the higher fitness categories.[59,60] Similarly, physical activity shares an inverse relationship with the risk for T2DM in a dose–response manner. Even just daily walking for more than 30 min has been shown to reduce the risk of developing T2DM by 20%–45%.[63,66–69] Brisk/faster walking was associated with a lower risk independent of time spent walking.[63,66,67] In an interventional trial involving 18 previously sedentary middle-aged men and women, 6 months of walking (minimum of 3 days/week for 30 min) resulted in improved insulin sensitivity.[70] Sedentary behaviors such as excessive television watching have been demonstrated to increase the risk for T2DM even after – controlling for diet and physical activity levels. It has been estimated that 43% of new cases of diabetes could be prevented by watching TV less than 10 h/week and engaging in brisk walking for ≥30 min/day.[68] Modest improvements in diet and exercise habits have been shown to reduce the incidence of T2DM even in those at highest risk for developing it—those with IFG and/or IGT.[71–73]

Glycemic Control

Studies of aerobic exercise training have shown significant but modest reductions in glycosylated hemoglobin (HbA1C, long-term index of glycemic control) of about 8% from baseline.[74,75] The exercise intensity in these studies accounted for almost 83% of the differences in post-intervention HbA1C compared to 21% determined by exercise volume. Those interventions with an intensity >65% of VO_{2max} demonstrated the greatest improvement in HbA1C. As such, exercise interventions for glycemic control should include some vigorous exercise.[76]

Strength Training

Resistance training, especially in combination with aerobic exercise training, can significantly improve HbA1C levels, fasting blood glucose, and insulin sensitivity.[77] Additionally, other risk factors, such as blood pressure, have been shown to be significantly reduced in diabetics with a program combining strength and aerobic training compared with either aerobic or resistance training alone.[77] As such, The American Diabetes Association now recommends strength training, in addition to aerobic exercise training as part of a program to prevent or manage T2DM.[78] Weight training has been found to be safe in persons with CVD, ST depression, myocardial ischemia, ventricular dysrhythmias, and other cardiovascular complications.[78] The myocardial demands of high-intensity weight training are comparable to activities such as stair-climbing, walking uphill, or carrying 20–30 lb of groceries.[78]

Following are some of the specific recommendations from the American Diabetes Association Consensus Statement on Physical Activity/Exercise and Type II Diabetes[78]:

- People with IGT should begin and continue a program of weight control, including at least 150 min/week of moderate to vigorous physical activity and a healthful diet with modest energy restriction.
- To improve glycemic control, assist with weight maintenance, and reduce risk for CVD, the panel recommends 150 min/week or more of moderate-intensity aerobic physical activity and/or 90 min/week or more of vigorous aerobic exercise. The physical activity should be distributed over at least 3 days/week, with no more than two consecutive days without physical activity.
- Compared with lower volumes of activity, performing at least 4 h/week of moderate to vigorous aerobic and/or resistance exercise is associated with greater CVD risk reduction.
- For long-term maintenance of major weight loss (≥13.6 kg or 30 lb), larger volumes of exercise (7 h/week of moderate or vigorous aerobic physical activity) may be helpful.
- Unless contraindicated, people with type 2 diabetes should be encouraged to perform resistance exercise three times per week, targeting all major muscle groups. This should progress to 3 sets of 8–10 repetitions at a weight that cannot be lifted more than 8–10 times. Initial supervision and periodic reassessments by a qualified exercise specialist are recommended to ensure that resistance exercises are performed correctly, to maximize health benefits, and to minimize the risk of injury.

OBESITY

Based on the most recent data from the NHANES, and using body mass index (BMI, body weight in kg/(height in m)^2) as the criterion measure, the prevalence of overweight and obesity in the United States continues to rise and has increased significantly just from 1999 to 2008.[79] In adults, overweight is defined as a BMI of 25–29.9 kg/m^2. Obesity is defined as a BMI ≥ 30; extreme (formerly morbid) obesity is defined as a BMI ≥ 40. Among men, the prevalence of obesity increased from 27.5% in 1999–2000 to 31.1% in 2003–2004 to 32.2% in 2007–2008.[79] In women, the prevalence of obesity was even higher: 33.4% in 1999–2000 to 33.2% in 2003–2004 to 35.5% in 2007–2008.[79] The prevalence of extreme obesity also rose from 2003–2004 (2.8% for men and 6.9% in women) to 2007–2008 (4.2% for men and 7.2% for women).[79] Finally, differences in the prevalence of obesity by race/ethnicity continued with 44.1% and 39.3% reported for non-Hispanic blacks and Mexican Americans, respectively.[79]

Over the last two decades, it has become increasingly apparent that abdominal adipose tissue has unique metabolic properties and may be more predictive of CVD, metabolic syndrome, and diabetes than BMI or measures of overall adiposity.[80–84] Abdominal or central obesity is most commonly assessed by measuring waist circumference or waist-to-hip ratio (WHR). From 1988–1994 to 1999–2000 (most recent data available), mean waist circumference of adult Americans increased from 95.3 to 98.6 cm in males and from 88.7 to 92.2 cm in females.[85]

Despite these rather alarming trends, only 40.3% of obese patients were advised to lose weight by their family physician in 2004, down from 42.3% in 1994.[86] An evaluation of an academic pediatric hospital found that only little more than half (53%) of the children who met the NHANES criteria for overweight (≥95th percentile for BMI) were identified as such by their primary care physician.[87] Interestingly, while a majority (69%) of the children's charts contained an "adequate" dietary history, only 15% included information regarding physical activity and/or television watching.

Central Adiposity, Inflammation, and CVD

Atherosclerosis has now come to be understood as an inflammatory disease.[88–91] A growing body of evidence further demonstrates that greater adipose tissue mass, especially visceral adipose tissue, directly contributes to systemic inflammation.[92–94] The proinflammatory state associated with abdominal obesity has been proposed as a common

underlying condition linking CVD, IR/type 2 diabetes, and the metabolic syndrome.[95–97] While a complete discussion of the complex physiology and mechanisms of adipose-related inflammation is beyond the scope of this chapter, it is increasingly evident that visceral adipose tissue secretes a veritable host of proinflammatory cytokines. Greater levels of central adiposity have been shown to be associated with higher circulating levels of these proinflammatory proteins such as interleukin-6 (IL-6), tumor necrosis factor α (TNF-α), and C-reactive protein (CRP).[98–100]

A published review of lifestyle interventions and systemic inflammation observed that 9 of 12 studies reviewed demonstrated an inverse relationship between physical activity or fitness and markers of inflammation, after controlling for BMI or other measures of adiposity.[101] For example, in a 20 year follow-up of 4252 elderly men (aged 40–59 at baseline), Wannamethee et al.[102] found that physical activity level was inversely associated with levels of CRP and other inflammatory markers, even after adjusting for BMI and other covariates. In those men who went from "at least lightly active" to inactive, the levels of these markers were similar to those men who had been inactive throughout the follow-up period. Those who were inactive at baseline but increased their level of activity had levels similar to those men who had remained continuously active.

The HERITAGE Family Study examined the effects of 20 weeks of exercise training on CRP levels in 652 sedentary, but healthy, adults.[103] The training program was performed on cycle ergometers 3 days/week progressing to 50 min at 75% of baseline VO_{2max}. This protocol resulted in a substantial (17.8%) increase in VO_{2max}. However, reduction in CRP levels occurred only in the individuals with high baseline levels of CRP. The positive relationship between baseline CRP levels and exercise-induced changes has been observed elsewhere[104] and may explain, at least in part, why some studies have not found that an exercise intervention reduces levels of inflammatory markers.[105–110]

"Fitness versus Fatness" Debate

While it is well established that both increased body fat and low levels of physical activity and/or fitness are associated with increased mortality, T2DM, and CVD, it is not precisely clear as to their relative importance or how they interact. An extensive review of the literature addressing the fitness versus fatness debate as it pertains to CHD and/or CVD concluded "… physically active lifestyle and/or a moderately high fitness level (i.e., not in the bottom 20% of the population) reduces the risk of CVD/CHD in overweight or obese persons."[111] While they suggest that overweight or obese individuals who are physically fit or active have levels of risk that approach those associated with those of lean, unfit persons, they also concede that their risk is still greater than those who are fit/active and of normal weight. The authors further observed that the risk reduction associated with increased fitness or activity is greater in those who are overweight or obese compared with those of normal weight. Finally, they recommend that physical activity should be encouraged regardless of whether or not that activity induces weight loss. This recommendation is supported by the majority of the studies reviewed that found physical activity/fitness to be independent risk factors for CHD/CVD.

Addressing obesity begins with the understanding that weight gain is caused by a cumulative positive energy balance where energy intake exceeds energy expenditure. As such, weight loss can *only* occur in the presence of a negative energy balance. Maintenance of body weight, therefore, requires that energy intake matches energy expenditure. While the concept of energy balance or imbalance is conceptually simple, the respective role of diet and exercise in weight loss and management is less clear. Following is a brief summary of recent and relevant investigations of the role of physical activity in (1) preventing weight gain, (2) weight loss, and (3) weight loss maintenance.

Preventing Weight Gain

In 2003, the International Association for the Study of Obesity (IASO) released the following statement regarding physical activity and prevention of unhealthy weight gain:

> The current physical activity guideline for adults of 30 minutes of moderate intensity activity daily, preferably all days of the week, is of importance for limiting health risks for a number of chronic diseases including coronary heart disease and diabetes. However for preventing weight gain or regain this guideline is likely to be insufficient for many individuals in the current environment. There is compelling evidence that prevention of weight regain in formerly obese individuals requires 60–90 minutes of moderate intensity activity or lesser amounts of vigorous intensity activity … For children, even more activity time is recommended. A good approach for many individuals to obtain the recommended level of physical activity is to reduce sedentary behaviour by incorporating more incidental and leisure-time activity into the daily routine …[112]

Physical Activity and Sustained Weight Loss

Unfortunately, most studies do not support increasing physical activity, either alone or in combination with a calorie-restrictive diet, to be an effective means to produce short-term weight loss.[113–115] However, physical activity appears to play a major role in long-term maintenance of weight loss.[113–116] An extensive review of the role of exercise in promoting weight loss combined data sets and used weighted mean differences (WMD) to explore the efficacy of exercise interventions.[116] The randomized clinical trials (RCTs) in this review only included studies that incorporated a follow-up of at least 12 months duration to assess long-term maintenance of weight loss. A summary of their findings follows:

- Compared to diet alone, diet plus exercise produced significantly greater weight loss at 12 months (WMD = −1.95 kg), 18 months (WMD = −7.83 kg), and 36 months (WMD = −8.22 kg). In addition, there were small but significantly greater differences/improvements in high-density lipoprotein (HDL) and triglycerides (TG) at 12 months.

At 18 months, diet plus exercise demonstrated large and significantly greater reductions in SBP (WMD = −8.90 mm Hg) and DBP (WMD = −12.10 mm Hg).
- A separate analysis in this review compared diet plus behavior therapy with diet plus behavior therapy and exercise. The addition of exercise produced significantly greater weight loss at 12 months (WMD = −3.02 kg) and at 24 months (WMD = −2.16 kg). There were no significant differences between groups for cholesterol, blood pressure, or glucose.

These data suggest that regular physical activity is advantageous for sustained weight loss.

How Much Physical Activity Is Required for Sustained Weight Loss?

There is a general consensus that 2500–2800 kcal/week (60–90 min/day of moderate-intensity physical activity) is required for long-term weight loss as reflected in the recommendations and consensus statements of the U.S. Department of Health,[117] ACSM,[118] and IASO.[112] These recommendations are supported by data from the National Weight Control Registry (NWCR), a database of approximately 5000 individuals who have minimally lost 30 lbs for at least 1 year (average weight loss is about 30 kg for an average of 5.5 years).[119] Data collected on these "successful losers" indicate that more than 90% of participants expend ~2800 kcal/week in physical activity.

Resistance Training and Weight Loss

Despite claims in the popular literature, strength training is not recommended as the primary mode of exercise for weight loss.[118] While strength/resistance training has been shown to preserve fat-free mass when coupled with a calorie-restrictive diet, it has not been shown to enhance weight loss either alone or in combination with a dietary intervention.[113,115,116,118] Despite the apparent ability of resistance training to maintain muscle mass in the presence of calorie deficit, it does not appear to be able to prevent the decrease in resting energy expenditure associated with weight loss.[118,120] In the absence of a dietary intervention, some studies have shown that high-intensity resistance training can significantly increase resting energy expenditure for 16 h or more.[121–125] However, these findings are based on a very small number of subjects and are not supported by the results of other investigations.[126–128] As such, in the absence of stronger evidence, resistance training is not recommended as the primary form of exercise to promote or enhance weight loss.[118] However, weight training may provide an advantage in maintaining fat-free mass and enhancing body composition with a weight loss intervention.[118]

LIPIDS

The role of blood lipids in the pathology of atherosclerosis is well established and dyslipidemia is understood to be an important contributing factor for CHD.[129] Dyslipidemia includes elevations in total cholesterol (TC), low-density lipoprotein cholesterol (LDL-C), triglycerides (TG), and low levels of HDL cholesterol (HDL-C).[129] In addition, newer lipid and lipoprotein measures such as lipoprotein particle size and number, apolipoproteins, and TG-rich lipoproteins (TRL) are emerging as risk factors that may also increase CVD risk.[130] The National Cholesterol Education Program Adult Treatment Panel III has published guidelines establishing lipid and lipoprotein modification goals for both primary and secondary prevention.[129] However, data from NHANES indicates that many Americans have not achieved recommended levels for all lipids and lipoproteins.[131]

One of the proposed mechanisms by which regular physical activity reduces the risk for CHD is its effect on blood lipids, especially the increases in HDL-C and reduction in TG levels.[132–134] Cross-sectional studies have consistently shown a positive association between the volume and intensity of aerobic activities and HDL-C levels and a negative association with TG levels.[135] However, reviews of the literature reveal a surprisingly inconsistent response of other blood lipids to regular aerobic exercise.[135,136] These findings may be further confounded by concurrent changes in body weight or composition. In studies without a dietary intervention, the most commonly reported change in lipids was an increase in HDL averaging 4.6%, ranging from a decrease of 5.8% to an increase of 25%. Simultaneous reductions in TG (3.7%), LDL-C (5.0%), but not TC, were also observed.[135] Changes in TC and LDL-C are much less frequently reported, are modest when they do occur, and may be more attributable to weight loss than the exercise intervention per se. As such, regular exercise alone cannot be recommended as an effective strategy to lower TC or LDL-C.[134]

Relatively few studies have attempted to evaluate the effect of the exercise prescription (intensity, volume, etc.) on blood lipids and, as such, there is no consensus on the optimal exercise regime for improving cholesterol profile. In most of the studies reviewed, the exercise intervention was performed at moderate to high intensity, three to five times per week for at least 30 min per session. Total caloric expenditure, as opposed to exercise intensity, has been proposed to be of greatest importance for blood lipids, and a threshold of between 1200 and 2500 kcal/week has been proposed.[137]

A meta-analysis of studies that explored the effect of strength training on blood lipids and dating back to 1955 found that strength training resulted in modest but significant improvements in blood lipid profiles (but not HDL-C).[138] However, while earlier studies generally demonstrated an improvement in blood lipid profile with resistance training, at least some suffered from design flaws including no or poor dietary control,[139–142] no control group,[139–141] or no control for fat loss.[140,141,143] Better designed and/or more recent studies have not found an improvement in lipoprotein profiles with resistance/strength training.[144–148]

METABOLIC SYNDROME

The clustering of established risk factors for CVD and T2DM has been recognized for decades.[149–165] In 1988, Gerald Reaven drew immense attention to risk factor clustering and CVD in his now famous "Banting Lecture" at the annual meeting of the American Diabetes Association.[153] He described a constellation of risk factors leading to development of T2DM and CVD which he termed *Syndrome X*. Reaven postulated the etiology and clinical course of three major related diseases—T2DM, CVD, and hypertension—all having a common foundation of IR and hyperinsulinemia. However, at that time, adiposity was not considered a major etiological factor.

The metabolic syndrome has been recognized as a global public health problem that is strongly linked as a seminal cause of CVD and T2DM, both of which are responsible for premature mortality and morbidity worldwide.[166–169] The metabolic syndrome is characterized by the clustering of specific cardiovascular risk factors including IR, central obesity, hypertension, and atherogenic dyslipidemia (specifically elevated triglycerides and low levels of HDL-C).[169–174] Also, depending on the medical society definition applied, microalbuminuria may also be considered another risk factor.[174]

Different Medical Society Definitions of the Metabolic Syndrome

In establishing an *official diagnosis* for the metabolic syndrome, the American Association of Clinical Endocrinologists (AACE) championed the creation of the International Classification of Disease 9th revision (ICD-9) Code 277.7 for the metabolic syndrome.[171] Currently, there are five working medical society definitions proposed for the diagnosis of the metabolic syndrome. Table 4.1 summarizes the various definitions published by the following medical societies: (1) World Health Organization (WHO),[174] (2) European Group for the study of Insulin Resistance (EGIR),[170] (3) AHA and the National Heart, Lung, and Blood Institute (NHLBI) definition[175] which refers to the updated National Cholesterol Education Program (NCEP) (2001) definition, (4) the American College of Endocrinology (ACE) and AACE consensus definition for epidemiological research,[171] and (5) the International Diabetes Federation (IDF).[172]

TABLE 4.1
Metabolic Syndrome Definitions Issued by Various Medical Societies

	WHO (1999)	EGIR (1999)	ACE/AACE (2003)	IDF (2005)	AHA/NHLBI (2005)
Requisite criteria	IGT, IFG, type 2 diabetes, insulin in top quartile of population	Insulin in top quartile of population	High risk[a]; BM1 >25 kg/m^2 or WC >102 cm (men) or >88 cm (women)	WC ≥94 cm (men) and ≥80 cm (women), and population specific for ethnic groups[b]	N/A
Other criteria—plus ≥2 of:					
Glucose	N/A	≥100 mg/dL, 2 h post-OGTT ≥140 mg/dL but not diabetes	≥100 mg/dL, 2 h post-OGTT ≥140 mg/dL but not diabetes	≥100 mg/dL, diabetes	≥100 mg/dL, diabetes or Rx
Obesity	W:H ratio >0.9 (men) or >0.85 (women); BMI >30 kg/m^2	WC ≥94 cm (men) or ≥80 cm (women)	N/A	N/A	WC ≥102 cm (men) or ≥88 cm (women)
Lipids	TG ≥150 mg/dL and/or HDL-C <35 mg/dL (men) or <39 mg/dL (women)	TG >180 mg/dL and/or HDL-C <39 mg/dL in men or women or Rx	TG>150 mg/dL or HDL-C <40 mg/dL (men) or <50 mg/dL (women)	TG ≥150 mg/dL or Rx or HDL-C <40 mg/dL (men) or <50 mg/dL (women) or Rx	TG ≥150 mg/dL or HDL-C <40 mg/dL (men) or <50 mg/dL (women) or Rx
Hypertension	≥140/90 mm Hg or Rx	≥140/90 mm Hg or Rx	>130/85 mm Hg or Rx	≥130/85 mm Hg or Rx	≥130/85 mm Hg or Rx
Other	Microalbuminuria ACR ≥30 mg/g				

WC, waist circumference; *W:*H, waist:hip; TG, triglycerides; OGTT, oral glucose tolerance test; Rx, medication; ACR, albumin:creatinine ratio; others designated in text. WHO, World Health Organization; EGIR, European Group for the study of Insulin Resistance; AHA/NHLBI, American Heart Association/National Heart, Lung, and Blood Institute; ACE/AACE, American College of Endocrinology/American Association of Clinical Endocrinologists; IDF, International Diabetes Federation.

[a] Family history of type 2 or gestational diabetes, known CVD, polycystic ovary syndrome, physically inactive lifestyle, >40 years of age, and ethnic population at high risk for a type 2 diabetes.

[b] In this analysis, Mexican American men were classified using a WC cutoff value of ≥90 cm and Mexican American women ≥80 cm.[9]

The majority of the recent research focusing on the metabolic syndrome involved the use of the NCEP definition because of its clinical utility (see Table 4.1). The NCEP definition requires that three of the following five criteria be present for a diagnosis of the metabolic syndrome: IFG represented by a fasting blood sugar ≥110 mg/dL, including T2DM; HDL-C <40 mg/dL in men and <50 mg/dL in women; triglycerides ≥150 mg/dL; an augmented waist circumference (WC) of ≥102 cm in men and ≥88 cm in women; or a blood pressure value of ≥130/85 mm Hg.

Current Prevalence Estimates

It is estimated that close to 1 billion people worldwide have the metabolic syndrome.[176] Global prevalence estimates of the metabolic syndrome vary considerably, depending on the population under study, definition applied, and study design utilized. Using the NCEP definition, the age-adjusted prevalence for the metabolic syndrome in the United States is estimated to be 34.6%. These data also showed a 10% increase in the prevalence of the metabolic syndrome in U.S. adults, from 1988 to 2002. With the metabolic syndrome becoming more common in Western societies,[176] the prevalence and incidence are anticipated to increase in line with the prevalence and incidence of obesity[177] and T2DM.[178]

Physical Activity and Prevalence of the Metabolic Syndrome

The association between physical activity or inactivity and prevalence of the metabolic syndrome is not clear, at least based on cross-sectional studies.[179–187] In most studies, the initial analysis often shows a negative relationship between physical activity level and the prevalence or risk of metabolic syndrome but this association typically disappears after controlling for other factors such as gender, age, education, socioeconomic status, or other risk factors (i.e., smoking).

Several longitudinal studies showed that increased levels of physical activity, especially of vigorous intensity, were associated with significantly and dramatically reduced risk for developing the metabolic syndrome and in a dose–response manner. Interventional studies are fewer in number but at least one study showed that 20 weeks of vigorous exercise performed for 30 min, three times per week resulted in a decreased prevalence of the metabolic syndrome (16.9%–11.8%) in 621 men and women aged 17–65 years.[188] That is, of the 105 participants with the metabolic syndrome at baseline, 32 no longer had the syndrome at the end of the study.

Cardiorespiratory Fitness and the Metabolic Syndrome

The relationship between cardiorespiratory fitness, as measured by VO_{2max}, and the metabolic syndrome has not been studied as extensively as that with physical activity. However, cardiorespiratory fitness can be more objectively measured and may be more predictive of the metabolic syndrome than physical activity per se. Cardiorespiratory fitness has been shown to be predictive of the metabolic syndrome with men of low fitness (VO_{2max} < 29.1 mL/kg/min) being almost seven times more likely to have metabolic syndrome compared with those men with a VO_{2max} ≥ 35.5 mL/kg/min.[183] Over a 4 year period, and after controlling for age, BMI, socioeconomic status, presence of CVD, smoking, and alcohol consumption, the incidence of metabolic syndrome was found to be 47% and 75% lower in middle-aged men with a VO_{2max} of 29.0–35.6 and ≥37.0 mL/kg/min, respectively, compared with those men whose VO_{2max} was less than 28.9 mL/kg/min.

The relationship between aerobic fitness and the prevalence of the metabolic syndrome appears to hold for women as well. Women with a VO_{2max} of 11 METs or greater had a prevalence of the metabolic syndrome that was one-third to one-fourth that of women of lower fitness.[189]

The precise amount and intensity of physical activity required to prevent or reverse the clustering of risk factors known as the metabolic syndrome has yet to be definitely determined. While there is evidence to suggest that regular, moderate-intensity, physical activity (such as walking 30 min on most if not every day of the week) may be preventive of the metabolic syndrome, other evidence suggests that activity of greater intensity may be required to optimally minimize risk. Greater cardiorespiratory fitness has demonstrated an even stronger negative association with the metabolic syndrome. Attainment of higher levels of fitness requires more vigorous physical activity.[11]

Muscular Strength and the Metabolic Syndrome

Evidence from the Aerobics Center Longitudinal Study (ACLS) suggests that even after controlling for age, examination date, smoking status, alcohol intake, number of metabolic syndrome risk factors at baseline, family history of diabetes, hypertension, and early onset coronary artery, men above the 75th percentile for muscular strength have a 24% lower risk for developing the metabolic syndrome compared to men in the lowest strength category.[190] Others have also illustrated the benefits of resistance training and increases in muscular strength on metabolic risk.[191–195] Muscular fitness appears to add another level of protection against the metabolic syndrome in men and may help with daily and long-term glycemic control. However, strength training is recommended as an adjunct to regular aerobic exercise, but not the sole or primary form of activity to prevent or manage the metabolic syndrome.[196]

CONCLUSION

CVD, in all its forms, represents the greatest threat by far to health and longevity in the United States and the world. The major risk factors for CVD are well known and their prevention and/or management are crucial in reducing the prevalence of CHD, stroke, hypertension, and HF. Greater physical activity and especially greater cardiovascular fitness have been shown to significantly reduce the risk for these

manifestations of CVD. The reduction in risk is largely mediated via the risk factors as described in this chapter. As such, an appropriate and individually prescribed program of regular physical activity or exercise should be a standard lifestyle intervention for individuals of all ages and abilities.

INTRODUCTION

Dyslipidemia is defined as elevated fasting blood levels of total cholesterol (TC), low-density lipoprotein (LDL), and triglycerides (TG) and/or a reduced level of high-density lipoprotein (HDL), alone or in combination. A high prevalence of dyslipidemia exists in the United States, in particular elevated TC and LDL cholesterol (LDL-C).[1] There is generally a strong environmental/lifestyle contribution to dyslipidemia with a polygenic mode of inheritance. Familial hypercholesterolemia, an inherited monogenic, autosomal dominant form, is much less common.[2] Although lipids contribute to many vital functions in the body, an abnormal blood level of lipids and their lipoprotein carriers contributes significantly to the pathophysiology of atherosclerosis and the development and progression of coronary heart disease (CHD).

ELEVATED TOTAL AND LDL CHOLESTEROL

Large-scale, long-term, longitudinal, observational studies[3–7] have demonstrated a continuous, positive association of TC (from >180 mg/dL, a 2% increase in CHD risk for every 1% increase), even in the presence of other major risk factors.[3] Other observational studies have indicated that a concentration of apolipoprotein B-100 (apo B-100) is an even stronger predictor of CHD than LDL-C.[8,9] There also have been a number of studies that have shown an association of lipoprotein (α) (Lp (α)) with increased risk of CHD.[8,10,11] Randomized, controlled clinical trials using cholesterol-lowering drugs such as HMG-CoA reductase inhibitors (statins), cholestyramine, niacin, and fibrates have all been successful in reducing CHD risk.[10,11]

A landmark meta-analysis included results of large-scale, placebo-controlled, statin trials, involving >30,000 participants over an average of 5.4 years, indicated that statin use resulted in a mean reduction of 30% in initial or recurrent CHD events.[12] Further analysis indicated that this CHD reduction was primarily related to a 28% reduction in LDL-C, with some benefits being derived from 20% reduction in TG and an increase of 5% in HDL-C. In addition, it should be noted that statin drugs have pleiotropic antiatherosclerotic effects, contributing to the reduction in the development and progression of CHD.[13,14]

HDL

Low HDL-C is also associated with development and progression of atherosclerosis and is generally considered a secondary target for therapeutic intervention. A clear inverse association of HDL-C to CHD has been shown by a number of major prospective cohort studies. Gordon et al. reported in 1989 (based on four prospective studies) that a 1 mg/dL decrease in HDL-C was associated with a 2%–3% increased CHD risk. Interestingly, for each 1 mg/dL increase in HDL-C there appears to be a 6% lower risk of fatal CHD events.[15] Support for the protective role of HDL against CHD has been shown by numerous randomized, controlled trials through several cardioprotective effects including antioxidant effects, improved endothelial function, anti-inflammatory effects, reduction in endothelial-derived adhesive proteins, antithrombotic and profibrinolytic effects, reverse cholesterol transport from

foam cells to the liver, and even regression of atherosclerotic plaques.[12,15–18] HDL functions in the body to remove cholesterol from cell membrane and transport it to the liver for disposal in the bile as cholesterol or as bile acids.[19] Cholesterol acyltransferase (LCAT), an enzyme carried by HDL and activated by HDL's apo A-I, acts by esterifying HDL's newly acquired cholesterol and the resulting cholesterol ester (CE) is drawn into the core of HDL. Cholesterol ester transfer protein (CEPT) is another enzyme involved in reversed cholesterol transfer by catalyzing the transfer of CE from HDL to other lipoproteins in exchange for TG. If CEPT is inhibited via pharmacological measures or inherited, there is a resultant increase in HDL-C levels postulated to result in a reduction in atherogenesis. However, it appears that recently developed drugs that impair the function of CEPT result in an increase level of HDL-C as designed, but in contrast to a hypothesized reduction in atherogenesis, this does not protect against CHD and may even promote progression of CHD.[20–22] These studies suggest that very high levels of large HDL particles laden with cholesterol may lose their cardioprotective properties and may even be atherogenic.[23] Interestingly, individuals who has a specific genetic variant of apo A-I (i.e., apo A-I Milano) have low levels of HDL-C and a very low risk of CHD, and vegetarians also generally have reduced levels of HDL-C (and LDL-C) and have a low risk of CHD.[24,25] Measurement of nascent or newly formed HDL particles, cholesterol, and apo A-I levels apparently better reflects the cardioprotective effects of HDL. It is clear that additional research is needed to elucidate the cardioprotective effect of HDL and to develop techniques to better reflect the antiatherogenic functions of HDL.

TRIGLYCERIDES

TG levels in the blood are elevated for about an hour following a meal, primarily as part of TG-rich chylomicrons, and in the fasting state they are primarily carried by very-low-density lipoprotein (VLDL). Apo C-II (carried by chylomicrons and VLDL) activates lipoprotein lipase (LPL) found in the capillaries of skeletal and heart muscle, and in the adipose tissue. Associated LPL then acts on the TG of the lipoproteins to release free fatty acids and glycerol.[19] Hypertriglyceridemia does not appear to be as strong a risk factor for CHD as LDL-C. This may in part be due to a greater biological and laboratory measurement variability, as compared to the other dyslipidemia components, as well the other atherogenic risk factors that commonly accompany hypertriglyceridemia.[26] It should also be noted that TG-rich VLDL is the precursor of circulating LDL via intermediate-density lipoprotein (IDL), which (together with other apo B-100-containing remnants of VLDL) and appears to be able to cross the arterial endothelium and contribute to atherogenesis.[27] Numerous epidemiological studies have suggested that elevated TG is predictive of CHD, although this association appears to be lost (in some studies) following multivariate analysis that included HDL-C and other CHD risk factors.[28] For example, a meta-analysis of six cohorts involving 46,000 men and 10,000 women indicated that each 1 mmol/L (88.5 mg/dL) increment in TG level was associated with an increase in risk of CHD of 76% in women and 32% in men. However, after adjusting for HDL-C, the increased risk was reduced to 37% and 14% for women and men, respectively.[29] It has further been postulated that nonfasting TG may give a more accurate assessment of risk of CHD because postprandial TG-rich remnant lipoproteins can penetrate the endothelial cell layer and contribute in the subendothelial space to development of atherosclerosis. Although there have not been any intervention trials specifically targeting TG, subgroup analysis of trials using fibrate or statin drugs indicated ~1% reduction in incidence of CHD associated with each 1% reduction in TG level.[30]

NON-HDL CHOLESTEROL AND APO B

Reduction of the concentration of cholesterol within all apo B-containing lipoprotein particles (i.e., non-HDL-C, TC – HDL-C) has been proposed by the National Cholesterol Education Program (NCEP) Adult Treatment Panel III (ATP III) as a secondary therapeutic goal in the presence of elevated TG following primary targeting of LDL-C.[31] In fact, non-HDL-C appears in observational studies to be an even better predictor of cardiovascular disease (CVD) than LDL-C or HDL-C alone.[32] Since LDL and VLDL and its remnants following TG lipolysis each contain 1 molecule of apo B, it is postulated that plasma level of apo B represents the total atherogenic particle number.[32–34] A strong correlation (0.8–0.9) exists between non-HDL-C and apo B; however, they are only modestly concordant.[34]

LIPID CLASSIFICATION AND TREATMENT TARGETS

The screening battery for blood lipids consists of TC, LDL-C, HDL-C, and TG. LDL is usually estimated using the Friedewald formula (LDL-C = TC – TG/5).[35] If TG levels are >400 mg/dL, isolation of the LDL fraction and direct quantification of its cholesterol content are required. ATP III guidelines recommend classifying patients with dyslipidemia by their relative overall/global risk of an initial or recurrent major CHD event. This is done to stratify those with elevated LDL-C by a recommended intensity of intervention and to set target level (Table 5.1). Those with CHD equivalent conditions (e.g., diabetes) or prior CVD diagnosis are automatically classified as being at high risk.

All patients with elevated LDL-C should be screened for the presence of five additional major risk factors (in addition to elevated LDL-C), i.e., cigarette smoking, age >45 years in men or >55 years in women, family history of premature CHD events in first-degree relatives (i.e., <55 years of age in men or <65 years of age in women), and treated or untreated hypertension. If two or more of these risk factors are present, the patient's global risk score for probability of nonfatal or fatal CHD events over 10 years should be determined using ATP III-modified tables, based on an algorithm derived from Framingham Heart Study data.[24,37] Patients should

Notes: Lipid classification based on values after a 12 h or longer fast and the values shown are in mg/dL. Values for non-HDL cholesterol are 30 mg/dL higher than the value for LDL-C. To convert mg/dL to International Unit mmol/L, divide cholesterol values by 38.7 and triglycerides by 88.54.

be classified according to ATP III guidelines as high risk (10 year risk probability of CHD >20%), moderately high risk (10 year probability of 10%–20%), moderate risk (a 10 year probability of <10%), or lower risk (0–1 additional risk factor). Clinicians may upgrade a person at moderately high risk if additional clinical findings or biomarkers are available (e.g., elevated C-reactive protein [CRP] or a high coronary calcium CT scan risk score). Elevated LDL-C is designated as the primary target by NCEP ATP III guidelines for lipid management (Table 5.2).

ATP III guidelines were revised in 2004[36] and current advise considering a therapeutic intervention goal of <70 mg/dL for high risk patients and a goal of <100 mg/dL for moderately high risk patients. TLC are indicated for patients in all risk categories and are recommended initial treatment option for patients in the lower risk category for 6–12 months prior to initiation of pharmacological management. For those in the high risk category, initiation of TLC is recommended as an adjunct concurrent with LDL-C-lowering drug therapy. An HMG-CoA reductase inhibitor or statin drug therapy is currently recommended by ATP III for all patients with CHD or a CVD equivalent (e.g., diabetes), unless contraindications

TABLE 5.2
Risk Category and Recommended LDL Levels

Risk Category	LDL Goal	TLC Initiation	Drug Consideration
High risk			
CHD or CHD equivalent (10 year risk >20%)	<100 (option <70)	>100	≥100
Moderately high			
2+ risk factors (10 year risk 10%–20%)	<130 (option <100)	>130	>130
Moderate			
(10 year risk <10%)	<160	<130	>160
Lower risk			
(0–1 risk factor)	<160	>160	>190 (160–189: lipid-lowering drug optional)

exist, due to their beneficial pleiotropic effects (independent of LDL-C lowering) on reducing atherogenesis.

If target LDL-C level is not achieved using the recommended maximal levels of a statin drug, another LDL-C-lowering drug should be considered as an adjunct treatment option. ATP III guidelines further recommends using a combination of statin therapy, and fibrate or nicotinic acid, or fish oil supplement (1–4 g/day) in addition to TLC to help control low HDL-C or high TG levels (Table 5.3).

ATP III considers elevated TG and low HDL-C levels as secondary lipid targets. It should be noted that a TG level

TABLE 5.3
Percent Changes in Blood Lipid/Lipoprotein Levels for Each Specific Class of Drugs

Class	LDL-C (%)	HDL-C (%)	TG (%)
HMG-CoA reductase inhibitors (statins, e.g., atorvastatin)	↓20–63	↑5–15	↓10–37
Bile acid sequestrants (e.g., cholestyramine)	↓15–30	↑5	±
Fibric acid derivatives (e.g., gemfibrozil)	↓10–15	↑5–20	↓20–50
Niacin (e.g., sustained release)	↓5–25	↑15–35	↓20–50
Cholesterol absorption inhibitor (eczetimide)	↓20	↑5	±

>500 mg/dL requires immediate attention due to increased risk of acute pancreatitis. Treatment guidelines specify the addition of a fibrate drug or nicotinic acid, in addition to a very-low-fat diet (<15% of calories), weight reduction, and increased physical activity. For a moderate elevation of TG (200–499 mg/dL), a recommended goal is a reduction in non-HDL-C levels to at least 30 mg/dL below the LDL-C goal for the patient's risk status. Intensive TLC is considered first choice of treatment if HDL-C is low (i.e., <40 mg/dL) after achieving LDL-C and non-HDL-C targets or for management of an isolated low HDL-C level, followed by the addition of a nicotinic acid or a fibrate drug if target treatment is not achieved.[39]

ROLE OF LIFESTYLE IN THE MANAGEMENT OF DYSLIPIDEMIA

Lifestyle, particularly dietary habits, body weight, physical activity, alcohol consumption, and smoking, accounts for the major differences in blood lipid levels in the population (although heritability can make a substantial contribution as well). These lifestyle habits are considered major TLC targets for the management of dyslipidemia.

Impact of Diet

The primary dietary targets for a cholesterol-reducing program are to reduce intake of animal food sources, specifically red meat, dairy products, butter, hard margarines, and commercial baked goods[25] that contain saturated fatty acids (SFAs), since these are the principal environmental/lifestyle contributors to elevated levels of blood lipid/lipoprotein levels. In addition, intake of *trans*-fatty acids (TFAs) should be minimized because they raise LDL-C and lower HDL-C. Observations from the seven countries study indicated that 60%–80% of the variance among the population in mean TC levels could be accounted for by variation in mean percentage of energy from SFAs; specifically the cohorts who consumed 17%–22% of their daily energy intake from foods high in SFAs had elevated mean TC levels, which was associated with a high incidence of CHD, whereas those with a lower SFA intake (3%–14% of daily energy) displayed a lower CHD rate. This observation has been confirmed in the past two decades by both observational studies and controlled intervention trials.[4,25,40,41] Metabolic ward studies have shown that omega-6 PUFAs, particularly linoleic acid (18:1, n-6), have a cholesterol-lowering effect, which is illustrated by the so-called Keys' equation[42]: $\Delta TC = 1.3(2\Delta S - \Delta P) + 1.5\Delta Z$ (ΔTC is the change in TC; ΔS is the change in percent of total calories provided by SFAs; ΔP is the change in percent of energy from omega-6 PUFAs; and ΔZ is the square root of the dietary cholesterol expressed in milligrams per 1000 kcal of dietary energy). This equation shows that for every 1% reduction in SFAs, serum TC is expected to be reduced 2%. The relatively small impact of dietary cholesterol on blood cholesterol levels is due to the limited absorption of dietary cholesterol with about two-thirds of circulating cholesterol synthesized de novo by the liver from acetyl coenzyme A products of metabolism.[43] It should be noted that only three long carbon-chained SFAs have been shown experimentally to be responsible for increasing TC (i.e., lauric [12:0], muristic [14:0], and palmitic [16:0] acid). These SFAs appear to markedly downregulate hepatic synthesis of LDL apo B/E cell receptors, which reduces the removal of circulating LDL, as well as VLDL, IDL, and apo B-100 containing lipoprotein remnants and results in a significant increase in cholesterol level.[43,44] Stearic acid (18:0) and SFAs with 10 or less carbons have no effect on TC and are not included in Keys' equation.[42] Omega-6 PUFAs, in contrast, lower cholesterol levels by upregulating hepatic LDL receptors and increasing the removal of lipoproteins and reduce the rate of conversion of VLDL to LDL. The current ATP III recommendation is to keep intake of omega-6 PUFAs to 10% or less of daily energy intake, since a higher intake appears to lower HDL-C levels. Linoleic acid (18:2, n-6), the parent compound for the omega-6 family of PUFAs, is found in sunflower, corn, and soybean oils, seeds, and nuts. Linoleic acid forms arachidonic acid (AA; 20:4, n-6) via enzymatic stepwise elongation of its carbon chain. AA is the precursor of prostaglandins and eicosanoids via cyclooxygenase (COX) enzyme activity and is essential for regulation of blood circulation, blood clotting, and inflammatory responses.[19]

Omega-3 PUFAs are a family of long-chained, essential fatty acids required in the diet. They have an initial double bond/unsaturated carbon atom at the third rather than the sixth position from the methyl end of the molecule for omega-6 PUFA. There has been a steady increase in the interest in omega-3 PUFA due to their apparent importance for eye and brain health through the lifecycle, and their postulated contribution to primary and secondary prevention of CHD.[44,45] The parent compound of this family is α-linolenic acid (ALA; 18:3, n-3). Its carbon chain is enzymatically converted to longer chain and eventually become the more unsaturated fatty acids, eicosapentaenoic acid (EPA; 20:5, n-3) and docosahexaenoic acid (DHA; 22:5, n-3). It should be noted that DHA competes with AA for conversion via COX enzyme to alternative eicosanoids and prostaglandins, which are believed to be cardioprotective. Because of the limited conversion of ALA to EPA and DHA, all three are currently considered essential dietary nutrients; however, DHA appears to be the most biologically active form of the omega-3 PUFAs.[46] ALA is primarily present in vegetable oils, in particular canola and soybean oils, whereas fatty fish such as salmon, mackerel, herring, and sardines are rich sources of EPA and DHA. The apparent relationship of omega-3 fatty acids to cardiovascular health was first observed during studies of the unique dietary habits in Greenland Inuits.[47] Despite a diet consisting primarily of very fatty meat from sea mammals, they had a surprisingly low rate of CVD. This was eventually attributed to their high intake of EPA and DHA from these food sources. Other epidemiological observational studies have consistently reported an inverse association between consumption of fish or fish oil supplements, with morbidity and mortality from CVD.[48] The cardioprotective effects of these fatty acids have further been confirmed in animal models and by primary and secondary

TABLE 5.4
Experimentally Identified Mechanisms Postulated to Contribute to the Apparent Cardioprotective Effects of Omega-3 PUFAs

- Reduced dyslipidemia (decreased TG and VLDL-C and increased HDL-C)
- A moderate reduction in elevated blood pressure
- Improved endothelial function and endothelial-dependent and endothelial-independent vasoreactivity
- Anti-inflammatory effects, inhibiting progression of atherosclerosis
- Antithrombotic effects
- Increased parasympathetic activity, as evidenced by increased heart rate variability
- Improved myocardial electrical stability, reducing risk of a fatal ventricular arrhythmia

Sources: Von Schacky, C., *Am. J. Clin. Nutr*., 71, 224S, 2000; Harris, W.S., *Lipids*, 31, 243, 1996; Holub, B.U., *CMAJ*, 116, 608, 2002.

CHD prevention trials, indicating a 20%–30% reduction in fatal and nonfatal CHD events.[49,50] It appears that a modest intake of fatty fish, i.e., two to three portions per week or a daily fish oil capsule, can reduce risk of CHD, whereas consumption of ALA from vegetable oils does not appear to be as cardioprotective (Table 5.4).

DHA and EPA fish oil–based supplements appear to result in a reduction in TG (6%–10%/g of EPA and DHA), VLDL-C, VLDL-TG, and non-HDL-C and an increase in HDL-C.[52] Thus, large doses of EPA–DHA-based fish oil supplements in combination with a statin drug appear to be an effective therapeutic approach for treatment of mixed dyslipidemia.[38]

Attention was first directed to the benign relationship of monounsaturated fatty acids (MUFAs) in the diet to risk of CHD by the Seven Countries Study.[4] Approximately 80% of the fatty acids contained in olive oil are MUFAs, particularly oleic acid (18:1, n-9). Oleic acid either has no effect on blood lipids or, as reported in some studies, it reduces TC levels, but appears to have no effect on HDL-C or TG levels.[53] However, the presence of MUFAs in LDL makes it less susceptible to oxidation. MUFAs are plentiful in olive oil, canola and peanut oil, avocados, nuts, and fish.

TFAs have attracted attention in recent years due to their adverse effects on blood lipids. In fact, the FDA now mandates inclusion of quantities of TFAs on food labels along with that of SFAs and PUSFs. New York City and California even banned the use of TFAs in restaurants for food preparation. It should be noted that only a limited quantity of TFAs occurs naturally in meat and dairy products, while essentially all of the reported 2.6% of usual daily energy intake of TFAs results from intake of margarines and shortenings used in food preparation. This is due to the formation of TFAs by the partial hydrogenation of the double bonds of unsaturated fatty acids in liquid vegetable oils to solidify them since this makes products more heat stable and increases shelf life.[54] TFAs appear to promote an increase in cholesterol synthesis and a concomitant increase in LDL-C levels, but more importantly in contrast to SFAs they increase Lp (α) and lower HDL-C levels.[55] Currently, it is recommended that dietary intake is limited to less than 1% of total energy intake.

A diet high in nondigestible fiber may have a modest beneficial effect on TC and LDL-C levels.[25,38] Soluble fiber components, in particular β-glycans and pectin, contribute to blood cholesterol reduction. Soluble fibers are found in whole grains (especially oats), fruits and vegetables, and beans and legumes. Soluble fibers bind and thus prevent reabsorption of bile salts in the small intestine, which results in upregulation of hepatic LDL receptors, thereby enhancing LDL removal and reducing LDL-C levels. An intake of 30 g/day of soluble fiber has been reported to be associated with a 5 mg/dL reduction in total LDL-C levels and especially the smaller, dense, atherogenic LDL particles thereby reducing fatal and nonfatal CHD events.[25,56–59] It should also be noted that dietary fiber slows gastric emptying and glucose absorption, which decreases insulin response and thus reduces hepatic lipogenesis and promotes satiety.

Plant sterols and stanols (when esterified with a fatty acid or when emulsified such as Benacol) are plentiful in vegetable oils, seeds, and nuts.[60] It appears that PUFA margarines with or without the addition of 2 g/day of sterols/stanols to the diet may result in a reduction of 21 mg/dL in LDL-C (a 9%–27% reduction) and non-HDL-C levels.[60,61] LDL-C removal is enhanced via an upregulation of LDL receptors in the liver, in part due to competitive inhibition of dietary and biliary cholesterol uptake in the small intestine.[25] ATP III has endorsed the use of stanol-enriched margarines, as an adjunct for lowering LDL.

Plant-derived antioxidants such as lipid-soluble vitamin E and β and other carotenes, water-soluble vitamin C, and a large variety of non-nutrient phytochemicals are postulated to reduce the development and progression of CHD by preventing oxidative stress and reducing LDL oxidation, and endothelial dysfunction.[38,62] Vitamin E, found in vegetable oil, nuts, and seeds, is transported by LDL and has been associated with a reduction of CHD risk and reduction of oxidized LDL.[38,62] However, it should be noted that numerous large-scale randomized controlled clinical trials have failed to demonstrate any protective effect against CVD mortality by supplementation of antioxidant vitamins (vitamin E, vitamin C, or β-carotene).[38,62,63] Another type of plant chemicals (phytochemicals) of significant health-promoting interest in recent years has been flavonoids, found in fruits, vegetables, tea, red wine (and grape juice from which wine is derived), and cocoa bean products. These phytochemicals have been demonstrated in in vitro studies to be potent inhibitors of LDL oxidation.[38] However, there have been inconsistent results from clinical trials and current evidence does not clearly support their use in a clinical setting.[38]

A moderate alcohol intake of —one to two drinks per day has been associated with about one-third lower risk of mortality from CHD when compared to either no alcohol or heavy alcohol consumption, possibly due to both antithrombotic effects and ethanol-involved increased HDL-C levels by ~12%.[38,64] However, it should be noted that alcohol also produces a concomitant increase in TG and VLDL production and therefore raises non-HDL-C

levels. Moreover, excessive use of alcohol raises blood pressure, is potentially addictive, and can contribute to major health problems, in addition to increasing risk of accidents and violent death. Thus, it is considered unethical to encourage nondrinkers to start using alcohol for prevention of CHD.

WEIGHT MANAGEMENT

Health consequences associated with excess body weight include dyslipidemia, all components of the metabolic syndrome, and thereby an increased risk of type 2 diabetes and CHD.[65] Thus, weight reduction is a critical component in the management of dyslipidemia. Obesity results generally from a combination of overeating and sedentary lifestyle, causing a positive energy balance and thus an increase in lipogenesis and fat storage. In order to lose weight, a sustained negative energy balance must be achieved. The ATP III,[31] the AHA,[66] and the American College of Sports Medicine[79] recommend a sustained weight reduction by achieving a modest negative energy balance of 500–1000 kcal/day. This is expected to result in a 1–2 lb (0.45–0.99 kg) weight loss per week. The initial goal is to achieve a 5%–10% weight loss over a 6 month period. If this weight loss is achieved via dietary changes only, about 75% of this loss is generally from fat and 25% fat-free mass (FFM). If exercise is combined with a reduced energy intake, FFM is generally better preserved during weight reduction and weight regain appears to be less likely.[65–67]

It is essential to include behavioral modification of eating habits and regular PA to successfully achieve and maintain a more desirable body weight.[65–67] Bariatric surgery commonly results in a substantial weight loss; however, there are serious risks associated with the surgical procedures, including postsurgical complications related to the induced nutrient malabsorption.

Numerous dietary approaches have been promoted for weight reduction. These diets often target a specific macronutrient (i.e., fat, carbohydrates, or protein). However, it should be noted that the greatest impact on the initial amount of weight loss is the level of energy deficit achieved, irrespective of the dietary approach. Current guidelines specify that daily energy intake should not be lower than 1000–1500 kcal/day, in order to provide all essential nutrients while achieving an adequate negative energy balance.[56–67] The approach that is most commonly recommended by authoritative sources for successful long-term weight loss and maintenance includes limitation of dietary fat intake (since fat provides 9 kcal/g compared to 4 kcal/g for carbohydrates and protein).

It appears that a successful 10% weight loss may result in a significant decrease in TC of 30.5 mg/dL (–13.2%), LDL-C 15.1 mg/dL (–11.3%), VLDL-C 15.5 mg/dL (–36.5%), and TG 58.4 mg/dL (–32.2%); HDL-C initially declines during the active weight loss phase and then increases 5.5 mg/dL (+12.6%) after weight stabilization. This represents about a 0.35 mg/dL increase in HDL-C for every kilogram of weight lost.[68] In a recent meta-analysis, Nordmann et al.[69] compared the effects of a reduced-fat and a low-carbohydrate diet (i.e., the Atkin's diet) on weight loss and cardiovascular risk factors. The fat content of the reduced-fat diets was limited to 25%–35% (current recommendation) of daily energy in four of these studies and to 10% in one study. The low-carbohydrate diet was unlimited in protein and fat intake. The mean weight loss at 6 months was significantly greater on the low-carbohydrate diet, while at 12 months there was no statistically significant difference between the low-carbohydrate and the reduced-fat diets. However, the reduction in TC and LDL-C was more favorable on the low-fat diets compared to the low-carbohydrate diets (mean difference in LDL-C between diets was –5.4 mg/dL). Interestingly, changes in HDL-C (+4.6 mg/dL) and TG (–22.1 mg/dL) were significantly more favorable on the low-carbohydrate diets.

A recent randomized study[70] investigated the effects of weight loss and blood lipid changes between a low-carbohydrate, non-restricted-calorie diet and a reduced-fat (<35% of daily energy), restricted-calorie diet, following AHA guidelines, and a restricted-calorie Mediterranean-type diet. The mean weight loss after the 2-year follow-up was 2.9 kg for the AHA diet, 4.4 kg for the Mediterranean diet, and 4.7 kg for the low-carbohydrate diet. There was a mean increase in HDL-C of 8.4 (+22.4%), 6.3, and 6.4 (+16%) mg/dL for the low-carbohydrate, AHA, and Mediterranean diets, respectively. TG reduction (23.7 mg/dL) was also significantly more favorable with the low-carbohydrate diet. Surprisingly, in this study there was no significant change in LDL-C in any group.

The combination of dietary modification and regular exercise has consistently been shown to be the most effective approach for achieving and maintaining long-term weight reduction (~1 kg/week greater weight loss than dieting alone).[65–67] Aerobic exercise (as well as resistance exercise) may attenuate FFM loss that will occur with weight loss.[67] Regular aerobic exercise for 60–90 min/day is critical for preventing weight regain.[71,72] However, exercise alone is generally not effective for inducing sizable weight loss, unless one performs supervised, large-volume, prolonged aerobic exercise 5–7 days/week.[67]

EXERCISE EFFECTS

It has been well established that increased physical activity and exercise training reduce morbidity and mortality from CHD through multiple cardioprotective effects including reducing dyslipidemia.[73–76] Studies have consistently shown that aerobic exercise training results on the average a modest increase in HDL-C of 2–3 mg/dL, or about 4%–5% with an associated increase in apo A-I and LPL activity.[77–80] However, it should be noted that there is a great deal of variability in the response of HDL-C following exercise training,[81] which appears to be related to genetic factors as well as to weight change.[82–86] Additionally, individuals with a low baseline level of HDL-C or sedentary women with genetically high HDL-C levels appear less likely to respond to exercise training.[84] Exercise-induced reductions in LDL-C and TG have appeared to be rare in the absence of an associated weight loss.[77–80] The majority of well-controlled studies on the effect of exercise on blood lipids have used a standard exercise prescription of a moderate- to high-intensity aerobic exercise for 30–60 min, three times per week with a weekly energy expenditure of 900–2000 kcal (or about 10–20 MET h) for at least 12 weeks (about 15–20 miles/week of walking).[77–80]

Smoking Effects

Cigarette smoking has been associated with reduced apo A-I and HDL-C levels about 4–6 mg/dL or 11%–14% lower than nonsmokers.[87–89] These findings are despite the fact that smokers tend to weigh less and drink more alcohol. More importantly, smoking cessation appears to result in a rapid improvement in HDL-C (an average 6–8 mg/dL increase).[90] In addition, smokers have been reported to have slightly higher LDL-C levels than nonsmokers. These adverse effects of smoking on blood lipids are postulated to be due both to nicotine and carbon monoxide exposure.[91]

CONCLUSIONS AND RECOMMENDATIONS

Therapeutic lifestyle components are major contributors to dyslipidemia and resulting CHD, in particular eating habits and low levels of physical activity. The high consumption of red and processed meat, high-fat milk and dairy products, fried and salty foods, refined grain products, and sugar-laden desserts and soft drinks is principally responsible for the obesity epidemic and associated dyslipidemia in this country.[92–95] It has been well established that eating patterns associated with reduced rates of dyslipidemia and CVD include

- Vegetarian and near-vegetarian diets[96,97]
- Mediterranean-style diets[4,40,41,98,99]
- The Dietary Approach to Reduce Hypertension (DASH) diet[100–102]
- The "Prudent Heart Healthy Diet" advocated by the AHA (formerly the AHA Step II Diet), ATP III, and the U.S. Departments of Agriculture (USDA) and Health and Human Dietary (DHHS) Guidelines for Americans 2010[31,102–104]

Successful dietary patterns to improve blood lipid profile should be characterized by a low intake of saturated and *trans*-fat and dietary cholesterol via a reduction of red meat, hard fats, full-fat milk; an increased intake of whole grains, legumes, fruits, and vegetables; and a moderate intake of fish and poultry and low-fat or fat-free milk and dairy products. The recommended macronutrient content of this eating pattern, as a percentage of daily energy intake, is as follows[31,105]:

Total fat	25%–35%
Saturated fat	<7%
trans-fats	<1%
Monounsaturated fats	15%
Polyunsaturated fats (with an omega-6 to omega-3 ratio of 3-4:1)	10% or less
Cholesterol	≤200 mg/day
Protein	About 15%
Carbohydrates	50%–60%

The combination of a proper dietary plan and regular aerobic exercise has been reported to lower TC, LDL-C by 7%–18% and TG by 4%–18%, respectively, while increasing HDL-C by 2%–18%.[106] Weight management is critically important in improving blood lipid profile. Table 5.5 summarizes the effects of specific dietary components and other TLC reviewed in this chapter on dyslipidemia.

TABLE 5.5
Effects of Specific Dietary Components and Other TLC on Dyslipidemia

Dietary Component or TLC Change	TC	LDL-C	HDL-C	TG (and Non-HDL-C)
Decrease SFAs, *trans*-fats, and cholesterol	↓↓	↓↓	↓	↓
Increase omega-6 PUFAs	↓	↓	→	→
			↓	
Increase omega-3 PUFAs	→	→	↑	↓↓
		↑	→	
Increase MUFAs	→	→	↑	↓
	↓	↓	→	
Increase soluble fiber	↓	↓	→	→
Moderate alcohol	→	→	↑↑	↑↑
Phytosterols	↓	↓	→	→
Soy proteins	↓	↓	→	↓
Vitamin E (recycled by vitamin C)	—	↓ OxLDL	—	—
Negative energy balance (weight loss)	↓	↓	↑	↓↓
Aerobic exercise	↓	↓	↑	→
	→	→		
Smoking cessation	→	→	↑	↓

Notes: ↑, increase; ↓, decrease; →, no change.

INTRODUCTION

Hypertension is a well-established major risk factor for cardiovascular disease (CVD) morbidity and mortality.[1–4] Despite the fact that major advances have been made in our understanding of hypertension and pharmacological therapy, it continues to be poorly controlled in the over 50 million U.S. adults diagnosed with hypertension, including ~70% of all adults >50 years of age, with blacks having an even higher incidence than nonblacks.[5–7] Pharmacotherapy has traditionally served as the primary treatment modality for hypertension. This is despite strong evidence of the benefit of lifestyle modifications to reduce both incidence of hypertension and blood pressure levels in individuals with established hypertension.

The Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure Seventh Report (JNC-7)[1] highlights the importance of therapeutic lifestyle changes (TLC) by recommending five TLC for both the prevention and initial treatment of pre- and stage 1 hypertension, which include the following : (1) weight loss to achieve a BMI <25 kg/m^2; (2) a minimum of 30 min of moderate-intensity aerobic exercise ≥5 days/week; (3) if consuming alcohol, limiting consumption to no more than two drinks (2 oz) per day for men and no more than one drink per day for women; (4) eating a healthy diet, rich in fruit, vegetables, and whole grains, moderate in fat-free and low-fat dairy products, and low in saturated and total fat (e.g., Dietary Approaches to Stop Hypertension [DASH] diet); and (5) lower sodium/salt intake ≤100 mEq/L/day. These measures have been shown to reduce systolic blood pressure levels (2–20 mm Hg) and potentiate antihypertensive drug therapy.[1] Target blood pressure levels should be <140/90 or <130/80 mm Hg in the presence of diabetes, chronic kidney disease, or CVD, with the initial goal to lower the systolic blood pressure (Table 6.1).[1] Currently, a BP level of <115/75 mm Hg is considered optimal for health promotion.[1]

ETIOLOGY OF HYPERTENSION AND RELATIONSHIP TO CVD

Primary or essential hypertension, the most common cause of hypertension in the United States, (90%–95%) has no specific known underlying cause, while secondary hypertension results from medical conditions such as chronic kidney disease, renal artery stenosis, or adrenal tumors (e.g., pheochromocytoma, primary aldosteronism, and Cushing's disease).[8,9] Essential hypertension cannot be cured, but it can be controlled with TLC and/or pharmacotherapy.[1,8,9] Nonmodifiable risk factors for essential hypertension include a positive family history (generally via a polygenic mode of inheritance), age (>30 years old in men), sex (more common in men than women), and ethnicity (more common in blacks than in nonblacks). Modifiable risk factors are excess weight (BMI > 25 kg/m^2); excess alcohol consumption; a sodium-rich diet, low in calcium, potassium, and magnesium; and physical inactivity.[1,8,9,10–13] Any physiological factor that increases cardiac output or total peripheral vascular resistance can result in an elevation of blood pressure, since blood pressure level is determined hemodynamically by the product of these two variables. Other contributing factors that increase blood pressure levels include endothelial dysfunction, increased sympathetic nervous system activation,

TABLE 6.1
Adapted from JNC-7: Classification of Blood Pressure for Adults 18 or Older

BP Classification	SBP	DBP	Lifestyle Modification	Drug Treatment
Optimal	<115	<75	Encourage	None
Normal	<120	<80	Encourage	None
Prehypertension	120–139	80–89	Yes	Usually not indicated[a]
Stage 1 hypertension	140–159	90–99	Yes	Indicated[b]
Stage 2 hypertension	>160	>100	Yes	Indicated[c]

Source: Adapted from Chobanian, A.V. et al., *JAMA*, 289, 2560, 2003.

[a] Initiate pharmacological treatment if compelling indications such as chronic kidney disease, diabetes, or CVD with a blood pressure goal <130/80 mm Hg.

[b] Thiazide diuretic for most (if therapeutic lifestyle modifications have failed to reduced blood pressure within 6–12 months), add other drugs as indicated if blood pressure is more than 20/10 mm Hg above the blood pressure goal.

[c] Two-drug combination, usually consisting of a thiazide diuretic plus another, may be needed as indicated.

and renin–angiotensin–aldosterone system (RAA) activity. It is postulated that a sustained elevation in blood pressure from any of these physiological disturbances results in a resetting of the baroreceptors, hypertrophy of the arteriolar smooth muscle, and an increase in peripheral vascular resistance, the principal hemodynamic disturbances associated with essential hypertension.[8] Hypertension-induced LVH (a major cardiac consequence of hypertension) is postulated to be related to both an increase in preload and afterload (i.e., chronic volume and pressure overload) resulting in eccentric or concentric volumetric ventricular changes associated with dysfunctional systolic contraction.[8–11] The reader is referred to a recent review by Rosendorff et al.[8]

PHYSICAL ACTIVITY, EXERCISE, AND HYPERTENSION

Observational studies also have reported an inverse association between leisure time physical activity, physical fitness (relative risk 1.5–1.9), and development and severity of hypertension even after adjusting for other risk factors.[14–26] For example, Kokkinos et al.[27] reported in a cross-sectional study an 8–9 mm Hg lower systolic and 4–5 mm Hg diastolic mean 24 h ambulatory blood pressure in individuals with high and moderate physical fitness, compared to persons with a low fitness levels. These studies suggest that increased levels of physical activity and moderate physical fitness result in ~5 mm Hg lower systolic blood pressure level, compared to age- and sex-matched individuals who are less active and less fit.[26]

The effect of exercise training on blood pressure levels have been well-established in over 70 randomized, controlled trials and over 15 meta-analyses.[28–43] In general, these studies have shown that a moderate-intensity aerobic exercise training program 30–60 min per session, three times per week, for 12–16 weeks lowers elevated blood pressure levels.[44,45] These studies have indicated a mean reduction in resting blood pressure levels in normotensive individuals of 2.6–4.7 mm Hg in systolic and 1.8–3.1 mm Hg in diastolic blood pressure and a reduction in systolic of 6–10 mm Hg and diastolic blood pressure of 2.4–7.6 mm Hg in patients with diagnosed hypertension. There also appears to be a significant difference in blood pressure reduction between moderate or vigorous exercise intensity training, and based on BMI, sex, and age.[28–46]

Aerobic exercise training also appears to reduce mean 24 h systolic blood pressure of 6–10 mm Hg and diastolic blood pressure of 5–8 mm Hg in hypertensive participants, and 3.0–3.3 mm Hg systolic blood pressure and 3.3–3.5 mm Hg diastolic blood pressure in normotensive individuals[30,44,45] although no change was found in overnight blood pressure.[44] It is concluded from these data that moderate-intensity (40%–70% of maximal aerobic capacity) aerobic exercise training 30–60 min 3–5 days/week is effective for both prevention and management of hypertension. Moreover, immediately following cessation of each bout of aerobic exercise there is a temporary reduction in systolic (5–15 mm Hg) and diastolic (4–6 mm Hg) blood pressure that appears to last several hours (up to 24 h).[45,47–49] The mean acute post-exercise reduction in blood pressure levels of hypertensive individuals has been reported to be higher in controlled settings (15/4 mm Hg) than in uncontrolled settings (~5/4 mm Hg).[45] It is postulated that the mechanism of this acute blood pressure reduction following each exercise session includes the following:

- Immediate decrease in sympathetic adrenergic stimulation of the precapillary vessels
- Attenuated response to α-adrenergic stimulation
- Laminar flow-mediated release of endothelial-derived vasodilatory chemicals (e.g., nitric oxide, prostacyclin, and adenosine)
- Resetting of the arterial and cardiopulmonary baroreceptor operating points
- Neural adaptations involving central vasopressin V_1 receptors and substance P receptors[48–53]

Resistance exercise training has been reported in some studies to result in a reduction in blood pressure ~7/6 mm Hg, while in other studies it failed to result in a blood pressure reduction.[44,45,54] However, meta-analyses on the effect of resistance training on mean resting blood pressure have reported a blood pressure reduction of approximately 3/3.5 mm Hg in normotensive individuals.[44,54] However, it should be noted that only the diastolic pressure reduction reached statistical significance in the largest meta-analysis. The current recommendation for resistance exercise training is that it should only be used as a supplement and not a substitute for aerobic exercise training. It is advised that resistance exercise in the management of pre- or stage 1 hypertension should be performed at a moderate intensity with 1–3 sets

of 10–15 repetitions per session, 2–3 times/week involving 8–10 exercises of the large muscle groups.[45,55] Limited available evidence suggests that combined aerobic and resistance exercise training may result in a reduction of 5.6 mm Hg in systolic and 5.5 mm Hg in diastolic blood pressure levels in hypertensive individuals. The reader is referred to the American College of Sports Medicine's guidelines and contraindications to exercise testing and training in patients with hypertension.[56]

There have been many postulated and plausible mechanisms for the blood pressure–reducing effects of exercise training. Poiseuille's law explains that a small change in vessel diameter has a large effect on resistance to fluid flow (i.e., inversely proportional to the fourth power of the vessel radius).[45] Therefore, it appears that a reduction in total peripheral vascular resistance, specifically by a change in small vessel diameter, is responsible for at least one part of the observed blood pressure reduction with exercise training (7.1% reduction).[44] The exercise-induced reduction in peripheral vascular resistance is postulated to be mediated by several factors including

1. Improved vascular endothelial function and arterial elasticity/compliance
   a. Due to increased nitric oxide (NO) synthase activity from exercise-induced laminar shear stress and prolonged NO activity via reduced oxidative deactivation of NO, and reduction of collagen deposition on the media of the arteries
2. Reduction in endothelial-derived endothelin-1
3. Attenuation of α-adrenergic receptor-responsive and reduced sympathetic tone
4. Reduction in peripheral vascular resistance
5. Improved baroreceptor reflex sensitivity
6. Reduced circulating catecholamines[44,57–64]

The effects of exercise training on the RAA system are less well known. There have been a few reports of an exercise training-induced reduction in renin activity[44] and angiotensin II activity in normotensive persons, but not in hypertensive persons.[45] There is also an exercise training-induced improvement in insulin sensitivity, which has been associated with increased renal sodium excretion.[45,65] In addition, exercise training-induced vascular adaptations also include an increase in skeletal muscle precapillary and capillary vessel numbers (i.e., angiogenesis), and adaptations in vascular structure including vascular remodeling (arteriogenesis) resulting in a larger conduit artery lumen diameter, which further contributes to reduced vascular resistance.[45,66]

The genetic impact on the exercise-induced reduction in blood pressure is not well known and the interactions between genes and environment are complex. It is plausible that genes affecting NO synthase activity are involved in the blood pressure response to exercise training, as shown by the *He*alth *Ri*sk Factors Exercise *Tra*ining and *Ge*netics (HERITAGE) Family Study.[67,68]

DIETARY MODIFICATIONS IN THE PREVENTION AND MANAGEMENT OF HYPERTENSION

Dietary-induced prevention and management of hypertension through a combination of sodium intake reduction; increased intake of potassium, calcium, and magnesium; and moderation of alcohol consumption have been shown to very effective and is strongly supported by evidence from randomized, controlled trials.[69–72] The most effective dietary intervention for blood pressure control and reduction to date is known as the DASH diet, which is rich in fruit and vegetables, moderate in low-fat dairy products (and hence, low in sodium and high in potassium, calcium, and magnesium), and low in total and saturated fat (Table 6.2).[70]

The DASH diet was shown in a controlled randomized study to be very effective in reducing blood pressure levels ~11.4/5.5 mm Hg hypertensive participants versus 3.5/2.2 mm Hg in prehypertensive participants. Interestingly, it appeared to be more effective in lowering BP in black as compared to white study participants (6.9/3.7 and 3.3/2.4 mm Hg, respectively).[70]

TABLE 6.2
Dietary Approaches to Stop Hypertension (DASH) Dietary Plan

Nutrient	Percentage of Total Caloric Intake
Total fat (% of total kcal)	25–35
Saturated fat	<7
trans-fats	<1
Monounsaturated fats	15
Polyunsaturated fats (with an omega-6 to -3 ratio of 3-4:1)	10 or less
Cholesterol	≤200 mg/day
Protein (% of total kcal)	About 18
Carbohydrates (% of total kcal)	50–60
Dietary fiber (g/day)	31
Potassium (mg/day)	4700
Calcium (mg/day)	500
Sodium (mg/day)	1500–2400
Number of servings per day based on 2000 kcal diet	Daily servings
Fruit	7–8
Vegetables	4–5
Grains	4–5
Low-fat dairy products	2–3
Meats, poultry, fish	≤2
Nuts, seeds, dry beans	4–5
Fats, oils	2–3
Sweets	≤5 per week

Source: Adapted from Appel, L.J. et al., *Hypertension*, 47, 296, 2006.

Note: Total effect of blood pressure reduction using the DASH diet is approximately 11/6 mm Hg.

Other dietary studies have reported a 6–10 mm Hg blood pressure reduction in normotensive participants versus a 12–16 mm Hg reduction in participants with hypertension following a diet high in fruit and plants, as well as diets high in carbohydrate, protein, or unsaturated fat.[69,72] Moreover, an increased dietary fiber intake of 11.5–14 g/day intake found in whole grains, fruit and vegetables, beans, nuts, and legumes is associated with a small reduction in systolic (1.1–1.6 mm Hg) and diastolic blood pressure levels (1.3–2.0 mm Hg).[73–75] Currently, it is recommended that for BP management, an appropriate diet is one rich in fruit and vegetables, and whole grains, as found in the DASH dietary eating pattern.

Effect of Sodium Restriction

Observational prospective and cross-sectional studies, animal studies, clinical trials, and meta-analyses have established a positive independent association between sodium (and table salt) intake and blood pressure levels.[35,76–78] The largest dose–response sodium restriction blood pressure trial to date was the DASH-Sodium Trial. This randomized study compared three levels of reduced sodium intake (150, 100, 50 mmol/day) with changes in blood pressure levels. This study found an apparent dose–response relationship between reduced sodium intake and systolic blood pressure reduction.[71]

Generally, sodium restriction reduces elevated systolic blood pressure levels by 4.7–7 mm Hg and elevated diastolic blood pressure levels by 2.5–2.7 mm Hg, and reduces the risk of progression of prehypertension to hypertension (a relative risk reduction of 20%). Further, it potentiates pharmacological treatment.[35,69,76–81] It is important to note that there is a great interindividual variability in blood pressure response to sodium restriction. In general, black, middle-aged, older individuals, and patients with over activity of the RAA system appear to respond best to sodium restriction with large reductions in blood pressure.[69,71,80,81] The current American diet is high in sodium levels, mostly from commonly used processed foods, therefore making it difficult for many Americans to achieve a lower sodium goal. The AHA therefore recommends 2.3 g/day as the upper limit of sodium intake for blood pressure control,[1,69] whereas the JNC-7 recommendations are to reduce sodium chloride intake to 1.5 g/day.[69]

Effects of Increased Dietary Potassium Intake

Fluid homeostasis in the body is in part controlled via sodium and potassium balance. In general, serum sodium levels increase to promote fluid retention in response to a reduction in serum potassium levels, whereas increased serum potassium levels lead to an increase in renal sodium excretion (natriuresis) and an associated diuresis. Although clinical trials have reported mixed blood pressure response to increased dietary potassium intake, there is in general a trend between increased potassium intake from 1.3 to 4.7 g/day and reduced systolic blood pressure (2.42–4.4 mm Hg) and diastolic blood pressure (1.5–2.5 mm Hg) in patients with hypertension. In general, a greater blood pressure–reducing effect of increased potassium intake is observed in black as compared to matched white hypertensive individuals.[35,69,70,82–84] However, the combination of a diet rich in potassium and low in sodium does not appear to be additive.[69] Currently, it is recommended that a 4.7 g/day dietary intake of potassium should be consumed via a dietary eating pattern similar to that of the DASH diet, instead of potassium supplement use.[69,70] However, patients with medical conditions that are associated with impaired urinary excretion of potassium (e.g., renal disease) or are using medications that reduce potassium excretion (e.g., angiotensin-converting enzyme [ACE] inhibitors) should consume a lower daily potassium intake to avoid hyperkalemia.[1,69]

Effect of Alcohol Consumption

A J-shaped dose-dependent association between alcohol consumption and blood pressure levels has been demonstrated in clinical trials. It appears that relatively light alcohol consumption has no effect on blood pressure, whereas higher daily alcohol consumption increases blood pressure levels.[76,85–88] Controlled trials have demonstrated that 50%–70% reduction of daily alcohol consumption independently reduces blood pressure levels approximately 3.5/3 mm Hg. On the other hand, a 10 g/day increase in alcohol consumption is associated with an increase in blood pressure of 2/1 mm Hg.[35,88] Current recommendations are for individuals who consume alcohol to limit their intake to no more than two drinks per day for men and no more than one drink per day for women to reduce the risk of adverse effects of alcohol on blood pressure levels. A drink is defined as a serving of either a 12 oz beer, 5 oz wine, or 1.5 oz of 80-proof distilled spirits.[1,69]

Effect of Omega-3 Polyunsaturated Fatty Acids

Fatty fish and fish oil supplements are rich in long-chain omega-3 polyunsaturated fatty acids, which are postulated to play an essential role in blood pressure regulation via the production of eicosanoids and prostaglandins. Small-scale studies in patients with hypertension using large doses of fish oil supplements (>3 g/day) have reported an associated blood pressure reduction of 2.3–4.0 and 2.2–2.5 mm Hg in systolic and diastolic blood pressure, respectively.[35,89–91] The current recommendations is to consume fatty fish (or use of fish oil supplements) two or more times per week for blood pressure management and other cardioprotective effects.[69]

WEIGHT MANAGEMENT

The association of obesity and hypertension had been well-established by both observational studies and clinical trials.[69,92] In general, it appears that a reduction in body weight of 5–10 kg in overweight individuals reduces blood pressure levels approximately 6–12/5–8 mm Hg.[35,69,93–97] Exercise training remains an important component for weight management, although exercise training alone generally only results in a 2 kg weight loss. Regular exercise training

improves maintenance of lost weight as well as reduces the loss of lean body mass as associated with weight loss.[98–100] Exercise training appears to selectively reduce visceral abdominal fat, thereby potentiating blood pressure reduction. In fact, it appears that the combination of exercise and a reduction in energy intake generally results in a greater blood pressure reduction than either alone.[100,101] Currently, it is recommended that in order to achieve and maintain a significant weight loss and lower blood pressure, 60–90 min/day of moderate-intensity aerobic exercise should be combined with a reduced-calorie DASH diet.[69]

Intervention trials that utilized comprehensive lifestyle modification programs to lower blood pressure levels have in general had very encouraging results. The most notable large-scale trials are the PREMIER[102] and the *E*xercise and *N*utritional Interventions for *C*ardi*o*vascula*r* H*e*alth (ENCORE)[103] studies. These controlled, randomized studies have reported a mean reduction in blood pressure in hypertensive individuals of 11–16 and 6–10 mm Hg in systolic and diastolic blood pressure, respectively, following comprehensive lifestyle intervention (including weight reduction). In addition, the ENCORE trial reported a significant reduction in mean 24 h ambulatory blood pressure in the comprehensive intervention group. These studies confirm current guidelines and the value of comprehensive therapeutic lifestyle interventions for the prevention and management of hypertension.[1,79]

PHARMACOLOGICAL MANAGEMENT OF HYPERTENSION

JNC-7 recommends that all patients with Stage 2 hypertension initiate pharmacological treatment in conjunction with lifestyle change whereas those with uncomplicated Stage 1 hypertension should initiate lifestyle change for a trial of 6–12 months prior to initiation of pharmacotherapy.[1] Numerous different types of antihypertensive drugs are available including thiazide and potassium-sparing diuretics, β-adrenergic blockers, α-adrenergic blockers, ACE inhibitors, AR blockers, calcium channel inhibitors, centrally acting drugs, and direct acting vasodilators.[1] A thiazide diuretic is usually prescribed as the initial drug choice for patients with Stage 1 hypertension, whereas a two-drug combination is usually the initial prescription for patients with Stage 2 hypertension (e.g., a thiazide diuretic along with an ACE inhibitor or AR blocker, or β-adrenergic blocking agent, or calcium channel inhibitor).[1] Generally, multiple antihypertensive drugs are required to achieve the therapeutic target level; it is therefore imperative that the prescribing clinician pay particular attention to contraindications, drug interactions, and comorbidities when selecting antihypertensive drug therapy. The reader is referred to the JNC-7 report[1] for a more complete discussion of pharmacological therapy. To potentiate the efficacy of pharmacotherapy, initiation of the previously described lifestyle modifications is strongly recommended.[1]

TABLE 6.3
Lifestyle Modifications for Management of Hypertension

Modification	Recommendation	Blood Pressure Reduction
Weight reduction	Maintain a BMI between 18.5 and 24.9	5–20 mm Hg per 10 kg weight loss
DASH diet pattern	Consume a diet rich in fruit and vegetables Moderate in fat-free or low-fat dairy products Reduce saturated fat and cholesterol	8–14 mm Hg
Exercise	Regular aerobic exercise >150 min/week Or 60–90 min daily for weight reduction and maintenance	4–9 mm Hg
Reduced sodium/ salt intake	Lower salt intake as much as possible (1.5 g/day of sodium or 3.8 g/day of sodium chloride)	2–8 mm Hg
Limit alcohol consumption	No more than two drinks per day for men No more than one drink per day for women	2–4 mm Hg
Increase potassium	Increase intake to 4.7 g/day (level of DASH diet) Content from fruit, vegetables, and low-fat dairy products	2–4 mm Hg

Sources: Adapted from Chobanian, A.V. et al., *JAMA*, 289, 2560, 2003; Appel, L.J. et al., *Hypertension*, 47, 296, 2006.

SUMMARY OF CONCLUSIONS

The available evidence is robust in supporting TLC for the prevention and management, and as an adjunct to pharmacotherapy, of hypertension as is summarized in Table 6.3.

INTRODUCTION

Up to 70% of deaths in the United States are due to chronic diseases, with heart disease, cancer, and stroke making up over half of all annual deaths [1]. Health care advances and public health efforts at local, state, and federal levels have contributed to marked decreases in death rates among 10 of the 15 leading causes of death [2]. While rates of heart disease and/or cardiovascular disease (CVD) have decreased by 3.7% since 2009 [2], they remain leading causes of death nationally and worldwide. It is estimated that one in three adults in the United States has at least one type of CVD [3]. The term "cardiovascular disease," or CVD, encompasses an array of syndromes that affect cardiovascular function, the most prevalent forms being coronary heart disease (CHD), cerebrovascular disease (i.e., stroke), hypertension, and heart failure [4]. The burden of CVD is substantial, resulting in diminished quality of life [5], disability [6], losses in productivity [6,7], and health care costs adding up to more than $400 billion dollars annually [7]. The burden is also impacted by health disparities that exist not only for overall CVD incidence and mortality, but also for the majority of CVD risk factors. CVD burden is even more remarkable given that the major CVD risk factors are preventable and modifiable [8].

Notably, the risk factors associated with the different types of CVD are fairly consistent and have a multifactorial etiology [9]. Contributing risk factors include nonmodifiable factors (age, gender, heredity/genetics), modifiable factors which include both sociodemographic characteristics (e.g., education or income) and behavioral or lifestyle factors (e.g., smoking, poor diet, physical inactivity, and obesity) [4,10,11], and physiological factors or conditions such as hypertension, hypercholesterolemia, or diabetes that impact CVD risk [12]. It is likely that nonmodifiable and modifiable factors are interrelated and function synergistically to impact CVD [9]. For example, a nonmodifiable risk factor (age) is one of the most important risk factors for CVD. What is modifiable, however, are the lifestyle risk factors associated with the aging process, such as physical inactivity or excess weight gain. Most interventions that target CVD attempt to intervene on one or more lifestyle risk factors (e.g., physical activity, diet, or weight) or risk conditions (e.g., hypertension, hypercholesterolemia, or diabetes) while acknowledging the biosociodemographic characteristics (e.g., race and age) that may be directly or indirectly related to CVD incidence and mortality.

Behavioral modifications to decrease or eliminate smoking, physical inactivity, unhealthy dietary patterns, excess weight/obesity, and stress management have demonstrated significant reductions in CVD risk [8,13,14]. For example, cigarette smoking, which is considered to be the most preventable risk factor for CVD, is associated with a two- to fourfold increase in CHD risk [15]. Smoking cessation interventions have demonstrated a reduction in risk from acute coronary syndrome by 61% [16] and a 35%–40% risk reduction in acute coronary syndrome among smokers with a previous CVD diagnosis [17]. Nevertheless, 17.2% of U.S. adults continue to report using tobacco products [18] including 44 million reported smokers. An estimated 443,000 smokers suffer premature smoking-attributable deaths each year [19]. As with other CVD risk factors, disparities in smoking rates exist. For example, American Indian and Alaskan Natives have the highest smoking rates in the country [19], and blue

collar workers have a smoking prevalence nearly twice that of white collar workers [20].

Interventions addressing physical activity, another behavior affecting CVD risk, have been effective at decreasing inactivity and CVD risk [13,21–25]. Regular moderate physical activity has been shown to decrease CVD incidence and mortality in a dose–response relationship with CHD risk reductions between 30% and 50% [23,24,26]. Additionally, moderate physical activity is linked to decreases in other CVD risk factors including obesity, hypertension, and hypercholesterolemia [27,28]. According to the 2008 National Health Interview Survey, however, only 18% of U.S. adults are currently meeting the national recommendations of getting at least 150 min of moderate physical activity on a weekly basis [18].

High levels of dietary cholesterol and saturated fat intake in the diet have also been linked to CVD [29]. Interventions to promote healthy diets have been shown to substantially decrease CVD risk, through modifications in glycemic load (e.g., how foods affect blood sugar and insulin levels) and through various dietary changes including increasing daily consumption of dietary fiber [30], decreasing total and saturated fats [30], and increasing omega-3 fatty acids [31]. Additionally, because of the association between hypertension and CVD, diets lower in sodium content are believed to decrease CVD risk [32,33].

Obesity is at epidemic proportions in the United States. Over 36% of adults are overweight (BMI = 25.0–29.9) and 27.6% are obese (BMI = 30.0+) and both increase risk of CVD [13]. Disparities exist in obesity rates such that compared to Caucasians, African Americans have a 51% higher obesity prevalence and Hispanics have a 21% higher prevalence [34]. Across racial groups, one theory explaining the biological link between high body mass index (BMI) and CVD risk is the "metabolic syndrome," which refers to a cluster of symptoms linked to excess weight, measured by waist circumference, fasting triglycerides, cholesterol, blood pressure, and plasma glucose levels [29]. Importantly, interventions to decrease body weight among adults have produced decreases in overall CVD incidence [35,36].

Psychological stress is defined as the response to perceived or actual environmental demands that burden or exceed one's ability to adapt [37]. Acute and chronic psychological stress has been linked to all types of CVD [38] and CVD risk [39], as well as CVD-attributable morbidity and mortality [40]. There is also research on the association between CVD and depression (e.g., Type D personality) [41] and measures of hostility [42], which are examples of psychological stress responses. Psychological/social stressors can include financial hardship, relationship and family problems, and work stress, and the subsequent psychological stress can manifest as mood and cognitive changes, as well as impact behaviors like smoking and alcohol consumption [40,43]. Stress reduction interventions have been effective in reducing CVD risk [40] through various pathways, including decreased activation of the "fight or flight" stress response [37].

Several conditions increase CVD risk, especially high blood pressure, high blood cholesterol, and high blood glucose levels. Hypertension, or high blood pressure (HBP), is a unique risk factor because it is simultaneously a chronic form of CVD and a risk factor for other types of CVD (e.g., stroke). Even after controlling for race, age, or gender, hypertension has been linked to CVD risk and increased mortality [44–47]. Interventions to reduce HBP have been effective in decreasing overall CVD risk [48–50]. High blood cholesterol, or hypercholesterolemia, is also a common risk factor for CVD [51]. CVD risk decreases 2%–3% for every 1 mg/dL incremental increase in high-density lipoprotein cholesterol (HDLC) [51,52]; additionally CVD risk can be decreased by treating hypercholesterolemia, with pharmacotherapy and behavioral interventions focused on diet and physical activity [53,54].

Diabetes mellitus (Type 1 and Type 2) is another CVD risk factor. Individuals with diabetes do not properly convert glucose (sugar) into energy. More than 18.8 million individuals are diagnosed with diabetes mellitus and it is estimated that another 7 million remain undiagnosed [55]. Ninety percent of individuals with diabetes have Type 2 diabetes [56], and Type 2 diabetes itself is the seventh leading cause of death in the United States [55,57]. Between 60% and 75% of individuals with Type 2 diabetes will die of a CVD [58]. African Americans, Hispanics, Native Americans, and Asian Americans have increased prevalence of Type 2 diabetes compared to Caucasians [57–59]. Type 2 diabetes risk is increased with obesity and physical inactivity. Interventions to decrease diabetes have also been shown to reduce CVD risk [60,61]. For example, the Diabetes Prevention Program (DPP) lifestyle intervention, which will be described in greater detail later in this chapter, was able to decrease the incidence of diabetes by 58% as compared with a diabetes medication placebo group [62]. The DPP has successfully been adapted for use in multiple community settings [63,64].

CVD-related disparities in risk, incidence, and mortality are a serious public health concern [65]. Health disparities are broadly defined as the difference in disease incidence, prevalence, mortality, burden, access to care, and care quality linked to demographic characteristics (e.g., age, race, ethnicity, gender, and sexual identity) and socioeconomic factors (e.g., income, education, and geographic location) [65–68]. For over 20 years, national initiatives have targeted disparities and these efforts continue, as evidenced by the Healthy People 2020 goals to "achieve health equity, eliminate disparities, and improve health for all groups" [69]. Despite the evidence that interventions to reduce HBP, HBC, tobacco use, stress, and increase physical activity can be effective in reducing both CVD risk factors and CVD incidence/mortality, and despite the 3.7% overall drop in CVD rates since 2009, there are certain population groups that consistently suffer CVD-related disparities and are not experiencing these positive outcomes.

Gender-, race-, and income-based differences in CVD prevalence and mortality are among the most prominent health disparities. CHD rates per 1000 males are 81.1 and nearly

double those of females whose CHD rates are 49.6/1000 [70]. Similarly, for all CVD types except stroke, males have higher CVD mortality rates than females. Racial/ethnic disparities related to CVD risk exist well. CVD incidence and mortality are higher among African Americans, American Indians, and Asian or Pacific Islander groups compared with Caucasians [7,65,66]. In 2009, although Caucasian males had the highest prevalence of CHD (67.2/1000 vs. 59.8/1000 among African American males), African Americans were significantly more likely to die from the condition (403.5/1000 vs. 292.7/1000) [70]. Individuals with low education and income levels suffer increased incidence and mortality across most types of CVD [7,65,66]. Income-related disparities are often linked with income inequality (i.e., large inequality between groups of individuals in income distribution often measured using the Gini coefficient or the Robin Hood index) [71]. Even after controlling for race, income-related disparities are associated nationally and globally with obesity and sedentary lifestyle [72], as well as overall CVD incidence and mortality [73,74].

To continue to make progress in reducing CVD incidence and mortality among U.S. adults, health professionals must find ways to reach and intervene with subgroups who suffer disparities in health. We advocate for community-based participatory research and practice to work collaboratively with those intended to benefit from the interventions. By engaging those who suffer disparities in health to participate in formative research, implementation, and evaluation, we are better able to reach these populations in settings where they live, work, play, pray, and socialize. Moreover, with community-based approaches we build relationships and trust with groups who are at highest risk of CVD when we enlist them to be active partners in eliminating health disparities. In addition to improving engagement and reach within these high-risk communities, we also need to identify effective interventions that can be adapted in culturally and contextually appropriate ways if we are to eliminate these disparities in health.

ADDRESSING CVD WITH COMMUNITY-BASED APPROACHES: PRINCIPLES AND GUIDING FRAMEWORKS

An effective community-based approach to addressing CVD disparities engages the community and also ensures that the interventions/programs are adapted to fit the needs and characteristics of the target community [75]. Ensuring that a program or intervention is culturally relevant—that is, it takes into account social and cultural aspects of health behavior, including family history and relationships, traditions, cultural norms, spending priorities, living arrangements, and support systems [76]—is a major strength of the participatory nature of most community-based approaches. Community representatives and leaders are knowledgeable about the needs and interests of their members, as well as barriers or challenges in a community that will affect program adoption and implementation. Community-based approaches establish connections with these local leaders, engaging them as equal partners in identifying and clarifying the health problem, deciding how to best reach the intended population, developing workable solutions, and tailoring interventions for the unique needs and interests of the community [75].

Community-based approaches begin with community-organizing and community-building activities [77]. Empowering community members to take ownership of their health promotes and facilitates the social change process needed for health promotion programs to be considered, adopted, implemented, and able to produce the desired behavioral and health outcomes [77]. Community growth, group identification, and working toward a collective health goal are believed to foster group cohesion and community pride [75]. The collective social support is believed to promote long-term behavioral changes [25]. Community-based approaches also draw attention to important health factors, available resources, and assets within communities, and work toward changing the health-related norms and culture of a given community [75,78,79].

In the previous edition of this book, Dr. Thompson gave a thorough account of the history of chronic diseases, the role of lifestyle behavior change in CVD, the use of experimental designs to modify these behaviors, and the role of community approaches to decrease risk by challenging/altering the health culture of a community. After highlighting several key studies, including the Community, Hypertension, Atherosclerosis, and Diabetes (CHAD) program, the Stanford Three-Community Study, the North Karelia Study, the Switzerland National Research Program, the Coronary Risk Factor Study (CORIS), the Stanford Five-City Project, the Minnesota Heart Health Program (MHHP), the Pawtucket Heart Health Program (PHHP), The Australian Studies, and the Community Intervention Trial for Smoking Cessation (COMMIT), Dr. Thompson recommended that health care providers become more engaged in community-based approaches as health advocates for their patients by participating in media advocacy efforts or collaborating with voluntary health groups. Here, we conduct a review of selected literature on more recent CVD intervention efforts, document advances in community-based approaches to reducing CVD, and emphasize the importance of ecological approaches and robust evaluation efforts that will help prioritize interventions to address and eliminate CVD disparities.

Guiding Frameworks for Community-Based Approaches

Social ecological models are fundamental guiding frameworks for a wide range of community-based health behavior change efforts. Social ecological models emphasize the importance of multiple factors and influences on health, including environmental, cultural, social, and psychological factors [80]. The core of an ecological model is that it serves as a useful heuristic for planning a comprehensive intervention that targets multiple levels and targets of influences on health behavior [81]. There are four key assumptions of

ecological models: (1) factors at multiple levels of influence impact behavior; (2) factors interact within and between levels of influence; (3) multilevel interventions (vs. single level) should be most effective in producing effective behavioral outcomes; and (4) multilevel interventions will be most effective when they are behaviorally specific. Multilevel interventions are a cornerstone of community-based approaches [82]. By nature, communities are complex, multidimensional, multilayered entities composed of interconnections of individuals, social networks, organizations, and are governed by social policies. The social ecological framework allows one to articulate these relationships and provides a useful guide for developing interventions that address the complexity of community-based approaches to decreasing CVD incidence and mortality.

According to Stokols [82] and McLeroy et al. [81], health behavior outcomes will be optimized when there are interventions at the intrapersonal, interpersonal, organizational, community, and/or social policy levels of influence [80,81]. Figure 7.1 depicts these multiple levels of influence within the social ecological framework. The intrapersonal level includes interventions to address the knowledge, attitudes, beliefs, intentions, and other characteristics within an individual that influence his/her health behavior choices and chances. These are often traditional educational efforts aimed at the individual. Interpersonal-level interventions target individuals as they interact with others (e.g., peers, parents, spouses, supervisors, health care providers). These interventions may include efforts to increase social support, improve communications between parents-kids, spouses, or patient providers. Organizational-level interventions target the places where individuals congregate such as worksites, health care settings, churches, beauty salons, libraries, and many other locations. Organizational-level interventions seek to influence the social and physical environment, and policies within selected institutions to support the health of those who are members of the organization. Community-level interventions target entire towns, cities, or regions with interventions that influence social and physical environment of these larger units where multiple organizations may be influenced via media efforts, community-organizing efforts, new walking trails, or other community-based strategies. Social policy influences all members of a larger community or society with broad social, political, or economic interventions such as national policies to promote healthy school lunches, tax credits for small businesses that offer health promotion programs for their employees, and national food labeling requirements. If interventions are simultaneously mounted at all levels of the SEF, then we assume that the likelihood of desired health behavior changes would be increased.

FIGURE 7.1 The social ecological framework, illustrating multiple levels of influence that affect health behavior.

The story of tobacco use in the United States offers a brilliant example of how interventions designed and delivered at multiple levels of the SEF have conspired to reduce tobacco use among adults from 25.5% to 17.2% over the past two decades [83,84]. Initially, all intervention strategies were aimed at individual smokers to get them to quit—this strategy worked for some, but not all smokers. Individual strategies were not as effective for smokers who were highly addicted to nicotine, for those who worked in blue collar or other smoke-filled work settings, or for smokers who lived with other smokers. And, it was realized that nonsmokers who were exposed to smoke were at increased risk of CVD and cancer. As a result, interventions moved beyond individually focused approaches at the intrapersonal or interpersonal level of the SEF, to more "upstream" intervention approaches that would restrict access to tobacco among youth; restrict tobacco use (and exposure to smoke) at schools, workplaces, and other public places; and limit tobacco advertising. Over time, interventions utilized media campaigns and "Quit and Win" contests at the community level, utilized free or low-cost quitline services, and offered access to effective pharmacologic treatments that would help smokers quit with higher success rates. And, policy and regulatory-level interventions utilized cigarette sales taxes, and other social policies to further prohibit smoking that completed a set of multilevel interventions running simultaneously at each level of the SEF. With this concerted effort, decreasing tobacco use and the resulting premature death and disability attributable to tobacco use and exposure to smoke have been a true public health success story. Now, similar multilevel intervention efforts are being applied to the problem of obesity.

Just as the social ecological framework is useful in the development of community-based approaches, RE-AIM is an effective framework for evaluating and prioritizing among community-based intervention approaches. RE-AIM, developed by Glasgow et al., evaluates the impact of health promotion programs using measures of "*R*each, *E*ffectiveness, *A*doption, *I*mplementation, and *M*aintenance" [85]. *Reach* is an individual-level construct and is defined as the proportion of the population that participates in a given program. *Effectiveness* refers to the success rate of the program; *adoption* measures the uptake of the program by organizations. Representativeness is a crucial consideration for assessing both *reach* and *adoption* because it relates to the type of individuals and organizations that participate in these

programs with an understanding that one seeks to attract a representative group of individuals/organizations versus a select, nonrepresentative group that may already be "healthy." *Implementation* assesses the extent to which a health program is implemented as designed and *maintenance* measures the sustainability of the program over time with individuals and organizations [85]. Community-based approaches benefit from applying the RE-AIM evaluative process because it reveals that interventions which reach the greatest numbers of individuals (i.e., high "reach"), with highly effective programs (i.e., high "effectiveness"), and are adopted by the greatest number and most representative organizations (i.e., high "adoption"), with the best or greatest fidelity to the implementation success (i.e., high "implementation"), and can be sustained over time within individuals/organizations (i.e., high "maintenance") are those that will be most effective and desirable to support. When interventions are evaluated using RE-AIM constructs, we can assess, identify, and prioritize among many competing strategies using a data-driven approach. In resource-limited times, RE-AIM allows practitioners and policy makers to invest wisely and provides crucial information for resource allocation. Moreover, for researchers, RE-AIM provides essential information that steers recruitment strategies at the individual and organizational levels, helps clarify fidelity and implementation challenges, and offers guidance on planning for sustainability of interventions once funding is done. Additionally, it provides critically important information to aid in the adaptation of effective interventions for diverse populations and communities. Using the RE-AIM framework, programs can be evaluated in ways that will assist with program improvements, translation, adaptation, and long-term sustainability within individuals, organizations, and communities.

EFFECTIVE COMMUNITY-BASED INTERVENTIONS TO ADDRESS CVD

We conducted a limited review of community-based approaches to decreasing CVD risk factors, incidence, and mortality. A PubMed search was conducted using each of the targeted risk factors (smoking, physical activity, diet, weight, and stress), and the key words "cardiovascular disease," "community-based," and "community programs CVD prevention," yielding 668 results. After excluding papers published after 1999 (to avoid redundancy with those reviewed by Thompson in the previous edition [86]), those focusing on non-adult populations, papers written in languages other than English, papers describing baseline or one-time data collection efforts, and those that described interventions based on DPP, CHIP, or MoRo (which we will describe in greater detail in the next section), 14 studies met our inclusion criteria. In Table 7.1, we organize study information by identifying the target population or community, the targeted risk factors, theories (if any) upon which the intervention was based, intervention components, level of SEF, settings, study design(s), and available results. While this table does not represent a comprehensive inventory of all multilevel community-based approaches to CVD prevention (due to exclusionary criteria and/or inadequate information of program components), it does provide a useful summary of some community-based efforts.

As previously mentioned and evidenced in Table 7.1, the term "community" refers to a population within a defined place or location or context [77]. Thus, "community" can describe individuals located within many settings, including worksites, faith-based organizations, individuals located within a specific geographic area, or individuals who identify with a specific cultural/ethnic or age group, or any number of defining characteristics. In the studies reviewed, we identified interventions that took place in a variety of community settings.

A myriad of intervention strategies were used in these studies to decrease CVD risk factors, or CVD incidence/mortality. The community-based intervention methods used included improving access to health educational materials (e.g., through educational classes, media campaigns, or group cooking classes), improving access to resources (e.g., increasing access to healthy foods through farmers markets or fitness activities), altering the physical environment (e.g., neighborhood cleanup and beautification projects or installation of treadmills), intervening with community health workers (CHW), and policy changes (e.g., paid exercise time for employees). Additionally, all of the studies reviewed utilized multilevel intervention strategies, categorized according to the SEF. All of the programs reviewed included both intrapersonal (e.g., individual knowledge and skill development) and interpersonal components (e.g., group fitness and healthy eating classes). Half of the programs (7 of 14) had interventions at the organizational level including programs that attempted to influence health of individuals at worksites and faith-based organizations. Thirty-five percent of the programs (5 of 14) had community-level components that included collaborations between different organizations (e.g., community organizations and primary care facilities). However, only two of the programs reviewed implemented a policy change; one implemented a provision for healthy food at meetings and in another, employees received paid time for exercise (see Table 7.1). The following descriptive data describe outcomes based on the type of community-based method implemented (e.g., educational interventions were associated with increased physical activity).

Each of the projects had an educational component to either increase awareness about CVD risks or intervene on a CVD risk factor or factors. Several of the studies were successful in improving CVD awareness [87–89], implementing environmental change [87,90], improving CVD screening [88], improving physical activity and diet [91], decreasing BMI and weight [92–94], improving self-reported health and mood [94], decreasing blood pressure [89,95,96], improving cholesterol levels [93], improving blood glucose levels [92,93], and decreasing smoking [95].

Policy changes can expedite transformations in the physical and social environment, as well as the health culture of

TABLE 7.1
Effective Community-Based Interventions to Address CVD

Project/Author	Target Population/ Community	CVD Risk Factor	Theory Used	Intervention Components	SEF	Settings	Methods	Results
Kansas City—Chronic Disease Condition (KC-CDC) / Collie-Akers et al. [87,126]	African Americans and Hispanics in Kansas City, MO	• Diabetes • Other CVD risk factors selected by participating collaborators, primarily diet and physical inactivity	Not reported	• Community organizing and coalition building • Educational literature • Group education sessions (including cooking demonstrations) • Group fitness activities • Provision of healthy food at meetings	1, 2, 3, 5	• Community organizations • Faith-based organizations	• Case study and time-series design • Time-series design for community change outcomes	• 321 documented community changes from October 2001 through December 2004. 75% of these were designed to reduce risk for both CVD and diabetes; 56% targeted primarily • Most community changes represent ongoing efforts, rather than one-time events (64.8% among neighborhood associations and 60% among faith organizations)
Union Town Community Health Project/ Cornell et al. [99]	African American women in Union Town, AL	• Smoking • Diet • Physical inactivity	Community empowerment, diffusion of innovation, and social cognitive theory	• CHW delivered • Community-wide screening and educational events • Group fitness activities • Group cooking classes • Neighborhood cleanup and beautification projects • Educational literature added to public library collection • Increased availability of ingredients and implements needed for healthy cooking in local stores	1, 2, 3, 4	• Community	• Pre–post community inventories	• CHWs reached 574 individuals through structured community-wide events, in addition to those reached in informal education and awareness raising activities • CHWs taught a total of 108 aerobics classes during the 12-month intervention period, attended by a total of 107 people, 74.7% of whom attended four or more classes per month • Monthly group cooking classes were attended by 76 community residents most of whom were regular attendees • Six community members attended two multi-session smoking cessation courses

Charlotte REACH 2010/DeBate et al. [90]	Northwest Corridor of Charlotte, NC, predominantly African American population	• Smoking • Diet • Physical inactivity • Diabetes	Not reported	• Group fitness activities • Farmers markets • Door-to-door visits from CHWs • Cue-to-action prescription pads for physicians to provide referrals to REACH programming and secondary prevention activities • Diabetes support groups • Grocery store tours	1, 2, 3, 4	• Community • Health care providers	• Focus groups	• Changes within and between ecological levels of change were observed • REACH participants reported an increase in knowledge of preventative health behaviors, the development of health-related skills, and the diffusion of knowledge to family • CHWs reported changes in individual health perceptions from disease- to prevention-oriented, and positive community changes
Farag et al. [21]	Employees of rural public school system in Southwestern Oklahoma	• Physical inactivity	Not reported	• CVD risk factor screening • Installation of treadmills at worksites • Educational literature on walking • Paid time for exercise	1, 2, 3, 5	• Worksite	• Pre/post-screening	• Pre/post-significant differences in: • Lower total ($p < 0.0001$), low- ($p = 0.01$), and high-density lipoprotein cholesterol ($p < 0.0001$) • Lower systolic blood pressure ($t = 2.9$, $p = 0.004$) • Trend toward higher self-reported physical activity levels ($p = 0.06$)
Goldhaber-Fiebert et al. [92]	Adults in rural Costa Rica	• Diabetes • Physical inactivity	Not reported	• Group fitness activities with family participation, facilitated by local community leaders • Group nutrition classes	1, 2	Community	• RCT	• Intervention group lost 1.0 ± 2.2 kg compared to 0.4 ± 2.3 weight gain in the control group ($p = 0.028$) • Fasting glucose decreased 19 ± 55 mg/dL in the intervention group and increased 16 ± 78 mg/dL in the control group ($p = 0.048$) • Glycosylated hemoglobin decreased 1.8% ± 2.3% in the intervention group and 0.4% ± 2.3% in the control group ($p = 0.028$)

TABLE 7.1 (continued)
Effective Community-Based Interventions to Address CVD

Project/Author	Target Population/ Community	CVD Risk Factor	Theory Used	Intervention Components	SEF	Settings	Methods	Results
• Graffagnino et al. [93]	Overweight and obese adults	• Overweight • Obesity	Not reported	• Individualized nutrition counseling based on the Therapeutic Lifestyle Diet • Individualized physical activity regimen • Group classes on stress management, lifestyle change, healthy eating, physical activity • Optional behavioral health assistance	1, 2	• Community	• Retrospective analysis of 6-month intervention	• Weight loss of 7.3% in men and 4.7% in women • Significant improvement were noted in body weight ($p < 0.0001$), total cholesterol ($p < 0.0001$), LDL cholesterol ($p < 0.0001$), HDL cholesterol ($p < 0.005$), triglycerides ($p < 0.0001$), and fasting glucose ($p < 0.02$)
Un Corazón Saludable/ Harralson et al. [94]	Low-income urban Latinas	• Diet • Physical inactivity • Depression	Not reported	• Group fitness classes • Group educational classes (recognizing CVD risk factors and heart attack symptoms, communication with health care providers, healthy eating and recipe modification, depression and health, and physical activity)	1, 2	• Community	• Pre–post	• Statistically significant improvements • BMI ($p = 0.001$) • Abdominal obesity ($p < 0.001$) • Waist-to-hip ratio ($p = 0.04$) • Self-rated health ($p < 0.001$) • CES-D scores ($p < 0.001$)
Healthy Connections Project/Harvey et al. [88]	Latina and African American women at high risk for diabetes and/or hypertension in Detroit, MI	• Diabetes • High blood pressure	Not reported	• Screenings • Awareness raising and educational activities in a social, group setting, delivered by CHWs	1, 2, 3, 4	• Community	• Training program evaluation using observation, document review, group interviews, process surveys, and CHW knowledge tests	• Increased awareness and number of individuals screened • Eight CHWs conducted 124 house parties, conducted 1428 blood pressure screenings, and provided health education to 1646 individuals

Cardiovascular Health Awareness Program (CHAP)/ Kaczorowski et al. [98]	Older adults	• High blood pressure	Not reported	• CVD risk assessment and blood pressure screenings; results shared with family physicians • Peer education about blood pressure monitoring	1, 2, 3, 4	• Community pharmacies	• Cluster randomized trial	• Intervention communities experienced a significant reduction in admissions for acute MI (rate ratio 0.87, 0.79 to 0.97; $p = 0.008$) and congestive heart failure (rate ratio 0.90, 0.81 to 0.99; $p = 0.029$) but no significant decrease in hospital admissions for stroke
Finnmark Intervention Study/Lupton et al. [127]	Adults in Arctic coastal communities	• Physical inactivity • High blood pressure	Not reported	• Community empowerment • Cooperation between different organizations and the primary health care system • Mass media communications • Smoke-free policies at health centers and schools • Fitness class offerings at voluntary organizations • Group cooking classes	1, 2, 3, 4	• Community	• Quasi-experimental	• Males in the intervention community experienced an 8.6% ($p = 0.047$) increase in physical activity as compared to the control community, a 0.01 mm Hg ($p = 0.002$) reduction in systolic blood pressure and a 0.1 mm Hg ($p < 0.001$) decrease in diastolic blood pressure • Females in the intervention cohort experienced an 11.2% increase in use of low-fat milk ($p = 0.046$) as compared to the control community, an increase in systolic blood pressure by 2.1 mm Hg ($p = 0.024$), and a reduction in diastolic blood pressure by 2.1 mm Hg ($p < 0.001$)
The Ostego-Schoharie; Healthy Heart Program/Nafziger et al. [95]	Rural adults living in New York State	• Overweight • Smoking • Diet • Physical inactivity	Not reported	• Community organizing • Mass media communications • Screenings • Posting of fact sheets in workplaces and locations throughout the community • Supermarket tours, recipe contests • Walking groups • Smoking cessation referrals and education • Professional education • School classroom demonstrations	1, 2, 3, 4	• Community	• Pre–post	• Smoking prevalence declined (from 27.9% to 17.6%) • Systolic blood pressure was decreased • No change in diastolic blood pressure • Body mass index increased significantly

TABLE 7.1 (continued)
Effective Community-Based Interventions to Address CVD

Project/Author	Target Population/ Community	CVD Risk Factor	Theory Used	Intervention Components	SEF	Settings	Methods	Results

Pasos Adelante/ Staten et al. [91]	Adults living in United States–Mexico border counties in AZ	• Smoking
		• Diet
		• Physical inactivity
		• Diabetes
		• High blood pressure
			Not reported	• Group educational classes
				• Group fitness activities
				• All intervention components delivered by CHWs
					1, 2	• Community	• Pre–post	• Increased mean number of minutes/week spent on moderate-to-vigorous walking ($p < 0.001$)
								• Reductions in weekly consumption of sweetened soda ($p < 0.001$)
								• Increases in weekly consumption of:
								  • Salads pre to post ($p < 0.001$)
								  • Vegetables ($p < 0.001$)
								  • Fruits ($p < 0.001$)

The Barber-Assisted Reduction in Blood Pressure in Ethnic Residents (Barber-1) Study/ Victor et al. [96,120]	African American men	• High blood pressure	Not reported	• Screening • Educational posters and literature • Peer education	1, 2	• Community barbershops	• Cluster randomized trial	• Greater improvement in hypertension control rate than the comparison treatment ($p = 0.04$)
Villablanca et al. [89]	Women, primarily African American	• Overweight • Physical inactivity	Not reported	• Risk-specific counseling • Heart and stroke education • Medical screenings	1, 2	• Community organizations • Faith-based organizations	• Longitudinal cohort • 32 sites • Pre–post-educational intervention	• Improved awareness of health disease, calling 911, and risk factors ($p < 0.05$) • Improved control of hypertension ($p < 0.05$) • Improvement of stage of change ($p < 0.05$)

Note: Levels of the Socioecological Framework: Key: Interpersonal = 1, Intrapersonal = 2, Organizational = 3, Community = 4, Policy = 5.

a community. For example, Collie-Akers et al. demonstrated that policy change (i.e., provision for healthy foods at meetings) was successful in facilitating broad-level environmental change in African American and Hispanic community and faith-based organizations [87]. Additionally, a worksite-based study adopted a policy of paid exercise time [21].

Increasing access to services (e.g., fitness activities and healthier foods) is another community-based intervention strategy. Efforts to increase access to fitness activities to decrease CVD risks within their community samples were successful in improving CVD awareness [87], promoting environmental change [87,90], improving physical activity [21,91] and diet [91], decreasing BMI and weight [92–94], increasing self-reported health and mood [94], improving blood pressure [21], improving cholesterol levels [21,93], and improving blood glucose levels [92,93]. Efforts to increase access to healthier foods were also successful in improving CVD awareness [87] and facilitating environmental change [90] within several community-based programs.

Other community-based intervention methods include using CHWs, individual and group counseling, and screening campaigns. CHWs serve as a bridge between health care organizations/providers and the intended beneficiaries of their programs/services [97] and because CHWs live in the communities where they work, they understand the needs and barriers of a community. In the studies reviewed, interventions using CHWs were effective in implementing environmental change [90], and improving physical activity and diet [91]. Individual and group counseling improved overall CVD risk [89], decreased BMI and weight [93], improved blood pressure [89], improved cholesterol levels [93], and improved blood glucose levels [93]. Lastly, the interventions that were designed to increase screening rates improved CVD awareness [88], improved screening rates [88], improved CVD-related hospital admittances [98], and improved blood pressure [96].

This review of community-based studies designed to decrease CVD risk using community-based approaches revealed that numerous intervention strategies were applied at multiple levels of the SEF to increase physical activity, decrease weight, increase healthy eating, decrease blood pressure, smoking rates, blood cholesterol, and blood glucose. And 4 of the 14 studies reviewed targeted a single-risk factor, while the remaining 10 used a multiple-risk factor design. Unfortunately, almost no studies reported that theory guided their intervention efforts. However, the influence of the SEF can be seen in many of the projects that used multilevel interventions targeting not only individual-level behavior but also community-wide environmental change. Notably, many targeted a population suffering CVD health disparities, specifically low-income populations [88,91,94], rural populations [21,92,95], older populations [98], and minority populations [87–91,96,99]. Study designs were varied and included randomized controlled trials (RCTs), longitudinal cohort studies, pre- and posttest designs, and mixed method designs. In some cases, the measures used to assess outcomes were not necessarily valid or reliable, or were complicated (e.g., reach of a screening awareness media campaign). This type of challenge can be exacerbated by multilevel interventions which also produce multilevel outcomes that may have synergistic outcomes. Less focus overall was attached to process measures that reveal important reasons why an intervention may prove effective, or not.

Since publication of the previous edition of this book, which highlighted a number of sentinel community-based CVD risk reduction programs such as the Stanford Five-City Project, the North Karelia Study, and the Minnesota and PHHP, several recent studies have attempted to build on the successes of these previous trials and have produced effective CVD outcomes and/or improvements in CVD risk factors. Here we select three community-based approaches: the DPP, the Coronary Health Improvement Program (CHIP), and the Romsås in Motion (MoRo) studies as examples of more recent community-based interventions that produced effective outcomes. Additionally, each of these studies has operated on at least two levels of the social ecological framework.

The Diabetes Prevention Program (1996–2001)

Diabetes is an important risk condition for CVD, and both of them share several common risk factors, including obesity and overweight, physical inactivity, and hypertension. Effective community interventions that address risk factors for diabetes, therefore, can provide useful lessons for preventing or reducing CVD. The DPP was a multicenter clinical trial involving 3324 adults with prediabetes who were randomized to one of three study arms: placebo, medication (metformin), or a lifestyle modification program [60,62]. In order to be eligible for the program, adults needed to have a BMI of 24 or higher (22 or higher in Asians), fasting glucose concentration of 95–125 mg/dL, and 140–199 mg/dL 2 h after 75 g oral glucose [62]. The lifestyle modification arm focused on achieving and maintaining a weight reduction of at least 7% through dietary changes and engaging in moderate physical activity for at least 150 min/week. The intervention's core education curriculum targeted the intrapersonal level of the social ecological framework and consisted of 16 educational modules delivered over a 24-week period by lifestyle coaches using motivational interviewing techniques. The educational modules covered basic information about balancing nutritional input with energy output, but also covered potential barriers to lifestyle change, including motivational and social challenges [60]. Participants were taught self-monitoring techniques and recorded physical activity and fat and calorie intake for at least 1 week/month [60]. To address the interpersonal level of the social ecological framework, participants learned strategies to leverage social relationships to help, rather than hinder, achievement of their behavior change goals by finding physical activity partners and using social cues to promote healthy behavior [60]. Finally, participants attended group education classes on topics such as healthy cooking and resistance training [60]. After 3 years of follow-up, the incidence of diabetes in the lifestyle intervention was reduced by 58% (95% CI = 48%, 66%) and 31%

(95% CI = 17%, 43%) in the metformin group as compared to the placebo group [62]. With regard to weight, participants in the lifestyle intervention lost a mean of 5.6 kg, whereas the mean weight loss for the metformin and placebo groups was 2.1 and 0.1, respectively ($p < 0.001$) [62]. Particularly relevant to the goal of eliminating health disparities, minority groups that suffer disproportionately from Type 2 diabetes (African Americans, Hispanic Americans, Asian Americans and Pacific Islanders, and Native Americans) comprised 45% of the participants enrolled in the original DPP study [100]. Results in the DPP lifestyle intervention were similar across gender and racial/ethnic groups [62].

Since its original success, the DPP lifestyle intervention has been adapted for use in many new community settings and for diverse populations. In her review of seven studies of community-based translations of the DPP, Jackson summarized characteristics and results for these translation efforts [101]. One such effort was a modified DPP lifestyle intervention in a semi-urban YMCA that demonstrated a significant difference ($p < 0.001$) in 6-month weight reduction between intervention (6.0% of body weight; 95% CI = 4.7, 7.3) and control groups (2.0% of body weight; 95% CI = 0.6, 3.3) and in total cholesterol (−22 vs. +6 mg/dL) [63]. The DPP educational modules were also used in rural African American churches, integrating prayer with church leadership and peer support into DPP-based group activities [102]. Following the 4-month intervention, participants had significant ($p < 0.05$) decreases in weight (7.5 lb [3.6%]), systolic (16 mm Hg [11.7%]) and diastolic (12 mm Hg [14.0%]) blood pressure, and fasting glucose (5 mg/dL [4.8%]) [102]. Cramer et al. adapted the DPP to implement a less costly and more sustainable intervention in a low-resource urban environment with a primarily African American population [103]. The intervention arm of the 9-month RCT delivered an adapted DPP curriculum and also integrated case management program with a family medicine clinical care services. This adapted DPP program resulted in greater reductions in the intervention group compared to the usual care group in HbA1c levels (−1.87 vs. −0.54) and weight (−2.47 vs. +0.88 kg) ($p = 0.011$) [103]. In addition to these three examples of the extension of the DPP into the organizational level (i.e., YMCAs, churches, and community clinics) of the social ecological framework, the DPP has also been applied to worksites [104]. For example, Aldana et al. reported that 2 years after a 12-month DPP-based worksite intervention, participants maintained significant improvements as compared to baseline in oral glucose tolerance (26.59 mg/dL decline; $p < 0.05$) and aerobic fitness (18.65 mL/kg/min; $p < 0.05$) [104]. Additional DPP translation efforts using a CBPR approach have been undertaken with underserved Latino populations in Chicago [105] using a CHW model to deliver intervention components. These efforts resulted in participants' forward movement along the stages of change model for the behaviors of increasing fruit and vegetable intake, increasing physical activity, and reducing fat intake. Additional translations of the DPP are being implemented with Native American youth in Montana (results not yet available) [106] and with low-income African American women and Latinas (results not yet available) [107].

The Rockford Coronary Health Improvement Project (2000–2002)

The CHIP was initially designed as a 30-day, 40 h outpatient hospital-based education program in Kalamazoo, MI, that aimed to reduce blood lipid levels, blood pressures, and blood sugar levels, decrease excess weight, eliminate smoking, enhance daily exercise, adopt better stress coping strategies, and decrease medication for hypertension, diabetes, and heart disease for high-risk adults [73]. The original CHIP study enrolled 304 adults over age of 40 years all of whom were designated "at risk" for developing coronary artery and related diseases based on body weight, diagnosis of diabetes or hypertension, and/or a history of coronary artery disease [73]. Participants were encouraged to exercise for 30 min daily and to adhere to "The Optimal Diet," a plant-centered, high-fiber, low-fat, low-sugar, low-salt diet. The Kalamazoo feasibility study yielded statistically significant ($p < 0.001$) improvements between baseline and 4-week follow-up in blood pressure, weight, BMI, and decreases in triglyceride levels [73].

CHIP was subsequently implemented in five Rockford, IL communities through the Center for Complementary Medicine of Swedish American Health System in Rockford, IL. The "Consolidation Phase" of this 7-year project, for which results are available, enrolled 1517 self-selected adults from the general population through presentations at service clubs, churches, and corporations and through exposure to billboards, brochures, and health care providers [108]. Pooled results from the five Rockford community programs showed a significant ($p < 0.001$) reduction in the mean number of coronary risk factors for men and women from 3.4 to 2.3 [108]. Individuals with the greatest number of coronary risk factors (≥3 risk factors) showed clinically significant improvements in total cholesterol, LDL, weight, systolic and diastolic blood pressure, and glucose levels [108]. In addition to these individual outcomes, researchers reported community-level changes due to consumer demand for healthier foods, resulting in changes in nutritional offerings in several major grocery stores, 25 restaurants, and a fast food chain [108]. Englert et al. acknowledge the need for RCTs to evaluate CHIP; however, the program shows potential in creating a "critical mass" to effect change at the community level of the social ecological framework [108].

CHIP has also been adapted for use in six workplaces in Rockford, IL [109]. The modified 32 h program consisted of 15 educational models, delivered over 8 weeks via twice-a-week videos and facilitated group discussions. After the 8-week intervention, employees in all participating worksites demonstrated significant improvement in weight, BMI (−1.3 and −1.6 for overweight and obese

participants, respectively), total cholesterol (–28.8 and –47.3 mg/dL for participants with borderline and high total cholesterol, respectively), and LDL cholesterol (–35.4 and –61.7 mg/dL for participants with high and very high LDL, respectively) [109]. The CHIP video-based intervention has subsequently been implemented in community- and faith-based organizations in addition to workplace and outpatient clinical settings [110]. These video-based interventions focus on the intrapersonal level, interpersonal level (through social support and encouragement of family participation), and organizational level (when implemented at worksites, community- and faith-based organizations) of the social ecological framework.

Romsås in Motion Study (2000–2003)

The MoRo study was a quasi-experimental test of the effectiveness of a 3-year community-based intervention to reduce risk factors for diabetes and CVD among adults in a multiethnic, low-income district of Oslo, Norway, with a large non-Western immigrant population. The intervention was designed using a CBPR approach that established a local resource group consisting of lay members of the community and solicited input from local politicians, lay leaders, and health and welfare workers to assist in planning and implementation [22]. The program design drew upon aspects of expectancy-value theories, Social Cognitive Theory (SCT), and the stages of change model to specifically target physically inactive individuals with low psychosocial readiness for change [22]. Intervention components included strategies to increase awareness, improve knowledge, and change attitudes about physical activity using brochures, individual counseling, group fitness activities involving participants' friends and family members, and a mass media campaign [22]. BMI, cholesterol, blood pressure, blood glucose, and self-reported physical activity and smoking status were measured at baseline and at the end of the 3-year intervention period. Significant differences between individuals from the intervention district and individuals from a matched comparison district of Oslo were found in smoking status (net proportion of quitting was 2.1% in favor of the intervention community; $p = 0.043$), higher self-reported physical activity (9.5% net increase in favor of the intervention; $p = 0.008$), resting heart rate for men (–1.70 beats/min; 95% CI = –3.31,–0.10; $p = 0.038$), systolic blood pressure for men and women (–3.79 mm Hg; 95% CI = –5.74, –1.84; $p \leq 0.001$ and –3.52 mm Hg; 95% CI = –5.17, –1.86; $p < 0.001$, respectively), and body weight and BMI change for men (–1.24 kg; 95% CI = –1.88, –0.60; $p < 0.001$ and –0.42 kg/m^2; 95% CI = –0.63, –0.21, respectively) [22]. Body mass increased in both districts, but 50% less so in the intervention district as compared to the control. The net proportion that increased body mass was significantly lower overall 14.2% ($p < 0.001$) and even lower among non-Western immigrants in the intervention with a 27.5% lower proportion of increased body mass as compared to the comparison district [111]. MoRo was able to successfully leverage community- and intrapersonal-level influences to encourage behavior change among physically inactive individuals.

CONCLUSIONS AND RECOMMENDED FUTURE DIRECTIONS

While impressive progress has been made in reducing CVD mortality by nearly 4% over the past 15 years, significant and alarming disparities in CVD risk behaviors, incidence, and mortality persist, particularly among low-income and ethnic minorities. Moreover, because of the aging baby boomer generation and longer life span, the population over 65 years will double over the next 15 years [112], dramatically increasing chronic disease burden and rates. Therefore, identifying effective interventions that will reach large numbers of individuals who suffer disparities (e.g., race-, age-, and income-based) in CVD disease risk and incidence/mortality are increasingly important. Moreover, multilevel interventions that are adoptable by large numbers of organizations and communities, plus "upstream" intervention approaches that embrace social, political, and economic intervention strategies, are needed. Like the successes we have experienced in tobacco, the new twenty-first-century public health challenges that will need to be surmounted in a resource diminished environment demand that they are effective, adaptable, and sustainable over time. Applying evaluation constructs like RE-AIM to these multilevel intervention strategies will allow us to prioritize among and between different strategies that can help maximize the use of resources at any given time point to address disparities in CVD incidence and mortality.

The results of our selected review of community-based approaches to address CVD provided a number of important insights. First, 100% of these programs used multilevel interventions and 10 of 14 targeted multiple risk factors. The community-based projects we identified were effective in decreasing targeted CVD risk factors using a myriad of intervention strategies such as education materials, mass media campaigns, environmental and policy changes, and improving access to health care services via CHW. Programs were successful in modifying most of the targeted risk factors for CVD, including physical activity, decreasing weight, increasing healthy eating, and decreasing blood pressure, smoking rates, cholesterol, and blood glucose. In particular, we singled out three community intervention strategies for special consideration. Of these, the DPP is a unique and important success story because this clinically based intervention has been adapted now for a wide range of community settings and diverse populations. The intervention has been modified for easier implementation while maintaining its effectiveness—a crucially important outcome. The story associated with the DPP and the ongoing evolution of this program will be important to chart so that all key lessons can be learned from this effort.

This review also demonstrated that many programs focused on target communities who suffer a disproportionate

CVD burden including low-income communities [88,91,94], rural communities [21,92,95], older populations [98], and minority groups [87–91,96,99]. However, very few reported use of theory to guide the interventions and many did not adopt community-based participatory research principles that might have enhanced program recruitment, acceptance, outcomes, and long-term sustainability. We remain advocates for CBPR approaches when addressing populations who suffer disparities in health.

Despite the effectiveness of these community-based approaches, several important challenges were identified. One of the challenges of community-based approaches efforts is matching the agenda of researchers and health professionals with the needs and expectations of community who suffer disparities in health [78]. Adopting a co-learning process that embraces and values both community and academic methods is an inherently valuable aspect of community-based participatory research principles [78]. Researchers may be challenged to reconcile the strict application of community-based approaches with funding constraints; however, such challenges can be met when researchers, health professionals, and community partners are respectful about community collaborations and the development or implementation of evidence-based programs with community partners. Academic and community partnerships take time to develop and may operate differently depending upon project-specific and community contexts; however, many have found a balance for optimizing resources with community needs and expectations [75,77,78].

Another challenge is that community-based intervention studies often have limited power to detect statistically significant changes [113]. New analytic strategies provide some opportunity for overcoming this challenge; however, this concern remains. Measurement efforts that are reliable and valid, as well as allow us to detect small improvements in CVD risk factors, have proven that they can have long-term clinical effects. For example, a 1% drop in blood cholesterol levels led to a 2%–3% drop in CVD mortality [113]. On a population basis, these small effects can produce large changes in CVD incidence and mortality [113]. New study designs that move beyond the limits of RCTs are gaining favor [114]. Optimizing designs [115,116] and interrupted time series [117] maximize power, preserve the opportunity to study "natural experiments" involving policy changes, and give researchers new opportunities to study the influence of multilevel interventions. Pennant et al. observe that preventing contamination between intervention and comparison groups in multilevel, community-based interventions is challenging [113]. Community-wide interventions and mass media campaigns will reach all members of a community. Using matched community comparison designs, like the one adopted for the MoRo evaluations, is one way to address this issue, which also ameliorates the threat of differential attrition. Cheadle et al. note that rigorous evaluations, especially those that measure health outcomes of individual health behavior, are costly and can even exceed implementation costs of community-based studies [118]. For this reason, they advocate for the use of community-level indicators (CLIs) to monitor and demonstrate changes over time in important intervention outcomes, such as changes in store inventories to support healthy eating [118]. Such indicators offer an opportunity to measure change in multiple levels of the social ecological framework to supplement findings at the individual level. Cost analyses, cost-effectiveness, and return on investment analyses are growing in importance and popularity.

We also believe that the mechanisms of behavior change, and certain key influences on behavior, have not been adequately addressed in community-based interventions to date. For example, very few of the projects we reviewed account for psychosocial factors like mood (e.g., depression and anxiety) and stress. It is possible that psychosocial factors are a barrier that may play more of a role in behavior change in some populations (e.g., those with high stress or depression rates) than currently hypothesized. Few community-based interventions have been developed to address stress or other mental health issues in healthy communities. There is much room for new thinking and new intervention approaches to address this important area of influence on CVD.

Very few studies clarified the frameworks or theories used to guide interventions they were testing. The field will advance when we can learn from each other and build on intervention successes and failures. To do this well, we need to understand the basis upon which interventions are developed and tested. To improve upon and maximize the benefits of community-based approaches, the development of new theories, research questions, designs, and methods is essential to ensure that this field of research continues to expand. For example, there are potentially unlimited possibilities in emerging technology. The use of social media and other tools (e.g., texting) to recruit, unite, remind, or educate is an intriguing and growing trend.

Nontraditional community settings are another way to advance community-based approaches and improve reach. For example, barbershops and beauty salons are located in all communities and are unique, historical places which may be particularly well suited for reaching African Americans [119]. One of the community-based interventions we reviewed [120] was effective in increasing blood pressure screening among African American men who visit barbershops. Other barbershop interventions have improved hypertension [96,121–123], smoking rates [124], diabetes [122,123], and stroke awareness [125].

SUMMARY

To deal with the complexity and burden associated with CVD, health professionals must be creative and strategic with community-based approaches to decrease CVD risk factors, incidence, and mortality. Many CVD risk factors overlap with risk factors associated with other chronic diseases, such as cancer, diabetes, and arthritis. Thus, what is learned with interventions applied to these chronic diseases can and should be considered in the development of CVD-related interventions. Evidence-based interventions that engage the

community and address multiple levels of the social ecological framework have universal appeal. Evaluating the impact of community-based interventions can be facilitated via rigorous research designs with measures taken from the RE-AIM framework. Strategies to maximize reach, adoption, and effectiveness, while attempting to ensure representativeness and sustainability, mindful of costs, are critically important. Full engagement of community members and community organizations in these efforts leverages the strengths of a community and fosters the type of mutual respect and trust that can lead to long-term, sustainable changes that have the potential for reducing or eliminating disparities in health.

INTRODUCTION

This chapter provides an overview of the tools that are available for evaluating dietary intakes of individuals. It describes the concepts of dietary status, nutritional status, and some simple tools for measuring them. The dietary reference intakes (DRI), which are the standards for nutrient intakes that are used in the United States and Canada, are described and their uses are discussed. The latest Dietary Guidelines for Americans, recommendations to help guide Americans in altering their current intakes in more healthful directions, are summarized. MyPlate (formerly MyPyramid and the Food Guide Pyramid), a guide that provides food-based recommendations based on the Dietary Guidelines for Americans and the DRI, is described. The Healthy Eating Index (HEI), a simple means of evaluating the balance, variety, and adequacy of intakes based on these standards, is also discussed. Finally, Healthy People 2020, a set of national goals for promoting health and preventing disease that involve nutrition, is briefly mentioned.

CONCEPT OF NUTRITIONAL STATUS AND ITS MEASUREMENT

Nutritional status is a component of health status that represents the bodily state resulting from the intake, absorption, utilization, and metabolism of food. It also reflects growth, development, and infectious, traumatic, or other factors that affect health.

TABLE 8.1
Forms of Malnutrition and Clinical Terms Used to Describe Them

Form and Cause of Malnutrition	Clinical Terms to Describe It	Comments
Dehydration: Inadequate fluid intake to meet bodily needs	Dehydration	Often occurs secondary to fever, exertion, very warm dry climate, or because of diets with high solute loads or drugs that have diuretic effects.
Starvation: Virtually totally inadequate intakes of all nutrients	Marasmus, emaciation, cachexia	Occurs with prolonged fasting; withholding of fluids worsens its effects.
Protein–calorie malnutrition	Kwashiorkor, protein–calorie malnutrition	Often occurs secondary to disease and infection, probably via cytokine-mediated responses to acute infection or trauma, e.g., HIV/AIDS. Sarcopenia due to inadequate intake of protein and/or cytokine-mediated responses to insult.
Vitamin, mineral, or other specific nutrient deficiencies	Pellagra (niacin/tryptophan), scurvy (ascorbic acid deficiency), rickets and osteomalacia (vitamin D deficiency in children and adults, respectively), iron deficiency anemia (iron deficiency), nutritional anemia (iron, vitamin B6, folic acid or vitamin B12 deficiency), essential fatty acid deficiency	Often occur secondarily to inadequate food intake or inadequate dietary quality. May also occur as conditioned deficiencies secondary to disease.
Increased diet-related chronic disease risk factors due to imbalances of nutrients	Excess of saturated fat, cholesterol, and other atherogenic and thrombogenic dietary lipids (hyperlipidemias and perhaps altered clotting factors), excess of salt and/or sodium (blood pressure risk factors)	Imbalance or excess of energy-yielding nutrients or related substances may give rise to metabolic aberrations and increase risk of ill health, especially in those with certain genetic patterns.
Obesity: Excess food energy intake and/or insufficient energy output	Excess food energy regardless of source gives rise to obesity and overweight	Physical inactivity may increase likelihood of excess energy intakes.
Alcohol excess	Alcoholism, problem drinking	At very high levels of alcohol intake, all persons develop physical signs of chronic disease; at lower levels of intake some individuals are particularly susceptible.
Excess of other specific nutritionist (vitamins, minerals, others)	Specific toxicities vary: hypervitaminosis A (vitamin A), hypervitaminosis D (vitamin D), fluorosis (fluoride), etc.	Intakes that exceed the upper level of the Dietary Reference Intakes generally increase risk of compromising one or more functions. The possible functions vary from nutrient to nutrient.
Toxicity: Excess of other constituents in food, drink, or supplements	Names vary depending on substance; lead poisoning, lathyrism, etc.	Many substances other than nutrients in food and supplements may cause illness.
Foodborne disease	Food poisoning or food intoxication: salmonellosis, botulism, staphylococcal food poisoning, others. Parasites such as beef tapeworm may cause problems. Prions or viruses as in bovine spongiform encephalopathy	Food is the carrier for a microorganism, virus, or parasite.

Table 8.1 summarizes the reasons why several measures of malnutrition are necessary to assess nutritional status. Because each method has its limitations, several different measures that tap many characteristics and different levels of effects are usually employed. Nutritional status assessment usually includes anthropometric, biochemical, clinical, and dietary measures as well as food-related quality of life. It also considers the individual's eating habits and metabolically relevant health characteristics.

Table 8.2 shows the various forms of malnutrition, which include deficiencies, excesses, and imbalances of nutrients. Nutritional assessment describes the specific form of malnutrition present, the stage in the development of malnutrition, and the severity of the problem.

The clinical signs of malnutrition, their effects on weight, on functions such as the activities of daily living and quality of life, are the end result of a pathological process of malnutrition that starts much earlier. This preclinical phase of malnutrition can often be identified by the use of dietary measures, biochemical, hematological, or other biomarkers in blood, urine, or other bodily secretions, as well as individual cells, tissues, and organ systems. If diet is the cause of the malnutrition, food intake alterations are usually apparent for days, weeks, or months before metabolism is altered and changes in biochemical measurements are present. Therefore, if the goal is to prevent malnutrition and to do it as early as possible, dietary assessment is worthwhile.

TABLE 8.2
Why Multiple Indicators of Nutritional Status Are Needed to Diagnose Malnutrition

Multiple forms of malnutrition exist.
See Table 8.1 for some examples

The causes of malnutrition vary.
Some are due to deficient quality or quantity of diet alone (primary malnutrition) but most are secondary to disease, social or psychological problems, and may occur even in the face of adequate and appropriate food in the environment. Many different pieces of information are necessary to arrive at an understanding of how these causes interact.

No single indicator for all the forms of malnutrition exists.
The most sensitive, least costly and most specific indicators of malnutrition vary from nutrient to nutrient.
Even for a specific form of malnutrition, indicators vary with respect to how sensitive, specific, valid, and reliable they are.

Severity of malnutrition varies.
Milder forms require different and more sensitive indicators (e.g., measures of tissue or blood stores) than the more severe (which may be evident with anthropometric or clinical measures alone).

DIETARY STATUS

This chapter focuses on only one aspect of nutritional status: dietary status. It involves the assessment of an individual's consumption of foods, food groups, or food patterns. Dietary status and nutritional status are not always similar, because food consumption is not the only factor involved in determining if dietary intakes are sufficient to maintain health.

The rationale for measuring dietary intake and status is that intake is a factor affecting nutritional status that can be altered. The most important aspects of dietary intake are the amount of food, the forms in which the nutrients are present in the diet (e.g., food, beverages, supplements, or nutrient containing medications, because they may affect absorption), and the presence of other bioactives in food that may have beneficial or harmful effects.

The usual goal of assessing diet is to obtain an estimate of habitual or usual intake, either by measuring diet directly by observation or indirectly by report. Because most health effects depend on usual or habitual intake, it is important that the report includes a sufficiently long period of time (e.g., many days or weeks) to be representative of usual intake. Only representative intakes over relatively long periods are meaningful for assessing the effects of diet on nutritional status or the associations between diet, health, and disease. The one exception is the type of very recent intake information that is usually collected when incidents of foodborne illness are being traced. Then, foods eaten in the hours or days before the poisoning accident, details on food preparation, and other factors that may have caused the contamination are also investigated.

The many methods for assessing dietary intake are reviewed in detail elsewhere [1]. Although the methods all have their limitations, they do provide a picture of food and nutrient consumption that may be useful for purposes of planning intakes or assessing what has been eaten.

The major shortcoming of most dietary assessment methods is that while they furnish a general profile of nutrient intakes, they are less accurate in providing information on the absolute amounts of nutrients or bioactives that are consumed. Most dietary assessment methods depend heavily on the eater's report of what was eaten, because it is very difficult for an outsider to collect duplicates or observe everything a person eats. But eaters' reports may be inaccurate and biased. People may forget what they ate, have difficulty judging the amounts they have eaten, report inaccurately because they want to appear to conform to what the questioner wants to hear, or they may unconsciously change what they eat when they are asked to record it. Therefore, information on dietary intakes is never perfectly accurate. These errors are usually quite large, perhaps 20% or more, and even higher among certain groups such as the very obese, or those with impaired memories, such as children, the very old, or individuals with mental health problems. A common error is failure to mention dietary supplements, which, in countries such as the United States, often contribute substantially to dietary intakes [2]. Forgetting what has been eaten is a particular problem when people are asked to remember what they have consumed over long periods, such as during the past year, especially if they are to provide estimates of the frequency and amounts they have eaten. Such estimates probably reflect more recent intake (e.g., a few weeks), and they are probably most accurate when individuals have fairly fixed intake patterns. When people are given lists of foods and asked to record their frequency of eating these foods, they often overestimate how much they ate, and results are usually adjusted to provide estimates that are more in line with plausible energy intakes. Also when people are asked to keep food records or diaries, often they unconsciously change what they eat to make the recording task simpler, or because they are surprised at how much they eat and decide to eat less to make their intakes appear more "balanced."

Dietary intake assessment is used as a proxy for nutritional status because it is less expensive and easier to obtain than a full-fledged nutritional status assessment, and can often provide enough useful information to remedy problems. For example, it can identify those who are very undernourished because they are eating too little, too much, or imbalanced amounts of foods and nutrients. Dietary assessment also helps to clarify and strengthen assumptions about the presumed causes of changes in nutritional status when it is synchronized with information derived from anthropometric, biochemical, clinical, and other measures. Questioning can also reveal many environmental factors that influence dietary intakes and nutritional status that may need to be changed, such as climate, living conditions, exposure to pathogens, and socioeconomic conditions.

However, dietary status assessment only measures what an individual eats, and not what is actually metabolized;

so, it may miss other causes of poor nutritional status, such as malabsorption. Although dietary assessment theoretically is an extremely sensitive indicator of malnutrition, since it reflects a very early stage in the development of the pathology, in practice it is often not useful by itself. Dietary data are less precise and reliable than biochemical and anthropometric indices. Because they are usually obtained by report from the patient or respondent, they are usually more subject dependent and vary more in validity and reliability from one person to the next. They often fail to reflect usual intakes and instead reflect only the prior few days. Intakes of nutrients from dietary supplements and oral nutritional supplements may be disregarded, causing more underestimation errors. Thus, it is difficult to determine whether suspected deficits in dietary intake are actually due to diet or to errors in reporting. Therefore, in order to fully assess nutritional status, dietary information must be combined with the other types of data.

BIOMARKERS

Because there are many problems involved in obtaining accurate information on food intakes, if precise estimates of intakes are necessary, as is the case in research studies, surrogate markers of intake such as biomarkers are often used. Biomarkers are reliable and accurate biochemical or other measurements that can be objectively measured and evaluated. They can be indicators of intake, normal biological processes, and nutritional status, pathological processes, pharmacological responses to an intervention, or health outcomes.

In order to be useful, biomarkers must be analytically valid, useful, clearly show associations between the biomarker and disease, and reflect interventions with changes in both the biomarkers and clinical outcomes.

The most common sources of biomarkers are indices in blood, urine, and other body fluids such as saliva. There are also functional biomarkers that measure processes such as immune function or cognitive function, and more nonspecific biomarkers, such as grip strength.

Some biomarkers reflect intake, others nutritional status, risk, or health outcomes. The biochemical biomarkers in blood or urine that reflect nutrient intakes or nutritional status are used most commonly. Some intake biomarkers are listed in Table 8.3. However, biomarkers also have their limitations. They reflect different things; some reflect dietary intake, others nutritional status, and still others risk or outcome of disease.

Among the biomarkers reflecting *intake* are ascorbic acid and serum folic acid; they are specific but often only reflect intake over a short time (e.g., hours or days) rather than a longer time. Most of the biochemical or other biomarkers of intake are very specific and only reflect intakes of a single nutrient rather than the overall diet. For some nutrients, there are no acceptable biomarkers that reflect long-term intake, and other biomarkers are available but very expensive and

TABLE 8.3
Some Biochemical Biomarkers of Intake (Exposure) and/or Nutritional Status

Nutrient	Biomarker	Comments
Iron	Hemoglobin	Low specificity (many different causes of anemia decrease hemoglobin, not just iron). Cutoffs vary by age, sex, and ethnicity. This is a good indicator for monitoring improvement in iron status if individual is iron deficient.
	Serum plasma ferritin	This is an acute phase protein, but it is nonspecific; it increases independently due to acute or chronic inflammation, infection, malignancy, hyperthyroidism, liver disease, heavy alcohol use.
	Serum transferrin receptor	A specific indicator of iron-deficient erythropoiesis that is not affected by inflammation.
	TIBC	Nonspecific and varies over the day.
	ZnPP erythrocyte zinc protoporphyrin	A sensitive indicator for diagnosis of the deficiency. However, the specificity is limited since it is affected by lead poisoning, the anemia of chronic disease, chronic infection and inflammation, hemoglobinopathy, and hemolytic anemias.
Zinc	Serum plasma zinc	Responds to zinc supplementation, but easily affected by contamination, and is also affected by inflammation, fasting, estrogen use, hemolysis, and chronic illness.
B12	Serum/plasma total zinc	Measures total biologically active B12. Poor correlation with dietary zinc. Also cutoffs are uncertain and kits for the test vary.
	Serum/plasma methylmalonic acid	Cutoffs are uncertain. Test is sensitive.
	Serum/plasma holotranscobalamin HoloTC	
Folate	Serum/plasma folate	Varies with recent intake, and kits to test vary.
	Erythrocyte folate	Kits vary. Samples are difficult to prepare and cannot be stored.
	Serum/plasma total homocysteine	Depends on B2 status, B12 status, B6 status, and MTHR polymorphism state.
Vitamin A	Serum retinol	Sensitive to intake, but only if stores are low. Also not very sensitive because it is under homeostatic control.

difficult to use except in research studies. Therefore, biochemical and other measures of dietary intake also have their limitations in clinical practice.

Other biomarkers reflect *nutritional status*. One is serum 25OH vitamin D, which reflects both dietary intake and exposure to the sunlight's ultraviolet rays that activate the provitamin D in the skin. Some of the nutritional status biomarkers are too nonspecific to be useful. For example, serum albumin is a marker of dietary intake, but it reflects not only protein nutritional status but also inflammation and infection. Other status markers, such as serum thiamine, are specific, but they only reflect status over a short time (e.g., hours or days) rather than habitual intakes. Other status markers, such as red blood cell folate, reflect intake over a somewhat longer period of time (e.g., several weeks).

A third type of biomarkers reflects *outcomes*, such as coronary artery disease or stroke. Often, instead of outcomes themselves that take so long to develop, surrogate endpoints are used such as serum cholesterol or blood pressure. These so-called surrogate endpoints are substitutes for a clinical endpoint that predicts a clinical benefit or a harm based on good evidence. For example, high levels of low-density lipoprotein cholesterol (LDL-C) reflect risk of coronary heart disease, and hypertension is associated with risk of stroke. Biochemical indices such as LDL-C and high blood pressure are therefore considered good *biomarkers of risk or outcome*.

DIETARY REFERENCE INTAKES

The DRI are quantitative standards for nutrient reference intakes used for planning and assessing the diets of healthy people. Prior to the development of the DRI, the 1989 Recommended Dietary Allowances (RDA) served as the standards for nutrient intakes. The DRIs were developed conjointly by Health Canada and the Food and Nutrition Board, U.S. National Academy of Sciences in the 1990s. They are used as the basis for other materials, such as the Dietary Guidelines for Americans, that provide food-based dietary guidance [3,4].

Overview of the DRI

The DRI consist of multiple reference points that serve as dietary standards for various uses instead of the single reference values used in the past [5–12]. They were developed because of the availability of new data on many nutrients and potential candidate nutrients. Also, new concepts on assessing dietary deficiency and excess were available by the 1990s. It was also felt that if possible, dietary recommendations should be based on standards that would prevent obesity and reduce risks for chronic disease and excess. Finally, new-user needs, such as nutrient labeling, made a revision of existing recommendations imperative.

The DRIs include the estimated average requirement (EAR), the RDA, or, if the RDA cannot be calculated, an adequate intake (AI). An upper reference level (UL) is also set. And, acceptable macronutrient distribution ranges and energy needs are also provided [13]. The EAR, RDA, and AI are defined with specific criteria of nutrient adequacy. The UL, in contrast, is defined using specific indicators of excess. The reference weights and heights for the adults and children for whom the dietary recommendations are designed are based on recent population-based surveys of the United States.

Criteria on Which Nutrient Recommendations Are Based

The criteria for adequacy upon which nutrient needs are formulated are critical, and these vary from nutrient to nutrient. Each EAR, RDA, and AI is described in terms of a selected criterion or criteria of adequacy. These criteria include the best level to determine the risk of an individual's nutrient stores becoming deficient. For example, the criterion for folic acid among women in the childbearing years is based on a combination of biochemical indicators, primarily red blood cell folate, and secondarily plasma homocysteine and serum folate levels. Other criteria relate to reducing the risk of disease if they are available, although often they are not. For example, a separate recommendation for folic acid is made for women capable of becoming pregnant based on a criterion related to reducing the level of neural tube defects. Prevention of chronic degenerative disease is a focus of some other nutrient adequacy criteria. For example, the calcium criterion was selected to be a level of intake sufficient to provide retention of calcium during growth and minimizing bone loss during adulthood. In the case of fluoride, the amount of fluoride needed to decrease rates of dental caries was chosen. However, the evidence base for a level of other nutrients including phosphorus, magnesium, vitamin D, the B vitamins, and choline is insufficient to define a function such as preventing chronic disease, and must rely on other criteria, such as mineral balance.

RDA

The RDA is the average daily dietary intake level that is sufficient to meet the nutrient requirements of nearly all (e.g., 97%–98%) of healthy persons of a specific gender at a particular stage of life or physiological condition, such as pregnancy or lactation. The only use of the RDA is to serve as a goal for individuals, not for populations. These are available on the World Wide Web at http://www.iom.edu/Activities/Nutrition/SummaryDRIs/DRI-Tables.aspx

To establish an RDA, agreement on the criterion to be used is the first issue that must be solved. This criterion is used to assess adequacy. An appropriate cutoff must then be established for each criterion that is used to determine the

difference between what is considered an adequate and an inadequate level of nutritional status. In order to set this cutoff, there must be sufficient data on individuals who are consuming levels of intake at which some reach the suggested cutoff for the criterion and at which others do not. This permits the establishment of a dose–response relationship. It is also necessary to have an understanding of the distribution of requirements among individuals in the group from which the requirement is estimated. When nutrient requirements are skewed for a population, other approaches are used to find the 97th to 98th centile to set the RDA.

Recommendations are also available for water and electrolytes.

The RDA is the values that should be used for planning individual intakes. The RDA is not appropriate for assessing the diets of either individuals or groups, or for planning diets for groups. An interactive tool for calculating the appropriate RDA/AIs and energy needs from an individual's age, sex, physiological condition, weight, height, and physical activity level is available at the following website: http://fnic.nal.usda.gov/interactiveDRI/dri_results.php, and it can also be accessed at http://www.iom.edu/Activity/Nutrition/SummaryDRIs/DRI-Tables.aspx

EAR

The EAR is the amount of a nutrient that is estimated to meet the requirement of half of the healthy individuals in a specific life stage and gender group. The EAR is used to assess adequacy of intakes of population groups, and along with knowledge of the distribution of requirements, to develop RDA. The requirement is the lowest level of a nutrient eaten chronically that will maintain a defined level of nutriture in a person. Before setting an EAR, a specific criterion of adequacy must be chosen. This selection is based on a careful review of the literature. Among the criteria that may be used, reduction of disease risk may be considered, along with other health parameters. It is assumed that the distribution of requirements is normal. Ideally, the standard deviation (SD) of the requirement, that is, an estimate of its variability of requirement, is also available. If the SD is not available, then a coefficient of variation (CV) is used, usually of 10%. Under these circumstances, the RDA is assumed to be 1.2 × EAR. Conversely, if the CV is 15%, the RDA is 1.3 × EAR.

Recommendations for energy intake differ from those for vitamins, minerals, and protein because individuals of the same age, sex, reference weight, and physiological condition often differ markedly in their energy needs, and such factors as actual weight, height, and physical activity level are also needed to calculate it. Moreover, the standard to achieve is the EAR to maintain weight and health, not an RDA. Two SD above the EAR as a recommendation would cause individuals to consume excess food energy, which would be stored as body fat, with adverse effects upon health.

AI

The AI is a recommended daily intake level based on observed or experimentally determined estimates of nutrient intake in a group of healthy people. The main use of the AI is as a goal for the nutrient intake of individuals. It is used when an RDA cannot be determined. The AI is usually based on observed levels of intake that appear to maintain an acceptable level of health or growth. The presence of an AI is an indication that experts believe that sufficient data on requirements are not yet present for the functional criterion that has been chosen, and that more research needs to be done. The AI is set at a level that is expected to cover the needs of at least 98% of people, but it might cover far fewer, or far more, since the EAR cannot be estimated. Unfortunately, the degrees to which AIs exceed average requirements differ among nutrients and population groups. Therefore, it is meaningless to describe the proportion of the population below the AI; it is more useful to report the proportion of the population *above* the AI.

In the DRI reports, AIs rather than RDA are provided for all nutrients in infants up to a year of age, and fluoride, pantothenic acid, biotin, and choline for persons of all ages (see http://www.iom.edu/Activity/Nutrition/SummaryDRIs/DRI-Tables.aspx). Both the RDA and AI are appropriately used for setting goals for intakes of individuals. However, greater uncertainty surrounds the AI.

UL

Nutrients are essential for basic functions of human life and well-being. However, at excessive levels of intake they have possible adverse effects. Adverse effects include any significant alterations in the structure or function or any impairment of a physiologically important function in an individual. Also, since intakes of one nutrient may alter the health benefits conferred by another, detrimental nutrient–nutrient interactions are also considered to be adverse health effects. These values are also available at the Institute of Medicine website (http://www.iom.edu/Activity/Nutrition/SummaryDRIs/DRI-Tables.aspx).

It is important to remember that at the levels of nutrient intakes from diets of foods, human experience is considerable. It is only in the past few decades that single concentrated sources of nutrients have become available in the form of dietary supplements and highly fortified foods; so now, the possibility of higher intakes is more likely. At present, there is no evidence to suggest that nutrients consumed at current RDA and AI levels in enriched or fortified foods pose a risk of adverse effects to most persons [14]. However, with very high amounts of fortified foods, dietary supplements, and over-the-counter medications that contain nutrients all consumed together, total intakes may reach or exceed the safe levels.

The tolerable (or safe) upper intake level (UL) is the highest level of chronic and usual daily nutrient intake that is likely to

pose no risks of adverse health effects to almost all individuals in the general population. The more the intake is above the UL, the greater the risk of adverse effects. The intakes included in the UL for most nutrients are food, water, and nonfood sources such as nutrient supplements and pharmacological preparations. The word "tolerable" is used because most individuals should be able to tolerate this level of intake. However, it does not imply that this high a level of intake is desirable. The UL is *not* an intended level of a nutrient to be consumed. Moreover, the UL is not a level at which there is a beneficial effect. Rather, it describes the intake level at which there is a high probability that the dose of the nutrient can be tolerated biologically. When total intakes have been associated with toxicity, this fact is stated. In a few cases, it may be that toxicities are only associated with nutrients used in supplements or as drugs. For example, excessive β-carotene appears to be associated with adverse outcomes but only in supplements; and therefore, the UL for β-carotene is based only on supplements. Many individuals use large amounts of nutrients containing dietary supplements for preventive or curative purposes. Excessive intakes are a particular concern for nutrients that are not easily metabolized or disposed of by the body, such as fat-soluble vitamins.

Risk assessments describe the relationships between exposure to a nutrient and the likelihood that adverse health effects will occur in the exposed population. Risk assessment systematically evaluates the probability of adverse health events occurring in humans from excess exposure to an environmental agent such as a nutrient or food component.

Risk–risk assessments involve both the risks of taking too much of the nutrient versus the risk of not taking enough of the nutrient or supplement [15]. Such assessments are becoming increasingly common. A constant set of scientific principles involving risk assessment is used to set the UL. The process involves identifying hazards, assessing dose–responses, intake assessment, characterization, and evaluation of risk. All evaluations and judgments are explicit and evidence is provided to document the conclusions that are reached. Both qualitative and quantitative types of evidence are considered. ULs are set by first reviewing the literature to determine levels at which no observed adverse effects (NOAEL) are noted, or at the lowest level of intake associated with observed adverse effects. Then an uncertainty factor is applied to reduce the intake level from the lowest adverse effect level to insure that even the most sensitive persons would not be affected by the UL dose chosen. At present, for many nutrients there is simply not enough evidence to develop a UL. The risk is expressed as the fraction of the exposed population, if any, that has nutrient intakes in excess of the estimated ULs [6].

ULs are not always certain, fixed, and unvarying values. For many nutrients, ULs are not available because data are so sparse. Often, although intakes are available, there are no data on the adverse effects of taking large amounts of nutrients, or the data are only anecdotal in nature. In such cases, the UL cannot be established. This does not mean that there is no risk of adverse effects from high intake of the nutrient; in fact, when data about adverse effects are very limited, extra caution may be warranted. The data that exist are often scanty or drawn on studies to address other questions.

AMDR

The acceptable macronutrient distribution range (AMDR) for the energy-yielding nutrients provides a range of intakes that appear to be compatible with good health for them. The DRI and AI for water and macronutrients, and AMDR ranges for fat, carbohydrate, and protein, as well as recommended ranges for dietary cholesterol, trans fatty acids, saturated fatty acids, and added sugars are available at http://www.iom.edu/Activities/Nutrition/SummaryDRIs/DRI-Tables.aspx. Energy needs can also be calculated from tables given in the DRI report on macronutrients and energy.

Current Status of the DRI

The most recent report on DRIs was completed in 2010 on calcium and vitamin D because of the substantial amount of new information available on both nutrients [16]. Both were given new EARs and RDA on the basis of new data which were available, and the recommendations for each were raised slightly over the previous report issued in 1997 [5]. The values for other nutrients in the 1997 report (magnesium and phosphorus) were not revised and remain the same. The report on folic acid and other B vitamins was issued in 1998 [10]. The report on "antioxidant" nutrients (ascorbic acid, vitamin E, and possibly others) was issued shortly thereafter [20], and then the macronutrients and energy [17], and a volume on electrolytes and water [7]. Volumes on the uses of the DRI for assessment [18] and planning [19] were also developed by a panel on the uses of the DRI. A composite volume is available for practitioners [20]. DRIs for all nutrients, energy, and water are also available.

For individuals who are ill, the best recommendations for nutrient intakes depend on the disease itself and its effects on the absorption, metabolism, storage, and/or excretion of specific nutrients. In such cases, recommendations are best set by medical specialists for the diseases involved. Most nutrient needs are not usually affected, however, and the DRI for healthy individuals can be used for them.

Individuals versus Populations

The DRI Committee set recommendations that apply to intakes of nutrients of individuals, but not to total populations. Eventually, the thorny issue of population recommendations must be addressed, but at present population recommendations have not been set for the United States or Canada, but only for individuals. Population recommendations for nutrient intakes are much more environmentally influenced and culture bound than estimates of population requirements, and likely vary much more between countries. This is because average intakes of nutrients differ greatly

between populations of one country and another, as do nutrient intake distributions, which are very wide in some countries and very narrow in others. Recommended levels for population intakes must therefore take into account not only EARs but also these distributions of nutrient intakes within each population. Strategies such as fortification, supplementation, nutrition education, limitation of excessive intakes, and others that may be acceptable for bringing intakes into an optimal range in one country may not be so in another. Also, variations in resource and environmental constraints exist. The desired percent of the population having access to, or actually achieving, intakes that meet whatever criteria are chosen for the DRI also vary from one country to another. Economic realities, usual intakes, and historical precedents are best considered separately from biological requirements. Setting population recommendations for intakes involves scientific judgment, but also political will.

Uses Outside the United States: Are the DRI Exportable?

In the past decade, the DRI have been used in whole or in part by many other countries. While the DRI are an excellent set of standards, North America is not the world repository of all nutrition scientific wisdom and truth, and, as time goes on, they will no doubt be refined by experts in other countries as well as in the United States. It may be useful to consider which of the DRI are likely to be useful and which are not.

Many factors influencing DRI values are based primarily on biological rather than environmental influences, and these are largely the same from one country to another. Determinations of the EAR and UL, which are determined largely by human biology, should also be useful in other countries. The evidence-based reviews of the scientific literature on experimental studies of requirements for each nutrient focus on these biological factors. As new studies become available, other experts can review the evidence, add to it, and come to their own conclusions. Other factors are not as easily exportable from one country to another. For example, the functional criteria that could be used to set the U.S./Canadian requirements are many, and the most appropriate ones for another country may vary with the environment, expert judgment, and health realities. Other countries may have circumstances that make different functional criteria and endpoints more appropriate.

Exportability of the AMDR is also likely to be limited since they rely more on U.S. and Canadian intake levels and not on direct experiment. Food patterns, nutrient intakes, and environmental factors vary from country to country. In other countries, population profiles, resource constraints, and expert judgment may lead to the choice of different criteria for adequacy, with the result that AMDR, EAR, RDA, AI, and UL values chosen may differ from one country to the next.

Diversity in expert judgments often helps to drive science forward and seek firmer evidence. For other countries, the DRI recommendations, which are more evidence-based than ever before, deserve examination. The DRI may serve as useful compendia to review for efforts in other countries. Exportability/importability judgments of existing U.S./Canadian values must be considered on a case-by-case basis.

Revising the DRI

Science is constantly changing and growing; therefore, there is always a need for revision as new data become available. The DRI were conceived as the first attempt, and not as the last word, leaving room for them to change and diversify. Because all scientific conclusions are subject to revision as new evidence emerges, constant review is needed [9,10,21]. Similar efforts are now in progress in the European Union, led by the European Food Standard Agency (EFSA) and elsewhere. Expert groups in other countries and regions will no doubt have useful suggestions and improvements that the U.S./Canadian committees can learn from and incorporate into revisions. There is growing realization that systematic evidence-based reviews tailored to nutritional data are important in evaluating the evidence and that these MUST go hand in hand with expert judgment [22–26].

Next Steps for the DRI

Dietary reference standards must be revised periodically as new science become available. There is current interest in the nutrition community developing DRI for omega 3 fatty acids and several other bioactives, such as flavonoids, polyphenols, and isothiocyanates. Alcohol, while not an essential nutrient, also requires more detailed consideration than it has yet received, because it appears to have both beneficial and detrimental health effects.

Eventually, it is likely that many of the processes of evidence review and other technical aspects of data collections will be conducted in one country and then used as the basis of recommendations in other countries. The World Cancer Research Foundation has adopted a systematic process for ongoing evidence reviews for dietary recommendations on cancers that may also be adaptable to reviews of nutrient requirements [27]. To learn more about the Canadian/U.S. DRIs, the World Wide Web address is http://www2.nas.edu//fnb.

USES OF THE DRI

For assessing the adequacy of individual intakes, the best criterion is to compare intake to the EAR, although only a very rough estimate of adequacy can be made (for this reason other indices of nutritional status are also necessary). The RDA is a useful target for planning individual intakes. The most appropriate ways to evaluate the intakes of groups are to use the EARs when they are available. The proportion of individuals below the 50th centile (e.g., the EAR) is estimated. These are the individuals who are at greatest risk of dietary inadequacy. Note that the percent of the population below the RDA is *not* the population at risk of inadequacy; doing

so will overestimate the proportion truly at risk because of the very definition of the RDA. The AI is probably close to the group mean intake in some but not all instances. If the mean intake of a group is at or above the AI for a nutrient, there is unlikely to be a problem. However, it is not possible to assess risk of inadequacy quantitatively with AIs, although qualitative statements can be made. The AI is a good target for planning group intakes.

DIETARY GUIDELINES FOR AMERICANS

The Dietary Guidelines for Americans [4] are recommendations to help guide individuals to make healthy dietary choices. They are targeted to people over the age of 2 years; other recommendations are more appropriate for small infants and toddlers who are not yet consuming family fare. The guidelines emphasize healthy eating, which involves not only getting enough food but also balance, variety, and moderation in consumption patterns to decrease diet-related risks of chronic degenerative diseases.

The original Dietary Guidelines, first issued in 1980 and presented in Table 8.4, have stayed quite constant over the years [28]. However, the messages have evolved from proscriptive suggestions that centered on foods and dietary constituents to be minimized or avoided, to more prescriptive recommendations about positive dietary behaviors. Also, as scientific evidence supporting them has increased, the emphasis and content have changed somewhat based on new information [29].

Chapter 10 presents an excellent, detailed overview of the 2010 Dietary Guidelines. Updates and details on the Scientific Advisory Committee Report [30] are available at http://www.dietaryguidelines.gov. Current Dietary Guidelines for Americans recommend that to stay healthy, one should eat a variety of foods, maintain or improve one's weight by balancing food intake with physical activity, choose a diet that is plentiful in grain products, vegetables, and fruits, moderate in salt, sodium, and sugars, and low in fat, saturated fat, and cholesterol. For those who consume alcoholic beverages, they need to do so in moderation [4]. Note that the guidelines are qualitative for the most part, recommending patterns of foods and food groups, rather than very specific amounts of foods or nutrients. This qualitative emphasis reflects both scientific uncertainty about exactly how much of each nutrient should be eaten, and the Dietary Guidelines' educational purpose. Some of the guidelines are more quantitative. For example, the variety goal is defined more precisely in the text that accompanies the dietary guidelines. Also, specific goals are provided for dietary fatty acids, since the evidence base on intakes of these nutrients is now very well developed.

It goes without saying that providing guidelines is one thing, incorporating them into one's daily life is quite another and much more difficult task for experts as well as laypersons. Recommendations for putting Dietary Guidelines into action are available and downloadable in consumer-friendly format. They deserve careful reading by health professionals and consumers. Many other guidelines are also available, including many disease-specific guidelines, such as those issued by the American Heart Association, the American Cancer Society, and the American Association of Cancer Research [31]. In most respects, these other guidelines are similar to the Dietary Guidelines for Americans. There is no evidence that they promote better health or decreased risk of chronic disease than the Dietary Guidelines, although they may be helpful and reassuring to those who know they are at risk for particular health problems.

TABLE 8.4
Original Dietary Guidelines for Americans in 1980

Dietary Guidelines for Americans, 1980
Eat a variety of foods
Maintain desirable weight
Avoid too much fat, saturated fat, and cholesterol
Eat foods with adequate starch and fiber
Avoid too much sugar
Avoid too much sodium
Drink alcohol in moderation, if you drink
Calorie levels assuming choices are low fat, lean foods from the five major food groups, using foods from the fats, oils, and sweets group sparingly.
Women who are pregnant or breast-feeding, teenagers, and young adults age of 24 years need three servings.

USDA'S FOOD GUIDE PYRAMID, MYPYRAMID, AND CHOOSEMYPLATE

Over the years, there have been various efforts to develop graphics to accompany guides for healthy eating. Fifty years ago, the most popular guide was called the Four Food Groups. It focused only on intakes of foods that were necessary to assure AIs of protein, vitamins, and minerals and assumed that people would eat additional foods to meet their energy needs. Over time, the need for a graphic representation that included entire intakes including energy became evident. The U.S. Department of Agriculture introduced the Food Guide Pyramid in 1992 in response to these requests. Figure 8.1 presents this "first" pyramid. It provided a simple graphic tool that assisted people in choosing healthy dietary patterns that were varied, balanced, and moderate. The pyramid also suggested the number of recommended servings per day from each food group that people were likely need to eat to meet their nutrient needs from food alone. The reason for dividing foods into groups was that each of the food groups provided some, but not all, of the nutrients people need eat every day. The pyramid design emphasized the importance of consuming a menu that was based on plenty of breads, cereals, rice and pasta, vegetables and fruits, two

to three servings from the milk group, and two to three servings from the meat group, with an emphasis on minimizing foods high in fats, sugars, and alcohol, and avoiding excessive energy intakes.

The suggested serving sizes that were provided in the first pyramid were not necessarily those that people were accustomed to eating, and this led to confusion among consumers and health professionals. The amount people ate at a sitting would often be more than just one serving. For example, a usual dinner portion of spaghetti counted as two or three servings, and not a single serving of pasta. No serving sizes were given for fats, oils, and sweets, although it was noted that they should be limited if a person needed to lose weight. These calorie-dense foods, and alcohol, provide calories but relatively few vitamins or minerals.

The "second" pyramid, *MyPyramid*, was introduced in conjunction with the Dietary Guidelines of 2005. Figure 8.1 also provides an illustration of MyPyramid. Instead of an Egyptian style pyramid of bricks representing food groups, this pyramid appeared to many commentators to look more like a circus tent, with colored streamers representing each food group in tiers down the pyramid. The designers' hope was that the graphic better portrayed the desirability of eating nutrient-dense foods that were less calorically dense first (e.g., the base or bottom of each food group), and only later the more calorie-dense foods if energy needs had not been met (foods at the narrow top of the pyramid). However, the concept was difficult to grasp and the graphic was not successful in depicting the concept of "nutrient-dense foods first." Several other attempts to convey this concept have been made but none has gained traction with professionals or consumers [32,33]. Another web-based innovation in 2005 offered a calculator to tailor the pyramid to individual needs. It customized recommendations to the individual's age, sex, and weight and presented menus that were appropriate in calories and other nutrients. The MyPyramid Planner is still available on the World Wide Web and is useful for helping people tailor their intakes of specific foods. It is available at http://www.MyPlate.gov.

The third graphic, and the one that is now current, is the ChooseMyPlate icon, which consists of a plate (see Figure 8.1). A new interactive tool will soon be available at http://www.ChooseMyPlate.gov and will permit health professionals and consumers to develop their own personalized nutrition and physical activity plans and to track intakes and outputs. Other support on planning intakes and making healthier choices is also available there. Most of the information and educational materials that were developed for MyPyramid can also be used with ChooseMyPlate.

There are many other graphics, pyramids, and other shapes produced by other organizations and designed to help consumers. Oldways, an organization dedicated to changing the ways people eat and to featuring traditional cuisines, has produced Vegetarian, Asian, Latino, and Mediterranean diet pyramids. The pyramids are available on the World Wide Web at http://www.oldwayspt.org. Special Pyramids are also available for older Americans, children, and other groups. The extent to which these "other" pyramids meet the DRIs may vary however, and their construction needs to be reviewed before they are adopted for use in counseling.

HEALTHY EATING INDEX

The HEI is a summary measure of people's overall diet quality. In a sense, the score for the population as a whole provides a "report card" on how well Americans are eating [34,35]. The latest version, revised in 2005, consists of a score that is the sum of 20 components, each representing a different aspect of a healthful diet [36,37]. The first five components measure the degree to which a person's diet conforms to the USDA Food Guide Pyramid's recommendations for servings from the five major food groups: grains (bread, cereal, rice, and pasta), vegetables, fruits, milk (milk, yogurt, and cheese), and the meat group (meat, poultry, fish, dry beans, eggs, and nuts). The sixth component measures total fat consumption as a percentage of total food energy intakes (e.g., calories). The seventh component focuses on saturated fat consumption as a percentage of total food energy intakes. The eighth component measures total cholesterol intake, the ninth total sodium intake, and the tenth focuses on the variety in a person's diet. Each of these 10 components has a maximum score of 10 and a minimum score of zero.

The HEI score will probably be revised again to reflect the 2010 Dietary Guidelines for Americans. A high score on a component indicates that intakes are close to the recommended ranges or amounts, as stated in the USDA Food Guide Pyramid/ChooseMyPlate, the 2005 Dietary Guidelines for Americans, or some other similar authoritative food-based dietary guidance. Low scores indicate less adherence with recommended ranges or amounts of nutrients. Thus, the maximum overall score for the 20 components combined is 100.

A "report card" on the nation's eating habits was compiled using HEI data from the 1994–1996 Continuing Survey of Food Intakes by Individuals, a nationally representative food consumption survey. It was evident that most Americans could improve their intakes considerably. Approximately 12% of the population had a good diet, with an HEI over 80, and 18% had a poor diet, as signified by HEI scores of less than 51. Special areas needing improvement were consumption of fruit and milk and milk products. Males age 15–18 years, African Americans, people with low incomes, and those with a high school diploma or less education tended to have lower quality diets [38]. A recent study from England shows that a high HEI like score is positively associated with health literacy and sugar-sweetened beverage intake [39]. More recent assessments of HEI scores among Americans suggest that much remains to be done for eaters to bring their eating patterns more in line with recommendations [40]. The website which describes all of these and other studies is http://www.cnpp.usda.gov/HealthyEatingIndex.htm. Other recent studies reporting the

HEI scores for large groups in the population are available at these websites:

http://www.cnpp.usda.gov/Publications/NutritionInsights/Insight43.pdf
http://www.cnpp.usda.gov/Publications/NutritionInsights/Insight42.pdf

http://www.childstats.gov/americaschildren/health6.asp

Definitive, comprehensive reports on nutritional status were issued periodically by the Federal government for many years in a single document on national nutrition monitoring. Each report provided detailed discussions of dietary patterns and nutrient intakes, but the process of assembling them took many years [41] (Life Sciences Research Office 1989). Today, reports on specific issues are published periodically in a more timely manner by agencies in the relevant departments.

NUTRIENT LABELING

Another consumer education and awareness tool is the food label. Processed food products have had ingredient labeling for many years, with ingredients listed by weight and now many perishable foods and commodities are labeled as well. These ingredient lists are helpful for persons who want to include or avoid certain food ingredients in their diets for health or cultural reasons. New information is also available on labels now make it even easier for consumers. Nutrient labeling of processed foods was first made mandatory in 1993. The "Nutrition Facts" panel now provides information about the nutrient content of processed foods in standardized portion sizes. This label information can be used as a tool to help people select healthy diets. Today, the vast majority of processed foods and commodities, such as fresh fruits and vegetables, meats, poultry, and fish, have nutritional labels. The percentage of a standard population weighted value based on nutrient needs, called the USRDA, is used, which consists of the highest values for each adult age group by gender at the time when the label was promulgated. In addition to these labels, over-the-counter vitamin and mineral supplements have supplement facts that use a dietary standard known as the Daily Value (DV), which is also based on the RDA, to provide a comparison of the content with this nutrient standard.

Over the last two decades, nutrient content claims, health claims, and structure–function claims have also been permitted on foods. Nutrient content claims on food labels, such as "low in fat" or "good source of dietary fiber," are specified so that the same standard is used on all foods of the same type. Health claims describe the relationship between a nutrient or food and a disease. These provide additional information for consumers. Structure–function claims describe the association between a nutrient or other bioactive in food and a bodily function. Some permissible health claims for food packages are presented in Table 8.5. All health claims for foods that are currently allowed are found at the FDA website, and they are updated as new claims become available: http://www.fda.gov/Food/LabelingNutrition/LabelClaims/ucml11447.htm

HEALTHY PEOPLE

In the early 1970s, the need for explicit, measurable, prevention objectives for government, private, and voluntary groups became increasingly necessary. The Office of the Assistant Secretary for Health in the U.S. Department of Health, Education, and Welfare (now the U.S. Department of Health and Human Services) began the process of developing consensus on some national goals that could guide prevention efforts in the future. The first effort was a slim volume entitled Promoting Health, Preventing Disease: Objectives for the Nation [42]. It stated general goals and objectives in various areas of public health and preventive medicine and ways to measure progress in achieving them. In the late 1970s U.S. Surgeon General Julius Richmond, who was also Assistant Secretary for Health, commissioned a much larger effort, entitled Healthy People, that set forth an ambitious prevention plan [43]. Using a management by objectives planning process, the U.S. Public Health Service set out objectives focusing on improving health status, risk reduction, public and professional awareness of prevention, health services, and protective measures, surveillance, and evaluation. The objectives were organized in 15 priority areas under the general headings of preventive services, health protection, and health promotion. Targets for achieving the objectives were set, usually with a 10-year timeframe. It was recognized that in order to achieve the objectives, a health system reaching all Americans and integrating personal health care and public health measures focusing on the entire population (population-based measures) would be necessary. Moreover, it was clear that most prevention did not occur solely within the health system, but in community institutions as well, including schools, workplaces, families, and neighborhoods. Therefore, these environments as well as the traditional health care system were included as a focus for the preventive efforts.

Starting in 1980, and at the beginning of every decade thereafter, HHS has convened public, private, and voluntary groups to update the plan and assess progress toward achieving it. The resulting document is called Healthy People. It is now customary to issue a "mid-course review" halfway through the decade to make midterm corrections and redirect resources if this should prove to be necessary.

The current prevention plan is entitled "Healthy People 2020." The entire report is hundreds of pages long and accessible on the Internet at http://www.healthypeople.gov/2020/topicsobjectives2020/overview.aspx?topicid = 29. The overall goals of Healthy People are simple: Increase the span of healthy life, reduce health disparities among Americans, and achieve access to preventive services for all Americans. For each life stage, there are specific objectives stated in terms of reducing mortality and in the various areas. Goals are also

TABLE 8.5
Permissible Health Claims for Food Packages*

Health Claim	Example of Some Statements
Osteoporosis	
Calcium, vitamin D, and osteoporosis	A calcium-rich diet is linked to a reduced risk of osteoporosis, a condition in which the bones become soft or brittle.
Heart disease	
Dietary saturated fat and cholesterol and risk of coronary heart disease	A diet low in saturated fat and cholesterol can help reduce the risk of heart disease.
Fiber containing grain products, fruits, and vegetables, and cancer	A diet rich in high fiber grain products, fruits, and vegetables can reduce the risk of some cancers.
Soluble fiber from certain foods and risk of coronary heart disease	
Soy protein and risk of coronary heart disease	
Soluble fiber from certain foods and risk of coronary heart disease	
Soy protein and risk of coronary heart disease	
Stanols/sterols and risk of coronary heart disease	
Substitution of saturated fat with unsaturated fatty acids and risk of heart disease	
Whole grain foods and risk of heart disease and certain cancers	
Nuts and heart disease*	
Walnuts and heart disease*	
Omega 3 fatty acids and coronary heart disease*	
Unsaturated fatty acids from canola oil and coronary heart disease*	
Corn oil and heart disease*	
B vitamins and vascular disease*	
Monounsaturated fatty acids from olive oil and coronary heart disease*	
Unsaturated fatty acids from canola oil and coronary heart disease	
Corn oil and heart disease	
Dental caries	
Fluoride and the risk of dental caries	
Dietary non-cariogenic carbohydrate sweeteners and dental caries	
High blood pressure	
Sodium and hypertension	
Potassium and the risk of high blood pressure and stroke	
Calcium and hypertension, pregnancy-induced hypertension, and preeclampsia*	
Cancer	
Dietary lipids (fat) and cancer	A diet low in total fat is linked to a reduced risk of some cancers.
Fruits and vegetables and cancer	A diet high in fruits and vegetables and foods that are low in fat and may contain dietary fiber, vitamin A, or vitamin C is linked to lower risk of some cancers.
Whole grain foods and risk of heart disease and certain cancers	
Tomatoes and/or tomato sauce and prostate, ovarian, gastric, and pancreatic cancers*	
Calcium and colon/rectal cancer and calcium and recurrent colon/rectal polyps*	

TABLE 8.5 (continued)
Permissible Health Claims for Food Packages*

Health Claim	Example of Some Statements
Green tea and cancer*	
Selenium and cancer*	
Antioxidant vitamins and cancer*	
Other	
Choline	
100% whey protein partially hydrolyzed infant formula and reduced risk of atopic dermatitis*	
Chromium picolinate and diabetes*	
Phosphatidylserine and cognitive* dysfunction and dementia*	
0.8 mg folic acid and neural tube birth defects*	

Claims with an asterisk * are qualified health claims subject to enforcement discretion. These refer to claims when there is emerging evidence for a relationship between a food, food component, or dietary supplement and reduced risk of a disease or health-related condition, but the evidence is not established well enough to meet significant scientific agreement standard, and so qualifying language is needed.

set for each priority area. Nutrition is considered as one of these areas. They deal with health status, risk reduction, and services-related issues and set measurable objectives in each area. The nutrition-related goals for Healthy People 2020 are discussed in detail in Chapter 9.

For some objectives, the 2010 nutrition targets have been met. But for other objectives, such as obesity, little progress has been made or progress has been in the wrong direction. The 2020 goals reflect these problems. These are the areas where the nation must concentrate efforts in the future.

CONCLUSIONS

Dietary intake is only one facet of nutritional status, but it is an important one. The Dietary Guidelines for Americans provide recommendations for altering current intakes in more healthful directions. The DRIs, such as the RDA and UL, provide useful guides for planning nutrient intakes for individuals. Other tools, such as MyPyramid and ChooseMyPlate, are helpful food-based recommendations that, if followed, ensure that the DRI are met. Food labels aid in making wise choices in line with dietary recommendations. The HEI provides a simple tool for evaluating the balance, variety, and adequacy of intakes based on the Food Guide and Dietary Guidelines for Americans. Health professionals can use these simple tools to plan and assess their own eating patterns and those of their clients. For many practical purposes, these tools will suffice. For more elaborate planning and assessment and for research, other tools may be necessary.

The Year 2020 nutritional goals for promoting health and preventing disease provide additional useful health targets to aim for as a nation.

ACKNOWLEDGMENTS

This project has been funded at least in part with Federal funds from the National Institutes of Health and the U.S. Department of Agriculture, Agricultural Research Service, under contract number 53/3-K06-5-10. The contents of this chapter do not necessarily reflect the views or policies of the U.S. Department of Agriculture, nor do they mention trade names, commercial products, or organizations that imply endorsement by the U.S. government.

BACKGROUND

In 1979, Dr. Julius Richmond released *Healthy People: The Surgeon General's Report on Health Promotion and Disease Prevention* [1], which launched the Healthy People (HP) initiative that defined a national agenda to enhance the health of the U.S. population in five major life stages (infants, children, adolescence, adults, and older adults). Initially, 15 priority areas were identified with 226 targeted measurable health objectives for improving the health of the nation were set for HP1990. The initiative has continued with HP2000, 2010, and most recently 2020, which was launched in December 2010. The goals of HP1990 were to decrease mortality in infants through adults and increase independence among older adults. HP2000 focused on increasing the span of healthy life, reducing disparities, and achieving access to preventative services for all. HP2010 targeted increasing the quality and years of healthy life and eliminating health disparities. The newly launched HP2020 aims to attain high-quality longer lives free of preventable disease, achieve healthy equity, eliminate disparities, create social and physical environments that promote good health and promote quality of life, healthy development, and healthy behaviors across life stages with 42 focus areas and over 600 objectives. Nutrition has been a vital focus area in HP initiative, evolving from the Nutrition and Overweight chapter to the current Nutrition and Weight Status (NWS) Focus Area.

HIGHLIGHTS

Although *HP2020* incorporates several elements of HP2010, it expands the goals, topic areas, objectives, and outreach and is more action oriented than previous years. Promoting quality of life, healthy development, and healthy behaviors across life stages and creating social and physical environments that promote good health are included among the overarching goals of HP2020. These goals reinforce the importance of healthy lifestyles throughout the life span and introduce the social determinants of health, which is a major focus and new topic area of HP2020. There are a total of 13 new topic areas that are geared toward specific populations, diseases, and prevention-based strategies to improve health (Table 9.1).

Nearly 600 objectives were developed by federal experts from various topic areas and reflect input from the general public through public comment. It is important to note that objectives must have a reliable data source, baseline data, and an achievable target. Securing nationally representative data in order to ensure valid monitoring can be particularly problematic and has prevented several objectives from going forth to become a part of HP2020.

Communication and outreach efforts of HP2020 have significantly improved and facilitated accessibility to a broader group of users. HP2020 utilizes new media strategies and allows users to receive updates through social networking sites such

TABLE 9.1

Adolescent health
Blood disorders and blood safety
Dementias, including Alzheimer's disease
Early and middle childhood
Genomics
Global health
Health care–associated infections
Health-related quality of life and well-being
Lesbian, gay, bisexual, and transgender health
Older adults
Preparedness
Sleep health
Social determinants of health

as Twitter, and LinkedIn. Additionally, the recent unveiling of the redesigned HP website, a relational database of HP2020 objectives and implementation strategies, will make it possible for HP2020 to be more of a "living," action-oriented document compared to previous textbook versions. This interactive database will be updated regularly to reflect new data and changes to evidence-based resources. This website will be continuously evolving throughout the decade to include ongoing implementation strategies, collaborative efforts, data integration, and personalized information based on the specific needs of the user.

While HP2020 comprises 42 topic areas, this chapter will specifically highlight the NWS Focus Area of HP2020. It will focus on NWS as a public health concern, new developments impacting this topic area, and changes made to objectives since HP2010.

HEALTH PROMOTION AND HEALTH PREVENTION

Historically, HP has been a 10 year plan focused on improving health status and reducing disease risk for Americans. Similar to previous versions, many of the health promotion and disease prevention goals outlined in HP2020 can be helpful in preventing and managing chronic diseases. Many of the chronic diseases plaguing the United States are preventable and could be significantly reduced by diet and weight management. Increased portion sizes, high-calorie foods and beverages, and sedentary lifestyles have contributed to the obesity epidemic, which has been linked to an increased risk of heart disease, stroke, diabetes, arthritis, and some types of cancers. Therefore, it can be deduced that the prevention of some chronic diseases can be impacted by NWS.

HP2020 emphasizes a life stage approach. It focuses on promoting healthy behaviors throughout the life span, which can be helpful in preventing risk associated with age-specific developmental stages. For example, recent data suggest that poor nutrition in the early stages of life may be a predictor of chronic disease in adulthood [2]. Similarly, childhood obesity has been linked with cardiovascular risk factors later in life [3]. This knowledge suggests that health promotion and preventative actions should be geared toward early childhood to increase the benefit and the likelihood of sustainability.

IMPACT OF DETERMINANTS OF HEALTH ON NUTRITION AND WEIGHT STATUS (FOCUS OF HP2020)

HP2020 discusses how determinants of health can influence disease. It was developed to focus on societal determinants because they are linked to the root cause of disease, have the potential to aid in controlling disease, and must be addressed in order to achieve health equity. Social, behavioral, and biological factors have all been associated with health outcomes. These factors can also be linked to dietary and obesity patterns seen in individuals and certain populations.

Social

Social determinants of health refer to environments in which people are born, live, learn, play, work, and age. These determinants of health encompass economic and environmental conditions, and may be the contributors of obesity and poor dietary choices. The National Center for Health Statistics Data Brief on Obesity and Socioeconomic Status in Children and Adolescence concluded that low-income children were more likely to be obese than their higher-income counterparts, although this trend was not consistent across race and ethnicity groups [3]. However, it is important to note that between 1988–1994 and 2007–2008, the prevalence of childhood obesity increased at all income and education levels [3]. In regard to environment, availability and affordability to nutritious foods may be challenging in low-income neighborhoods. In studies performed in Baltimore, Atlanta, and New York, supermarkets were significantly more common in white and higher-income areas than in predominantly black and lower-income neighborhoods [4–6].

Individual Behavior

An individual's behavior is shaped by his or her beliefs, perceptions, values, and social environment. Recognition of specific behaviors has been attributed to increased risk of disease. For example, the consumption of *trans* fat and sedentary behaviors are associated with an increased risk of cardiovascular disease [7]. Likewise, the Centers for Disease Control and Prevention (CDC) identified tobacco, poor diet, and inactivity as the leading contributors of death—all of which are linked to behavioral choices [8]. The relationship between health and behavior is an enormously complex one and is controlled by multiple environmental factors (physical, biological, social, political, and economical), which makes promoting sustainable behavior change difficult. Yet the recent advances in evidence-based research, medical innovations, surveillance monitoring, and understanding of the many aspects of behavior have led to the development of multifaceted public health strategies and interventions aimed at behavior change.

Biology

Biological determinants of health refer to genetic factors that are attributed to the likelihood of disease. It is important to point out, genes can be considered only as contributors to a greater or lesser risk of health outcomes; they are not predictors. Several studies have suggested that obesity is heavily influenced by genetics and linked to causal genes [9,10] and attributed appetitive traits to genetically determined phenotypes [11,12]. Even with this knowledge, the interplay of behavior, lifestyle, and social influence cannot be removed from the equation. Obesity is a multiple causation disease that will require a multifactorial approach to reduce its prevalence.

Health Disparities

As previously mentioned, one of the overarching goals of HP2020 focuses on achieving health equity and eliminating health disparities. The elimination of health disparities remained in HP2020 because the gaps between ethnic and racial minorities and their white counterparts still exist in terms of incidence of chronic disease and obesity. HP2020 defined health equity as achieving the highest level of health for all people. Health equity entails focused societal efforts to address avoidable inequalities by equalizing the conditions for health for all groups, especially for those who have experienced socioeconomic disadvantage or historical injustices [13]. By definition, the pursuit of healthy equity promotes the elimination of health disparities. For this reason, the inclusion of health equity in HP2020 is progressive and prevention oriented.

EMERGING TRENDS IN NUTRITION AND WEIGHT MAINTENANCE

The increased rate of obesity has given rise to increased use of treatment, and prevention options in science, medicine, and government aimed at reducing and controlling the obesity epidemic.

Dietary Intake Trends

Before exploring emerging nutritional trends, it is important to establish the dietary intake patterns of Americans to help understand why some of the options outlined in this section are being pursued. The overall food supply has significantly increased. Yet Americans are still failing to meet the minimum requirements of MyPyramid's (now MyPlate's) nutrient-rich food groups like vegetables, whole grains, fruits, and milk products. On the other hand, many American diets include an overconsumption of solid fat and added sugars. In an article on dietary sources of energy [14], grain desserts (cakes, cookies, doughnuts, etc.), pizza, and soda were found to be the top three contributors of energy for 2–18 year olds. Many of these food selections contain "empty" calories with very little nutritional value. Americans are also consuming an increased amount of food outside of the home and eating more frequently at fast-food restaurants. This trend has significantly affected America's youth, among whom fast-food consumption was associated with higher intake of total energy, fat, saturated fat, carbohydrates, sugar, and carbonated soft drinks and lower intake of micronutrients, fruits and vegetables, and milk [15,16].

HEALTHY PEOPLE 2020 GOALS FOR NUTRITION AND WEIGHT STATUS TOPIC AREA

The name of the topic area "Nutrition and Overweight" used in HP2010 was changed to "Nutrition and Weight Status" in HP2020. "Weight status" was used because it can refer to healthy weight, overweight, and obesity—all of which are used in this topic area. There are 18 objectives found in the NWS topic area of HP2020. These objectives reflect both health promotion and prevention through consumption of a healthful diet and weight reduction or maintenance. They are geared around healthier food access, health care and worksite settings, weight status, food insecurity, food and nutrient consumption, and iron deficiency. Since no targets were met in HP2010, many of the objectives in HP2010 have been carried forward to HP2020 in an identical or somewhat modified manner. As of the latest HP2010 progress review, eight objectives moved away from its target, seven showed little or no progress, and two were moving toward its target. There were three objectives that were not carried forward to HP2020 (growth retardation among low-income children, consumption of calories from total fat, and anemia among low-income children [Table 9.2]).

HEALTHY PEOPLE 2020 OBJECTIVES FOR THE NUTRITION AND WEIGHT STATUS TOPIC AREA

The following section contains the objectives for the NWS. Each objective, some with sub-objectives, is listed with the rationale for choosing them within the focus group. The baseline, target, and data source for all objectives can be found in Table 9.3.

NWS-1: Increase the number of states with nutrition standards for foods and beverages provided to preschool-aged children in childcare.

Approximately one of every four children aged 2–5 years in the United States is either overweight or obese (at or above the 85th percentile on the 2000 CDC growth curves) [19]. About 75% of preschool children aged 3–5 years participate in child care at least once per week; 41% of preschool children are in child care for 35 h or more per week. Thus, young children have the potential to consume a large portion of their caloric intake in childcare settings [20]. Most states' childcare licensing regulations lack specific nutrition standards for child care sites aimed at improving dietary quality and preventing childhood obesity within those facilities [20–22]. Enhancing state regulations for nutrition could help address poor diet quality and the obesity epidemic in young children in the United States.

TABLE 9.2
Justification for the Removal of Objectives from the Healthy People 2020 Nutrition and Weight Status Topic Area

Objective	Justification
Reduce anemia among low-income pregnant females in their third trimester	• The data used for measuring this objective are not nationally representative • The objective ascertains anemia and not iron deficiency or iron-deficiency anemia, which is the outcome of interest under this nutrition section • Efforts to address iron-deficiency anemia are needed for both lower- and higher-income pregnant women. This objective focuses on only low-income women • The measurement of iron-deficiency anemia in a nationally representative sample of pregnant women will be captured in the retention of NWS-22 (reduce iron deficiency among pregnant females). As such, this objective does not add a sufficient amount of new information to guide public health interventions
Reduce growth retardation among low-income children under the age of 5 years	• The prevalence of growth retardation at the 1997 baseline (6%) and at the 2008 progress review (6%) was relatively low. In addition, this prevalence is very close to the prevalence that would be expected due to normal biological variation (5%) • The 2010 target (based on better than the best objective setting criteria) is 4%. There is a relatively small difference between the 2008 progress review level and the target • Public health interventions that address this issue such as WIC are already in place. It is unclear what addition public health efforts would be undertaken to continue to lower this prevalence
Increase the proportion of persons aged 2 years and older who consume no more than 30% of calories from total fat	• This objective was primarily based on the *2000 Dietary Guidelines for Americans* recommendation that Americans consume a diet moderate in fat—aiming for a total fat intake of no more than 30% of calories [17] • We propose to remove this objective because the emphasis on promoting heart health in the *2005 Dietary Guidelines for Americans* is more on types of fat than on total amount of fat consumed [18]

NWS-2: Increase the percentage of schools that offer nutritious foods and beverages outside of school meals.

There are two sub-objectives under this objective: *NWS-2.1 Increase the proportion of schools that do not sell or offer calorically sweetened beverages to students*; and *NWS-2.2 Increase the proportion of school districts that require schools to make fruits or vegetables whenever other food is offered or sold*.

The need to promote healthy eating among youth has intensified as a result of the growing national epidemic of obesity. Their failure to meet fruit and vegetable guidelines and the obesity prevalence highlight the need for school-based nutrition education, and supportive school environments encourage youth to eat more healthfully [23]. Schools are in a unique position to influence and promote healthy dietary behaviors and help ensure appropriate nutrient intake. Research has shown a relationship between the availability of high-calorie, low-nutrient snacks and drinks sold in schools and students' high intakes of total calories, soft drinks, total fat, and saturated fat, and lower intake of fruits and vegetables [24]. Conversely, students in schools with restricted snack availability had higher intakes of fruits and vegetables than students in schools without restricted snack availability [25]. System-level interventions, policy, and environmental approaches have the potential to influence individual dietary behavior through improvements to the food environment [20,26]. Tracking this objective as part of HP2020 will promote a food environment for children that more closely aligns with current dietary guidance.

NWS-3: Increase the number of states that have state-level policies that incentivize food retail outlets to provide foods that are encouraged by the *Dietary Guidelines*.

Poor dietary patterns and obesity, established as risk factors for chronic disease, have been linked to neighborhood deprivation, neighborhood minority composition, and low area population density [27]. Research suggests that neighborhood residents with better access to supermarkets and other retail stores that provide healthful foods and limited access to convenience stores tend to have healthier diets, including higher intakes of fruits and vegetables [27–31].

Evaluation of a food retail provision intervention in a low-income deprived area of England showed a modest, positive impact of the retail intervention on fruit and vegetable consumption [32]. The intervention consisted of provision of a major food supermarket to an area considered a "food desert" because access to healthy affordable food was poor. Among respondents who consumed ≤2 servings of fruits and vegetables in the pre-intervention period, 60% increased their fruit and vegetable consumption in the post-intervention [32]. An evaluation of the Apache Healthy Stores Program, a multicomponent intervention that included stocking healthier food items, found an increase in the purchase of healthy food,

TABLE 9.3
NWS Focus Area Objectives: Status, Baseline, Target, and Data Source

2020 Objective	Status	Baseline	Target	Data Source
NWS-1	New	24 States had nutrition standards for foods and beverages provided to preschool-aged children in child care in 2006	34 States with standards	National Resource Center for Health and Safety in Child Care and Early Education, and child care licensing websites from each State government and the District of Columbia
NWS-2	New	9.3% of schools did not sell or offer calorically sweetened beverages to students in 2006	21.3%	Health Policies and Programs Study, CDC
NWS-2.2	New	6.6% of school districts that require schools to make fruits or vegetables whenever other food is offered or sold to students in 2006	18.6%	School Health Policies and Programs Study, CDC
NWS-3	New	Eight states (including the District of Columbia) had state-level policies that incentivized food retail *outlets* to provide foods that are encouraged by the *Dietary Guidelines* in 2009	18 States	CDC State Indicator Report on Fruit and Vegetables. The Report gathers data sources: (1) CDC Nutrition, Physical Activity, and Obesity Legislative Database, (2) National Conference of State Legislatures Health Community Design and Access to Healthy Food Legislative Database, (3) The Food Trust
NWS-4	New	Developmental	Developmental	Developmental
NWS-5.1	New	48.7% of primary care physicians regularly assessed body mass index (BMI) in their adult patients in 2008	53.6%	National Survey on Energy Balance-Related Care among Primary Care Physicians
NWS 5.2	New	49.7% of primary care physicians regularly assessed body mass index (BMI) for age and sex in their child or adolescent patients in 2008	54.7%	National Survey on Energy Balance-Related Care among Primary Care Physicians
NWS-6.1	Retained/ modified from HP2010	20.8% of physician office visits made by patients with a diagnosis of cardiovascular disease, diabetes, or hyperlipidemia that include counseling or education related to diet and nutrition in 2001 (age adjusted to the year 2000 standard population)	22.9%	National Ambulatory medical Care Survey, CDC, NCHS
NWS-6.2	Retained/ modified from HP2010	28.9% of physician office visits made by adult patients who are obese that include counseling or education related to weight reduction, nutrition, or physical activity in 2007 (age adjusted to the year 2000 standard population)	31.8%	National Ambulatory medical Care Survey, CDC, NCHS
NWS-6.3	Retained/ modified from HP2010	12.2% of physician visits made by all children or adult patients that include counseling about nutrition or diet in 2007 (age adjusted to the year 2000 standard population)	15.2%	National Ambulatory medical Care Survey, CDC, NCHS
NWS-7	New	Developmental	Developmental	Developmental
NWS-8	Retained/ modified from HP2010	30.8% of persons aged 20 years and over were at a healthy weight in 2005–2008 (age adjusted to the year 2000 standard population)	33.9%	National health and Nutrition Examination Survey (NHANES), CDC, NCHS
NWS-9	Retained/ modified from HP2010	34.0% of persons aged 20 years and over were obese in 2005–2008 (age adjusted to the year 2000 standard population)	30.6%	National health and Nutrition Examination Survey (NHANES), CDC, NCHS
NWS-10.1	Retained/ modified from HP2010	10.7% of children aged 2–5 years were considered obese in 2005–2008	9.6%	National Ambulatory medical Care Survey, CDC, NCHS
NWS-10.2	Retained/ modified from HP2010	17.4% of children aged 6–11 years were considered obese in 2005–2008	15.7%	National Ambulatory medical Care Survey, CDC, NCHS

(*continued*)

TABLE 9.3 (continued)
NWS Focus Area Objectives: Status, Baseline, Target, and Data Source

2020 Objective	Status	Baseline	Target	Data Source
NWS-10.3	Retained/ Modified from HP2010	16.2% of children aged 6–11 years were considered obese in 2005–2008	14.6%	National Ambulatory medical Care Survey, CDC, NCHS
NWS-11.1–5	New	Developmental	Developmental	Developmental
NWS-12	Retained/ modified for HP2010	1.3% of households with children had very low food security among children in 2008	0.2%	Food Security Supplement to the Current Population Survey, U.S. Department of Commerce, Bureau of the Census
NWS-13	Retained/ modified from HP2010	14.46% of households were food insecure in 2008	6.0%	Food Security Supplement to the Current Population Survey, U.S. Department of Commerce, Bureau of the Census
NWS-14	Retained/ modified from HP2010	0.5 of cup equivalents of fruits per 1000 calories was the mean daily intake by persons aged 2 years and older in 2001–2004	0.9 cup equivalents per 1000 calories	National health and Nutrition Examination Survey (NHANES), CDC, NCHS
NWS-15.1	Retained/ modified from HP2010	0.8 cup equivalents of total vegetables per 1000 calories was the mean daily intake by persons aged 2 years and older in 2001–2004 (age adjusted to the year 2000 standard population)	1.1 cup equivalents per 1000 calories	National health and Nutrition Examination Survey (NHANES), CDC, NCHS
NWS-15.2	Retained/ modified from HP2010	0.1 cup equivalents of dark green or orange vegetables or legumes per 1000 calories was the mean daily intake by persons aged 2 years and older in 2001–2004 (age adjusted to the year 2000 standard population)	0.3 cup equivalents per 1000 calories	National health and Nutrition Examination Survey (NHANES), CDC, NCHS
NWS-16	Retained/ modified from HP2010	0.3 of cup equivalents of whole grains per 1000 calories was the mean daily intake by persons aged 2 years and older in 2001–2004 (age adjusted to the year 2000 standard population)	0.6 cup equivalents per 1000 calories	National health and Nutrition Examination Survey (NHANES), CDC, NCHS
NWS-17.1	New	18.9% was the mean percentage of total daily calorie intake provided by solid fats for the population aged 2 years and older in 2001–2004 (age adjusted to the year 2000 standard population)	16.7%	National health and Nutrition Examination Survey (NHANES), CDC, NCHS
NWS-17.2	New	15.7% was the mean percentage of total daily calorie intake provided by added sugars for the population aged 2 years and older in 2001–2004 (age adjusted to the year 2000 standard population)	10.8%	National health and Nutrition Examination Survey (NHANES), CDC, NCHS
NWS-17.3	New	34.6% was the mean percentage of total daily calorie intake provided by solid fats and added sugars for the population aged 2 years and older in 2001–2004 (age adjusted to the year 2000 standard population)	29.8%	National health and Nutrition Examination Survey (NHANES), CDC, NCHS
NWS-18	Retained/ modified from HP2010	11.3% was the mean percentage of total daily calorie intake provided by saturated fat for the population aged 2 years and older in 2003–2006 (age adjusted to the year 2000 standard population)	9.5%	National health and Nutrition Examination Survey (NHANES), CDC, NCHS
NWS-19	Retained/ modified from HP2010	36,418 mg of sodium from foods, dietary supplements, antacids, drinking water, and salt use at the table was the mean total daily calorie intake by persons aged 2 years and older in 2003–2006 (age-adjusted to the year 2000 standard population)	2300 mg	National health and Nutrition Examination Survey (NHANES), CDC, NCHS

NWS Focus Area Objectives: Status, Baseline, Target, and Data Source

2020 Objective	Status	Baseline	Target	Data Source
NWS-20	Retained/ modified from HP2010	1118 mg of calcium from foods, dietary supplements, antacids, and drinking water was the mean total daily calorie intake by persons aged 2 years and older in 2003–2006 (age adjusted to the year 2000 standard population)	1300 mg	National health and Nutrition Examination Survey (NHANES), CDC, NCHS
NWS-21.1	New	15.9% of children aged 1–2 years were iron deficient in 2005–2008	14.3%	National health and Nutrition Examination Survey (NHANES), CDC, NCHS
NWS-21.2	New	5.3% of children aged 3–4 years were iron deficient in 2005–2008	4.3%	National health and Nutrition Examination Survey (NHANES), CDC, NCHS
NWS-21.3	New	16.1% of pregnant females aged 12–49 years were iron deficient in 2005–2008	14.5%	National health and Nutrition Examination Survey (NHANES), CDC, NCHS
NWS-22	Retained/ modified from Hp 2010	16.1% of pregnant females with iron deficient in 2003–2006	14.5%	National health and Nutrition Examination Survey (NHANES), CDC, NCHS

including fruits and vegetables, by households located near the program stores [33]. Therefore, policy and infrastructure that support introducing supermarkets to underserved areas and improving the quality of foods sold at supermarkets and other retail venues may provide an opportunity to increase access to and availability of healthy food options for Americans.

NWS-4: Increase the proportion of Americans who have access to a food retail outlet that sells a variety of foods that are encouraged by the *Dietary Guidelines.*

Research in the United States suggests that neighborhood residents with better access to supermarkets and other retail stores that provide healthful foods tend to have healthier diets, including higher intakes of fruits and vegetables [27–31].

While supermarkets generally offer a wider variety of foods at affordable prices, some have limited shelf space devoted to fresh fruits and vegetables, and other encouraged foods. Moreover, in some neighborhoods, supermarkets do not exist [34] and residents may be unable to travel to areas where they do exist due to a lack of reliable transportation [28,35]. In rural and lower-income neighborhoods, convenience stores and other small grocery or "corner" stores may be more prevalent than supermarkets [36,37]. These stores generally stock little or no encouraged foods such as fruits and vegetables due to limited space or lack of refrigerators or storage equipment, and they may charge more for what is sold [36,38]. Low-income communities and areas with limited access to public and private transportation often rely on these stores as their primary venues for groceries. Thus, research suggests that characteristics of local food environments can play a role in both healthy diet and the prevention of overweight and obesity [39].

NWS-5: Increase the proportion of primary care physicians who regularly measure the body mass index (BMI) of their patients.

There are two sub-objectives under NWS-5: *NWS-5.1 Increase the proportion of primary care physicians who regularly assess body mass index (BMI) in their adult patients*; and *NWS-5.2 Increase the proportion of primary care physicians who regularly assess body mass index (BMI) for age and sex in their child or adolescent patients.*

Obesity is a significant health problem for both children and adults. Within the medical care setting, screening can identify persons whose weight increases their risk for other chronic conditions. For adults, the U.S. Preventive Services Task Force (USPSTF) recommends that clinicians screen all patients for obesity and offer intensive counseling and behavioral interventions to promote sustained weight loss for obese adults [40]; body mass index is the recommended measure for screening. However, other clinical organizations recommend routine screening. The American Academy of Pediatrics recommends that that body mass index be calculated and plotted once a year in all children and adolescents [41]. An expert committee convened by the American Medical Association (AMA) recommends that physicians and allied health care providers perform, at minimum, a yearly assessment of weight status for all children and that this assessment include calculation of height, weight, and BMI for age and that these measures are plotted on standard growth charts. In addition to recommendations from these clinical organizations, the routine assessment of body mass index for adults and body mass index percentile for children is also a Health Effectiveness Data and Information Set measure of the National Committee for Quality Assurance.

NWS-6: Increase the proportion of physician office visits that include counseling or education related to nutrition or weight.

This objective has three sub-objectives: *NWS-6.1 Increase the proportion of physician office visits made by patients with a diagnosis of cardiovascular disease, diabetes, or hyperlipidemia that include counseling or education related*

to diet and nutrition; *NWS-6.2 Increase the proportion of physician office visits made by adult patients who are obese that include counseling or education related to weight reduction, nutrition, or physical activity*; and *NWS-6.3 Increase the proportion of physician visits made by all child or adult patients that include counseling about nutrition or diet*.

Primary care providers are well positioned in the health care system to provide preventive services including nutrition screening and assessment, referral, and counseling. For persons with chronic conditions, the USPSTF found sufficient evidence to recommend counseling for two groups of adult patients—those with cardiovascular and diet-related chronic disease and those with obesity. Specifically, the USPSTF recommends intensive behavioral dietary counseling for adult patients with hyperlipidemia and other known risk factors for cardiovascular and diet-related chronic disease and that clinicians screen all patients for obesity and offer intensive counseling and behavioral interventions to promote sustained weight loss for obese adults [40,42].

The USPSTF [42] concluded that the evidence was insufficient to recommend for or against routine behavioral counseling to promote a healthy diet in unselected patients in primary care settings. However, both the AMA Guidelines for Adolescent Preventive Services [43] and the Bright Futures Guidelines for Health Supervision of Infants, Children, and Adolescents include recommendations [41] to provide guidance about nutrition during health visits.

NWS-7: (Developmental) Increase the proportion of worksites that offer nutrition or weight management classes or counseling.

The recommendation to retain this intervention is based on potential research, evidence that worksite health programs can alter health outcomes. However, we recommend that making this a developmental objective as the data source for this objective is not currently funded. Other groups within the federal government have expressed interest in potentially fielding a study in this area.

Approximately two-thirds of the U.S. civilian population aged 16 and older is employed [44]. As such, worksites provide a channel to reach significant numbers of adults and older adolescents. Research supports the use of worksite interventions to change health behaviors or outcomes. For example, the Task Force on Community Preventive Services recommended worksite programs to improve diet and/or physical activity behaviors based on strong evidence of their effectiveness for reducing weight among employees [45]. In 1988–1999, only 54% of worksites offered nutrition or weight management classes or counseling. This is 30% lower than the 2010 target [46].

NWS-8: Increase the proportion of adults who are at a healthy weight.

Maintaining a healthy weight can be a key factor in helping to reduce the burden of many illnesses and chronic diseases. Based on the ongoing National Health and Nutrition Examination Survey (NHANES) data sets, collected throughout the decade from 1999 to the present, the proportion of population within the healthy weight BMI range (18.5 to <25) continued to decrease. For this reason, this objective remains and is part of HP2020.

NWS-9: Reduce the proportion of adults who are obese.

The rates of obesity in the United States among adults remain high. Obesity is a major public health concern and is associated with chronic diseases such as type 2 diabetes, stroke, cardiovascular diseases, and some types of cancer that have significant morbidity and mortality.

NWS-10: Reduce the proportion of children and adolescents who are considered obese.

This objective has four sub-objectives: *NWS-10.1 Children aged 2–5 years*; *NWS-10.2 Children aged 6–11 years*; *NWS-10.3 Children aged 12–19 years*; and *NWS-10.4 Children aged 2–19 years*.

On January 28, 2010, Health and Human Services (HHS) released *The Surgeon General's Vision for a Healthy and Fit Nation* [47], in which it is stated "Children and adolescents with a BMI at or above the sex-and age-specific 95th percentile of this reference population [the data set used to derive the 2000 CDC BMI Growth Curve] are often considered obese…" The publication states that these cutoff points are not diagnostic criteria, although elevated BMI among children most often indicates increased risk for future adverse health outcomes. In order to provide consistency between the definition that has been proposed for this objective and the terminology most recently adopted in the HHS publication, the wording of the objective was changed to use the term "considered obese" rather than "overweight and obese." A sub-objective to monitor youth ages 2–5 years was added due to the observed increase in the prevalence of obesity in this age group.

NWS-11: (Developmental) Prevent inappropriate weight gain in youth and adults.

There are five sub-objectives under this objective: *NWS-11.1 Children aged 2–5 years*; *NWS-11.2 Children aged 6–11 years*; *NWS-11.3 Children aged 12–19 years*; *NWS-11.4 Children aged 2–19 years*; and *NWS-11.5 Adults aged 20 years and older*.

Gradual inappropriate weight gain with age has been the primary contributor to the obesity epidemic. Multiple factors have contributed to this gradual upward shift in weight. This trend suggests that for both youth and adults, many Americans are not engaging in or sustaining the healthful behaviors needed to prevent inappropriate weight gain. This objective provides a major emphasis on the prevention of inappropriate weight gain (maintaining energy balance) in youth and adults in order to prompt actions that will be more effective and realistically achievable than weight reduction.

NWS-12: Eliminate very low food security among children.

Although most Americans are food secure (with access to enough food for an active, healthy life for all household members throughout the year), many are not. Over 6 million households with children were food insecure in 2007. Even when resources are inadequate to provide food for the entire

family, children are usually shielded from the disrupted eating patterns and reduced food intake that characterize very low food security. However, children as well as adults experienced instances of very low food security in 323,000 households in 2007. Although the number of children that experience the most severe form of food insecurity is small, no child should go hungry when the nation has the agricultural abundance, economic means, and resources to ensure an adequate diet for all. As a result, President Obama's administration has committed to end childhood hunger.

NWS-14: Increase the contribution of fruits to the diet of the population aged 2 years and older.

The *Dietary Guidelines for Americans (DGA), 2005* [18], recommends that individuals consume a sufficient amount of fruits daily. Reduced risk of chronic diseases (stroke and perhaps other cardiovascular diseases, type-2 diabetes, and cancers in certain sites) is associated with increased intake of fruits and vegetables as part of a healthful diet.

NWS-15: Increases the variety and contribution of vegetables to the diets of the population aged 2 years and older.

There are two sub-objectives within this objective: *NWS-15.1 Increase the contribution of vegetables to the diets of the population aged 2 years and older*; and *NWS-15.2 Increase the contribution of dark green vegetables, orange vegetables, and legumes to the diets of the population aged 2 years and older.*

The *DGA, 2005* [18], recommends that individuals consume a sufficient amount of vegetables daily. Reduced risk of chronic diseases (stroke and perhaps other cardiovascular diseases, type-2 diabetes, and cancers in certain sites) is associated with increased intake of fruits and vegetables as part of a healthful diet. Instead of combining the measures into one objective, the HP2020 sub-objectives address (1) quantity and (2) variety. It has been modified to take into account the recommendations in the 2005 DGAs for vegetable consumption—which are linked to calorie levels and expressed in cups.

One sub-objective assesses the contribution of vegetables to the diets of the population aged 2 years and older rather than the proportion of the population that met a single recommendation for consumption of total vegetables (i.e., at least three daily servings). This change was made since recommendations are linked to calorie levels and estimated calorie requirements vary substantially for the population by age and gender and physical activity level.

The DGAs recommend that Americans consume a variety of vegetables daily and select from all five vegetable groups (dark green, orange, legumes, starchy vegetables, and other vegetables) several times a week. Many Americans fall short of these recommendations (see the data presentation for April 2008 progress review in the above link).

NWS-16: Increase the contribution of whole grains to the diets of the population aged 2 years and older.

A key recommendation in the *DGA, 2005* [16], was for Americans to consume sufficient amounts of whole grain products daily. Whole grains are an important source of fiber and other nutrients. Diets rich in foods containing fiber, such as fruits, vegetables, and whole grains, may reduce the risk of heart disease.

The HP2010 objective was based on the recommendation in the 1995/2000 DGAs for Americans aged 2 years and older to consume at least six daily servings, with several from whole grain foods. The most recent assessment of progress on this HP2010 objective showed little change from baseline (i.e., 4% in 1994–1996 compared to 3% in 2003–2004) [48] with a much greater proportion of the population meeting the 2000 DGA recommendation for consumption of total grain products (i.e., 54%) than for whole grains (3%).

The HP2020 objective has incorporated a modification to be in line with the recommendations of the 2005 DGAs, which emphasize consumption of sufficient amounts of whole grains and identify grain recommendations in ounce-equivalents for different calorie levels. The modified wording and operational definition for this objective would allow progress to be assessed in meeting DGA recommendations, without the need to change the operational definition for recommendations (and consequently baseline estimates) as these guidelines are updated in 2010, 2015, and beyond.

NWS-17: Reduce consumption of calories from solid fats and added sugars in the population aged 2 years and older.

NWS-17 contains three sub-objectives: *NWS-17.1 Reduce the consumption of calories from solid fats*; *NWS-17.2 Reduce the consumption of calories from solid fats and added sugars*; and *NWS-17.3 Reduce the consumption of calories from solid fats and added sugars.*

Americans frequently consume diets that provide an excess of energy and that are also inadequate in meeting nutrient needs [49–51]. An examination of usual dietary intakes of Americans aged 1 year and older found that mean energy consumption from solid fats and added sugars was 780 kcal/day (425 kcal from solid fats and 355 kcal from added sugars). Clearly, consumption of solid fats and added sugars is contributing significant amounts of excess energy to the diets of Americans and is a public health concern because of the alarming prevalence of overweight and obesity in the United States. Additionally, there is evidence that the amount of energy provided by energy-dense, nutrient-poor foods in the diets of Americans is increasing [52–55].

Tracking consumption of solid fats and added sugars in adults and children 2 years of age and older will enable health and nutrition professionals and policy makers to evaluate success of nutrition education programs and policies designed to persuade Americans to increase the nutrient density of their diets and to balance energy intake with energy expenditure.

NWS-18: Reduce the consumption of saturated fat in the population aged 2 years and older.

A key recommendation in the *DGA, 2005* [18], is for Americans to consume less than 10% of calories from saturated fats, less than 300 mg/day of cholesterol, and to keep *trans* fat consumption as low as possible. High intake of saturated fats, *trans* fats, and cholesterol increases the risk of

unhealthy blood lipid levels, which, in turn, may increase the risk of coronary heart disease.

The most recent assessment of progress on the 2010 saturated fat objective showed little change from baseline (i.e., 36% in 1994–1996 compared to 34% in 2003–2004) [56].

NWS-19: Reduce consumption of sodium in the population aged 2 years and older.

A key recommendation in the *DGA, 2005* (2005 DGAs), is for Americans to consume less than 2300 mg (about 1 teaspoon of salt) of sodium daily. Decreasing salt intake is advisable to reduce the risk of elevated blood pressure. Keeping blood pressure in the normal range reduces an individual's risk of coronary heart disease, stroke, congestive heart failure, and kidney disease.

The most recent report of progress on the 2010 sodium intake objective, which assessed the proportion of the population that consumed less than 2400 mg daily, showed little change from baseline [56]. In 2003–2004, only an estimated 11% of Americans aged 2 years and older consumed less than 2300 mg of sodium daily. The median total usual daily intake of sodium was an estimated 3556 mg/day for the population aged 2 years and older, with males 19–50 years having an estimated median total daily intake of more than 4590 mg [56]. The mean total daily sodium intake for the population aged 2 years and older was an estimated 3627 mg.

NWS-20: Increase consumption of calcium in the population aged 2 years and older.

Calcium intake is of continued public health importance. Calcium plays a key role in bone health, and adequate intake may reduce the risk of osteoporosis. The most recent assessment of the 2010 objective suggests some improvement in increasing total calcium intakes (from foods, dietary supplements, and antacids). That is, the proportion of persons aged 2 years and older who had total usual calcium intakes at or above 100% of the Institute of Medicine Adequate Intake values increased from 1988–1994 to 2003–2004 [56].

NWS-21: Reduce iron deficiency among young children and females of childbearing age.

There are three sub-objectives under NWS-21: *NWS-21.1 Children aged 1–2 years*; *NWS-21.2 Children aged 3–4 years*; and *NWS-21.3 Females aged 12–49 years.*

This objective was recommended based on the adverse health effects of iron deficiency, the availability of potential interventions, and the finding that iron deficiency is still a prevalent condition. Iron deficiency is associated with poorer cognitive performance, lower work performance and endurance, anemia, and, in more severe cases of anemia, increased maternal and child mortality [57]. Young children, because of their transition in feeding practices, and women of reproductive age, because of the loss iron with menstruation, are at risk for iron deficiency [57]. Obesity may represent an additional risk factor for iron deficiency [58]. For both young children and women of reproductive age, public health strategies to address iron deficiency exist. These include education on appropriate dietary practices, and screening and/or supplementation for high-risk individuals [59]. Public health nutrition programs such as Women, Infants and Children can also support high-risk women and children in improving their iron status.

For two of these subgroups, iron deficiency is relatively high and does not appear to be declining [60]. Data from NHANES 2003–2006 indicate that the prevalence of iron deficiency among nonpregnant women has not declined [61].

NWS-22: Reduce iron deficiency among pregnant females.

This objective was retained based on the health effects associated with iron deficiency in pregnant women, the potential for intervention, and the prevalence of the condition. Iron deficiency is associated with poorer cognitive performance, lower work performance and endurance, anemia, and, in more severe cases of anemia, increased maternal and child mortality [57]. For pregnant women, iron deficiency with anemia is associated with birth outcomes such as premature birth and low birth weight [57]. Pregnant women are at risk for iron deficiency because of the iron requirements of pregnancy. Screening, supplementation, and education about appropriate dietary practices are strategies to improve the iron status of pregnant individuals [62].

INTRODUCTION

Nutrition and physical activity are vital components of a healthy lifestyle; poor nutrition and physical activity choices over time are associated with an array of chronic diseases and conditions. The purpose of the *Dietary Guidelines for Americans* (Dietary Guidelines) is to help Americans navigate their food, beverage, and activity choices to optimize long-term health and prevent chronic disease. Health care professionals are uniquely positioned to disseminate Dietary Guidelines' messages among the American public, in an effort to reduce chronic disease risk and burden at the individual and population levels.

The *Dietary Guidelines for Americans, 2010* (2010 Dietary Guidelines) [1] was developed during a particularly challenging era of modern public health: the epidemic of overweight/obesity in the United States. Approximately two-thirds of adults [2] and one-third of children and adolescents [3] are overweight or obese. Poor diet and physical inactivity are the most significant factors contributing to this public health crisis.

Even in the absence of overweight, poor diet and physical inactivity are associated with major causes of morbidity and mortality, including cardiovascular disease, hypertension, type 2 diabetes, osteoporosis, and some types of cancer. Poor diet and physical inactivity are second to tobacco as the leading cause of death in the United States [4]. Some racial and ethnic population groups are disproportionately affected by the high rates of overweight, obesity, and associated chronic diseases. In addition, risk factors for adult chronic diseases are increasingly found in children and adolescents.

The recommendations contained in the Dietary Guidelines traditionally have been intended for healthy Americans ages 2 years and older. However, since the 2010 Dietary Guidelines was released at a time of rising concern about the health of the American population, its recommendations accommodate the reality that the majority of Americans are overweight or obese and/or at risk of various chronic diseases. Therefore, the recommendations in the 2010 Dietary Guidelines are intended for Americans ages 2 years and older, including those who are at increased risk of chronic disease. Despite this expansion, the Guidelines are not appropriate as a therapeutic tool; the focus of the Guidelines remains on prevention.

The Dietary Guidelines serve as the cornerstone for nutrition policy and education efforts in the United States. They are the basis for the nutrition standards of many federally funded nutrition programs such as the National School Lunch Program and the Home Delivered Nutrition Services program for older Americans; they are also at the core of national nutrition education campaigns and resources. The Dietary Guidelines are considered the authoritative resource for nutrition guidance for the general population, and go hand-in-hand with the *Physical Activity Guidelines for Americans*, which provide more detailed physical activity recommendations.

This chapter will provide a brief background on the development and major themes of the 2010 Dietary Guidelines, as well as a more detailed examination of the key recommendations and resources within. Also, this chapter will conclude with some ideas on how physicians and other health professionals could implement the Guidelines in both clinical and nonclinical settings.

BACKGROUND

The Dietary Guidelines are congressionally mandated under the 1990 National Nutrition Monitoring and Related Research Act (Public Law 101-445, Section 301 [7 U.S.C. 5341], Title III), which requires the Dietary Guidelines to be based on the preponderance of current scientific and medical knowledge. The Dietary Guidelines have been jointly released by the U.S. Department of Agriculture (USDA) and the U.S. Department of Health and Human Services (HHS) every 5 years since 1980.

Over time, Federal dietary guidance has expanded from a traditional focus on nutrient adequacy to also address the impact of diet on chronic disease. The Dietary Guidelines have generally been consistent in their recommendations about the components of a health-promoting diet, but they have also evolved to reflect the emerging body of scientific evidence on nutrition, the food and physical activity environment, and health.

The development of the 2010 Dietary Guidelines occurred in two stages. In the first stage, an external scientific advisory committee, the Dietary Guidelines Advisory Committee (DGAC), was appointed to provide recommendations to the Federal government for updating the 2005 Dietary Guidelines. The DGAC was charged to conduct an analysis of new scientific information on diet and health and to prepare a report summarizing its findings. The 2010 DGAC considered approximately 180 questions pertinent to the Dietary Guidelines that covered a broad range of topics, such as calorie balance, nutrient adequacy, dietary patterns, food groups, beverages, behaviors, and food safety. The 2010 DGAC worked with the newly established USDA Nutrition Evidence Library (NEL) to conduct evidence-based systematic reviews to answer the majority of their questions. The NEL uses a systematic process to objectively review, evaluate, and synthesize scientific research to answer specific diet-related questions. The DGAC graded the strength of the evidence supporting their conclusions and provided recommendations based on the strongest available scientific evidence. The methodology used by the NEL [5] ensures government compliance with the Data Quality Act, which mandates that Federal agencies ensure the quality, objectivity, utility, and integrity of the information used to form Federal guidance. The evidence relevant to each review is publicly available at www.NEL.gov. The remaining questions were addressed using analyses of dietary intake data,* food pattern modeling

* Usual nutrient, food group, and selected dietary component intakes by Americans in the 2010 Dietary Guidelines and 2010 DGAC Report were drawn from analyses conducted by the National Cancer Institute, a component of HHS's National Institutes of Health, and by USDA's Agricultural Research Service, using data from the National Health and Nutrition Examination Survey (NHANES). Updated data are available at http://riskfactor.cancer.gov/diet/usualintakes/ and http://www.ars.usda.gov/ba/bhnrc/fsrg

analyses, and existing authoritative reviews and reports. The DGAC summarized their findings in a 445-page report, *Report of the Dietary Guidelines Advisory Committee on the Dietary Guidelines for Americans, 2010* [6].

During the second stage, USDA and HHS developed the policy document, *Dietary Guidelines for Americans, 2010.* The policy document writing group consisted of nutritionists who assisted the DGAC as they reviewed the evidence and prepared the resulting conclusions. The policy document's organization and recommendations are based on the DGAC's report, with consideration of public and Federal agency comments received throughout the process. More information about the development of the 2010 Dietary Guidelines is available at www.dietaryguidelines.gov

OVERVIEW OF THE DIETARY GUIDELINES FOR AMERICANS, 2010

The Dietary Guidelines represent the body of current knowledge about individual nutrients and food components, summarized and synthesized into an interrelated set of recommendations for healthy eating that can be adopted by the public. Taken together, the 2010 Dietary Guidelines recommendations encompass two overarching concepts:

- *Maintain calorie balance over time to achieve and sustain a healthy weight.* People who are most successful at achieving and maintaining a healthy weight do so through continued attention to consuming only enough calories from foods and beverages to meet their needs and by being physically active. To curb the obesity epidemic and improve their health, many Americans must decrease the calories they consume from foods and beverages and increase the calories they expend through physical activity.
- *Focus on consuming nutrient-dense* foods and beverages.* Americans currently consume too much sodium and too many calories from solid fats (i.e., saturated fatty acids and *trans*-fatty acids), added sugars, and refined grains, making it difficult to achieve recommended nutrient intake while controlling calorie and sodium intake. A healthy eating pattern limits intake of sodium, solid fats, added sugars, and refined grains and emphasizes nutrient-dense (i.e., high nutrient-to-calorie ratio) foods and beverages—vegetables, fruits, whole grains, fat-free or low-fat milk and milk products, seafood, lean meats and poultry, eggs, beans and peas, and nuts and seeds.

* Nutrient-dense foods and beverages provide vitamins, minerals, and other substances that may have positive health effects, with relatively few calories. They are lean or low in solid fats, and minimize or exclude added fats, sugars, starches, and sodium. All vegetables, fruits, whole grains, seafood, eggs, beans and peas, unsalted nuts and seeds, fat-free and low fat milk and milk products, and lean meats and poultry—when prepared without solid fats or added sugars—are nutrient-dense foods.

The organization of the 2010 Dietary Guidelines corresponds to major themes that emerged from the DGAC's review of the evidence, and the previously mentioned overarching concepts are woven throughout. The recommendations that are provided are based on the preponderance of scientific evidence for nutritional factors that are important for promoting health and lowering risk of diet-related chronic disease.

The 2010 Dietary Guidelines are divided into sections that focus on particular aspects of eating patterns:

- Balancing Calories to Manage Weight
- Foods and Food Components to Reduce
- Foods and Nutrients to Increase
- Building Healthy Eating Patterns
- Helping Americans Make Healthy Choices

Although divided into these sections, the Dietary Guidelines are intended to be integrated recommendations for health. To get the full benefit, individuals should carry out the recommendations in their entirety as part of an overall healthy eating pattern. The key recommendations and strategies identified in the 2010 Dietary Guidelines are highlighted in the following pages.

BALANCING CALORIES TO MANAGE WEIGHT

Achieving and sustaining appropriate body weight across the lifespan is vital to maintaining good health and quality of life. Because of the high prevalence of overweight and obesity in the United States, the 2010 Dietary Guidelines provide recommendations and strategies to help Americans balance calories to manage body weight. Calorie balance refers to the relationship between calories consumed from foods and beverages and calories expended in normal body functions and through physical activity. The current high rates of overweight and obesity among virtually all subgroups of the population demonstrate that many Americans are in calorie imbalance—that is, they consume more calories than they expend. All Americans—children, adolescents, adults, and older adults—are encouraged to achieve and maintain a healthy body weight.

Key Recommendations

- Prevent and/or reduce overweight and obesity through improved eating and physical activity behaviors.
- Control total calorie intake to manage body weight. For people who are overweight or obese, this will mean consuming fewer calories from foods and beverages.
- Increase physical activity and reduce time spent in sedentary behaviors.
- Maintain appropriate calorie balance during each stage of life—childhood, adolescence, adulthood, pregnancy and breastfeeding, and older age.

AN OBESOGENIC ENVIRONMENT

The overall environment in which many Americans now live, work, learn, and play has contributed to the obesity epidemic. Environment affects both sides of the calorie balance equation; many environments currently promote the overconsumption of calories and discourage physical activity and calorie expenditure. For example, many portion sizes offered for sale have increased in recent decades, and research has shown that when larger portion sizes are served, people tend to consume more calories. Also, since the 1970s, the number of fast food restaurants has more than doubled. Evidence shows that children, adolescents, and adults who eat out, particularly at fast food restaurants, are at an increased risk of weight gain, overweight, and obesity. As a result of the changing food environment, individuals need to deliberately make food choices, both at home and away from home, that are nutrient-dense, lower in calories, and appropriate in portion size. Similarly, many home, school, work, and community environments do not facilitate a physically active lifestyle; thus, many people today need to make a special effort to be physically active to meet physical activity needs.

Calorie Balance: Calories from Foods and Beverages

Controlling calorie intake from foods and beverages is fundamental to achieving and attaining calorie balance. The total number of calories consumed is the essential dietary factor relevant to body weight. The number of calories a person needs each day varies and depends on a number of factors, including the person's age, gender, height, weight, and level of physical activity. In addition, a desire to lose, maintain, or gain weight affects how many calories should be consumed. Estimated calorie needs (see Table 10.1) range from 1600 to 2400 cal/day for adult women and 2000 to 3000 cal/day for adult men. Calorie needs are lower for sedentary individuals than active individuals of the same age and gender. Also, due to reductions in basal metabolic rate that occurs with aging, calorie needs generally decrease for adults as they age. Estimated needs for young children range from 1000 to 2000 cal/day, and the range for older children and adolescents varies substantially from 1400 to 3200 cal/day, with boys generally having higher calorie needs than girls. These are only estimates, and the best way for people to assess whether they are eating the appropriate number of calories is to monitor body weight

TABLE 10.1
Estimated Calorie Needs per Day by Age, Gender, and Physical Activity Level[a]

		Physical Activity Level[b]		
Gender	**Age (Years)**	**Sedentary**	**Moderately Active**	**Active**
Child (female and male)	2–3	1000–1200[c]	1000–1400[c]	1000–1400[c]
Female[d]	4–8	1200–1400	1400–1600	1400–1800
	9–13	1400–1600	1600–2000	1800–2200
	14–18	1800	2000	2400
	19–30	1800–2000	2000–2200	2400
	31–50	1800	2000	2200
	51+	1600	1800	2000–2200
Male	4–8	1200–1400	1400–1600	1600–2000
	9–13	1600–2000	1800–2200	2000–2600
	14–18	2000–2400	2400–2800	2800–3200
	19–30	2400–2600	2600–2800	3000
	31–50	2200–2400	2400–2600	2800–3000
	51+	2000–2200	2200–2400	2400–2800

Notes: Estimated amounts of calories needed to maintain calorie balance for various gender and age groups at three different levels of physical activity. An individual's calorie needs may be higher or lower than these average estimates.

[a] Based on Estimated Energy Requirements (EER) equations, using reference heights (average) and reference weights (healthy) for each age/gender group. For children and adolescents, reference height and weight vary. For adults, the reference man is 5 ft 10 in. tall and weighs 154 lb. The reference woman is 5 ft 4 in. tall and weighs 126 lb. EER equations are from the Institute of Medicine (2002).

[b] Sedentary means a lifestyle that includes only the light physical activity associated with typical day-to-day life. Moderately active means a lifestyle that includes physical activity equivalent to walking about 1.5–3 miles/day at 3–4 miles/h, in addition to the light physical activity associated with typical day-to-day life. Active means a lifestyle that includes physical activity equivalent to walking more than 3 miles/day at 3–4 miles/h, in addition to the light physical activity associated with typical day-to-day life.

[c] The calorie ranges shown are to accommodate needs of different ages within the group. For children and adolescents, more calories are needed at older ages. For adults, fewer calories are needed at older ages.

[d] Estimates for females do not include women who are pregnant or breastfeeding.

and adjust calorie intake and participation in physical activity based on changes in weight over time. A calorie deficit of ≥500 cal/day is a common initial goal for adult weight loss. However, maintaining a smaller deficit can have a meaningful influence on body weight over time. The effect of a calorie deficit on weight does not depend on how the deficit is produced—by reducing calorie intake, increasing expenditure, or both.

Calorie Sources: Carbohydrate, Protein, Fat, and Alcohol

Carbohydrate, protein, and fat are the main sources of calories in the diet. Most foods and beverages contain combinations of these macronutrients in varying amounts. The Institute of Medicine (IOM) has established ranges for the *percentage of calories* in the diet that should come from carbohydrate, protein, and fat [7]:

- Young children (1–3 years): 45%–65% carbohydrate, 5%–20% protein, 30%–40% fat
- Older children (4–18 years): 45%–65% carbohydrate, 10%–30% protein, 25%–35% fat
- Adults (19 years and older): 45%–65% carbohydrate, 10%–35% protein, 20%–35% fat

These recommendations take into account both chronic disease risk reduction and intake of essential nutrients. Strong evidence shows that there is no optimal proportion of macronutrients that can facilitate weight loss or assist with maintaining weight loss; the critical issue is whether or not the eating pattern is reduced in calories and the individual is able to maintain this reduced calorie intake over time.

Alcohol is also a source of calories. Moderate evidence suggests that moderate drinking of alcoholic beverages* is not associated with weight gain. However, heavier than moderate consumption of alcohol over time is associated with weight gain. Reducing alcohol intake is a strategy that can be used by adults to consume fewer calories.

Individual Foods and Beverages and Body Weight

When total calorie intake is held constant, there is little evidence that any individual food groups or beverages have a unique impact on body weight. However, intake of some foods and beverages that are widely over- or underconsumed has been associated with effects on body weight. For example, strong evidence shows that children and adolescents who consume more sugar-sweetened beverages have higher body weight compared to those who drink less, and moderate evidence supports this relationship in adults. Also, moderate evidence among adults shows that increasing intake of whole grains, vegetables, and fruits may protect against weight gain. As individuals vary a great deal in their dietary intake, the best advice is to monitor dietary intake and replace foods higher in calories with nutrient-dense foods and beverages relatively lower in calories. Since body weight is not the only important factor to consider when making food and beverage choices, additional guidance on these foods and beverages is provided throughout the 2010 Dietary Guidelines.

Placing Individual Food Choices into an Overall Eating Pattern

Because people consume a variety of foods and beverages throughout the day as meals and snacks, a growing body of research has begun to describe overall eating patterns that promote calorie balance and weight management. The concept of eating patterns is the primary focus of the section entitled "Building Healthy Eating Patterns". One aspect of these patterns that has been researched in relation to body weight is the concept of calorie density, or the amount of calories provided per unit of food weight. Strong evidence shows that eating patterns that are low in calorie density improve weight loss and weight maintenance. Foods high in water and/or dietary fiber typically have fewer calories per gram and are lower in calorie density, while foods higher in fat are generally more calorie-dense. A dietary pattern low in calorie density is characterized by a relatively high intake of vegetables, fruit, and dietary fiber and a relatively low intake of total fat, saturated fat, and added sugars. Consuming an eating pattern low in calorie density may help to reduce calorie intake and improve body weight outcomes and overall health.

Calorie Balance: Physical Activity

Physical activity is the other side of the calorie balance equation and should be considered when addressing weight management. Additionally, participating in adequate amounts of physical activity conveys many health benefits independent of body weight. In 2008, HHS released the *2008 Physical Activity Guidelines for Americans* (Physical Activity Guidelines) [8], a comprehensive set of physical activity recommendations for Americans ages 6 years and older. The Physical Activity Guidelines include specific recommendations for various types of activity, including aerobic, muscle-strengthening, and bone-strengthening activities. Weight management, along with other outcomes, including premature death, diseases (such as coronary heart disease, type 2 diabetes, and osteoporosis), and risk factors for disease (such as high blood pressure and high blood cholesterol), were considered in developing the Physical Activity Guidelines.

The amount of physical activity necessary to successfully maintain a healthy body weight depends on calorie intake and varies considerably among adults, including older adults. To achieve and maintain a healthy body weight, adults should do at least the equivalent of 150 min of moderate-intensity aerobic activity[†] each week. If necessary, adults should

* Moderate alcohol consumption is the consumption of up to one drink per day for women and up to two drinks per day for men.

[†] Moderate-intensity physical activity is aerobic activity that increases a person's heart rate and breathing to some extent, while vigorous-intensity physical activity greatly increases a person's heart rate and breathing. One minute of vigorous-intensity physical activity counts as 2 min of moderate-intensity physical activity toward meeting the recommendations.

increase their weekly minutes of aerobic physical activity gradually over time and decrease calorie intake to a point where they can achieve calorie balance and a healthy weight. Some adults may need to participate in more than the equivalent of 300 min/week of moderate-intensity activity to meet weight control goals.

For children and adolescents ages 6 years and older, 60 min or more of physical activity per day is recommended. Although the Physical Activity Guidelines do not include a specific quantitative recommendation for children ages 2–5 years, young children should play actively several times each day. Children and adolescents are often active in short bursts of time rather than for sustained periods of time, and these short bursts can add up to meet physical activity needs. Physical activities for children and adolescents of all ages should be developmentally appropriate and enjoyable, and should offer variety. Additional information on the Physical Activity Guidelines, including materials for consumers, is available at www.health.gov/paguidelines

Principles for Promoting Calorie Balance and Weight Management

To address the current calorie imbalance in the United States, individuals are encouraged to become more conscious of what they eat and what they do. This means increasing awareness of what, when, why, and how much they eat, deliberately making better choices regarding what and how much they consume, and seeking ways to be more physically active. Several behaviors and practices have been shown to help people manage their food, beverage intake, and calorie expenditure and ultimately manage body weight. The behaviors with the strongest evidence related to body weight include

- *Monitor food intake*. Monitoring intake has been shown to help individuals become more aware of what and how much they eat and drink. The Nutrition Facts label found on food packaging provides calorie information for each serving of food or beverage and can assist consumers in monitoring their intake. Also, monitoring body weight and physical activity can help prevent weight gain and improve outcomes when actively losing weight or maintaining body weight following weight loss.
- *When eating out, choose smaller portions or lower calorie options.* When possible, individuals are encouraged to order a small-sized option, share a meal, or take home part of the meal. By reviewing the calorie content of foods and beverages offered, individuals can choose lower calorie options. Calorie information may be available on menus, in a pamphlet, on food wrappers, or online. Or, instead of eating out, individuals can cook and eat more meals at home, where they can control what and how foods are prepared.
- *Prepare, serve, and consume smaller portions of foods and beverages, especially those high in calories.* Individuals eat and drink more when provided larger portions. Serving and consuming smaller portions is associated with weight loss and weight maintenance over time.
- *Eat a nutrient-dense breakfast*. Not eating breakfast has been associated with excess body weight. Consuming breakfast also has been associated with weight loss and weight loss maintenance, as well as improved nutrient intake.
- *Limit screen time*. In children, adolescents, and adults, screen time, especially television viewing, is directly associated with increased overweight and obesity. Children and adolescents are encouraged to spend no more than 1–2 h each day watching television, playing electronic games, or using the computer (other than for homework). Also, eating while watching television can result in overeating.

Although obesity is related to many chronic health conditions, it is not the only lifestyle-related public health problem confronting the nation. Eating patterns that are high in calories, but low in nutrients can leave a person overweight but malnourished. Nutritionally unbalanced diets and a sedentary lifestyle can negatively affect a person's health regardless of weight status. Improved eating patterns and increased physical activity have numerous health benefits beyond maintaining a healthy weight.

FOODS AND FOOD COMPONENTS TO REDUCE

Recommendations to reduce intake of certain foods and food components were developed after consideration of the current dietary intake of Americans in relation to research on chronic disease risk associated with overconsumption of these foods and food components. As such, this section of the 2010 Dietary Guidelines focuses on particular foods and food components that are currently consumed by Americans in excessive amounts and may increase the risk of certain chronic diseases. Many children, adolescents, adults, and older adults currently overconsume sodium, solid fats (major sources of saturated and *trans*-fatty acids), added sugars, and refined grains. In addition, the diets of most men exceed the recommendation for cholesterol, and some people consume too much alcohol.

This excessive intake replaces nutrient-dense forms of food in the diet, making it difficult for people to achieve recommended nutrient intake and control calorie intake. Many Americans are overweight or obese and are at a higher risk of chronic diseases such as cardiovascular disease, diabetes, and certain types of cancer. Even in the absence of overweight or obesity, consuming too much of the previously mentioned foods and food components increases the risk of some of the most common chronic diseases in the United States. The recommendations in this section are based on evidence that eating less of these foods and food components

can help Americans reduce their chronic disease risk, while meeting their nutritional needs and staying within appropriate calorie ranges.

Key Recommendations

- Reduce daily sodium intake to less than 2300 mg and further reduce intake to 1500 mg among persons who are 51 and older and those of any age who are African American or have hypertension, diabetes, or chronic kidney disease. The 1500 mg recommendation applies to about half of the U.S. population, including children and the majority of adults.
- Consume less than 10% of calories from saturated fatty acids by replacing them with monounsaturated and polyunsaturated fatty acids.
- Consume less than 300 mg/day of dietary cholesterol.
- Keep *trans*-fatty acid consumption as low as possible, especially by limiting foods that contain synthetic sources of *trans*-fats, such as partially hydrogenated oils, and by limiting other solid fats.
- Reduce the intake of calories from solid fats and added sugars.
- Limit the consumption of foods that contain refined grains, especially refined grain foods that contain solid fats, added sugars, and sodium.
- If alcohol is consumed, it should be consumed in moderation—up to one drink per day for women and two drinks per day for men—and only by adults of legal drinking age.

Sodium

Sodium is an essential nutrient and is needed by the body in relatively small quantities. On average, the higher an individual's sodium intake, the higher the individual's blood pressure. A strong body of evidence in adults documents that as sodium intake decreases, so does blood pressure. Moderate evidence in children also has documented that as sodium intake decreases, so does blood pressure. Since keeping blood pressure in the normal range reduces an individual's risk of cardiovascular disease, congestive heart failure, and kidney disease, adults and children should limit their intake of sodium. However, virtually all Americans consume far too much sodium. While the IOM has defined the tolerable upper intake level (UL) for sodium to be 2300 mg/day [9], the estimated average intake for all Americans ages 2 years and older is closer to 3400 mg/day. Most of this sodium comes from salt added during food processing.

The 2010 Dietary Guidelines emphasize the importance of sodium reduction, in light of emerging evidence on sodium and blood pressure in children as well as updated data on the percentage of the population at high risk for sodium-related health consequences. Americans should reduce their sodium intake to less than 2300 or to 1500 mg/day, depending on age and other characteristics. African Americans; individuals with hypertension, diabetes, or chronic kidney disease; and individuals ages 51 years and older comprise about half of the U.S. population ages 2 years and older. While nearly everyone benefits from reducing their sodium intake, the blood pressure of these individuals tends to be particularly responsive to the hypertensive effects of sodium; therefore, these groups should reduce their intake to 1500 mg/day.

Fats

Fats supply calories and essential fatty acids and help in the absorption of the fat-soluble vitamins A, D, E, and K. The IOM established acceptable ranges for total fat intake, as a percentage of calories, among children and adults (ages 1–3 years: 30%–40%; ages 4–18 years: 25%–35%; ages 19 and older: 20%–35%), which provide adequate intake of essential nutrients while not elevating risk of cardiovascular disease [7]. The most recent data indicate that total fat intake contributes an average of 34% of calories in Americans' diets. Fatty acids are categorized as being saturated, monounsaturated, or polyunsaturated; *trans*-fatty acids and cholesterol are particular types of fat commonly targeted in disease-prevention efforts. The types of fatty acids consumed are more important in influencing the risk of cardiovascular disease than is the total amount of fat in the diet.

Saturated fatty acids. A strong body of evidence indicates that higher intake of most dietary saturated fatty acids is associated with higher levels of blood total cholesterol and low-density lipoprotein (LDL) cholesterol. Consuming less than 10% of calories from saturated fatty acids *and* replacing them with monounsaturated and/or polyunsaturated fatty acids is associated with low blood cholesterol levels and lower risk of cardiovascular disease. Lowering the percentage even more, to 7% of calories, can further reduce risk. Americans currently consume an average of 11% of their calories from saturated fatty acids.

trans-fatty acids. trans-fatty acids can be either naturally occurring ("natural" or "ruminant") or formed during food processing ("synthetic" or "industrial") by the process of hydrogenation. *trans*-fatty acids have been associated with increased risk of cardiovascular disease, due in part to an LDL-cholesterol raising effect. There is limited evidence to conclude whether synthetic and natural *trans*-fatty acids differ in their metabolic effects and health outcomes. Americans are advised to keep their intake of *trans*-fats as low as possible; however, the complete elimination of natural *trans*-fatty acids (e.g., in low-fat milk and lean meats) is not recommended because of the potential implications for nutrient adequacy. Levels of synthetic *trans*-fats in the food supply have been significantly reduced due to public health measures in recent years.

Cholesterol. Cholesterol is produced by the body in quantities sufficient for necessary structural and physiological functions; therefore, dietary cholesterol is unnecessary. Cholesterol from

food sources has been shown to raise blood LDL-cholesterol levels in some individuals, and moderate evidence shows a relationship between higher intake of cholesterol and increased risk of cardiovascular disease. However, the potential negative effects of dietary cholesterol are relatively small compared to those of saturated and *trans*-fatty acids. Consuming less than 300 mg/day of dietary cholesterol can help maintain normal blood cholesterol levels; consuming less than 200 mg/day can further help individuals already at high risk of cardiovascular disease. Currently, cholesterol intake among American men exceeds these recommendations, averaging 350 mg/day; average intake among women is 240 mg/day.

Added Sugars

Fructose and lactose are examples of naturally occurring sugars that are found in foods such as fruits and milk; however, the majority of sugars in the typical American diet are sugars that are added to foods during processing, preparation, or at the table. Unlike most foods that contain naturally occurring sugars, often, foods that contain *added* sugars supply calories but few or no essential nutrients. Currently, added sugars contribute an average of 16% of the total calories in American diets; the predominant source is sugar-sweetened beverages (e.g., soda, energy drinks, sports drinks). Reducing the consumption of added sugars will lower the calorie content of the diet without compromising its nutrient adequacy; this is an important measure in terms of achieving and maintaining a healthy weight.

[SIDEBAR:] Interestingly, solid fats and added sugars together comprise a substantial portion of the calories regularly consumed by Americans—nearly 800 cal/day—without a marked contribution to the overall nutrient adequacy of the diet. Foods containing solid fats and added sugars are no more likely to contribute to weight gain than any other sources of calories; however, as the amount of solid fats and/or added sugars increases in the diet, it becomes more difficult to attain sufficient dietary fiber and essential vitamins and minerals while staying within calorie limits. Of course, solid fats and added sugars also push many Americans' diets above required caloric levels.

Refined Grains

Grains are consumed either as whole grains or as refined grains. The refining of whole grains involves a process that results in the loss of vitamins, minerals, and dietary fiber. Most refined grains are enriched with iron, thiamin, riboflavin, niacin, and folic acid before entering the marketplace; however, this enrichment does not return all naturally occurring nutrients and fiber to the grains. Unlike solid fats and added sugars, enriched refined grain products have a positive role in providing some vitamins and minerals. When consumed beyond recommended levels, though, they commonly provide excess calories in the typical American diet. Although Americans generally eat enough total grains, most of the grains consumed are refined grains rather than whole grains. Refined grains should be replaced with whole grains, such that at least half of all grains consumed are whole grains. In particular, consumption of refined grain products that are also high in solid fats and/or added sugars (e.g., cakes, cookies, donuts) should be targeted for reduction.

Alcohol

The consumption of alcohol can have beneficial or harmful effects, depending on the amount consumed, age, and other characteristics of the person consuming the alcohol. Strong evidence from observational studies has shown that moderate alcohol consumption is associated with a lower risk of cardiovascular disease. Moderate consumption is defined as up to one drink per day for women and up to two drinks per day for men. Moderate alcohol consumption is also associated with reduced risk of all-cause mortality among middle-aged and older adults and may help to keep cognitive functioning intact with age. However, it is not recommended that anyone begin drinking or drink more frequently on the basis of potential health benefits because moderate alcohol intake is also associated with increased risk of breast cancer, violence, drowning, and injuries from falls and motor vehicle crashes.

Excessive (i.e., heavy, high-risk, or binge) drinking has no benefits but increases the risk of cirrhosis of the liver, hypertension, stroke, type 2 diabetes, cancer of the upper gastrointestinal track and colon, injury, auto-accidents, and violence. Further, excessive drinking over time is associated with increased body weight and can impair short- and long-term cognitive function. The 2010 Dietary Guidelines recommend that adults of legal drinking age not exceed moderate intake levels.

For the first time, the 2010 Dietary Guidelines provide information on alcohol consumption among lactating women. Evidence suggests that breastfeeding mothers may consume a single alcoholic beverage if she then waits at least 4 h before breastfeeding, provided that the infant's breastfeeding behavior is well established, consistent, and predictable (no earlier than 3 months of age). This information was included because of the substantial evidence clearly demonstrating the health benefits of breastfeeding and the concern that women may stop breastfeeding in order to occasionally consume an alcoholic beverage.

FOODS AND NUTRIENTS TO INCREASE

This section of the 2010 Dietary Guidelines describes food choices that should be emphasized to help Americans close nutrient gaps and move toward healthful eating patterns. Recommendations related to foods and nutrients to increase were made after examination of the current dietary intake of Americans in relation to nutrient needs as well as research on the particular foods or nutrients (i.e., the health benefits of consumption or the public health concern related to inadequate intake). Many Americans do not eat the array of foods that will provide all needed nutrients while staying within calorie needs.

This section highlights general recommendations to increase intake of certain food groups by replacing foods and

beverages currently consumed with more nutritious choices. More specific quantitative guidance is discussed in the section titled "Building Healthy Eating Patterns."

Key Recommendations

Individuals should meet the following recommendations as part of a healthy eating pattern and while staying within their calorie needs:

- Increase vegetable and fruit intake.
- Eat a variety of vegetables, especially dark-green and red and orange vegetables and beans and peas.
- Consume at least half of all grains as whole grains. Increase whole-grain intake by replacing refined grains with whole grains.
- Increase intake of fat-free or low-fat milk and milk products, such as milk, yogurt, cheese, or fortified soy beverages.
- Choose a variety of protein foods, which include seafood, lean meat and poultry, eggs, beans and peas, soy products, and unsalted nuts and seeds.
- Increase the amount and variety of seafood consumed by choosing seafood in place of some meat and poultry.
- Replace protein foods that are higher in solid fats with choices that are lower in solid fats and calories and/or are sources of oils.
- Use oils to replace solid fats where possible.
- Choose foods that provide more potassium, dietary fiber, calcium, and vitamin D, which are nutrients of concern in American diets. These foods include vegetables, fruits, whole grains, and milk and milk products.

Recommendations for Specific Population Groups

Women capable of becoming pregnant:

- Choose foods (such as meats) that supply heme iron, which is more readily absorbed by the body than nonheme iron, additional iron sources, and enhancers of iron absorption such as vitamin C-rich foods.
- Consume 400 mcg/day of synthetic folic acid (from fortified foods and/or supplements) in addition to food forms of folate from a varied diet.

Women who are pregnant or breastfeeding:

- Consume 8–12 oz of seafood per week from a variety of seafood types.
- Due to their methyl mercury content, limit white (albacore) tuna to 6 oz/week and do not eat the following four types of fish: tilefish, shark, swordfish, and king mackerel.
- If pregnant, take an iron supplement as recommended by an obstetrician or other health care provider.

Individuals ages 50 years and older:

- Consume foods fortified with vitamin B_{12}, such as fortified cereals, or dietary supplements.

Vegetables and Fruits

The recommendation for Americans to eat more vegetables and fruits is supported by three main facts. First, most vegetables and fruits are major contributors of a number of nutrients that are underconsumed in the United States, including folate, magnesium, potassium, dietary fiber, and vitamins A, C, and K. Second, consumption of vegetables and fruits is associated with reduced risk of many chronic diseases. Specifically, moderate evidence indicates that intake of at least 2½ cups of vegetables and fruits per day is associated with a reduced risk of cardiovascular disease, including heart attack and stroke. Additionally, some vegetables and fruits may be protective against certain types of cancer. Third, most vegetables and fruits, when prepared without added fats or sugars, are relatively low in calories. Eating them instead of higher calorie foods can help adults and children achieve and maintain a healthy weight.

Very few Americans ages 2 years and older consume the amounts of vegetables recommended as part of healthy eating patterns. Similarly, although most Americans 2–3 years of age consume recommended amounts of total fruits, most Americans ages 4 years and older do not. Children ages 2–18 years and adults ages 19–30 years consume more than half of their fruit intake as juice. Although 100% fruit juice can be part of a healthful diet, it lacks dietary fiber and can contribute extra calories when consumed in excess. The majority of the fruit recommended should come from whole fruits, including fresh, canned, frozen, and dried forms, rather than from juice. When juices are consumed, 100% juice should be encouraged.

Grains

Whole grains are a source of nutrients such as iron, magnesium, selenium, B vitamins, and dietary fiber. Moderate evidence indicates that whole-grain intake may reduce the risk of cardiovascular disease and is associated with a lower body weight. Limited evidence also shows that consuming whole grains is associated with a reduced incidence of type 2 diabetes. Consuming enough whole grains helps one meet his or her nutrient needs. Additional health benefits are offered by whole grains that are higher in fiber.

At least half of recommended total grain intake should be whole grains. Less than 5% of Americans consume the minimum recommended amount of whole grains, which for many is about 3 oz-eq/day. On average, Americans eat less than 1 oz-eq of whole grains per day.

Americans should aim to replace many refined grain foods with whole-grain foods in their nutrient-dense forms (i.e., few added sugars or fats) to keep total calorie intake within limits. Individuals may choose to consume more than half of their grains as whole grains.

Milk and Milk Products

Milk and milk products (also known as dairy products) contribute many nutrients, such as calcium, vitamin D (for products fortified with vitamin D), and potassium, to the diet. Moderate evidence shows that intake of milk and milk products is linked to improved bone health, especially in children and adolescents. Moderate evidence also indicates that intake of milk and milk products is associated with a reduced risk of cardiovascular disease and type 2 diabetes and with lower blood pressure in adults.

Intake of milk and milk products, including fortified soy beverages, is less than the recommended amounts for most adults, children, and adolescents ages 4–18 years, and many children ages 2–3 years. The majority of current fluid milk intake comes from reduced fat (2%) or whole (full-fat) milk, with smaller amounts consumed as fat-free (skim) or low-fat (1%) milk. Cheese, little of which is consumed in a lower fat form, comprises almost half of the dairy intake in the United States. Choosing fat-free or low-fat milk and milk products should be encouraged because they provide the same nutrients with less fat and thus fewer calories.

Protein Foods

Protein foods include seafood, meat, poultry, eggs, beans and peas, soy products, nuts, and seeds. In addition to protein, these foods contribute B vitamins (e.g., niacin, thiamin, riboflavin, and B_6), vitamin E, iron, zinc, and magnesium to the diet. However, protein is also found in some foods that are classified in other food groups (e.g., milk and milk products).

Some Americans need to increase their total intake of protein foods, while others are eating more than is recommended. Americans should consume protein foods in amounts recommended for their nutrient and calorie needs. Meat, poultry, and eggs are the most commonly consumed protein foods, while seafood, beans and peas, soy products, nuts, and seeds are consumed in proportionally smaller amounts. The fats in meat, poultry, and eggs are considered solid fats, while the fats in seafood, nuts, and seeds are considered oils. Meat and poultry should be consumed in lean forms to decrease intake of solid fats.

In recent years, evidence has emerged about the health benefits of consuming seafood. Therefore, the 2010 Dietary Guidelines include a new quantitative recommendation for seafood intake. An intake of 8 or more ounces per week (less for young children) of a variety of seafood is recommended; this represents approximately 20% of recommended intake of protein foods. Seafood contributes a range of nutrients, notably the omega-3 fatty acids, eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA). Moderate evidence shows that consumption of about 8 oz/week of a variety of seafood, which provide an average consumption of 250 mg/day of EPA and DHA, is associated with reduced cardiac deaths among individuals with and without preexisting cardiovascular disease.

Moderate, consistent evidence shows that the health benefits from consuming a variety of seafood in the amounts recommended outweigh the health risks associated with methyl mercury, a heavy metal found in seafood in varying levels. Eating a variety of seafood, as opposed to just a few choices, is likely to reduce the amount of methyl mercury consumed from any one seafood type. Seafood varieties that are commonly consumed in the United States are higher in EPA and DHA and lower in mercury including salmon, anchovies, herring, sardines, Pacific oysters, and trout.

In addition to the health benefits for the general public, the nutritional value of seafood is of particular importance during fetal growth and development, as well as in early infancy and childhood. Moderate evidence indicates that intake of omega-3 fatty acids, in particular DHA, from at least 8 oz of seafood per week for women who are pregnant or breastfeeding is associated with improved infant health outcomes, such as visual and cognitive development. Therefore, it is recommended that women who are pregnant or breastfeeding consume at least 8 and up to 12 oz of a variety of seafood per week, from choices that are lower in methyl mercury. Women who are pregnant or breastfeeding should not eat tilefish, shark, swordfish, and king mackerel because they are high in methyl mercury. Women who are pregnant or breastfeeding can eat all types of tuna, including white (albacore) and light canned tuna, but should limit white tuna to 6 oz/week because of methyl mercury content.

Oils

Fats with a high percentage of monounsaturated and polyunsaturated fatty acids are usually liquid at room temperature and are referred to as "oils." Oils are not a food group, but are emphasized because they contribute essential fatty acids and vitamin E to the diet.

Oils are naturally present in foods such as olives, nuts, avocados, and seafood. Many common oils are extracted from plants, such as canola, corn, olive, peanut, safflower, soybean, and sunflower oils. Foods that are mainly oil include mayonnaise, oil-based salad dressings, and soft (tub or squeeze) margarine with no *trans*-fatty acids. Coconut oil, palm kernel oil, and palm oil are high in saturated fatty acids and partially hydrogenated oils contain *trans*-fatty acids and, thus, are considered solid fats.

Americans consume more solid fats (saturated and *trans*) but less oil than is desirable. Replacing some saturated fatty acids (such as those in solid fats) with unsaturated fatty acids (such as those in oils) lowers both total and LDL blood cholesterol levels. Oils are a concentrated source of calories; therefore, Americans should replace solid fats with oils, rather than add oil to the diet, and should use oils in small amounts.

Nutrients of Concern

Because consumption of vegetables, fruits, whole grains, milk and milk products, and seafood is lower than recommended, intake by Americans of some nutrients is low enough to be

of public health concern. These are potassium, dietary fiber, calcium, and vitamin D. In addition, intake of iron, folate, and vitamin B_{12} is of concern for specific population groups.

Potassium. The recommended intake level for potassium ranges from 3000 to 5100 mg/day, depending on age and lactation status; the general recommendation for adults is 4700 mg/day [9]. Dietary potassium can lower blood pressure by blunting the adverse effects of sodium on blood pressure. Other possible benefits of an eating pattern rich in potassium include a reduced risk of developing kidney stones and decreased bone loss. Dietary sources of potassium are found in all food groups, notably in vegetables, fruits, and milk and milk products. Americans should select a variety of food sources of potassium to meet recommended intake rather than relying on supplements.

Dietary fiber. The recommended intake level for fiber is 14 g/1000 cal for all ages [7]. Dietary fiber is the nondigestible form of carbohydrates and lignin. Dietary fiber naturally occurs in plants, helps provide a feeling of fullness, and is important in promoting healthy laxation. Some of the best sources of dietary fiber are beans and peas, such as navy beans, split peas, lentils, pinto beans, and black beans. Additional sources of dietary fiber include other vegetables, fruits, whole grains, and nuts. Bran, although not a whole grain, is an excellent source of dietary fiber. Dietary fiber that occurs naturally in foods may help reduce the risk of cardiovascular disease, obesity, and type 2 diabetes. Children and adults should consume foods naturally high in dietary fiber in order to increase nutrient density, promote healthy lipid profiles and glucose tolerance, and ensure normal gastrointestinal function. Fiber is sometimes added to foods, although it is unclear if added fiber provides the same health benefits as naturally occurring sources.

Calcium. Individuals of all ages are encouraged to meet their Recommended Dietary Allowance (RDA) for calcium [10]. The RDAs for calcium range from 700 to 1300 mg for children and from 1000 to 1200 mg for adults. Adequate calcium status is important for optimal bone health. In addition, calcium serves vital roles in nerve transmission, constriction and dilation of blood vessels, and muscle contraction. Milk and milk products contribute substantially to calcium intake by Americans. Calcium recommendations may be achieved by consuming recommended levels of fat-free or low-fat milk and milk products and/or consuming alternative calcium sources. Removing milk and milk products from the diet requires careful replacement with other food sources of calcium, including fortified foods. Calcium in some plant foods is well absorbed, but consuming enough plant foods to achieve the RDA may be unrealistic for many.

Vitamin D. Adequate vitamin D status is important for health. The dominant function of vitamin D, in the form of the active metabolite, calcitriol, is its involvement in the regulation of serum calcium and phosphate homeostasis and, subsequently, the development and maintenance of bone health. Vitamin D is unique in that sunlight on the skin enables the body to make vitamin D. The RDAs for vitamin D, which assume minimal sun exposure, are 600 IU (15 mcg)/day for children and most adults and 800 IU (20 mcg) for adults older than 70 years [10]. In the United States, most dietary vitamin D is obtained from fortified foods, especially fluid milk and some yogurts. Some other foods and beverages, such as breakfast cereals, margarine, orange juice, and soy beverages, are also commonly fortified with vitamin D. Natural sources of vitamin D include some kinds of fish (e.g., salmon and tuna) and egg yolks, which have smaller amounts. It is also available in the form of dietary supplements. Although dietary intakes of vitamin D are below recommendations, recent data from the National Health and Nutrition Examination Survey (NHANES) indicate that more than 80% of Americans have adequate vitamin D blood levels. As intake increases above 4000 IU (100 mcg)/day, the potential risk of adverse effects increases.

Additional Nutrients of Concern for Specific Groups

- *Iron*: Iron is a component of a number of proteins, including hemoglobin, and thus, is important for the transport of oxygen to body tissues. Substantial numbers of women who are capable of becoming pregnant, including adolescent girls, are deficient in iron. They can improve their iron status by choosing foods that supply heme or nonheme iron; heme iron is more easily absorbed by the body. Sources of heme iron include lean meat and poultry, and seafood. Additional iron sources are nonheme iron in plant foods, such as white beans, lentils, and spinach, as well as foods enriched with iron, such as most breads and cereals. Absorption of nonheme iron can be increased by iron enhancers, such as vitamin C-rich foods. Women who are pregnant are advised to take an iron supplement as recommended by an obstetrician or other health care provider.
- *Folate*: Folic acid fortification of grain products in the United States has been successful in reducing the incidence of neural tube defects. However, many women capable of becoming pregnant still do not meet the recommended intake for folic acid. Dietary sources of folate include beans and peas, oranges and orange juice, and dark-green leafy vegetables such as spinach and mustard greens. Women who are capable of becoming pregnant are encouraged to consume synthetic folic acid (from fortified foods and/or supplements) in addition to food forms of folate from a varied diet.
- *Vitamin B_{12}*: Vitamin B_{12} is a cofactor for enzymes needed to support blood formation and neurological function. On average, Americans ages 50 years and older consume adequate vitamin B_{12}. Nonetheless, a substantial proportion of individuals ages 50 years and older may have reduced ability to absorb naturally occurring vitamin B_{12}. The crystalline form of the vitamin is well absorbed; therefore, individuals ages 50 years and older are encouraged to include foods fortified with vitamin B_{12}, such as fortified cereals, or take dietary supplements.

BUILDING HEALTHY EATING PATTERNS

The purpose of this section of the 2010 Dietary Guidelines is to integrate individual recommendations from previous sections into overall healthy eating patterns. An eating pattern is the combination of foods and beverages that constitute an individual's complete dietary intake over time. Many eating patterns have been associated with health benefits, and their variety demonstrates that people can eat healthfully in a number of ways.

Key Recommendations

- Select an eating pattern that meets nutrient needs over time at an appropriate calorie level.
- Account for all foods and beverages consumed and assess how they fit within a total healthy eating pattern.
- Follow food safety recommendations when preparing and eating foods to reduce the risk of foodborne illnesses.

Common Elements of Healthy Eating Patterns

The study of eating patterns is complex, but evidence from international scientific research has identified various eating patterns that may provide short- and long-term health benefits, including a reduced risk of chronic disease. Among the eating patterns with supporting evidence are the Dietary Approaches to Stop Hypertension (DASH) eating pattern, Mediterranean-style eating patterns, and various vegetarian eating patterns. Although healthy eating patterns around the world are diverse, some common threads exist. They are abundant in vegetables and fruits. Many emphasize whole grains. They include moderate amounts and a variety of foods high in protein (seafood, beans and peas, nuts, seeds, soy products, meat, poultry, and eggs). They include only limited amounts of foods high in added sugars. Most are low in full-fat milk and milk products; however, some include substantial amounts of low-fat milk and milk products. Compared to typical American diets, these patterns tend to have a high unsaturated to saturated fatty acid ratio, high dietary fiber and potassium content, and are relatively low in sodium.

Average eating patterns among Americans currently bear little resemblance to recommendations. Figure 10.1 graphically shows how the typical American diet compares to recommended intakes or limits. Americans eat too many calories and too much solid fat, added sugars, refined grains, and sodium. Americans also consume too little potassium; dietary fiber; calcium; vitamin D; unsaturated fatty acids from oils, nuts, and seafood; and other important nutrients. These nutrients are mostly found in vegetables, fruits, whole grains, and low-fat milk and milk products.

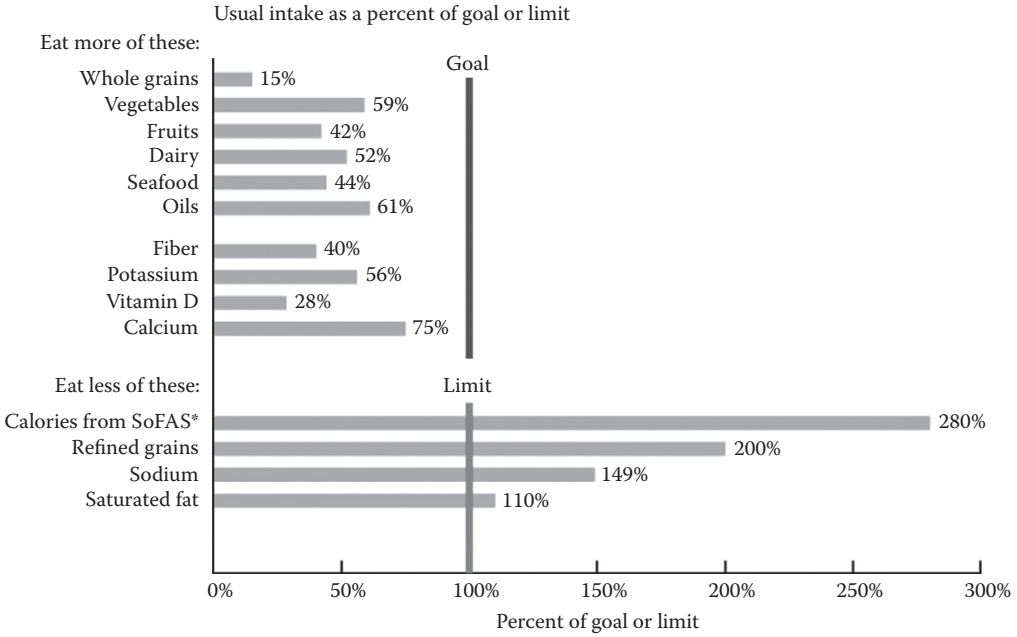

FIGURE 10.1 How do typical American diets compare to recommended intake levels or limits? *SoFAS, solid fats and added sugars. *Note*: Bars show average intakes for all individuals (ages 1 or 2 years or older, depending on the data source) as a percent of the recommended intake level or limit. Recommended intakes for food groups and limits for refined grains and solid fats and added sugars are based on amounts in the USDA 2000 cal food pattern. Recommended intakes for fiber, potassium. vitamin D, and calcium are based on the highest AI or RDA for ages 14–70 years. Limits for sodium are based on the UL and for saturated fat on 10% of calories. The protein foods group is not shown here because on average intake is close to recommended levels. (Based on data from U.S. Department of Agriculture, Agricultural Research Service and U.S. Department of Health and Human Services, Centers for Disease Control and Prevention. What We Eat in America. NHANES 2001–2004 or 2005–2006.)

Principles for Achieving a Healthy Eating Pattern

A healthy eating pattern is not a rigid prescription, but rather an array of options that can accommodate cultural, ethnic, traditional, and personal preferences and food cost and availability. Americans have flexibility in making choices to create a healthy eating pattern that meets nutrient needs and stays within calorie limits. The following are principles that can assist individuals in achieving a healthy eating pattern:

1. *Focus on nutrient-dense foods*—Nutrient-dense foods include vegetables, fruits, whole grains, fat-free or low-fat milk and milk products, lean meats and poultry, seafood, eggs, beans and peas, and nuts and seeds that are prepared without added solid fats, sugars, starches, and sodium. Combined into an eating pattern, these foods can provide the full range of essential nutrients and fiber, without excessive calories.
2. *Reduce intake of calories from solid fats and added sugars*—Most people's eating patterns can accommodate only a limited number of calories from solid fats and added sugars. These calories are best used to increase the palatability of nutrient-dense foods (i.e., adding a small amount of flavored syrup to fat-free milk) rather than to consume foods or beverages that are primarily solid fats, added sugars, or both.
3. *Remember that beverages count*—Beverages contribute substantially to overall dietary and calorie intake for most Americans. Their consumption should be planned in the context of total calorie intake and how they can fit into the eating pattern of each individual. The calorie content of beverages varies widely, and some of the beverages with the highest intake, including regular sodas, fruit drinks, and alcoholic beverages, contain calories but provide few or no essential nutrients. Other beverages, however, such as fat-free or low-fat milk and 100% fruit juice, provide a substantial amount of nutrients along with the calories they contain. Water and unsweetened beverages contribute to total water intake without adding calories. To limit excess calories and maintain healthy weight, individuals are encouraged to drink water and other beverages with few or no calories, in addition to recommended amounts of low-fat or fat-free milk and 100% fruit juices.
4. *Follow food safety principles*—Ensuring food safety is an important principle for building healthy eating patterns. The four basic food safety principles that work together to reduce the risk of foodborne illnesses are
   a. *Clean* hands, food contact surfaces, and vegetables and fruits.
   b. *Separate* raw, cooked, and ready-to-eat foods while shopping, storing, and preparing foods.
   c. *Cook* foods to a safe temperature.
   d. *Chill* (refrigerate) perishable foods promptly.

   In addition, some foods pose high risk of foodborne illness. These include raw (unpasteurized) milk, cheeses, and juices; raw or undercooked animal foods, such as seafood, meat, poultry, and eggs; and raw sprouts. These foods should be avoided.
5. *Consider the role of supplements and fortified foods*—A fundamental premise of the Dietary Guidelines is that nutrients should come primarily from foods. Dietary supplements or fortification of certain foods may be advantageous to increase intake of a specific vitamin or mineral. In some cases, fortification can provide a food-based means for increasing intake of particular nutrients or providing nutrients in highly bioavailable forms. Examples include vitamin D, folic acid, vitamin B_{12}, and iron.

Sufficient evidence is not available to support a recommendation for or against the use of multivitamin/mineral supplements in the primary prevention of chronic disease for the healthy American population. Supplements containing combinations of certain nutrients may be beneficial in reducing the risks of some chronic diseases when used by special populations. For example, calcium and vitamin D supplements may be useful in postmenopausal women who have low levels of these nutrients in their diets, to reduce their risk of osteoporosis. In contrast, high levels of certain nutrient supplements may be harmful.

Putting the Principles for a Healthy Eating Pattern into Action

The 2010 Dietary Guidelines provide healthy eating templates that can be used or adapted to suit individual and cultural preferences. The illustrations of varied approaches to healthy eating that are provided include the USDA Food Patterns (with lacto–ovo vegetarian or vegan adaptations) and the DASH Eating Plan. These eating patterns apply the Dietary Guidelines recommendations and provide flexible templates for making healthy choices within and among various food groups. They include recommended amounts from all food groups, targets for total calorie intake, and limits on calories from solid fats and added sugars.

USDA Food Patterns

The USDA Food Patterns identify daily amounts of foods, in nutrient-dense forms, to eat from five major food groups and their subgroups. The patterns also include an allowance for oils and limits on the maximum number of calories that should be consumed from solid fats and added sugars. The food patterns were developed to meet nutrient needs, as identified by the Dietary Reference Intakes and the Dietary Guidelines, while not exceeding calorie requirements.

Recommended amounts and limits in the USDA Food Patterns are provided at 12 cal levels, ranging from 1000 to

3200 cal. Individuals should follow a pattern that meets their estimated calorie needs. Patterns at 1000, 1200, and 1400 cal levels meet the nutritional needs of children ages 2–8 years. Patterns at 1600 cal and above meet needs for adults and children ages 9 years and older. A sample USDA Food Pattern at the 2000 cal level is provided in Table 10.2. Additionally, Appendix 7 of the 2010 Dietary Guidelines provides recommendations for the remaining calorie levels.

The USDA Food Patterns recommend selecting a variety of foods within each food group. This allows for personal choice, and helps to ensure that the foods and beverages selected by individuals over time provide a mix of nutrients that will meet their needs. Recommended weekly intake amounts are specified for the five vegetable subgroups (dark-green, red and orange, beans and peas, starchy, and other vegetables). In the protein foods group, ≥8 oz/week of seafood is recommended (less in patterns for young children), and in the grain group, selecting at least half of all grains as whole grains is recommended. In the fruit and dairy groups, there are no quantitative recommendations for making selections within the group. However, selecting more fruit rather than juice, and more fat-free or low-fat vitamin D-fortified milk or yogurt than cheese is encouraged.

Vegetarian Adaptations of the USDA Food Patterns

The types of vegetarian diets consumed in the United States vary widely. Vegans do not consume any animal products, while lacto–ovo vegetarians consume milk and eggs. Some individuals eat diets that are primarily vegetarian but may include small amounts of meat, poultry, or seafood. The USDA Food Patterns allow for additional flexibility in choices through their adaptations for vegetarians—a vegan pattern that contains only plant foods (Appendix 9 of the 2010 Dietary Guidelines) and a

TABLE 10.2
Sample USDA Food Pattern at the 2000 cal Level

Food Group or Subgroup	Amount	Description (All Foods Are Assumed to Be in Nutrient-Dense Forms, Lean or Low-Fat, and Prepared without Added Fats, Sugars, or Salt)
Fruits[a]	2 c	All fresh, frozen, canned, and dried fruits and fruit juices
Vegetables[a]	2½ c	All fresh, frozen, and canned vegetables and vegetable juices
Dark-green vegetables	1½ c/week	Examples: broccoli, spinach, romaine, and collard, turnip, and mustard greens
Red and orange vegetables	5½ c/week	Examples: tomatoes, red peppers, carrots, sweet potatoes, winter squash, and pumpkin
Beans and peas (legumes)	1½ c/week	Examples: kidney beans, lentils, chickpeas, and pinto beans (does not include green beans/peas)
Starchy vegetables	5 c/week	Examples: white potatoes, corn, and green peas
Other vegetables	4 c/week	Examples: iceberg lettuce, green beans, and onions
Grains[b]	6 oz-eq	All grain products and grains used as ingredients
Whole grains	3 oz-eq	Examples: whole-wheat bread, whole-grain cereals and crackers, oatmeal, and brown rice
Enriched grains	3 oz-eq	Examples: white bread, enriched grain cereals and crackers, enriched pasta, and white rice
Protein foods[c]	5½ oz-eq	All meat, poultry, seafood, eggs, nuts, seeds, and processed soy products. Beans and peas are considered part of this group as well as the vegetable group, but should be counted in one group only (vegetarian adaptations available).
Seafood	8 oz/week	Examples: *fish*, such as salmon, tuna, trout, and tilapia, and *shellfish*, such as shrimp, crab, and oysters
Meat, poultry, eggs	26 oz/week	Examples: chicken, turkey, beef, pork, lamb, and eggs
Nuts, seeds, soy products	4 oz/week	Examples: walnuts, almonds, peanuts, and pistachios
Dairy[d]	3 c	All milks, including reduced lactose products and fortified soy beverages, yogurts, frozen yogurts, dairy desserts, and cheese (excluding cream, sour cream, and cream cheese)
Oils	27 g	Includes oils found naturally in foods such as olives, nuts, avocados, and seafood; oils extracted from plants, such as canola, corn, olive, peanut, safflower, soybean, and sunflower oils; and foods that are mainly oil such as oil-based salad dressings and soft table spreads that have no *trans*-fats
Maximum SoFAS limit, calories (% of calories)	258 (13%)	Added sugars are sugars, syrups, and other caloric sweeteners added to foods during processing, preparation, or consumed separately. Solid fats may be naturally occurring in foods such as beef fat or added to foods during processing or preparation such as butter

Notes: For each food group or subgroup, recommended average daily intake amounts for a 2000 cal level are provided. Recommended intakes from vegetable and protein foods subgroups are per week. Amounts are shown in cups (c), ounce-equivalents (oz-eq), or grams (g).

[a] Fruits and vegetables, 1 cup equivalent is 1 c raw or cooked; ½ c dried; 1 c juice; 2 c leafy salad greens.

[b] Grains, 1 oz-eq is 1 oz slice of bread; 1 oz uncooked pasta or rice; ½ c cooked rice, pasta, or cereal; 1 tortilla (6 in. diameter); 1 oz ready-to-eat cereal.

[c] Protein foods, 1 oz-eq is 1 oz lean meat, poultry, seafood; 1 egg; 1 Tbsp peanut butter; ½ oz nuts or seeds; ¼ c cooked beans or peas.

[d] Dairy, 1 cup equivalent is 1 c milk, fortified soy beverage, or yogurt; 1 ½ oz natural cheese; 2 oz processed cheese.

lacto–ovo vegetarian pattern that includes dairy products and eggs (Appendix 8 of the 2010 Dietary Guidelines). The adaptations include changes in the protein food group and, in the vegan adaptation, in the dairy group. These vegetarian variations represent healthy eating patterns, but rely on fortified foods for some nutrients. In the vegan patterns especially, fortified foods provide much of the calcium and vitamin B_{12}, and either fortified foods or supplements should be selected to provide adequate intake of these nutrients.

DASH Eating Plan

The DASH Eating Plan was developed based on findings from the DASH research studies. This plan limits sodium, saturated fatty acids, and cholesterol and focuses on increasing intake of foods rich in potassium, calcium, magnesium, protein, and fiber. The DASH Eating Plan is another approach to meeting the Dietary Guidelines recommendations. A sample DASH eating pattern at the 2000 cal level is provided in Table 10.3. Eating patterns at six additional calorie levels are provided in Appendix 10 of the 2010 Dietary Guidelines.

TABLE 10.3
Sample DASH Eating Plan at the 2000 cal Level

Food Group	Amount	Serving Sizes
Grains (mostly whole grains)	6–8	1 slice bread; 1 oz dry cereal; ½ c cooked rice, pasta, or cereal
Vegetables	4–5	1 c raw leafy vegetables; ½ c cut-up raw or cooked vegetable; ½ c vegetable juice
Fruits	4–5	1 medium fruit; ¼ c dried fruit; ½ c fresh, frozen, or canned fruit; ½ c fruit juice
Fat-free or low-fat milk and milk products	2–3	1 c milk or yogurt; 1 ½ oz cheese
Lean meats, poultry, and fish	6 or less	1 oz cooked meats, poultry, or fish; 1 egg
Nuts, seeds, and legumes	4–5 per week	1/3 c or 1 ½ oz nuts; 2 Tbsp peanut butter, 2 Tbsp or ½ oz seeds; ½ c cooked legumes (dried beans, peas)
Fats and oils	2–3	1 tsp soft margarine; 1 tsp vegetable oil; 1 Tbsp mayonnaise; 1 Tbsp salad dressing
Sweets and added sugars	5 or less per week	1 Tbsp sugar; 1 Tbsp jelly or jam; ½ c sorbet, gelatin dessert; 1 c lemonade
Maximum sodium limit	2300 mg	

Notes: Daily servings recommended for each food group at a 2000 cal level are provided. Amounts of nuts, seeds, and legumes and sweets and added sugars are provided per week.

HELPING AMERICANS MAKE HEALTHY CHOICES

The preceding sections of the 2010 Dietary Guidelines include strategies that *individuals and families* can adopt to achieve dietary intake recommendations. In contrast, the purpose of this section is to outline actions that can be implemented by *various sectors of society* (e.g., educators, health professionals, communities and organizations, small and large businesses and policymakers) to support individuals and families in their daily nutrition and physical activity decisions.

Two points are emphasized: (1) the nutrition and physical activity environment influences individual decisions regarding food and beverage intake and activity level and (2) reversal of the current epidemic of overweight/obesity and related health outcomes will require a coordinated, system-wide approach spanning all sectors of society. For the first time, the 2010 Dietary Guidelines also includes a societal call to action.

This call to action is framed by an adapted Social–Ecological Model (Figure 10.2), one theoretical approach to explaining how the current food and physical activity environment evolved and exploring how it can be improved. This model describes the various elements of society and how they work together to influence individual behaviors. The elements include

1. Individual factors (e.g., age, socioeconomic status, psychosocial factors, knowledge, skills)
2. Environmental settings (e.g., schools, workplaces, foodservice/food retail establishments)
3. Sectors of influence (e.g., government, health care systems, agriculture, media, food/beverage industry, entertainment industry)
4. Social and cultural norms and values (e.g., belief systems, priorities, body image, heritage)

The model can help define the roles that various segments of society can play in making healthy choices more widely accessible and desirable. Thus, it can be used to develop, implement, and facilitate the use of multiple, coordinated primary prevention strategies. Efforts to improve dietary intake and increase physical activity are more likely to be successful when using this type of coordinated, system-wide approach. Building on the Social–Ecological Model, the 2010 Dietary Guidelines' call to action is based on three guiding principles:

1. Ensure that all Americans have access to nutritious foods and opportunities for physical activity.
2. Facilitate individual behavior change through environmental strategies.
3. Set the stage for lifelong healthy eating, physical activity, and weight management behaviors.

Each of these principles is explored and sample action steps for implementation by various elements of society are provided within this section of the 2010 Dietary Guidelines.

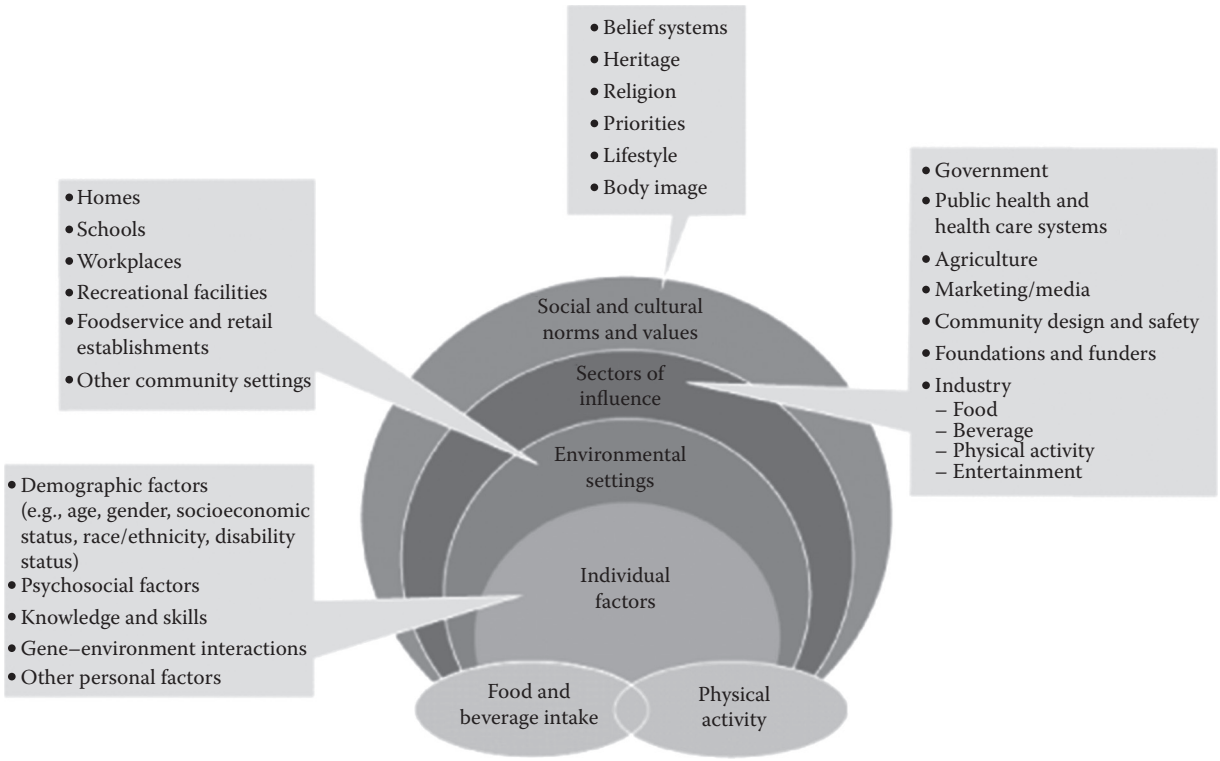

FIGURE 10.2 A social ecological framework for nutrition and physical activity decisions. (Adapted from Centers for Disease Control and Prevention, Division of Nutrition, Physical Activity and Obesity, State Nutrition, Physical Activity and Obesity (NPAO) Program: Technical Assistance Manual, January 2008, p. 36; http://www.cdc.gov/obesity/downloads/TA_Manual_1_31_08.pdf; Institute of Medicine, *Preventing Childhood Obesity: Health in the Balance*, National Academies Press, Washington DC, 2005, p. 85; Stroy, M., et al., *Annu. Rev. Public Health*, 29, 253, 2006.)

ADDITIONAL RESOURCES

The 2010 Dietary Guidelines also provides 16 appendices as resources that can be used in developing policies, programs, and educational materials. Examples of information provided in these appendices include a table of nutrition goals for age–gender groups (based on Dietary Reference Intakes and Dietary Guidelines recommendations); estimated calorie needs by age, gender, and physical activity level; examples of eating patterns at various calorie levels; estimated EPA and DHA and mercury content in certain seafood varieties; and food sources of the nutrients of concern (potassium, dietary fiber, calcium, and vitamin D). One appendix elaborates on the four basic food safety principles to reduce the risk of food-borne illness—Clean, Separate, Cook, and Chill—while another provides information on food labels, including discussion about Daily Values and the Ingredients List.

These resources are intended to complement existing Federal nutrition information and guidance that can be found at websites such as www.healthfinder.gov, www.nutrition.gov, www.mypyramid.gov, and www.dietaryguidelines.gov. Additional information on vitamin, mineral, and macronutrient recommendations are available in the Dietary Reference Intakes, accessible at http://fnic.nal.usda.gov/DRIreports and through an interactive tool at http://fnic.nal.usda.gov/interactiveDRI/

IMPLEMENTATION BY HEALTH PROFESSIONALS

The 2010 Dietary Guidelines emphasizes that everyone has a role in the movement to make America healthier. Health care professionals obviously play a particularly important and unique role as providers; however, they can also serve as trusted educators, respected advocates, and facilitators of change.

As providers, health care professionals engage in direct interactions with the American public, and can therefore serve as message purveyors. Health care providers should view the Dietary Guidelines as the authoritative source for evidence-based nutrition information, and should thus base any nutrition-related advice on the Guidelines' recommendations. Ideally, even providers who do not routinely dispense nutrition advice could incorporate the two main themes of the 2010 Dietary Guidelines (i.e., "Maintain calorie balance over time to achieve and sustain a healthy weight" and "Focus on consuming nutrient-dense foods and beverages") into their communications with patients, as a broad prevention effort. Nutrition messages should be brief, direct, and actionable; example nutrition messages (with consumer-tested wording) include

- Enjoy your food, but eat less.
- Avoid oversized portions.
- Make half your plate fruits and vegetables.
- Switch to fat-free or low-fat (1%) milk.

- Compare sodium in foods like soup, bread, and frozen meals—and choose the foods with the lower numbers.
- Drink water instead of sugary drinks.

Basing nutrition communication directly on the Dietary Guidelines reduces the risk of conflicting messages from authoritative sources and the resulting confusion for consumers. Outside of the direct provider role, health care professionals may facilitate the communication and implementation of the Dietary Guidelines in a number of ways. Potential examples include

- Collaborating to develop local, state, and national strategic plans to achieve Dietary Guidelines recommendations among individuals, families, and communities
- Recognizing health disparities among subpopulations and ensuring equitable access to safe and affordable healthy foods and opportunities for physical activity for all people
- Advocating for legislation, policies, and systems in key sectors such as public health, health care, retail, schools, and transportation to prevent obesity and associated health outcomes
- Supporting future research that will further examine the individual, community, and system factors that contribute to the adoption of healthy eating and physical activity behaviors; identifying best practices; and facilitating adoption of those practices
- Identifying approaches for assessing and tracking children's body mass index (or other valid measures) to identify overweight and obesity and implementing appropriate interventions
- Supporting effective policies to limit food and beverage marketing to children

The ultimate goal of the *Dietary Guidelines for Americans* is to improve the health of the nation's current and future generations by facilitating and promoting healthy eating and physical activity choices among all individuals. Meeting this goal will require comprehensive and coordinated system-wide approaches across the nation; health care professionals are vital to this endeavor and provide a uniquely influential role in behavioral and environmental change.

INTRODUCTION

Adolescent nutrition is complicated. This stage of development is marked by rapid changes that occur at different times for different individuals, and nutrient and energy needs are exceptionally demanding; it is challenging for parents and practitioners to know how much of which nutrients are essential for healthy growth, and when and how nutritional needs change. Dietary considerations for an active adolescent are even more complex given the additional physical and biological strains being placed on their bodies. While physical activity is critical for promoting cardiovascular endurance, as well as skeletal and muscular growth, these positive effects can be either enhanced or hindered by inappropriate dietary practices. Given research suggesting that adolescent dietary habits can predict lifelong health behaviors[1] and youth's dietary behaviors tend to worsen as they age,[2,3] it is critical to establish healthy dietary behaviors as early as possible. Accordingly, this chapter will start by providing a context for youths' nutrient needs by presenting an overview of the psychosocial and biological changes that occur during adolescence, followed by a discussion of which nutrients are important for growth and development, as well as those that tend to be consumed in insufficient and excessive amounts, and lastly provide practical knowledge for practitioners to help adolescents eat better given the context of their current food environment.

ADOLESCENCE

Adolescence is an important time in our maturation process, as our bodies, social relationships, self-identities, and lifestyle health behaviors are developing simultaneously.[4] This period can be conceptualized as three distinct stages: early adolescence (ages 11–14 years), middle adolescence (ages 15–17 years), and late adolescence (ages 18–21 years).[5] Different phases of development occur within each of these time periods. Early adolescence is marked by the onset

of physiological and physical changes related to puberty (e.g., menarche, gains in height and weight); during middle adolescence, teens begin to increase their social and psychological autonomy; puberty ends, and growth slows for females and continues for males. Lastly, in late adolescence, females' growth and development is usually complete while males are still experiencing growth in body mass. Both genders are typically more independent, have a more established self-identity, and are more future-oriented, having increased concern about life decisions, such as college or career choices.

Essentially, throughout this decade, adolescents experience rapid changes in hormonal composition, secondary sexual characteristics, brain development, and height and weight. During their peak 1 year growth spurt, males can gain an average of 4.1 in. and females, 3.5 in.[6] Females tend to experience this rapid growth before males, with their changes occurring during the ages of 10–13 years, vs. 12–15 years for males.[7] In terms of body composition, females tend to increase both their fat and muscle mass as they gain weight, whereas males tend to gain mostly lean mass. Both sexes experience gains in bone; in fact, 85%–90% of adult bone mass is accrued by the end of the adolescent years.[8,9] This growth spurt is especially important because it has been shown to predict 15% of ideal adult height and 50% of ideal adult weight.[10,11]

Given these significant changes, teens need more sleep. However, while the recommended amount of sleep for the average adolescent is 9.2 h,[12] 61% of youth ages 13–18 years report getting less than 8 h on school nights. To make up for this, on average, the typical adolescent consumes 3.1 caffeinated drinks/day[13]; more specifically, the consumption of caffeine was found to be 76% higher in adolescents (ages 12–18 years) who had difficulties falling asleep at night and staying awake during school.[14]

Sleep is also critical for supporting healthy brain development in adolescents, as their prefrontal, neuronal connections (between mental, physical, and emotional abilities) are not fully developed.[15] These emotional and behavioral alterations can result in heightened sensitivity to peer influence and opinion. Because adolescents tend to compare themselves with their peers, there are a number of psychological disturbances, such as depression, which can develop. For example, the prevalence of depression among adolescents is 5%–8%,[16] and has been associated with the onset of early menarche[17]; as a point of reference, the prevalence of depression among children is 2%,[16] and adults is 9%.[18]

Participation in athletics puts an even greater demand on adolescents' developing self-concepts, physical appearance, and biological changes; in fact, during different stages of adolescence, youth may present with increased insulin resistance and different physiological responses to exercise, such as glycolytic and metabolic rates, and higher fat oxidation levels.[19] Given the rapid growth in muscle and bone, adequate consumption of high-quality protein, carbohydrates, and fats, as well as vitamins and minerals such as vitamin D, calcium, and iron is especially important. Conversely, high intakes of some micronutrients, such as sugar and salt, can adversely influence healthy development.

To provide a more detailed context for how to support positive growth and development by maximizing the practice of good nutrition, the next section will focus on "energy balance," which generally refers to "calories in" equaling "calories out." More specifically, "calories in" refers to the amount and quality of nutrients that are consumed, whereas "calories out" refers to the expenditure of those calories, either through physical activity, exercise, metabolism, or the Thermic Effect of Food (TEF; the energy expended to digest food, 3%–10% of daily expenditure). Accordingly, the next section will be broken down according to the "calories in" part of this energy balance equation: first by discussing adolescents' total calorie needs; then going more in-depth about the quality and quantity of nutrients consumed; and ending with more information about contextual considerations, particularly as they relate to the active adolescent.

CALORIES IN

Energy Intake

Since adolescents move through developmental stages at different rates, setting energy requirements for this population is particularly difficult. The Food and Nutrition Board establishes estimated energy requirements (EERs) based on individuals' age, gender, height, weight, and activity level (sedentary, moderately active, active, and very active). Table 11.1 presents these equations used to calculate the EERs, and Table 11.2 provides the associated physical activity coefficients. Using these calculations, Table 11.3 outlines calorie intake ranges based on age and gender, within the context of three different levels of activity: sedentary, moderately active, and active.[20]

Notably, these energy reference values are organized by age category and not by sexual maturation stage; the latter are rarely available despite possibly being a better predictor of physical development. Accordingly, it is difficult to determine, more specifically, how many calories an adolescent of a given maturation stage needs. An additional challenge, then, becomes calculating how many more calories are needed to compensate for additional exercise to meet needs above and beyond adolescents' natural growth and development, given their maturation stage instead of age, as well

TABLE 11.1
EER Equations[a]

Females (9–18 years): EER = 135.3 – (30.8 × age [years]) + PA × [(10.0 × weight [kg]) + (934 × height [m])] + 25
Males (9–18 years): EER = 88.5 – (61.9 × age [years]) + PA × [(26.7 × weight [kg]) + (903 × height [m])] + 25

[a] Based on doubly labeled water experiments measuring the energy expenditure of normal-weight individuals.

TABLE 11.2
Physical Activity Coefficients for EER Equations by Gender

	Sedentary[a]	Low Active[b]	Active[c]	Very Active[d]
Females	1.0	1.16	1.31	1.56
Males	1.0	1.13	1.26	1.42

[a] Typical day-to-day activities, such as walking to school.
[b] Typical day-to-day activities, and 30–60 min of moderate activity/day (e.g., walking 3–4 mph).
[c] Typical day-to-day activities, and at least 60 min of moderate activity/day.
[d] Typical day-to-day activities, at least 60 min of moderate activity/day and 60 min of vigorous or 120 min of moderate activity/day.

TABLE 11.3
Calorie Estimates of Adolescents Based on Gender and Activity Level

Gender	Adolescent Stage	Sedentary[a]	Moderately Active[b]	Active[c]
Females	Early (9–13 years)	1400–1600	1600–2000	1800–2200
	Mid (14–18 years)	1800	2000	2400
	Late (19–30 years)	1800–2000	2000–2200	2400
Males	Early (9–13 years)	1600–2000	1800–2200	2000–2600
	Mid (14–18 years)	2000–2400	2400–2800	2800–3200
	Late (19–30 years)	2400–2600	2600–2800	3000

[a] Typical day-to-day activities.
[b] Walks 1.5–3.0 miles/day at 3–4 mph, in addition to typical day-to-day needs.
[c] Walks 3+ miles/day at a 3–4 mph pace, in addition to typical day-to-day needs.

as for an exercise level that is more vigorous than the "very active" category. Active adolescent energy needs will vary depending on the duration, intensity, and frequency of the sport in addition to maturation stage, as well as dietary patterns and/or restrictions. More specifics about these will be provided later.

Macronutrients

There are three macronutrients: carbohydrates, fats, and protein. They are called macronutrients because of the quantities required by our bodies, and because they are our only sources of energy. This section will discuss these three nutrients in more detail, including recommended intakes, roles in the body, and food sources.

How Intakes Are Calculated

In order to frame the following section, it is important to start with a context for how intake recommendations are calculated. The Food and Nutrition Board of the Institute of Medicine (IOM) establishes the dietary reference intakes (DRIs). These reflect intake reference values for macronutrients and micronutrients. There are five subcategories: estimated average requirement (EAR), recommended dietary allowance (RDA), the adequate intake (AI), and the tolerable upper limit (UL), as well as the acceptable macronutrient distribution ranges (AMDRs). The EAR reflects the average daily intake amount that is estimated to meet the needs of half of healthy individuals in a particular life stage and gender category. The RDA is the average daily intake amount that is sufficient to meet the needs of nearly the entire population (97%–98%) of healthy individuals in a particular life stage and gender category. An AI is calculated when there is insufficient data to establish an EAR (and thus an RDA); this amount is calculated from epidemiological data, and reflects the estimated intake of a given nutrient consumed by a group of apparently healthy people. The UL represents the maximum average intake amount of a given nutrient that is unlikely to cause an adverse health effect to a majority of the population; as intakes increase beyond this amount, the likelihood for an undesirable effect may also increase. The AMDR represents the range of intakes for a given macronutrient that provides a sufficient amount of essential nutrients while reducing the risk for a given chronic disease or condition. Intakes above or below these amounts may elevate risk for chronic diseases, and may result in the under- or overconsumption of micronutrients.

These reference values are based on research studies using biological data, as well as dietary data typically quantified by self-report, including 24 h food recalls, food journals, 3 day diet records, and food frequency questionnaires. Measurement errors implicit in these tools can lead to incorrect conclusions about the nutrient amounts consumed by a given target population. Examples of issues with dietary assessment include (1) respondent error (e.g., incorrect recall or social desirability bias); (2) interviewer error; (3) intake estimation errors (most people underestimate their intake); (4) failure to include food types—on the measure and in diet analysis computer programs; (5) errors in data entry and analysis; (6) intra- and inter-rater variability; and (7) insufficient recall duration to account for reporting errors.

Awareness of these limitations is particularly important given that most available data on measurement error is limited to adults. While there is little research validating the accuracy of adolescents' dietary recall, in their review of the literature, Livingstone et al. found that adolescents' nutrient intake variance ratios were twice that of adults, with males being more accurate in their reported vs. actual nutrient intake than females.[21] The variance ratio captures the discrepancy between within subject and between subject nutrient intakes. Moreover, validation studies of adolescents' reported vs. actual dietary intakes have consistently found biased results, which are associated with the type of diet assessment, weight, and adolescent age[21]; in fact, one study found adolescent girls' recall accuracy declines as they age, with greater underreporting occurring.[22]

Despite these limitations, there is a breadth of research dedicated to adolescent nutritional needs; using this data, the following sections will provide an overview of the roles of both macro- and micronutrients in the body, and more specifically, in the context of active adolescents.

Carbohydrates

Carbohydrates are chains of glucose molecules, either simple (sugars) or complex (fibers and starches). Carbohydrates, or more specifically glucose, are the human brain's and muscles' primary energy source. Accordingly, the AMDR for carbohydrates for adolescents is 45%–65% of total calorie needs; this is equivalent to an RDA of 130 g/day for all adolescents, and represents the amount of glucose needed for brain metabolism. While most youth consume enough carbohydrates, dietary sources tend to come from refined or processed food products, such as candy or sugar-sweetened beverages (SSBs), and fewer from whole foods, such as grains, legumes, fruits, and vegetables. Data from the federal government's Centers for Disease Control and Prevention's Youth Risk Behavior Surveillance System (YRBSS) found that, nationwide, 29% of adolescents report drinking at least one glass, can, or bottle of sugared (non-diet) soda/day.[23] Another study found that on any given day, 58% of adolescent males ages 11–13 years and 73% of males ages 14–17 years consume at least one soft drink; the figures for adolescent females were similar, with 63% of females ages 11–13 years and 62% of females ages 14–17 years.[24] Moreover, only 22% of high-school students reported consuming fruits and vegetables five times or more in the previous 7 days (excluding fried potatoes and potato chips).[23]

While carbohydrates are stored in the body as glycogen, it is noteworthy that adolescents' glycolytic capacity is still growing (only 0.4%–0.5% of body weight).[25] Accordingly, their muscle glycogen stores are 50%–60% less than adults and they have lower levels of circulating lactate[26]; this means "carb-loading" and other associated training tactics that increase glycogen stores may not have the same beneficial effect in adolescents, as they rely more on aerobic metabolism.[26] Thus, the source of carbohydrate is important because while all ingested glucose activates the release of the hormone insulin, which then signals cellular receptors to take up the glucose; the amount of insulin secreted, the time it takes for cells to absorb the glucose, and the time it takes for blood sugar levels to decline to normal (collectively referred to as the "glycemic index" or GI) vary across foods. Given that research also suggests adolescents may have greater insulin sensitivity,[25] it is important to choose foods with a lower glycemic load, such as those containing greater amounts of fiber. The next section will discuss fiber in more detail.

Fiber

While fiber represents parts of plants that are indigestible by humans, it provides the following benefits to the growing body: supports healthy GI function (by both promoting excretion and slowing digestion to encourage maximal nutrient absorption); provides a feeling of fullness; can be metabolized by gut bacteria to synthesize B vitamins; and binds to bile, which can lower cholesterol. In fact, too little fiber can lead to digestive problems, excessive calorie intake, and peaks in blood sugar levels; too much fiber, on the other hand, can lead to GI distress and micronutrient deficiencies (as fibers bind to minerals such as calcium and iron; heating grains weakens these bonds and encourages maximal absorption). Good sources of fiber include beans, whole grains (such as whole oats and whole wheat bread), as well as fruits and vegetables. Accordingly, there are different types of fibers; for example, fibers can be categorized by their water solubility: insoluble or soluble.

The AI for fiber is 31 g/day for males ages 9–13 years, and 38 g/day for males ages 14–18 years. For females ages 9–18 years, the AI is 26 g/day. Using National Health and Nutrition Examination Survey (NHANES) 2005–2006 data, Van Horn found that adolescents were consuming insufficient amounts of fiber. Males, ages 9–13 years ($n = 1009$) consumed 14.6 ± 0.59 g/day, and males ages 14–18 years ($n = 1351$) consumed 15.3 ± 0.39 g/day. Females ages 9–13 years ($n = 1039$) consumed 12.9 ± 0.39 g/day, and females ages 14–18 years ($n = 1250$) consumed 11.8 ± 0.34 g/day.[27]

Sugar

While sugars can provide a good source of quick energy—and are naturally occurring in fruits, vegetables, whole grains, and dairy products—added sugars in the diet are a major contributor to the nearly 40% of energy consumed in the form of empty calories (low nutrient value) among youth ages 2–18 years.[2] Using 2005–2006 NHANES data, this same analysis found that the primary source of energy for youth between the ages of 9 and 13 years was grain desserts; for youth between the ages of 14 and 18 years, it was soda (this category also included energy drinks, sports drinks, and sweetened bottled water).[2] As youth aged, the caloric contribution of SSBs to their added sugar consumption also increased from 169 kcal/day for 9–13 year olds to 260 kcal/day for 14–18 year olds.

In total, the average adolescent intakes of added sugars are as follows (measured in teaspoons): 29.2 ± 0.92 (males 9–13 years); 34.3 ± 1.03 (males 14–18 years); 23.2 ± 0.82 (females 9–13 years); and 25.2 ± 0.71 (females 14–18 years)[28]; notably, for both genders, intakes increase as they age. This equates to almost 400 kcal/day[2], with SSBs, alone, contributing an additional 173 kcal/day (soda: 116 kcal/day, fruit drinks: 55 kcal/day); as a point of reference, for an active adult male the (highest) intake reference for added sugar is 9 tsp/day, or 144 cal.[28] Excess sugar consumption has been linked with weight gain, dental carries, type II diabetes, micronutrient deficiencies, and a host of other adverse health effects.

To address the need for guidance on how much added sugar adolescents should be consuming, the American Heart Association (AHA) published dietary recommendations, which offered the following: "sweetened beverages and naturally sweet beverages, such as fruit juice, should be limited to … 8–12 oz per day for children 7–18 years old"[29]; in the AHA's 2009 report, adolescent-specific guidelines were not

published. Parents, coaches, and practitioners should seek to limit intakes of added sugars in adolescents' diets, including sources such as SSBs, sugar-sweetened cereals, candy, and baked goods.

Fat

Fats play an important role in human health: they protect internal organs and bones, are needed for vitamin absorption and storage, help regulate body temperature, and are used in cells' membrane and structure. There are different kinds of fats: unsaturated fats (including poly- and monounsaturated), saturated, and *trans*-fats (each of these prefixes refer to its chemical structure), as well as cholesterol. The AMDR for total fat is between 25% and 35% of total calories (with <10% from saturated and 0 g *trans*-fat); the AI is not determined. However, AIs are established for the two essential, unsaturated fatty acids: linoleic acid (n−6) and α-linolenic acid (n−3). For males ages 9–13 years, they are 12 and 1.2 g/day, respectively; males ages 14–18 years, the amount increases to 16 and 1.6 g/day, respectively. For females 9–13 years, the AI is 10 and 1.0 g/day for linoleic acid and α-linolenic acid, respectively; females ages 14–18 years, the amount increases to 11 and 1.1 g/day, respectively.

Most adolescents are consuming a sufficient amount of fat, and it appears, too much fat. A 2007 study using an ethnically diverse adolescent population found 68% of subjects were not meeting Healthy People 2010 Guidelines for <30% of calories from fat.[30] More recently, using data from the third School Nutrition Dietary Assessment Study (SNDA-III), Clark and Fox found middle-school students (n = 787) consumed 32.0% ± 0.35% of their total calories from fat and, more specifically, 11.0% ± 0.16% of their calories from saturated fat. High-school students (n = 795) consumed 32.8% ± 0.35% of their calories from fat; 11.1% ± 0.14% of total calories were from saturated fat.[31]

Too much dietary fat can lead to an increase in body weight and elevated cholesterol levels. Too little fat can impair vitamin absorption, metabolism and storage, increase risk of fracture after a fall, and impair body temperature regulation (e.g., increase perceived extremes of hot and cold). It is important for adolescents to pay attention to the kind of fat they are consuming: unsaturated fats are preferable given their role in neurological and visual development, and in the fluidity and permeability of cell walls; saturated fat, on the other hand, has been shown to increase low-density lipoprotein (LDL; "bad cholesterol"), and *trans*-fats have been shown to concurrently increase LDL and decrease high-density lipoprotein (HDL; "good cholesterol"). Good sources of dietary fat include fatty fish, such as salmon and sardines, nuts, avocado, and oils (e.g., canola, olive, and coconut).

Saturated fat has received much attention given its relationship to heart disease.[32,33] In light of research finding that adolescents exceed the recommended intake, it is worth briefly discussing the controversy. An April 2011 review of the literature found that when polyunsaturated fats replace saturated fats, risk for coronary heart disease (CHD) is reduced.[34] The evidence for monounsaturated fats, however, is mixed; carbohydrates as a replacement may be beneficial if the source is minimally processed and has a low GI (this relationship also works in its converse), such that a diet high in refined grains can adversely influence cholesterol, as well as blood glucose, levels. It is difficult to assess the effects of certain foods since their molecular interactions, and thus influence on CHD risk, vary; again, the quality of the nutrients matters. Accordingly, there seems to be consistent confounding by food type; most dietary assessments are based on self-report and not biological data, which makes it difficult to parse the influence of fat and other macronutrient types.[34]

Protein

Protein is needed in the body for multiple physiological and biological processes, including antibody synthesis, tissue repair, and cell structure. Proteins comprise amino acids. There are 20 amino acids, 9 of which are "essential." Animal products (e.g., meat and dairy) are considered to be "complete proteins" since they contain all nine essential amino acids, nonmeat, complete protein sources including quinoa and soy. Notably, it is possible to create a complete protein by pairing complementary proteins. Food pairing examples include beans and rice, peanut butter and whole wheat bread, and pasta with beans.

The RDA for protein ranges from 1.2 to 2.0 g/kg of body weight for the average adolescent,[35] and reflects the amount needed to maintain adequate nitrogen balance; the range reflects varying needs based on gender, age, height, weight, and physical activity. However, the evidence is inconclusive (and research is ongoing) about how much protein the active adolescent actually needs. Research does suggest that with increased physical activity, protein utilization efficiency improves,[36,37] which means greater intakes are likely unnecessary (and not research-supported), and needs may be met from dietary intake alone. Accordingly, any substantive and intentional increase in protein intake—especially from supplements—should be preceded by a dietary analysis given the consequences of excess protein consumption. More specifically, while insufficient intakes of protein can lead to an irregular heartbeat, impairments in blood clotting and tissue repair, and poor immune health, high intakes of protein can lead to renal damage and increased fat mass. There is an additional concern that too much protein can lead to increased urinary calcium excretion, and thus adversely influence bone health; however, the research findings on this are also mixed, and the effects seem to be influenced by the interaction of multiple variables including source (food or supplement) and intake amounts for both protein and calcium.[38]

Typically, adolescents consume a sufficient amount of protein. Using NHANES (2003–2004) data, Fulgoni found the average adolescent protein intake was 1.7 ± 0.7 g/kg body weight (ages 9–13 years) and 1.5 ± 0.6 g/kg body weight (ages 14–18 years); notably, nearly 8% of adolescent females ages 9–18 years were consuming less than the EAR[39] (contrasted with <3% of males).

Micronutrients

Micronutrients are those nutrients our body requires in much smaller amounts (micro- and milligrams instead of grams), noncaloric, and include vitamins and minerals. Vitamins are organic substances that our body uses for fundamental and essential physiological processes, such as cholesterol synthesis, vision, immune function, and blood clotting. Minerals are inorganic compounds that are also important for biological processes, including blood pressure and pH balance, hemoglobin synthesis, muscle contractions, and bone structure. This section will discuss a few key micronutrients for the active adolescent: vitamin D, iron, and calcium.

Vitamins

Vitamin D

Vitamin D is a fat-soluble vitamin that is essential for calcium absorption, cholesterol synthesis, cell differentiation, and insulin secretion. Human beings are able to absorb vitamin D from sunlight, and can also consume it from our diet. Egg yolks, fatty fish (such as salmon, herring, mackerel) are the only naturally occurring food sources; fortified milk, cereals, and orange juice also contain vitamin D. The vitamin D RDA for adolescents is 600 IU (15 μg).[40] Because sunlight has such a potent effect on vitamin D status, dietary intake is not as useful an indicator of nutritional status as it is for some other nutrients. For this reason, serum 25 hydroxy vitamin D (25OH D) is the standard for nutritional status. Until recently, a reference standard for 25OH D was not available; therefore, values obtained in many clinical settings were not always valid indicators of deficiency or excess. The serum measurement of vitamin D is currently used to establish the RDA, but there is controversy surrounding the methods used and what levels are most appropriate. An additional challenge is the body's compensatory mechanisms for responding to low levels, and the widespread perception that many individuals are deficient or insufficient. These considerations make establishing an optimal range difficult; thus, the definitions for optimal levels remain controversial.[41]

Currently, the definition for deficiency is <20 ng/mL,[42] and for insufficiency it is between 21 and 29 ng/mL.[43] There appears to be a high prevalence of both vitamin D insufficiency and deficiency among adolescents and athletes; now that a reference standard for serum 25OH D is present it will be important to confirm these findings. Using NHANES data, Reis et al. found the mean serum 25OH D level was 24.8 ng/mL (23.8–25.9), with the highest levels in non-Hispanic whites (28.0; 27.0–29.0) and the lowest levels in non-Hispanic blacks (15.5; 14.6–16.4).[44] In an athletically diverse, young population (mean age: 14.7 ± 3.0 years) Constantini et al. found 73% of subjects had insufficient vitamin D levels (25.3 ± 8.3 ng/mL), with a significant insufficiency prevalence difference between indoor and outdoor athletes (80% vs. 40%; $p = 0.002$).[45]

Low levels of vitamin D can increase risk of fracture, impair athletic performance, lead to a softening of the bones, and osteoporosis later in life; it can also cause increased muscle pain and weakness. Other populations at risk for deficiency include overweight and obese individuals (as excess body fat sequesters vitamin D, making it less available to the body); vegans and vegetarians (whose vitamin D intakes are often very low unless they drink fortified cow's milk or soy milk); and individuals with dark skin (who do not synthesize as much of the vitamin in their skin). In order to absorb enough vitamin D from the sun, it is recommended to expose face, arms, and legs, without sunscreen, twice/week between 10:00 a.m. and 3:00 p.m. for 5–30 min, depending on the season, latitude, and skin color, as SPFs of 8 and greater reduce skin synthesis by 95%.

Minerals

Iron

Given their rapid growth and development, adolescents need a sufficient amount of iron. The RDA is 8 mg for both males and females ages 9–13 years; it increases to 11 mg for males and 15 mg for females ages 14–18 years. Iron is used in the body for hemoglobin synthesis, cell growth, and oxygen transport. There are different kinds of iron: heme and nonheme. Heme iron is bound in hemoglobin, so it is found in animal products, such as fish and poultry; this form is the most bioavailable. Sources of nonheme iron include fortified cereals, dark green leafy vegetables (e.g., spinach, kale), and nuts. One of the concerns with nonheme iron is that its bioavailability is limited by multiple inhibitors such as polyphenols, phytates, and fiber. Accordingly, nonheme food sources should be consumed with vitamin C (red bell peppers, strawberries, citrus fruits), which maximizes its absorption; blanching dark green leafy vegetables can also improve iron bioavailability.

Iron intakes vary by gender. For example, using cross-sectional data, Juzwiak et al. found that among a population of male tennis players, 100% of youth ages 10–13 years and 85% of those ages 14–18 years were either meeting or exceeding the iron RDA.[46] Conversely, using 2006 NHANES data, Cogswell e al. found that the prevalence of iron deficiency was 15.6% ± 1.2% among females ages 12–19 years.[47] The low intakes observed in the female population could be explained by a combination of factors, including diet (low calorie and/or low meat), high iron turnover from increased activity, and increased losses through sweat and urine. Vegetarians are also at risk for deficiency given the limited bioavailability of nonheme iron. Consistently low intakes of iron can lead to chronic fatigue and decreased immune function, as well as impaired aerobic capacity and athletic performance. It has been recommended that populations at risk for deficiency take a low-dose iron supplement during intense training and with guidance from a physician.[48]

Calcium

Calcium performs multiple roles in the body. It is necessary for muscle contractions, nerve transmissions, blood vessel volume regulation, and bone health; bone mineral content (BMC) is about 80% calcium.[49] For adolescents, calcium

consumption is particularly important; Martin et al. found in a group of 228 youth, maximal calcium accretion occurs at rates of 282 mg/day for males at age 13.3 years, and 212 mg/day for females at age 11.4 years.[50] In fact, total body BMC more than doubles in children between the ages of 8 and 15 years, with peak gains attained between the ages of 12.5 (girls) and 14.0 (boys) years,[51] resulting in 85%–90% of total bone accrual by the age of 18 years for females and 20 years for males. Given the critical role calcium plays in laying down adequate bone, the RDA is 1300 mg/day (males and females ages 9–18 years).

Since blood levels of calcium are homeostatic, insufficient intakes from the diet can lead to the leeching of calcium from the bone, resulting in soft bones and elevated risk for stress fractures, as well as muscle cramps and arrhythmias. Calcium deficiency is of particular concern for adolescents, since, as a demographic, they tend to consume insufficient amounts. Larson et al. found an average intake of 1014 ± 17 mg in an ethnically diverse cohort of adolescents (n = 1521; mean age: 15.9 years), with more than 72% of females and 55% of males consuming less than the recommended intake.[52] There are many reasons for this, but most notably is the displacement of milk for SSBs.[53] More specifically, using 10 year data from the National Heart, Lung, and Blood Institute Growth and Health Study, Striegel-Moore et al. found the consumption of SSBs increased almost three times, while consumption of milk decreased >25% among a group of black and white female adolescents (n = 2371).[3] Thus, while activities that increase skeletal demand, such as running and gymnastics, positively contribute to BMC,[54] if adolescent athletes do not consume a sufficient amount of calcium, they increase their risk for injury and impaired performance.

Aside from dairy products such as milk, yogurt, and cheese, other good sources include calcium-fortified beverages such as orange juice and soy milk, as well as dark green leafy vegetables (e.g., spinach and kale). Calcium absorption can be maximized by consuming it concurrently with a source of vitamin D (such as eggs or salmon), and waiting an hour ingesting between a calcium-rich source and an iron-rich source, as they compete for absorption. In fact, Malczewska et al. found that iron-deficient female endurance athletes had greater calcium levels than their nonathletic peers with adequate iron status.[55] This underscores the importance of AI of all micronutrients—especially those that compete for absorption—among adolescent athletes in order to avoid deficiencies. This is especially important for vegans, as they are at risk for both iron and calcium deficiency.

Other Micronutrients

While the nutrients outlined earlier are of the most concern for active adolescents, other nutrients are also important for growth and development. Tables 11.4 and 11.5 provide an overview of intake recommendations for all the vitamins and minerals.

Supplements

Americans spend more than $20 billion on dietary supplements.[57] Hoffman et al. found 71% of adolescents (n = 3248, grades 8–12; 48% males) reported using at least one supplement.[58] According to their data, the most popularly used supplement was a multivitamin (59.3%), followed by high-energy drinks (31.5%). The use of weight gain aids (e.g., protein powders, creatine) was reported by 17.3% of students, and 35.1% used weight loss aids (e.g., ephedra, caffeine pills). The use of supplements increased as students aged for high-energy drinks (β = 0.19, SE = 0.09, p = 0.04, OR = 0.83), protein powders (β = 0.65, SE = 0.14, p = 0.000, OR = 1.92), creatine (β = 0.87, SE = 0.25, p = 0.000, OR = 2.38), weight gain aids (β = 0.80, SE = 0.22, p = 0.000, OR = 2.22), and anabolic steroids (β = 1.32, SE = 0.38, p = 0.000, OR = 3.75).

Research, however, has yet to consistently support the reliability, efficacy, and safety of dietary supplements.[59] This is especially true for adolescents. For example, research in

adults suggests creatine has positive effects on both changes in total body and fat-free mass, and performance in sports that require short, intense bursts of energy (e.g., power lifting)[60]; safety data for youth is limited.[61] In fact, the American College of Sports Medicine (ACSM) does not recommend supplements for persons under 18 years of age due to insufficient, supportive data, and the risk for developmental problems. Similarly, the widespread use of multivitamins is not generally medically warranted; in fact, consistent use of multivitamins could put some individuals at risk for nutrient toxicities.[62] Moreover, people who use multivitamins tend to lead a healthier lifestyle than nonusers.[63] Consequently, supplements should be taken by adolescent athletes with the consultation of a dietician or physician, and only in cases where there is an established nutrient deficiency (or significant risk for one).

Fluid Ingestion

Our body is about 60% water; our brain is 75%–85%. Water is needed for the digestion, absorption, metabolism, and transportation of nutrients; regulation of body temperature, physiological/biological reactions, and electrolyte balance; and adequate lubrication of joints. Being well-hydrated boosts cognitive and physical performance, helps protect against illness, and encourages the maximal use of dietary nutrients. The IOM's AI for water is 2.4 L/day for males ages 9–13 years, 2.1 L/day for females ages 9–13 years; 3.3 L/day for males ages 14–18 years, and 2.3 L/day for females ages 14–18 years.[64]

It is important to pay attention to hydration, as water losses of as little as 1%–2% can cause fatigue and negatively impact performance.[65] Water is lost through respiration, GI excretions, and sweat; electrolytes are also lost in perspiration. Consequently, appropriate fluid replenishment is important; this is particularly true when exercising in hot climates, as heat stress can both impair performance and increase risk for heat-related illness.[35,66] The body's ability to regulate temperature, maximize cardiorespiratory function, and otherwise adapt to increasing physical demands is largely predicted by hydration status, and are impaired when athletes are not sufficiently hydrated.[67]

While there is little data on the amount of water consumed by adolescents, a recent (2010) study used NHANES data to describe water consumption among young adults.[68] The findings are presented in Table 11.6.

The NHANES data in Table 11.6 show that ~70% of adolescents are consuming an insufficient amount of water. Accordingly, it is important to encourage the consumption of *water* as adolescents' first choice of beverage—especially if they are active—in lieu of sports drinks, juice, coffee, and soda.

TABLE 11.6
Mean Usual Water Intakes of Adolescent Americans and Percentages That Meet or Exceed the AI

Hydration Timing

The timing of water consumption is also important. Between 1 and 2 h prior to exercise, adolescent athletes should consume 2½ cups (~20 oz) of fluid; 15–30 min before, they should consume 1½ cups (12 oz). The purpose of drinking before exercise is to ensure that the athlete is sufficiently hydrated, and that his or her electrolyte balance is maximized for performance. During exercise, water consumption is needed to prevent drastic changes in electrolyte balance, as well as excess dehydration (>2% of body weight). For workouts lasting longer than 1 h, adolescent athletes should consume 6%–8% carbohydrate–electrolyte beverages frequently (about ½ cup every 10–15 min), as this will maintain appropriate fluid balance by replenishing sodium and potassium levels (thus preventing dehydration), and spare glycogen stores (particularly important if participating in multiple training sessions in 1 day).[69]

Due to differences in variables such as duration, frequency, type, and intensity of activity, training quality, hydration status, sweat rate, and exercise environment, individuals should monitor their hydration status in order to determine their appropriate rehydration strategy. For example, in a cohort of high-school football players, Yeargin et al. used urine osmolality analysis and found mild–moderate dehydration both before (881 ± 285 mOsmol/kg) and after (856 ± 259 mOsmol/kg) practice. While the researchers found the players adequately replenished during practice (approximately two-thirds of sweat loss), they insufficiently hydrated between practices.[70] Adolescent athletes can calculate their own replacement needs by calculating weight loss during workouts. For each pound lost, individuals should consume 16 oz of water and avoid caffeine.

Sports and Energy Drinks

Sports and energy drinks, in particular, have become a popular source of hydration among adolescents. With the recent surge of energy drinks available on the market, these beverages have become synonymous with sports drinks; this is especially problematic since these drinks contain significant amounts of caffeine and added sugar. Furthermore, while consuming sports drinks (containing protein, carbohydrates, or electrolytes) can be helpful for adolescent athletes, particularly if exercising for longer than 60 min,[35,71] a recent (2011) statement by the American Academy of Pediatrics found that energy drinks have "no place in the diets of children or adolescents."[35]

Sports drinks are appropriate, however, when adolescents are engaging in prolonged activity, especially if it requires short bursts of energy (e.g., soccer, basketball). As discussed earlier, adolescents' glycolytic capacity is still developing, which means they are relying on circulating carbohydrates (in the blood) for energy needs; sports drinks can satisfy this need. There are concerns with improper and unguided consumption of sports drinks; these include the displacement of calorie-free—and essential—water, which means an overall increase in daily caloric intake, as well as the displacement of other health-promoting beverages such as milk. Some strategies that can ensure adolescents are replenishing their electrolytes while hydrating properly include using sports drinks only during prolonged activity, diluting the sports drink with water (50/50), drinking seltzer water instead of soda, and tea instead of coffee.

Alcohol

While not an essential nutrient, alcohol provides a source of "empty calories" at 7 cal/g of intake. In adolescents and young adults, excessive drinking of alcohol can stunt cognitive and physical development and performance, impair judgment, and lead to increased engagement in risky behaviors such as drunk driving and unprotected sexual intercourse.[72–74] Therefore, it is concerning that consumption among adolescents is widespread, and increases linearly as youth age. More specifically, according to a 2010 Monitoring the Future Report (National Institute on Drug Abuse), 37% of current 8th graders, 59% of 10th graders, and 72% of 12th graders had tried alcohol. Heavy drinking for this report was defined as five or more drinks in a row at least once in the prior 2 weeks; reported percentages for this behavior were as follows: 8% of 8th graders, 18% of 10th graders, and 25% of 12th graders.[75]

Adolescents who play sports have been shown to drink more than their nonathlete peers. More specifically, using data from the 2005 YRBS, Mays and Thompson found male athletes were more likely to report having drinking in the past month (OR 1.204; 1.021, 1.419), and drinking and driving in the previous month (OR 1.428; 1.160, 1.757). This finding was the converse in females, however, with female athletes being less likely to drink than nonathlete peers (OR 0.807; 0.681, 0.958), drinking at 12 or earlier (OR 0.824; 0.691, 0.982), and drinking in the previous month (OR 0.843; 0.734, 0.969).[76] Given these data, and the documented mal effects of consumption on healthy growth and development, practitioners, parents, and coaches should explicitly talk with adolescents about the dangers of excess consumption.

DIETARY BEHAVIORS

Fluid and food consumption patterns are particularly important for the active adolescent, as intake habits have physiological and biological implications, and can serve to either impair or improve athletic and academic performance. Especially while in-season, dietary behaviors should be seen as part of training; athletes should be encouraged to "practice" eating in order to see the effects different foods have on them. Athletes' meal timing also matters. Prior to competitions, athletes should consume 1–4 g of carbohydrate/kg of body weight: 1 h prior, consume 1 g/kg; 4 h prior, 4 g/kg. While the meal should be high in carbohydrate, it should also be low in protein, fat, and fiber, and moderate in salt.

For athletes playing endurance sports that require short bursts of energy (e.g., soccer, volleyball), consuming a combination of simple sugars has been shown to be beneficial[69]; however, discretionary calories should be kept under 200. For every hour of exercise, adolescents should ingest 30–60 g of

carbohydrate, and drink 4–8 oz of fluid every 15 min. After an event, athletes should consume a mixed carbohydrate/protein meal or snack within 15–20 min; this will boost glycogen storage by as much as 300%. Waiting 2 h postexercise before refueling can reduce glycogen synthesis by 50%, thus impairing recovery.

Special Considerations: Weight Status and Eating Disorders

As adolescents grow older, the prevalence of eating disorders increases; dieting to lose weight is often a strong predictor of onset.[77] Using cross-sectional data from a nationally representative sample of 10,123 adolescents (ages of 13–18 years), Swanson et al. found that the lifetime prevalence of anorexia nervosa, bulimia nervosa, and binge eating disorder was 0.3%, 0.9%, and 1.6%, respectively.[78] Even for teens that do not meet the standard psychiatric DSM-IV criterion for an eating disorder, body image may still be an issue, which means they may exhibit disordered eating patterns. Ackard et al. found that among an ethnically diverse group of adolescents, many reported disturbances in body shape perception (41.5% females; 24.9% males) and unwarranted influence of body shape/weight on self-esteem (36.4% females; 23.9% males).[79] Moreover, data from the Youth Risk Behavior Surveillance System (YRBSS) found that in the 30 days prior to the survey, 39.5% of students had eaten fewer calories, less food, or more lower fat food to prevent weight gain; and 10.6% of students had not eaten for a 24 h period in order to either lose or prevent from gaining weight.[23]

Some sports, such as wrestling and martial arts, place competitors in certain weight classes. Others, such as gymnastics, ice skating, and dance, place a strong emphasis on a lean and slender physique. Since growth and development are so rapid during adolescence, it can be difficult for youth to maintain their status in a given weight class or sustain a certain body type. Accordingly, these athletes may need additional guidance to ensure that they are consuming a sufficient amount of nutrients (within potentially restrictive calorie allowances) in order to meet the demands being placed on their body.

Similarly, while active adolescents are at lower risk for becoming overweight or obese compared with their sedentary peers, they are still at risk for developing disordered eating and weight adjustment patterns such as anorexia, bulimia, and muscle dysmorphia (the self-perception that an individual lacks enough muscle, often characterized by excess usage of protein supplements and weight gainers), as well as behavioral patterns intended to lose water weight, such as wearing plastic suits, using diuretics, and sitting for long periods of time in saunas. For example, some athletes engage in purging or dietary restrictive behaviors prior to competition in order to "make weight." After competition, these athletes then compensate by consuming an excess amount of calories (binge), which leads to rapid weight gain. This dietary pattern can place such a strongly negative demand on the body that adverse physiological and developmental changes can occur.[80] Other athletes restrict calories as the competition nears. Using data from nine 16 year old female judo competitors, Boisseau et al. found a significant 19.7% decrease in daily caloric intake between 3 weeks and 1 week prior to competition (1076 ± 206 vs. 1666 ± 156, $p < 0.01$). Total water consumption also decreased significantly, from 4.22 L ± 0.41 to 3.87 L ± 0.18, $p < 0.01$.[80]

CURRENT FOOD ENVIRONMENT

A last critical consideration for practitioners, coaches, and parents is the current food environment; it has been referred to as "toxic" and "obesogenic."[81,82] Contributors to this include excessive advertising, crop subsidies that encourage the cheap creation of energy-dense, but nutrient-poor products, and a cultural lifestyle that is conducive to sedentary living. Aggregated, these variables make it difficult to make healthy choices, especially for heavily marketed-to populations, such as adolescents. Using data from 44 companies, it was found that they spent $1.6 billion on the marketing of food and beverages to adolescents and children; of that, $1 billion was spent specifically on adolescents.[83] Moreover, 89% of food advertisements seen by adolescents are for products high in sodium, fat, and sugar.[84]

This type of marketing increases the likelihood that adolescent athletes will consume products that may be high in calories, added sugars, fat, and salt, as well as ergogenic (performance) aids, such as creatine and caffeine. Moreover, the regular consumption of these high calorie foods and beverages as part of an adolescent's dietary intake can offset his or her energy balance—even if they are active—and lead to unhealthy weight gain over time. In fact, the prevalence of overweight and obesity has reached epidemic proportions in the United States; according to NHANES data (2007–2008), 18% of youth ages 12–19 years are obese.[85] There are racial trends as well; there is a higher prevalence of obesity among Mexican American boys (27%) than among non-Hispanic white adolescents (17%), and 29% of non-Hispanic black adolescent females were obese compared with 14% of non-Hispanic white females.[85] These changes could be resultant from the obesogenic food environment adolescents find themselves in, as it is increasingly difficult for teens to make healthy dietary choices, especially if they live in areas where access to affordable fruits and vegetables is limited. Recognizing that proper nutrition for adolescent athletes does not happen in a vacuum, and that youth are a heavily marketed-to population, is critical for adapting recommendations.

CONCLUSION

While adolescent athletes may have performance needs to consider when establishing their dietary intake patterns, their needs do not appear to warrant the default consumption of additional nutrients, such as sports nutrition supplements or ergogenic aids. On the contrary, research appears to support the need for adolescent athletes to pay increasing attention to

the quality of their diets—ensuring they are consuming a sufficient quantity of calories and micronutrients to meet their developmental and athletic performance needs, and limiting the intake of "empty calories" often found in SSBs and salty snack foods. Practitioners can support this by encouraging adolescent athletes to consider their food and fluid intake as part of their training, and by educating youth on the role nutrition plays in their competitive performance. Awareness of the challenges and social constraints placed on this population can aid practitioners in successfully communicating with this population.

INTRODUCTION: WHAT IS AN *ELITE* ATHLETE?

In the world of sport the title "elite" is typically reserved for those athletes who are the *best*. While this title might be given to a wide range of athletes based on subjective judgments, a more systematic classification might categorize elite athletes as those competing at the collegiate, professional, world-class, or Olympic level. Competition at these levels demands a lifestyle, including a nutrition and training program, that promotes optimal performance. Such a lifestyle may also be associated with a host of desirable health benefits [1]. Indeed, available research suggests that former elite athletes, especially those involved in endurance type sports, are at decreased risk for a number of chronic diseases including heart disease, stroke, diabetes, and certain types of cancer and on average live 3–6 years longer than the general population [2–4].

At the same time, however, the unique physical demands required of an elite athlete's lifestyle can create special nutritional needs and challenges, which under certain circumstances may negatively impact health. For example, heavy training loads require additional calories and nutrients to support performance and recovery. Demanding competition schedules often require frequent travel and may disrupt an athlete's normal eating and sleeping patterns and access to familiar foods. Competition in extreme environments (i.e., extreme temperature and/or altitude) may adversely affect appetite, energy requirements, and/or the ability of the athlete to properly hydrate. Furthermore, personal or outside pressure to perform may lead to risky lifestyle practices such as extreme weight-loss methods or use of dangerous or banned ergogenic supplements. Left unchecked, these factors may not only compromise the

short-term health of these athletes, but they may also have unintended long-term health consequences.

Unfortunately, even though athletes acknowledge the value of sports nutrition, relatively few are knowledgeable about current recommendations and even fewer achieve them [5–8]. This chapter provides a practical review of current nutrition recommendations that serve as the basis of elite performance while addressing the potential nutrition-related health risks associated with the elite athlete's lifestyle.

OPTIMIZING HEALTH AND PERFORMANCE VIA ADEQUATE ENERGY INTAKE

When energy requirements are met, individual requirements for the major macronutrients and micronutrients (i.e., carbohydrate [CHO], protein [PRO], fat, vitamins, and minerals) are typically achieved provided a well-balanced diet is consumed. A well-balanced diet that provides adequate energy supports the demands of training and competition, aids in the maintenance of an appropriate body composition, promotes recovery, sustains immune function, and reduces the risk of injury [9].

Unfortunately, however, elite athletes face several challenges that may prevent them from meeting their daily energy requirements, thus increasing their risk for inadequate intakes of other nutrients. To begin with, the frequency, intensity, and duration of physical activity may change dramatically over the course of a training cycle leading to inadequate or excessive energy intake. Additionally, an athlete may sustain an unexpected injury or illness that prevents a normal level of activity, travel to a culture where the food is unfamiliar, or simply restrict energy intake in an attempt to manipulate body composition. When presented with these challenges, a registered sports dietitian becomes an invaluable resource for the athlete by helping to ensure that appropriate dietary accommodations are made so that energy and nutrient requirements are met and health and performance do not suffer. The following sections provide an overview of the major macro and micronutrient requirements of elite athletes.

CHO Recommendations

As the primary substrate used during exercise intensities >65% of VO_{2max}, CHO is arguably the single most important nutrient for an elite athlete. The availability of CHO during exercise dictates both the intensity and duration at which an athlete is able to train and compete and has been directly related to subjective indices of fatigue [10,11]. Because the body's storage capacity for CHO is limited (approximately 100 g in the liver and another 300–400 g in the muscle) regular CHO consumption is imperative. Thus, current CHO recommendations seek to ensure a high level of CHO availability during training and competition by maximizing muscle glycogen stores prior to, during, and after training or competition.

Daily CHO Requirements

Table 12.1 summarizes the most recent general daily CHO requirements for athletes according to intensity and duration of activity. These general guidelines should be fine-tuned to the individual needs of the athlete taking into account total energy requirements and feedback from training performance [12]. For athletes with ≥24 h between glycogen depleting training or competition, meeting total daily CHO requirements is the most important factor that ensures adequate muscle glycogen repletion after strenuous exercise [13]. Two classic studies conducted by Costill and associates illustrated that after strenuous running, muscle glycogen stores were only maintained by runners who consumed adequate daily CHO and the results were independent of timing of CHO ingestion [14,15]. However, for athletes with fewer than 24 h between training sessions or those who engage in multiple training sessions per day, timing of CHO ingestion becomes more important to ensure adequate replenishment of glycogen stores between training sessions (see section on "CHO for Posttraining and competition" recommendations as follows).

CHO for Pretraining and Competition

CHO intake prior to training or competition seeks to "top off" muscle glycogen stores and has been shown to improve performance during subsequent exercise [10]. The amount and timing of CHO intake prior to training or competition depends largely on scheduling of training sessions or competition as well as on individual tolerance (Table 12.1). Events lasting longer than 90 min or those that involve repeated high-intensity sprints may benefit from CHO feeding strategies that provide CHO within 1–4 h prior to the event. To avoid any potential gastrointestinal distress during training or competition, it is recommended that the CHO, calorie, and fiber content of the pretraining or competition meal be reduced as the training session or competitive event nears. Furthermore, better designed and well-controlled studies have demonstrated that glycogen super-compensation (i.e., CHO loading) may be achieved without the traditional depletion phase and with as little as 24–36 h of high CHO intake and rest (Table 12.1) [12].

CHO Intake during Training and Competition

Exogenous CHO ingestion during endurance or intermittent high-intensity type training or competition lasting longer than 45–60 min supports performance and prevents fatigue [10,12,16,17]. The current recommendation for CHO consumption during exercise is based on the maximum rate of endogenous CHO oxidation (~1 g min^{-1}) and is set at 30–60 g of CHO per hour of exercise (Table 12.1) [17,18]. Athletes are encouraged to develop a personalized plan that provides CHO within this range, maintains adequate hydration, and is amenable to their individual tolerance and opportunities for intake during training or competition noting that consumption of ~15 g CHO at 15–20 min intervals is optimal [10,17].

An emerging body of evidence, however, suggests that the rate-limiting step of endogenous CHO oxidation occurs

TABLE 12.1
Nutrient Recommendations and Timing

	Daily Requirements	Pre-Training/Competition	During Training/Competition	Recovery
Carbohydrate Recommendations	• 3–5 g·kg^{-1}·day^{-1}; Light-intensity or skill based activity • 5–7 g·kg^{-1}·day^{-1}; Moderate-intensity short duration (~1 hr·day^{-1}) • 6–10 g·kg^{-1}·day^{-1}; Moderate-to-high intensity moderate duration (1–3 hr·day^{-1}) • 8–12 g·kg^{-1}·day^{-1}; Moderate-to-high intensity long duration (4–5 hrs·day^{-1})	Days prior to event: • 7–12 g·kg^{-1} per 24–36 hrs prior to event lasting <90 min • 10–12 g·kg^{-1} per 36–48 hrs prior to event lasting >90 min Hours prior to event: • 1–4 g·kg^{-1} 1–4 hrs prior to training or event lasting >60 min	• <45 min Exogenous CHO not needed • 45–75 min High intensity intermittent type exercise may benefit from small amounts of CHO or a CHO mouth rinse • 1–2.5 hrs Endurance or stop-and-go type sports 30–60 g·hr^{-1} • >2.5–3 hrs Ultra endurance exercise up to 90 g·hr^{-1}	• ≥24 hr recovery period ensure total daily CHO requirement is met • <8 hr recovery period 0.8–1.2 g CHO·kg^{-1}·hr^{-1} + 0.4 g PRO·kg^{-1}·hr^{-1} for the first 4 hrs then resume normal CHO feedings
Protein Recommendations	Endurance athletes • 1.2–1.6 g·kg^{-1}·day^{-1} Strength athletes • 1.2–1.7 g·kg^{-1}·day^{-1} Early training/Power athletes • 1.5–1.7 g·kg^{-1}·day^{-1} Steady state strength athletes • 1.2–1.4 g·kg^{-1}·day^{-1}	• 0.3–0.5 g PRO·kg^{-1} (~20–40 g) along with 0.8–1.5 g CHO·kg^{-1} ~ within 1 hr prior to, during, or within 1hr post resistance type exercise • Consuming a combination of whey and casein proteins may provide an anabolic advantage over other types of protein or consuming either protein individually		
Hydration and Electrolyte Balance	• Due to differences in sport, environment, and individual sweat rates no single total daily fluid and electrolyte recommendation is appropriate for all athletes • To maintain euhydration elite athletes should closely monitor daily hydration status • Several markers of hydration (BW, urine color, USG) should be used to ensure adequate hydration is being obtained	• Consume adequate fluids to begin euhydrated • Consume 5–7 mL·kg^{-1} (0.08–0.11oz·lb^{-1}) fluid 4 hrs before exercise, especially important for athletes with <24 hrs between events • If no urine is produced or is dark in color consume an additional 3–5 mL·kg^{-1} (0.05–0.08 oz·lb^{-1}) 2 hrs prior to event	• Drink periodically to prevent >2% body weight loss and excessive changes in electrolyte balance • Amount should be customized to each athlete according to individual sweat rate, sport, intensity, duration, and environment • For events lasting >1–2 hrs use of a CHO electrolyte beverage containing 6–8% CHO (~14–19 g·8 oz^{-1}), 20–30 mEq·L^{-1} sodium (~110–165 mg·8 oz^{-1}), and 2–5 mEq·L^{-1} potassium (~20–45 mg·8oz^{-1}) is warranted	• If the recovery period is >~12 hrs normal meals and snacks with adequate water will typically restore euhydration • For recovery periods lasting <~12 hrs consuming ~1.5 L·kg lost BW^{-1} (~24 oz·lb lost BW^{-1}) will promote rapid rehydration • Consuming sodium during the recovery period will help retain ingested fluids and stimulate thirst

at the site of intestinal absorption and that this rate is fluid depending on the form of CHO ingested [12]. Differences in the transport mechanism at the site of intestinal absorption between glucose and fructose, for example, allows for absorption rates that exceed 1.5 g min^{-1} (90 g h^{-1}) when these different CHOs are consumed in a 2:1 ratio [12]. The practical application of this finding, however, may be limited to those athletes with extreme fuel requirements during exercise that can also easily consume food and fluids during exercise (e.g., cycling events during the Tour De France or Ironman Triathlon).

Still, further interesting data is emerging regarding the use of a CHO mouth rinse for intermittent high-intensity short duration (45–75 min) events that are not limited by the availability of endogenous CHO [12]. Initial hypotheses postulate that CHO receptors in the oral space may signal the central nervous system and promote an enhanced sense of well-being and improved pacing [12]. In fact, some studies have reported a 2%–3% improvement in performance with very small amounts of CHO ingestion or use of a CHO mouth rinse, suggesting that a nonmetabolic role for CHO ingestion during exercise and improved performance exists [19].

CHO for Posttraining and Competition

As noted previously, muscle glycogen stores are typically replenished to preexercise concentrations within 24 h if total daily CHO needs are met. For athletes with <24 h between training or competition, however, rapid replenishment of muscle glycogen stores is critical to support activity during multiple training sessions or competitions on the same or successive days. For optimal short-term glycogen repletion ensuring adequate CHO availability seems to be dependent on the amount and frequency of CHO ingestion. Muscle glycogen content was 150% greater in glycogen-depleted cyclists who consumed 1.2 g kg^{-1} h^{-1} at 30 min intervals during postexercise recovery than those who consumed only 0.8 g kg^{-1} h^{-1} [20]. Additionally, no further benefits have been demonstrated with intakes up to 1.6 g kg^{-1} h^{-1} or by manipulating the form of CHO (i.e., liquid vs. solid) [13].

Adding PRO to the postexercise feedings, however, decreases the total need for postexercise CHO. Results from a study conducted by van Loon and Wagenmakers (2000) found no difference between muscle glycogen synthesis rates over a 5 h recovery period when glycogen depleted cyclists ingested 0.8 g CHO kg^{-1} h^{-1} plus 0.4 g PRO kg^{-1} h^{-1} or 1.2 g CHO kg^{-1} h^{-1} at 30 min intervals [20]. Since the majority of athletes do not consume solely CHO postexercise ingesting at least 0.8 g CHO kg^{-1} h^{-1} plus 0.4 g PRO kg^{-1} h^{-1} offers a more practical approach to optimizing glycogen repletion between strenuous exercise bouts spaced closely together when time does not allow for normal glycogen replenishment (Table 12.1).

PRO Recommendations

While PRO has many physiological roles (e.g., structure, transport, hormonal signaling, fluid balance, immune function, etc.) the role of PRO in the maintenance and building of lean body mass (LBM) in the form of skeletal muscle is of particular importance and interest for elite athletes. This section describes what is known about the PRO needs of athletes and offers practical recommendations regarding the amount, timing, and type of PRO.

Daily PRO Requirements

Although some controversy exists regarding PRO needs of athletes, data derived from both nitrogen balance and amino acid tracer studies suggests that athletes have greater PRO requirements than their sedentary counterparts [21,22]. The current PRO recommendations for endurance and strength/power athletes are summarized in Table 12.1. These recommendations should be modified to meet the individual needs of the athlete depending on the intensity, duration, and frequency of exercise as well as training status.

It should be emphasized, however, that while PRO requirements are likely higher for elite athletes compared to sedentary individuals, dietary intake surveys among both endurance and strength/power athletes reveal that the large majority of athletes either meet or exceed the current PRO recommendations. For example, habitual PRO intakes among endurance-trained athletes tend to fall within the recommended range of 1.2–1.6 g PRO kg^{-1} day^{-1} [21–24]. Furthermore, habitual PRO intakes among strength/power athletes in the range of 2–2.5 g PRO kg^{-1} day^{-1} to as high as 3 g PRO kg^{-1} day^{-1}, a level well above recommended intakes [21–24]. Even so, certain athletic populations such as female endurance athletes, vegetarians, weight-class athletes, or those restricting energy intakes may be at risk for inadequate PRO intakes [17].

Some concern has been raised among health professionals regarding the potential negative effects of chronically high PRO intake among athletes. In particular, excessive PRO intake may *crowd out* other nutrients, especially CHO, potentially impairing performance particularly for endurance-type athletes. Other concerns that excessive PRO intake may impair renal function or negatively impact bone health, however, remain largely unsubstantiated [22,25]. In fact, high PRO intakes have only been associated with impaired renal function in individuals with concurrent renal insufficiency [22,25]. Additionally, even though high PRO intakes tend to increase urinary calcium excretion, mounting evidence suggests that high PRO intakes actually result in greater peak bone mass and may actually reduce the risk of osteoporosis and related fractures [26].

PRO Timing, Type, and Amount

Since most athletes appear to be meeting or exceeding daily PRO recommendations, a more practical concern might be identifying the significance of the timing and type of PRO consumed as well as the effect that co-ingestion of other nutrient such as CHO might have on skeletal muscle hypertrophy, strength gains, and performance. From a timing stand point, research suggests that there is an *anabolic window* (approximately 1 h prior to and/or after exercise) during which PRO should be consumed to optimize strength gains and muscle hypertrophy [13,22,27–31]. However, whether consuming PRO prior to, during, or after exercise would be more advantageous remains unclear. Tipton and Wolfe (2001) showed a benefit on net PRO status only when 35 g of CHO with 6 g of essential amino acids (EAA) was consumed *immediately prior to training* as opposed to *immediately posttraining* [32]. A separate follow-up study, however, found no difference in PRO status regardless of whether 20 g of whey PRO was consumed *immediately prior to or immediately after* the training bout [32,33].

Other studies have highlighted possible performance benefits when PRO is consumed along with CHO *during* endurance type exercise. For example, Saunders and Herrick (2007) showed improvements in cycling performance and attenuation of muscle damage when PRO was added to a standard 6% CHO solution or CHO gel [34,35]. A major criticism of these studies, however, is that isoenergenic controls were not used and the caloric difference between the treatment vehicles likely accounts for the difference between treatment groups. Indeed, studies that have used isoenergenic controls have found no significant endurance performance benefits when PRO is added to a CHO solution consumed during endurance-type exercise [36–38]. For strength/power athletes, on the other hand, ingesting PRO plus CHO during prolonged resistance training (approx. >45 min) may ameliorate muscle catabolism, preserve muscle glycogen, and enhance muscle PRO accretion [31]. Although the mechanism by which CHO positively affects PRO status is not precisely known and is likely multifaceted, at least part of the effect is attributed to insulin which has been shown to be a potent inhibitor of muscle PRO breakdown (MPB) [39].

PRO type also seems to have an effect on muscle PRO synthesis (MPS). Interestingly, only EAA seem to be needed to effectively stimulate postexercise MPS [13,40]. In fact, leucine alone has been shown to independently stimulate expression of PROs that regulate MPS [41]. The majority of research, however, centers on common supplemental forms

of PRO such as whey, casein, soy, egg, and milk, or some combination thereof. The milk PROs whey and casein are particularly popular and seem to have unique anabolic properties. The soluble PRO whey elicits a rapid rise in plasma amino acid concentration and leads to both higher MPS and AA oxidation rates while the insoluble PRO casein clots in the stomach, delaying gastric emptying, leading to a slower more sustained rise in plasma AA that supports MPS over a longer period of time [42–44]. Despite these differences, however, both whey and casein seem to affect net PRO balance similarly [45].

Even so, it makes sense that some combination of these PROs might provide an anabolic advantage. Indeed, consuming milk, which is composed of approximately 80% casein and 20% whey PROs, after resistance-type exercise effectively stimulates MPS and has been shown to be superior to plant PROs (i.e., soy PRO) in eliciting strength gains and muscle hypertrophy [46–48]. Two studies have shown that consuming milk immediately after resistance-type exercise significantly increased muscle fractional synthetic rate and muscle fiber size ($p < 0.05$) when compared to an isonitrogenous isocaloric soy beverage or placebo [27,49]. Conversely, Candow and Burke (2006) found no difference in LBM, strength, or muscle damage between those who consumed a whey or a comparable soy supplement immediately postexercise [50].

The ideal amount of PRO needed to maximize MPS and strength gains has also been an area of interest. Recently Moore and Phillips (2009) demonstrated that MPS responded in a dose–response manner and was maximally stimulated by ingestion of 20 g of PRO after resistance exercise [51]. Ingestion of 40 g of PRO resulted in a significant increase in leucine oxidation, suggesting that a PRO intake ≥40 g exceeds the amount that may be incorporated into muscle tissue [51].

Based on the research presented previously, it is clear that much still stands to be elucidated regarding the optimal PRO prescription for the elite athlete seeking to optimize LBM and improve performance. Still, from a practical point of view the current research suggests that athletes seeking to maximize gains in LBM and strength and/or accelerate recovery should aim to consume between 0.3 and 0.5 g PRO kg^{-1} (~20 to 40 g) along with 0.8–1.5 g CHO kg^{-1} within 1 h prior to, during, or within 1 h post resistance and/or endurance type exercise [31,40,51].

Fat Recommendations

Dietary fat is a critical component of every elite athlete's diet. Aside from being calorically dense (9 cal g^{-1} of fat compared to 4 cal g^{-1} for CHO and PRO), fats play integral roles in cell structure, nervous function, hormone synthesis, insulin action, prostaglandin production, absorption and transport of the fat-soluble vitamins, and much more [52]. Fat requirements for athletes must be considered within the context of energy and macronutrient balance and typically fall within 20%–35% of total calories depending on the athlete's individual CHO and PRO requirements [17]. For example, a 90 kg (~200 lb) American football linebacker may require 3600 cal, 6 g CHO kg^{-1} (545 g CHO or ~60% CHO), and 1.6 g PRO kg^{-1} (145 g PRO or ~15% PRO) during a certain training cycle. It follows then that the fat recommendation for this athlete would be about 100 g (1.1 g fat kg^{-1}) or ~25% of total calories from fat.

Additionally, very-low-fat diets (<20% of total calories from fat) are not recommended for the athletes. Very-low-fat diets are typically too low in energy to support the demands of training and can lead to a lower intake of other nutrients, both of which can be detrimental to health and performance [53]. Like the general population, elite athletes should focus on obtaining adequate dietary fat from heart healthy sources such as low-fat dairy products, avocadoes, nuts, seeds, and olive oil and canola oil. Fish is also an excellent source of healthy fats and athletes should aim for at least two 3.5 oz servings of fatty fish such as salmon, herring, lake trout, and tuna per week [54].

Fat and Athletic Performance

Elite athletes have a greater ability to utilize fat than their untrained counterparts. Trained athletes typically have elevated levels of muscle lipoprotein lipase, muscle lipase, fatty acid acyl CoA synthetase and reductase, carnitine acyl transferase, and 3-hydroxyl acyl CoA dehydrogenase, all of which enhance fatty acid oxidation [55]. Furthermore, trained athletes store more intracellular fat, which leads to enhanced fatty acid availability and oxidation during exercise, potentially conserving glycogen stores helping to stave off fatigue during endurance-type exercise [55]. This potential performance-enhancing effect of glycogen sparing due to increased fat oxidation has led to the development of dietary strategies that might enhance fat utilization during endurance-type exercise. Some of these strategies include *fat adaptation* diets (>40% of energy from fat), supplementation with medium chain triglycerides (MCTs), or L-carnitine. Unfortunately, research has shown these strategies to be largely ineffective at best and, in the case of MCT supplementation, can actually impair performance due to gastrointestinal distress [56–59].

Hydration and Electrolyte Recommendations

Proper hydration mirrors adequate energy and CHO intake in terms of importance and the effect on performance and the overall health of elite athletes. Maintenance of euhydration during exercise is critical for normal thermoregulatory, metabolic, and nervous system function. Dehydration resulting in a little as a 2% body weight (BW) loss as water increases body core temperature, heart rate, glycogen utilization, perceived exertion, and, consequently negatively impacts performance [60]. If fluid loss continues, metabolic, nervous system, and cognitive functions become impaired and the likelihood of heat exhaustion or heat stroke dramatically increases [60].

Furthermore, excessive electrolyte loss, which often accompanies dehydration, may alter normal nervous system and cardiac function, lead to the development of muscle

cramps, and/or cause life-threatening shifts between extra- and intracellular fluid compartments [60]. Conversely, excessive consumption of hypotonic beverages may precipitate dilutional hyponatremia, resulting in cerebral, or pulmonary edema, and even death [60]. Clearly the importance of adequate hydration and electrolyte balance among the athletic population cannot be overstated. This section addresses the hydration needs of elite athletes, discusses practical ways of assessing hydration status, and summarizes current fluid and electrolyte recommendations.

Daily Hydration and Electrolyte Requirements

To avoid decrements in performance or adverse health outcomes elite athletes must maintain euhydration and electrolyte balance by matching daily fluid and electrolyte loss with intake. Inter-individual variability in sweat rate and electrolyte losses, differences in sport type, environment, and heat acclimation make it not only difficult, but also inappropriate to assign a universal fluid and electrolyte intake recommendation for all athletes. Consider that a football player practicing in the heat in full pads may lose as much as 8 L (~1.6 $L \cdot h^{-1}$) of fluid and greater than 9000 mg of sodium or the equivalent of 23 g of NaCl over the course of a 5 h practice, while a swimmer training only 1 h may lose less than 0.5 L of fluid and minimal amounts of sodium [61]. Obviously, in this situation the fluid and electrolyte needs of the football player are much greater than that of the swimmer and a standard fluid recommendation for both athletes would be inappropriate.

Since daily fluid requirements vary widely among athletes, it is imperative that each athlete monitor his/her individual daily hydration status to ensure adequate amounts of fluid is being ingested. Tracking chronic changes in first morning BW after voiding (BW should fluctuate by <1%) and monitoring urine color of the first void are simple methods athletes can employ to monitor their hydration status on a daily basis. Ideally, however, BW and urine color should be used in combination with other more objective status measures, such as urine specific gravity (USG) or plasma osmolality, to minimize any possible confounding factors that might affect BW or urine color [60]. Additionally, athletes should be reminded that both fluids and foods can serve as hydrating agents. Water, milk, fruit juices, sport drinks, coffee, tea, soup, and fruits, and vegetables all provide significant amounts of fluid and can contribute to daily fluid intake needs and help to maintain euhydration [61].

With regard to electrolyte needs, sodium is the electrolyte that is lost to the greatest extent during exercise and, thus, should be of most concern for elite athletes [61,62]. Potassium, magnesium, and calcium, along with several other organic compounds, are also lost with sweat; however, the amounts lost are relatively low and constant relative to the higher more variable loss of sodium [61,62]. Not unlike fluid losses, variability in sodium losses between athletes and challenges in accurately assessing sodium losses during exercise makes it difficult to establish a specific, universal sodium recommendation.

It is important to note that the current adequate intake (AI) for sodium (1500 mg Na^+ day^{-1} or ~3.8 g NaCl day^{-1}) set forth in the 2004 dietary reference intake (DRI) is likely inadequate for the athletic population [63]. Even so, the average athlete consuming a normal diet generally consumes adequate amounts of sodium making hyponatremia due to insufficient dietary intake rare. In contrast, sodium losses among athletes who lose large volumes of sweat on a daily basis (e.g., distance runners, tri-athletes, football players, etc.) and/or those who may be considered *salty sweaters* may be at increased risk of hyponatremia. For these athletes strategic consumption of salty snacks and electrolyte containing sports drinks will help to offset sodium losses and maintain electrolyte balance.

Hydration for Pretraining and Competition

Elite athletes should aim to enter a training session or competition euhydrated and in normal electrolyte balance. As noted previously, these conditions are typically met if adequate fluid and food is consumed over a prolonged recovery period (>12 h) [60]. For athletes who have not adequately hydrated between training sessions or for whom time between training does not allow for sufficient consumption of fluid and electrolytes, hydrating prior to training or competition is advocated. Hydration strategies set forth by the American College of Sports Medicine (ACSM) are summarized in Table 12.1 [60]. Following these recommendations, a 70 kg (154 lb) distance runner seeking to prehydrate should consume approximately 350–490 mL (~12 to 16 oz) of fluid about 4 h prior to training. Beverages containing sodium or sodium-containing foods may also help stimulate thirst and enhance retention of the consumed fluids [60].

Hydration during Training and Competition

The goal of hydrating during training or competition is to prevent excessive fluid loss (>2% BW) and drastic changes in electrolyte balance that may compromise performance or lead to more serious complications such as heat illness or rhabdomyolysis. Optimally, fluid intake and electrolyte intake should equal fluid and electrolyte loss. This scenario, however, is often not possible for many athletes. Bear in mind that the maximal rate of gastric emptying and subsequent intestinal absorption approximates 1 L fluid h^{-1}, while the average athlete may lose as many as 1–3 L of fluid in the form of sweat every hour [61,62].

Additionally, athletes with low gastric tolerance for fluids during exercise may find it difficult to consume the volume of fluid required to prevent excessive fluid losses even at sweat rates <1 L h^{-1}. Other athletes simply may not have the opportunity to drink depending on the nature of the sport. To prevent excessive fluid loss, athletes must develop a customized hydration program depending on the amount of fluid lost (i.e., sweat rate), sport, different training environments, and individual tolerance. An athlete's sweat rate may be calculated easily by routine measurement of pre- and postexercise BW. This method assumes that the amount of BW lost during exercise approximates fluid losses [60].

In contrast, consumption of copious amounts of fluid during training or competition that result in BW gains is

contraindicated. Excessive water consumption without adequate electrolyte replacement has the net effect of *diluting* plasma sodium. Dilutional hyponatremia (plasma sodium levels that rapidly drop to <130 mmol L^{-1}) has been reported in slow marathon runners consuming excessive amounts of hypotonic beverages (e.g., plain water) before, during, and after a race [60]. As plasma sodium levels drop symptoms such as headache, vomiting, fatigue, swelling in the extremities, confusion, and disorientation are common [60]. If not properly treated, dilutional hyponatremia eventually leads to cerebral and pulmonary edema, seizure, coma, respiratory arrest, and death [60].

In short, a reasonable hydration strategy for the elite athlete during exercise should aim to prevent BW loss >2% due to water deficits, while avoiding excessive fluid consumption that results in BW gains. The strategy should be customized to the individual needs of the athlete depending on sweat rate, sport, environment, and tolerance. Sodium-containing beverages and/or snacks are recommended to maintain electrolyte balance, stimulate thirst, and promote fluid retention, especially for endurance-type athletes exercising >1 h or other athletes with large fluid and sodium losses.

Hydration for Posttraining and Competition

The goal of postexercise hydration is to replenish fluid and electrolytes that were not adequately replaced during exercise and, thus, prepare for the next exercise session. Recall that for many athletes dehydration during training or competition is an inevitable situation since sweat rates (~1 to 3 L h^{-1}) often exceed the physiological ability (~1 L h^{-1}) to ingest and absorb fluid. Still, not unlike replenishment of glycogen stores, if adequate meals, snacks, and plain water are ingested over a long enough recovery period (>12 h) euhydration and lost electrolytes are typically restored. Situations in which recovery time is limited, however, may require more aggressive hydration tactics. When recovery time is limited (<12 h), athletes should aim to consume at least 1.5 L of fluid for every kilogram BW lost (24 oz lb^{-1} BW or 150% of BW lost) [60]. The additional fluid required during the recovery period is needed to offset losses due to increased urine production that occurs in response to ingestion of large volumes of fluid [60]. For that reason, it is recommended that fluids be consumed over time as opposed to immediate ingestion of the prescribed volume of fluid. Additionally, as mentioned previously, simultaneous ingestion of sodium in the form of food or as part of a sports drink can help to retain fluid and stimulate thirst throughout the recovery period, helping to restore euhydration and replace lost electrolytes more rapidly [60].

Vitamin and Mineral Recommendations

There is no question that micronutrients (i.e., vitamins and minerals) play a critical role in supporting training, competition, and the overall health of the elite athlete [17,64]. It remains unclear, however, whether or not training for sport increases micronutrient requirements or whether micronutrient intakes exceeding the RDA can enhance performance [65–67]. Theoretically, strenuous physical activity may alter micronutrient needs by increasing vitamin and mineral turnover or increasing losses via sweat, urine, or feces [17,67]. Moreover, higher micronutrient requirements may be needed to support physiological training adaptations such as the building, maintenance, and repair of LBM [17,65–67]. However, difficulty in accurately assessing micronutrient intake and status as well as fundamental differences in experimental design between studies has made it difficult to draw conclusions regarding the micronutrient needs of athletes.

The DRI published by Institute of Medicine (IOM) state that athletes do not have micronutrient needs that differ from the general population and that the elevated energy requirements among athletes more than likely compensate for any micronutrient deficit incurred as a result of regular strenuous exercise provided energy needs are met and a variety of foods are consumed [65,66,68]. Conversely, athletes who restrict energy, avoid or eliminate certain foods from their diet, or consume an overall poor diet may have marginal micronutrient intakes that could lead to poor status and negatively impact performance and/or health [17]. This section highlights common micronutrients found to be of concern among athletes, namely, certain B-vitamins, antioxidants, calcium and vitamin D, and iron.

B-Vitamins and Energy Metabolism

Although the water-soluble B-vitamins (thiamin, riboflavin, niacin, pantothenic acid, pyridoxine [B_6], and biotin) are essential for energy metabolism, limited research exists that regular strenuous exercise increases B-vitamin requirements [65,67,69]. Even so, dietary intake surveys often reveal marginal intakes of vitamin B_6, B_{12}, and folate among the athletic population, especially among vegetarian female athletes and/or those with disordered eating patterns [17]. Still, short-term deficiencies do not seem to negatively impact athletic performance and B-vitamin requirements are likely met when energy availability is adequate and a variety of foods are consumed [67].

Nevertheless, several sport supplements and energy drinks fortified with B-vitamins, often times at several times the recommended intake, are commonly marketed to athletes as a quick source of energy. This marketing scheme is misleading since vitamins do not in fact provide energy. Additionally, supplementing with B-vitamins has not been shown to enhance energy metabolism or improve performance [17,67].

In contrast, excessive supplementation of certain B-vitamins such as niacin, riboflavin, or pyridoxine can negatively impact both health and performance. Niacin supplementation >1 g day^{-1} has vasodilatory effects that may cause burning, itching, and tingling and/or gastrointestinal distress potentially impairing performance [69]. Riboflavin, a fluorescent yellow compound, in excess of only 1.7 mg day^{-1} is readily excreted by the kidneys producing a fluorescent yellow urine, thereby confounding the use of urine color as a marker of hydration [69]. Moreover, excessive long-term pyridoxine supplementation has in certain cases led to irreversible peripheral neuropathy [69].

Antioxidant Vitamins–Vitamin C, E, and Beta-Carotene

Oxidative stress occurs when endogenous and/or environmental oxidants (e.g., reactive oxygen and nitrogen species [RONS], pollution, solar radiation, etc.) surpass the body's inherent antioxidant capacity. Left unchecked RONS damage cellular macromolecules and interfere with cellular signaling pathways, ultimately resulting in cellular dysfunction [70]. It has been hypothesized that the cellular damage caused by RONS plays a major role in the pathophysiology of a majority of chronic disease states, including coronary artery disease (CAD), certain forms of cancer, and dementia and that increasing intake of dietary antioxidants vitamins may effectively prevent or slow this process [70]. Since regular exercise may result in a 10- to 20-fold increase in whole body oxygen consumption, and, thus an increase endogenous RONS formation, it has been hypothesized that athletes might require or could benefit from additional dietary antioxidants vitamins C, E, and beta-carotene [71].

Despite the logic of this hypothesis, however, research does not support a performance or health benefit from antioxidant vitamin supplementation in athletes who are meeting the recommended requirements. In fact, supplementation with antioxidant vitamins may actually impair performance by blocking and/or delaying many of the beneficial physiological adaptations that occur in response to regular exercise [72,73]. Ristow and Blüher (2009) observed that supplementation with a combination of vitamin C and E (1000 mg and 400 IU day^{-1}, respectively) over a 4 week training period effectively blocked induction of the antioxidant enzymes superoxide dismutase (SOD) and glutathione peroxidase (GPx) among healthy young men [74]. Moreover, a number of other recent studies have shown that supplementation with high doses of various antioxidant vitamin combinations actually delays recovery from exercise by slowing the increase in exercise induced stress PROs and delaying muscle recovery [72,75,76]. Finally, interventions that have investigated the use of antioxidant supplementations in the treatment of chronic disease have either shown no effect or actually shown an increase in the risk of mortality [70].

Bone Nutrients–Calcium and Vitamin D

While many nutrients are important for bone health, none are more important than calcium and vitamin D. Calcium and vitamin D work together to maintain calcium homeostasis by regulating bone metabolism and calcium absorption. Adequate calcium is also important for normal muscle contraction, nerve conduction, and blood clotting, while vitamin D has several other roles involving gene expression, immune function, modulation of inflammation, and potentially enhancement of muscular and athletic performance [77–81]. Current calcium and vitamin D recommendations are summarized in Table 12.2 [82].

TABLE 12.2
Calcium, Vitamin D, and Iron Recommendations

Age Group	Calcium[a]	Vitamin D[b]	Iron[c]
14–18 years	1300–1500 $mg \cdot day^{-1}$	600 $IU \cdot day^{-1}$	Males: 11 $mg \cdot day^{-1}$ Females: 15 $mg \cdot day^{-1}$
19–50 years	1000–1500 $mg \cdot day^{-1}$	600 $IU \cdot day^{-1}$	Males: 8 $mg \cdot day^{-1}$ Females: 18 $mg \cdot day^{-1}$
Dietary Sources	Excellent Sources: Low-fat dairy products and fortified cereals, juices, and soy products Poor Sources[d]: Dark green leafy vegetables and legumes	Good Sources: Fatty fish such as salmon, mackerel, and tuna as well as fortified dairy products and ***sensible sun exposure*** of arms and legs to 0.5 MED[e]	Excellent Sources: Red meat, shell fish and fortified grain and soy products Poor Sources[d]: Dark green leafy vegetables and legumes

[a] The standard practice for athletes with disordered eating, low energy availability, and/or amenorrhea is to recommend 1500 mg elemental calcium daily; The tolerable upper intake level (UL) for calcium is set at 2500 $mg \cdot day^{-1}$ [16,86].

[b] While 600 $IU \cdot day^{-1}$ is recommended to optimize bone health, some experts argue that as much as 1500–2000 $IU \cdot day^{-1}$ may be required to maintain 25(OH)D levels above 30 $ng \cdot mL^{-1}$; The UL for vitamin D is set at 4000 $IU \cdot day^{-1}$ [86,87].

[c] Iron requirements for distance runners have been estimated to be increased by as much as 30–70%; Vegetarians, blood donor, and endurance athletes should aim to consume more than their respective RDAs; The UL for iron is set at 45 $mg \cdot day^{-1}$ [16,92].

[d] Oxylates and phytates present in dark green leafy vegetables and legumes significantly decreases the bioavailability of calcium and iron [86,92].

[e] One minimal erythemal dose (MED) is defined as the amount of UVB exposure that produces redness of the skin 24 hrs after exposure; Exposure of arms and legs to 0.5 MED (~5–10 min depending on time of day, season, latitude, and skin sensitivity) is equivalent to ~3000 IU vitamin D_3 [87].

Although the IOM deemed athletes to have no greater requirement for calcium or vitamin D than their sedentary counterparts, research indicates that many athletes do not obtain adequate amounts of these two key bone nutrients [79–81,83–85]. In particular female athletes with inadequate energy availability and/or who have low-intake of or avoid dairy products are at an increased risk for low calcium intake [17]. Similarly, athletes at greatest risk for suboptimal vitamin D status (<30 ng mL^{-1} 25(OH)D) include those who primarily train or compete indoors, live or train at high latitudes (>37°N–40°N) during the winter months, have darkly pigmented skin, or regularly use sunscreen [79–81]. Inadequate calcium and vitamin D among this population significantly increases the risk of stress fractures and development of osteopenia or osteoporosis later in life [17,86]. A registered sports dietitian should be consulted to determine the adequacy of dietary calcium as well as develop strategies for meeting calcium needs via food or if appropriate recommendation of a suitable calcium supplement.

Additionally, assessment of serum 25(OH)D concentrations may also be warranted for athletes at risk for suboptimal vitamin D levels. For athletes with suboptimal 25(OH)D status, daily supplementation with 2000–6000 IU of vitamin D_3 for 6–8 weeks followed by a maintenance period of 600–2000 IU vitamin D_3 day^{-1} may be required to achieve and maintain a blood level of 25(OH)D > 30 ng mL^{-1} [87]. Because dietary sources of vitamin D are limited to a few foods (salmon, tuna, mackerel, and fortified dairy), and assessment of serum 25(OH)D concentrations may not be practical or affordable for all athletes, supplementation with 1500–2000 IU vitamin D_3 day^{-1} may be appropriate for the majority of athletes at risk for vitamin D deficiency [87].

Hematopoietic Nutrients–Iron, Folate, and Vitamin B_{12}

Iron, folate, and vitamin B_{12} play important roles in the formation and function of red blood cells (RBC) and thus oxygen transport. Maintaining adequate iron status, in particular, is not only important for optimal aerobic efficiency and endurance capacity but also affects mental acuity and immune function [17,88]. Current iron recommendations are summarized in Table 12.2 [89]. A detailed description of the prevention, diagnosis, and treatment of anemia is discussed in Chapter XXXX. In short, female athletes, especially adolescent females, distance runners, vegetarians, and/or those who avoid red meat are at the highest risk for iron deficiency [88]. At risk athletes should undergo routine iron status assessments. For athletes found to be deficient, increasing the intake of iron-rich foods (Table 12.2) should be encouraged. In most cases, however, dietary alterations are insufficient to correct the deficiency and supplementation is necessary [17].

SPECIAL CONSIDERATIONS

Elite athletes are faced with several unique challenges that may potentially have dire consequences for health and performance. This section addresses three common areas of concern for elite athletes namely, use of ergogenic aids, weight management, and extreme environments.

Ergogenic Aids: Classification, Effectiveness, and Dangers

An ergogenic aid may be defined as anything that is intended to enhance physical performance, stamina, or recovery. Using this definition, a wide range of dietary and herbal supplements, stimulants, as well as pharmaceutical drugs (e.g., human growth hormone [HGH], erythropoietin [EPO], diuretics, etc.) may be considered ergogenic. The American Dietetic Association (ADA) and ACSM categorize ergogenic aids into four separate categories based on supporting scientific evidence: (1) ergogenic aids that perform as claimed, (2) ergogenic aids that may perform as claimed, but for which there is insufficient evidence, (3) ergogenic aids that do not perform as claimed, and (4) ergogenic aids that are dangerous, banned, or illegal [17]. Similarly, the Australian Institute of Sport has devised a grading system (Grades A–D) for ergogenic aids used in sport based on safety, legality, and effectiveness (Table 12.3) [90]. From a quick review of Table 12.3, it is evident that the vast majority of ergogenic aids used in sport are ineffective at best or dangerous to an athletes career and health at worst [91–93]. Notwithstanding, use of some form of ergogenic aid is almost ubiquitous among the athletic population [94–97]. In one recent survey, more than 87% of elite athletes surveyed reported using at least one dietary supplement [94].

Furthermore, use of ergogenic aids such as anabolic steroids, HGH, and diuretics can result in serious side effects that not only put the athlete's career at risk but, also, jeopardize the short- and long-term health of the athlete [91,98]. Unfortunately, some athletes knowingly turn to ergogenic aids known to contain dangerous, banned, or illegal substances, while others inadvertently consume these substances via adulterated dietary supplements [99–102]. Both the National Collegiate Athletic Association (NCAA) and the World Anti-Doping Agency (WADA) ban certain substances known to adversely affect health and/or provide an unfair advantage and routinely test for such substances. Nevertheless, qualified health professionals (i.e., medical doctors and registered sports dietitians) must remain open-minded and well-educated regarding the use of ergogenic aids in order to most effectively assess, recommend, and educate athletes regarding responsible use of such products [17]. Many online resources are available for health professionals, trainers, coaches, and athletes alike that provide evidence-based information regarding safe and prudent use of ergogenic aids (see References).

Weight Management

While BW and body composition influence athletic performance, there is no singular ideal body composition that correlates with optimal athletic performance [17]. Genetics, gender,

TABLE 12.3
Ergogenic Aid Classification

Grade A-Perform as Claimed	Grade B-May Perform as Claimed
Caffeine	β-alanine
Creatine	HMB[a]
Probiotics	Colostrum
Protein and AA Supplements[a]	Glutamine
Sodium Bicarbonate and Citrate	Glucosamine
Sports Drinks, Gels, and Bars	Melatonin
Vitamin and Mineral Supplements (i.e. calcium, iron, vitamin D)	Ribose

Grade C-Do Not Perform as Claimed[b]		Grade D-Dangerous, Banned, or Illegal[c]
Individual AAs	Gamma Oryzanol	19-norandrosteneediol
Bee Pollen	Ginseng	19-norandrostenedione
BCAA[a]	Inosine	Androstenedion
Carnitine	MCT[a]	Dehydroepiandrosterone[a]
Chromium Picolinate	NO Supplements[a]	Ephedra
Coenzyme Q10	Pyruvate	Glycerol
CLA	Oxygenated Water	HGH[a]
Cordyceps	Vadium	Methylhexaneamine
Cytochrome C	Vitamin & Mineral Supplements (not listed in Grade A)	Tribulis Terrestris
Dihydroxyacetone		Strychnine

[a] Abbreviations: AA = amino acid; BCAA = Branched chain amino acids; CLA = conjugated linoleic acid; DHEA = Dehydroepiandrosterone; HGH = Human growth hormone; HMB = β-Hydroxymethylbutyrate; MCT = Medium chain triglyceride; NO = Nitric oxide.

[b] Not a conclusive list; Most sports supplements not found in this table fall into this category.

[c] Not a conclusive list; For an extensive list of banned substances see references blank and blank.

and environmental factors heavily influence an athlete's natural body composition. Moreover, elite athletes train and compete successfully over a wide range of body compositions. Body fat percentages between 5% and 20% for male athletes and 16% and 28% for female athletes are considered optimal depending on sport, position, and body type [103]. Still, a higher LBM to body fat ratio may be advantageous for many elite athletes in that it provides greater strength-to-weight ratio, may increase speed, agility, and/or endurance, and provides aesthetic appeal for sports in which appearance is important [103].

Ideally the best time to make changes in body weight and/or composition is during the off-season or precompetitive period versus during the competitive season when energy and performance demands are more critical [17,103,104]. Athletes seeking to lose weight should aim for a slow and steady weight loss (no more than 1 kg week^{-1}) and may benefit from a diet slightly higher in PRO (1.5–2.0 g PRO kg $^{-1}$) to minimize losses in LBM while still promoting fat loss [21]. Theoretically an energy deficit of 500 kcal day^{-1} obtained via a combination of reduced energy intake and increased energy expenditure will result in the loss of 1 lb of body fat per week (3500 kcal lb body fat^{-1}) [104].

Conversely, athletes seeking to gain weight or muscle mass must consistently consume calories in excess of those expended. In fact, a positive energy balance has been shown to be more important than increasing PRO intake when attempting to gain LBM [21]. It is generally recommended that male athletes increase their caloric intake by 400–500 cal day^{-1} to support an increase of ∼0.5 kg (∼1 lb) of muscle tissue per week, while females should increase their caloric intake to a somewhat lesser extent [104].

To ensure energy and nutrient needs are being met and body composition changes occur in a healthy fashion, body composition changes should be monitored by a qualified medical practitioner or registered sports dietitian. Supervision is especially important among athletes participating in weight-class/aesthetic sports or sports where a lower weight may provide a competitive advantage (e.g., wrestlers, light-weight rowers, jockeys, gymnastics, diving, figure skating, distance running and cycling, etc.). Inadequate direction or supervision may result in the athlete utilizing extreme and/or dangerous methods of weight control.

For example, weight-class athletes have been reported to exercise in sweat suits, sit for long periods in saunas, abuse

diuretics and laxatives and/or engage in severe caloric restriction and self-induced vomiting in order to lose weight quickly for a competition [105]. These tactics not only lead to dehydration, impaired cognitive function, difficulty recovering, and building LBM, but they may also compromise bone health and in some cases have even resulted in death [105]. Moreover, athletes who engage in chronic weight cycling (i.e., rapid weight-loss followed by rapid weight-gain) are more likely to be over-weight later in life putting themselves at an increased risk for weight-related chronic diseases [106].

Similarly, research indicates that athletes who participate in aesthetic and endurance sports often engage in unhealthy dieting practices to reduce body weight and/or change body composition in the hopes of improving performance [107]. Not only can these pathogenic weight control practices be dangerous to health and performance, but they may develop into more clinical conditions including body image distortion and eating disorders (i.e., anorexia nervosa and bulimia nervosa) [107]. A team approach (i.e., medical doctor, mental health professional, and sport dietitian) is highly recommended for effective treatment of such athletes.

Extreme Environments Heat and Humidity, Cold, and Altitude

Elite athletes are often faced with the challenge of competing under extreme environmental conditions (i.e., heat, humidity, cold and/or altitude). Exercise in hot and/or humid environments significantly increases physiological heat stress that may lead to excessive water and sodium losses, thereby decreasing the body's ability to thermoregulate. As previously described (see section on "Hydration and Electrolyte recommendations"), excessive fluid and sodium losses may result in anything from performance-inhibiting heat cramps to life-threatening heat exhaustion. Similarly, athletes who exercise in cold environments experience increased water losses via the lungs and sweat, have blunted thirst reflexes, and may even voluntary fluid restrict in an attempt to decrease the need to urinate [17]. For elite athletes training or competing in such environment's adherence to established hydration guidelines as well as routine monitoring for heat-related illness or hypothermia is imperative.

Moreover, training or competing at altitude presents unique nutrition-related challenges. Athletes who exercise at >2500 m (8200 ft) have increased rates of CHO utilization, an elevated basal metabolic rate (BMR), altered fluid balance, suppressed appetite, and may experience cachexia [108]. As such, a diet that focuses on CHO and energy-rich foods is warranted and may even decrease the symptoms of acute mountain sickness [108]. Attention to fluid intake is also important as, exposure to high altitude results in an increase in ventilation that results in a loss of water to the environment and a concomitant loss of plasma volume. A sports drink that contains both CHO and electrolytes offer a practical option that helps to provide extra CHO and maintain the drive to drink and minimizes urine production helping to maintain fluid balance [108].

SUMMARY

In summary, while the active lifestyle of an elite athlete may afford long-term health benefits for some athletes, the unique physical demands required of an elite athlete's lifestyle can create special nutritional needs and challenges, which under certain circumstances may negatively impact health. Under such circumstances nutritional guidance and counseling from a qualified sports dietitian is imperative in helping elite athletes meet their unique nutritional requirements and prevent undue health issues and decrements in performance.

INTRODUCTION

In 2010 approximately 14% of the U.S. population was over 65 years of age. This percentage is expected to increase to approximately 21% by the year 2030. Accompanying this shift in the demographic makeup of U.S. population is a greater need for specific nutrition guidance to achieve and maintain optimal physical and cognitive function with advancing years. Evidence suggests that within a population, older adults who score in the higher categories for diet quality [1–4] and physical activity measures [5,6] have the best survival rates.

CURRENT RECOMMENDATIONS

The revamp of the recommended dietary allowances (RDA) by the Food and Nutrition Board of the Institute of Medicine starting in the early 1990s brought about more precise recommendations for individuals above the age of 50 years [7–14]. The current recommendations, termed dietary reference intakes (DRI), include guidance for adults in categories of 31–50 years, 51–70 years, and greater than 70 years [15]. No further distinction is made for individuals aged 70 years and above. This lack of precise further guidance for those over 70 years is likely a consequence of limited information from the older aged groups [15].

DRIs for most nutrients, including vitamin A, vitamin C, vitamin E, vitamin K, thiamin, riboflavin, niacin, folate, vitamin B_{12}, pantothenic acid, biotin, choline, chromium, copper, fluoride, iron, magnesium, manganese, molybdenum, phosphorus, selenium, and zinc, do not differ between adults above and below the age of 50 years. The nutrient recommendations for three nutrients, vitamin D, calcium, and vitamin B_6, increase for older adults. The DRIs for vitamin D increase from 15 µg/day for females and males less than 70 years, to 20 µg/day for adults above 70 years [16]. The DRIs for calcium increases from 1000 to 1200 mg/day for females above the age of 50 years, and for males above the age of 70 years [16]. The DRIs for vitamin B_6 increase from 1.3 mg/day for both females and males below 50 years to 1.5 and 1.7 mg/day, respectively, for females and males 51 years and older [9]. Emerging evidence suggests future revisions in the DRIs for individuals over the age of 70 years may be

necessary [17], but any recommendations must await a thorough review of the new literature.

Although the DRIs for most nutrients do not increase with advancing age, with the exceptions of vitamin D, calcium, and vitamin B_6, it can become increasingly difficult to achieve the recommended intakes as one ages. In general, total energy need decreases with advancing years to compensate for the diminished need associated with lower levels of physical activity, and a higher proportion of fat mass relative to lean muscle mass and a lower basal metabolic rate [18]. Nutrient needs must be met within the context of lower food intakes. This can be accomplished ensuring that the nutrient density of the diet (nutrients per calorie) is relatively high. A food guide pyramid has been developed specifically for older adults (Figure 13.1). Differences from the food guide pyramid for Americans include a narrower base to reflect lower energy needs, examples that emphasize nutrient-dense foods within each category, illustrations of foods that are particularly useful to older adults (e.g., bags of frozen vegetables), and added to the base, one row containing water glasses to emphasize the importance of maintaining adequate fluid intake and a second row emphasizing the continued need for regular physical activity throughout the lifespan.

NUTRIENTS OF CONCERN

Adequacy of some nutrients can be a concern for older adults. These include calcium; vitamins D, E, and K; potassium; and fiber (Table 13.1) [19,20]. The mean intake for these nutrients ranges from 33% to 50% of the RDA, or adequate intake (AI) values for individuals over the age of 70 years. These data suggest that to ensure adequate nutrient intake, efforts should be focused on providing food-specific guidance for these essential components of the diet.

Vitamin D

Adequate vitamin D intake is of concern for older adults [21]. There are a number of factors that may compromise their vitamin D status. These include decreased efficiency of skin to synthesize vitamin D after exposure to sunlight [22] and the tendency to spend less time outdoors to accumulate sun exposure. Limited sun exposure due to latitude or concern about sun exposure because of skin cancer risk can minimize endogenous vitamin D synthesis, especially in older adults [23,24]. Additionally, overweight and obese individuals have been reported to have lower circulating vitamin D concentrations. As rates of excess body weight

increase in the older population [18,25], this factor may also contribute to compromised vitamin D status [26]. Up until recently, fluid milk was the only reliable food source of vitamin D in the United States [21]. Recent changes to the vitamin D fortification regulation have resulted in an increased availability of vitamin D- and calcium-fortified juices and juice drinks, and vitamin D-fortified dairy products other than fluid milk [27,28].

Calcium

The richest naturally occurring and bioavailable source of calcium is dairy products. A wide range of low-fat and nonfat dairy products is currently available. There are two factors to take into consideration when recommending dairy products to older adults. The first is lactose intolerance. With increasing age, the rate of lactose intolerance increases [29–31]. Fortunately a wide range of lactose free and low lactose dairy products are now available, as well as enzyme preparations (lactase) that can be taken when consuming foods containing lactose to decrease the symptoms of lactose intolerance. It is important to note that although the prevalence of lactose intolerance increases with age, intolerance symptoms among lactose maldigesters tends to decease with age, suggesting that as people get older they may have more, rather than less, flexibility in their choice of calcium rich dairy foods [30]. The second consideration with regard to dairy products is saturated fat. Dairy products can be a major source of saturated fat. Saturated fat intake is associated with the increased risk of developing cardiovascular disease [32,33]. Older adults should be encouraged to take advantage of reduced fat versions of dairy foods. In addition to fat-free and low-fat dairy products, other good sources of dietary calcium are fortified drinks, such as calcium-fortified orange juice and soy milk.

Vitamins E and K, and Potassium

Rich dietary sources of vitamin E, vitamin K, and potassium, are plant foods, primarily vegetables and fruits. Depending on the individual food, they can be good sources of one or more of these nutrients. Higher fruit and vegetable intakes have been associated with a number of positive health outcomes including bone health, blood pressure, metabolic syndrome, stroke, and cardiovascular disease [34–43]. Older adults should be encouraged to choose deeply colored vegetables and fruits, as they tend to be nutrient dense. Liquid soybean and canola oils, and products made thereof, such as margarine spreads, are also a good source of vitamins, and are low in saturated and *trans* fatty acids.

Fiber

A major function of dietary fiber is its laxative effect in the gut. In addition to vitamins E, K, and potassium, vegetables and fruits are a good source of dietary fiber, along with whole grains and whole grain products. For this reason, older adults should be encouraged to consume whole fruits and vegetables rather than the juice form. They should also be encouraged to choose whole grain products rather than refined and processed grain products. In general, fiber supplements are not routinely recommended because excessive fiber can decrease the bioavailability of calcium, iron, zinc, copper, and magnesium [44,45].

SPECIAL DIETARY CONSIDERATIONS FOR OLDER ADULTS

The area of maintaining optimal nutrient status in older adults must be considered in terms of physiological factors and psychological factors. Special attention to both of these factors is critical for ensuring optimal health outcomes.

Organ Systems

The way the body handles nutrients can change with advancing age [46]. These changes are mostly due to changes in the functioning of organ systems, which impact the utilization of specific nutrients (Table 13.2). Interestingly, few adverse nutritional consequences resulting from advancing years have been noted that are independent of ancillary biological changes. These exceptions include vitamin B_{12}, vitamin D, and calcium. With increasing years, many individuals experience a decline in gastric hydrochloric acid secretion [46]. The resulting hypochlorhydria results in a decline in the bioavailability of vitamin B_{12}. As previously noted, due to changes in

TABLE 13.2
Potential Biologic Changes Contributing to Altered Nutrient Status in Older Adults

System	Change
Digestive system	↓ Hydrochloric acid secretion
	↓ Digestive juice secretion (pancreas and small intestine)
	↓ Absorptive capacity (malabsorption)
	↓ Muscles tone large intestine (↓ gastrointestinal motility)
	↓ Chronic blood loss due to ulcers and hemorrhoids
Liver	↓ Hepatic and biliary function
	↓ Rate detoxification
Heart	↓ Cardiac output
	↓ Strength and flexibility of blood vessels
Kidneys	↓ Blood flow
	↓ Glomerular filtration
Senses	↓ Acuity vision and hearing
	↓ Taste (loss taste buds, mainly salt and sweet)
	↓ Smell
Skin	↓ Synthesis vitamin D
Body composition	↓ Lean muscle mass and ↑ fat mass
	↓ Physical activity
Immune system	↓ T cell-mediated function
	↑ Susceptibility to infection and malignancy
Pharmacokinetics	↑ Prescription and nonprescription drug use
	↑ Chronic drug therapy
	↓ Capacity to metabolize drugs
Mouth	↓ Salivary secretion
	↑ Altered bite pattern due to tooth loss

skin and nutritional lifestyle, older adults may be at a compromised status for vitamin D and for calcium. Impairments or decreases in the function of the heart, blood vessels, and kidneys can stress the normal demands on everyday life. Changes in body composition (decreased lean muscle mass and increased fat mass) result in decreased basal metabolic rates, energy needs, and capacity for physical activity [47]. Increased use of prescription and nonprescription medications, chronic drug therapy, and decreased capacity of the liver to metabolize drugs can compromise nutrient unitization. All these factors need to be addressed on a regular basis by the health care provider.

Taste and Smell

Retaining the desire to eat a variety of foods is integral to ensure optimal nutrition for older adults. This issue is of particular concern because diminished taste and smell acuity associated with aging can lead to poor appetite. This change includes loss of taste buds, primarily those involving salt and sweet, resulting in greater sensitivity to acid and bitter [48]. Other changes frequently observed in older adults include a diminished sense of smell. Older adults with poor odor perception have lower nutrient intakes than those with good odor perception [49–51].

Vision, Dexterity, and Mobility

Diminished vision, dexterity, and mobility can make food accusation and preparation difficult, which severely impacts on variety and quality of foods (Table 13.3). Difficulty opening jars, cans, or packaged foods due to arthritis or diminished strength can lead to decreased variety and ability to consume preferred foods. Small accommodations in an individual's environment such as ergonomically designed kitchen aides (e.g., can openers and scissors), kitchen reorganization (e.g., eliminating clutter and moving frequently used items to most accessible places) and shifts to the use of partially prepared foods can minimize a decline in diet quality. For example, resealable bags of frozen vegetables and fruits are particularly good choices for older adults because they allow for easy apportioning of single or double servings, minimize prepreparation, which can be difficult or even painful with advanced years, eliminate waste due to spoilage, reduce the need for frequent trips to the market, and provide variety during winter months or long periods of inclement weather. Likewise, purchasing boneless chicken breasts can decrease preparation and cooking times, and is adaptable to preparation of individual small portions. Older adults may not automatically take advantage of newer forms of common food items (e.g., prewashed and cut salad, shredded cheese) and require some regular guidance in this area.

Social Factors

In addition to adapting with declines in physical capacity associated with the aging process, there are also changes in the social environment of older adults that can have an impact on nutritional status (Table 13.4). With increasing years, the loss of a spouse or other family members with whom an individual shared and prepared meals is common. This can lead to social isolation, especially during mealtime, and diminished desire to prepare well-balanced and varied meals. Due to deterioration in mental or economic status, older adults are

TABLE 13.3
Activity of Daily Life Factors Contributing to Compromised Food Intake in Mature Adults

Factor	Change
Oral cavity	↑ Peritoneal disease
	↑ Ill-fitting dentures
	↓ Salivary gland function
Mobility	↓ Physical activity
	↓ Respiratory capacity
	↓ Lean muscle mass (strength, physical disability)
	↑ Physical isolation
Senses	↓ Acuity (taste, smell, sight)
Dexterity	↑ Arthritic involvement finger and hand joints
	↑ Tremor
	↓ Manual dexterity
Energy needs	↓ Energy requirements
	↓ Caloric intake
	↓ Volume

TABLE 13.4
Psychosocial Factors Contributing to Compromised Food Intake in Mature Adults

Factor	Change
Companionship	↑ Loss of spouse
	↑ Social isolation
	↑ Loss of companions
	↓ Social interaction secondary to ↓ mobility
Mental State	↑ Depression
	↑ Mental deterioration (dementia)
	↑ Alcoholism
	↑ Loneliness
	↑ Chronic disease
Economic	↑ Fixed income (poverty)
	↓ Choice and availability
	↓ Quantity needs
	↓ Variety
Nutrition knowledge	↑ Susceptibility to food fads
Housing	↑ Change in status (loss of home)

frequently faced with having to adapt to a new living environment. This can result in dramatic changes in meal times, food preparation, and foods available. The onset of chronic disease can further limit food choices and make older adults susceptible to the lures of food fads or dietary supplements promising a fountain of youth. At worst, these claims risk draining scarce resources from food purchases and overconsumption of individual nutrients. The latter can interfere with prescription drug actions or the utilization of essential nutrients. Depression frequently accompanies the aging process in individuals without adequate support to make the necessary adaptations that come with advancing age. Older adults are also at increased risk of alcohol abuse. All of these factors may contribute to poor food consumption patterns [52].

PHYSIOLOGICAL CHANGES OF CONCERN IN OLDER ADULTS

Nutrient-related chronic diseases particularly prevalent in middle and later years include cardiovascular disease, cancer, type 2 diabetes, hypertension, osteoporosis, disorders of dentition and associated senses, and declines in immune function. In some cases, the goals of nutrient recommendations for older adults are aimed at delaying the onset of chronic disease while in other cases they are intended to treat or accommodate to the disorder.

Dentition and Associated Senses

Salivary secretions decrease with increasing age. Changes in bite pattern from partial or complete extraction/loss of teeth are common. Poorly fitted dentures can make eating painful and distasteful. The prevalence of root canals is higher in older than younger adults [53,54]. Increased incidence of tooth disease in older adults has been related, in part, to high levels of sugar consumption [55]. Any one, or a combination of these factors, can restrict the type and variety of foods consumed. For example, chewing and swallowing fibrous foods may be difficult due to poor dentition, resulting in a shift toward highly processed foods or juices that are low in fiber content [56]. It is critical when evaluating dietary intakes of older adults to consider possible concerns regarding food textures and preparation methods, and to assess dentition.

Cardiovascular Disease

The rate of cardiovascular disease increases with age, especially after menopause in females [57]. Higher saturated fat coupled with lower polyunsaturated fat intakes has consistently been associated with higher rates of cardiovascular disease [58]. The American Heart Association [33], the National Cholesterol Education Program [59], and the 2010 Dietary Guidelines for Americans [60] recommend dietary patterns that are rich in vegetables and fruits, whole grains, legumes (beans), fat-free and low-fat dairy products, fish, and lean meat. No specific recommendations for dietary change are made for adults as they age. The response to these recommendations in terms of plasma lipids appears consistent for both genders and age groups [32].

Osteoporosis

Age-related or type II osteoporosis (bone loss) is positively associated with the aging process. It has been estimated that osteoporotic fractures affect 50% of females and 30% of males over the age of 50 years [61]. Age-associated bone loss is attributed to diminished estrogen production, decreased calcium absorption from the gastrointestinal tract, decreased calcium resorption by the kidney, decreased rates of physical activity, compromised vitamin D status, and decreased calcitriol production secondary to hyperparathyroidism [61,62]. In older adults, calcium balance is favorably affected by vitamin D intake and negatively affected by high sodium, protein, alcohol, and caffeine intakes [62]. Supplemental calcium and vitamin D in postmenopausal women living in northern latitudes (42°N) may minimize bone loss [63]. Because serum osteocalcin, calcidiol, and vitamin D fluctuate seasonally due to sun exposure, vitamin D intake is particularly important during the period of winter and spring in this group. These data strongly support routinely screening older adults for vitamin D status.

Glucose Intolerance/Type 2 Diabetes

The incidences of glucose intolerance and type 2 diabetes mellitus increases with age [64,65]. The increased incidence has been strongly associated with weight gain in later years. Lifestyle interventions have been shown to be efficacious in preventing or delaying the onset of type 2 diabetes mellitus [66–68]. These include regular daily physical activity, weight loss, and dietary modification consistent with that advocated for the prevention and treatment of cardiovascular disease.

Hypertension

The incidence of hypertension increases with age [57]. This increase is associated with changes in the vasculature and kidneys, and is exacerbated by weight gain. A number of clinical trials have demonstrated clear benefits of dietary modification to treat hypertension in older adults. The dietary approaches to stop hypertension (DASH) type dietary pattern, rich in vegetables, fruits, and fat-free and low-fat dairy products, decreases blood pressure in a wide range of individuals [42]. Further coupling this dietary pattern with sodium restriction has been shown to further decrease blood pressure [43].

Immune Function

The most commonly associated age-related change in the immune response is cell-mediated function [69,70]. Limiting data suggests vitamin E supplementation may be beneficial in decreasing the incidence of respiratory infections in older adults [71].

Cancer

The incidence of cancer shows tremendous variability on the basis of worldwide distribution, type, and site in the body. The incidence of all types of cancer increases with age. Support for a diet/cancer incidence link comes from data suggesting associations between markedly divergent food consumption patterns and incidence rates of cancer among different population groups [72]. Some data have been reported for associations involving the following dietary component: alcohol intake (laryngeal), calcium and vitamin D intake (stomach, colon, breast), fat intake (breast, colon, prostate), fiber intake (breast), antioxidant vitamin and/or orange and dark green vegetable intake—vitamin A and beta-carotene, vitamin C, vitamin E, and trace elements (wide range of sites) [72–76]. Results from randomized controlled trials are limited [77]. At this time the general dietary guidance to reduce cancer risk is consistent with the dietary guidance to prevent the onset of chronic diseases of concern in the twenty-first century.

CONCLUSIONS

The aim of dietary guidance specifically targeted for older adults is to maintain optimal health and forestall the onset of chronic disorders. The actual dietary recommendations, for the most part, are consistent throughout the adult lifecycle. Evidence suggests that there is a direct relationship between the nutrient quality of the diet and survival rates. Due to decreased levels of physical activity, decreased metabolic rates, and increased proportions of fat to lean muscle mass, energy requirements decline with advancing years yet nutrient requirements remain unchanged, or increase. This situation requires a greater emphasis on choosing nutrient dense foods within each food category. Special attention needs to be given to adapting living environments with advancing years to retain the ability to acquire and prepare food. Changes in social situations that could impact on food intake should be monitored on a regular basis. Evidence suggests that diet and lifestyle interventions can forestall the onset of cardiovascular disease, osteoporosis, diabetes, hypertension, immune function, and possibly cancer. There are no data to suggest a person is too old to benefit from improvements in diet quality. The definitions for old age and expectations for the period of time individuals can remain active, productive, and live independently are expanding. Efforts toward improving diet quality and levels of physical activity with advancing years should keep up with this trend.

INTRODUCTION

An old saw says that "food is not food until it is eaten." To paraphrase, "a behavior is not a behavior until it is adopted." That is, science-based evidence, no matter how solid, is of little value until it is adopted by those to whom it applies. The Dietary Guidelines for Americans, first issued in 1980 by the U.S. Department of Agriculture (USDA) and the U.S. Department of Health, Education, and Welfare (USDHEW), later renamed Health and Human Services (HHS), articulate science-based recommendations for healthy diets that provide adequate amounts of all essential nutrients and at the same time minimize the risk of chronic diseases associated with dietary factors. The problem is that the gap between the recommendations, which have been modified relatively little since they were first released, and their adoption by the American public remains wide. The advisory committee that wrote the 2010 report observed that "now, as in the past, a disconnect exists between dietary recommendations and what Americans actually consume. On average, Americans of all ages consume too few vegetables, fruits, high-fiber whole grains, low fat milk and milk products, and seafood and they eat too much added sugars, solid fats, refined grains, and sodium. SoFAS (added sugars and solid fats) contribute approximately 35% of calories to the American diet" [1].

The power of nutrition to shape public health is indisputable. In a 2009 World Health Organization report describing

the ten leading risk factors for death in high-income countries, seven of the factors—high blood pressure, overweight and obesity, physical inactivity, high blood glucose levels, high cholesterol levels, low fruit and vegetable intake, and alcohol use—are related to diet and physical activity [2]. The same report estimated that in 2004 these risk factors contributed to an estimated 4.1 million deaths in high-income countries, and that modifying food intake and increasing physical activity (along with reducing tobacco use) could increase global life expectancy by 5 years.

There is no logical starting point to the discussion of why Americans have not made greater shifts toward the recommendations of the Dietary Guidelines, and there is no single approach to modifying eating behaviors at the population level. What people eat depends on individual factors, on interpersonal interactions through multiple networks, and on the environments in which eating behaviors occur. Simply telling people what to do or what not to do, no matter how well the advice is grounded in scientific evidence, is unlikely to lead to wholesale adoption of the Dietary Guidelines. More successful nutrition communications will likely evolve through identification of barriers to change and solutions to address those barriers, at both the individual and the environmental levels.

Public health communication has been defined as the production and exchange of information to inform, influence, or motivate individual, institutional, and public audiences. That definition can be applied to communication about nutrition-related health issues [3]. Importantly, it is not limited to the interaction between nutrition communicators and individual consumers of information, but also incorporates structural and social factors. Indeed, successful nutrition communications must be delivered in the context of multilevel interventions that promote and support behavior change. As such, this chapter addresses the role of nutrition communication in interventions incorporating individual, social, and environmental components.

The design of effective nutrition communications must include specification of the target audience(s) and behavioral objectives, a message strategy and execution plan, and a selection of dissemination channels and settings. It must also include ongoing formative research, campaign monitoring, and outcome evaluation that makes it possible not only to measure effectiveness but also to make course corrections. An IOM report on health communication strategies for diverse populations aptly describes the fluid nature of this work: "A campaign is not defined by a specific and static mix of messages, audiences, and channels. Rather, it is defined as a program that makes decisions about these operational details, decisions that will vary over time" [4].

What we know about the potential of public health media campaigns comes mainly from efforts to influence population behavior by targeting individual-level antecedents to the behavior of concern, factors such as knowledge, perceptions, and self-efficacy [3]. However, addressing individual factors alone may not be sufficient to drive health behavior change; indeed, the limited available evidence from national nutrition campaigns confirms that behavioral shifts require far more than messages promoting personal behavior change. For example, the 5-A-Day Campaign, launched jointly by the National Cancer Institute and the Produce for Better Health Foundation in 1991, was designed to increase public awareness of the importance of eating at least five servings of fruits and vegetables every day. Results from 5-A-Day program surveys 6 years after it was launched showed that the majority of the population still did not know the fruit and vegetable recommendation, and, more importantly, that there were no significant changes in fruit and vegetable consumption [5].

In the 20 years since the campaign was introduced there have been numerous communications efforts, extensive programming at the community level, and environmental and policy changes. Yet the most recent data available indicate that more than half of the U.S. population fails to consume recommended intakes. Approximately 33% of adults meet the recommendation for fruit consumption and 26% get the recommended servings of vegetables [6]. To add to the challenge, the 5-A-Day program was renamed "Fruits and Veggies: More Matters" to reflect the change in the 2005 Dietary Guidelines from five servings a day to five to nine servings a day. What effect, if any, this campaign branding shift had on consumer recognition of the fruit and vegetable message or on consumer reaction to a higher goal is unclear. There are many possible explanations for the limited shifts in fruit and vegetable consumption; further research is needed to identify the relative importance of taste, cost, convenience, accessibility, and of course, the role of communication in persuading Americans to eat more fruits and vegetables.

Over the past two decades, public health researchers have broadened their approach to understanding and influencing population health, including issues around eating behavior. Maibach, Abroms, and Marosits propose a framework which posits that population health is influenced by the attributes of, and interplay between people and place-based factors [3]. In their framework, people are analyzed through three levels: the individual field, the social network field, and the community or population field. Places are understood in terms of both local and distal influences (see Figure 14.1). Maibach et al. use this framework to discuss avenues for health communication within each field of influence. We will attempt to adapt this model to address challenges specific to nutrition communication, and particularly to address the gap between dietary recommendations and the public's behavior.

PEOPLE

Individual Level

In the ecological framework proposed by Story et al., individual factors such as cognitions, skills and behaviors, lifestyle, biology, and demographics are at the core of the model [7]. All are critical to understanding whether communication can have its intended effect, some because they are impossible

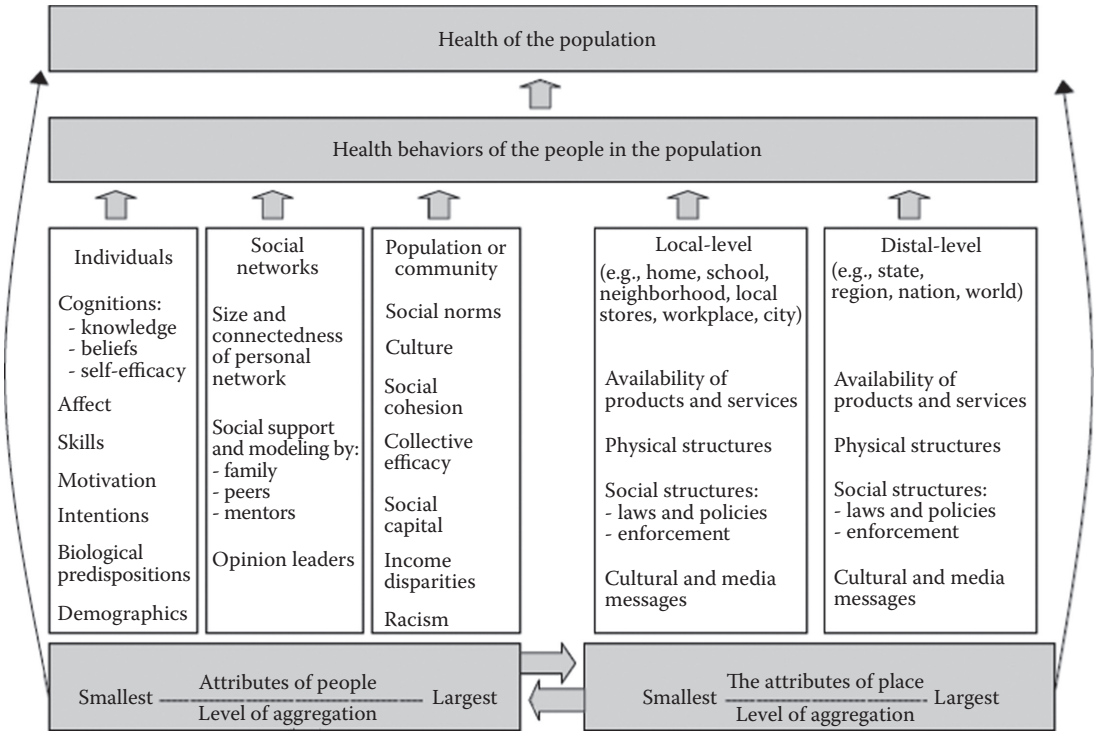

FIGURE 14.1 Maibach et al.'s People and Places framework for public health communication. (From Maibach, E.W. et al., *BMC Public Health*, 7, 88, 2007. With permission.)

to change, others because they can be modified. Whether a proposed intervention focuses solely on nutrition or includes nutrition among other components, formative research to identify both barriers to the recommended behavior and solutions to enable that behavior are critical. We will place greater focus on the barriers that evidence suggests can be modified. These include taste, cost, convenience, and self-efficacy, and health literacy or lack of it, with respect to the specific behavior being targeted.

Fundamental Importance of Taste

At the individual level, the disconnect between dietary recommendations and dietary intake is explained in large part by consumers consistently ranking taste as the major factor driving their food choices [8,9], with concern about health ranking third or fourth, behind cost and convenience. Unfortunately, for the majority of individuals, foods that taste good tend to be high in fat, sugar, and salt. In a food environment described in the extreme as "toxic" [10], these highly palatable foods are widely available at relatively reasonable prices, posing a challenge on the individual level as well as at the local and distal levels within the environment. In short, at the individual level, people make choices about whether to prepare and consume energy-dense foods, but policies affecting the cost and availability of these items serve as powerful place-based influences on behavior.

It follows, then, that attitudes toward taste must be addressed in any nutrition communication activities if we are to nudge the population toward more healthful diets. Some tastes, like sweetness, are innately preferred, while others, like bitterness, are innately rejected. Exposure to different flavors can modify these preferences [11]. Clearly, consumers' preferences for certain types of food are linked to market availability; for example, most Americans prefer refined grains over whole grains [12]. This preference has only emerged in the past 200 years, as commercial milling made refined grains more widely available [13]. Increasing recognition of the benefits of whole grains has led to the public health recommendation to "Make half your grains whole." However, that seemingly simple message requires modification of taste preferences and consumer understanding of the difference between whole and refined grains. In some cases, to get consumers to cook, buy, and eat more whole grains may require reformulation of products, a challenge to industry at the distal level.

Such change is possible, but, whether the recommendation focuses on alterations of fat, sugar, salt, or whole grain intake, population shifts require action at multiple levels. While we lack comprehensive studies to fully explain changes in consumption, examples such as the slow increase in low-fat and fat-free milk consumption and decrease in whole milk consumption in the United States over time are probably explained both by messages that promote lower fat milk and by changes in taste preferences as more palatable products appeared in the marketplace [14].

Unfortunately, taste preferences often conflict with nutrition advice. To compound the problem, most nutrition advice is based on evidence related to long-term outcomes, such as

reduced risk of heart disease and certain cancers. The dietary advice related to risk reduction, as well as to weight loss and maintenance, competes with the short-term gratification of indulging in energy-dense foods. There are no immediate, perceptible benefits to adopting nutrition recommendations and generally no immediate consequences to ignoring them either. The challenges, therefore, are to address the tension between the palatability of many unhealthful foods and the advice to cut back on them, and also to get people to increase their intake of foods they often find unpalatable. Which approach or combination of approaches will be most effective depends on understanding the target audience.

Cost, Convenience, and Self-Efficacy

Cost, convenience, and self-efficacy interact to affect food choice and food consumption. The relative importance of each of these factors varies from one individual to another and can change over time. They are related to family economics, time (or perceived time) available to purchase and prepare food, and skills and confidence to make cost-effective purchase decisions and to efficiently prepare appetizing food. At times of high unemployment and rising food prices, for example, it is reasonable to expect increased attention to low-cost shopping than during better economic times. Identifying whether cost, convenience, or self-efficacy is the strongest driver of food choice requires formative research. For example, formative research for the *Sisters Together* campaign, described more fully later in this chapter, identified self-efficacy, specifically the lack of kitchen skills, as a major barrier to preparing healthier meals. In turn, the intervention incorporated the promotion of a cable television cooking show hosted by a member of the *Sisters Together* Advisory Board, which supported the development of these needed skills.

Health Literacy: Special Case of Nutrition Communication

A key consideration in the development of any form of nutrition communication is the health literacy of the intended audience, or the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions [15]. In a national survey, 36% of adults exhibited basic health literacy, and only 12% demonstrated proficient health literacy [16].

Low health literacy has been called a silent killer, linked with higher mortality rates, poor utilization of preventive health care services, improper use of medications, and delayed or inadequate care for chronic diseases such as diabetes and heart disease [17,18]. Increased awareness of these adverse effects has made efforts to improve health literacy a high priority; the Healthy People 2020 objectives, for example, strongly advocate for improved health literacy among Americans [19].

Early efforts to improve health literacy focused on simplifying the language of health communication materials, but current approaches also address social, cultural, and environmental factors, all of which influence health literacy. Addressing health literacy in this multifaceted manner is difficult, especially given the diversity of the American public. The development of clear and usable nutrition communication presents a special health literacy challenge for a number of reasons. Most nutrition information does not lend itself to succinct, actionable messages, and scientifically sound information often competes with advertising and other messages that are concise and persuasive, but not necessarily accurate or balanced. Moreover, understanding of the role of nutrition in health promotion and chronic disease prevention continues to evolve, and so too must guidance to consumers about how to integrate that knowledge into their daily food practices. The role of fat in the diet illustrates the problem. Since the first edition of the Dietary Guidelines was released in 1980, there have been recommendations regarding fat intake. In the first two editions, the guidance was to "avoid too much fat, saturated fat, and cholesterol." In the next two editions, the guidance was modified to convey a positive tone: "Choose a diet low in fat, saturated fat, and cholesterol." Then, in 2005, it was modified to emphasize the need to limit saturated fat, to include "moderate amounts" of unsaturated fat, and to limit cholesterol to less than 300 mg/day. In the 2010 Guidelines, Americans are advised to "Consume less than 10% of calories from saturated fatty acids by replacing them with monounsaturated and polyunsaturated fatty acids" and to "Consume less than 300 mg of cholesterol" [1]. Evidence from periodic studies of consumer comprehension of these guidelines suggests that there is a wide gap between recommendations and consumer understanding of what they mean and, more importantly, how to translate them into actionable behaviors [20,21]. To be sure, the Guidelines were intended for use by health professionals whose challenge is to translate them into language that consumers—even those with limited health literacy—can understand and act on. Unfortunately, popular materials designed to translate the Guidelines into actionable steps tend to use the same scientific language found in the Guidelines themselves.

There is no simple solution to this problem. Information about dietary fats (and many other nutrition topics) is complex. It is not always possible to simplify complex information to a point where it remains accurate, actionable, and comprehensible to the target population. As a first step, it is probably logical to consider a basic question: what does the individual or group need to know in order to implement the dietary guidance? Given that not all information on a particular topic is equally important, it is the role of the health professional to determine which information is needed most urgently and to prioritize those messages accordingly. For example, it is probably more important to help people to understand how to substitute unsaturated for saturated fats than to focus on dietary cholesterol. It is also a good idea to take advantage of existing resources, but to evaluate such materials with members of the target population to ensure they are both accurate and clear. If no available materials are suitable for the target population, it may be possible to modify relevant sources to make them more

audience-appropriate. Many useful resources are now accessible on the Internet. For example, an article on the complex topic of salt-reduction strategies can be found at the Harvard School of Public Health's website "The Nutrition Source" (http://hsph.harvard.edu/nutritionsource/salt/). The article, which was developed to help individuals implement the recommendations of the National Academy of Sciences Report [22], is divided into reasonable "bites," which could easily be adapted to a series of instructional sessions. While some of the language may be above the literacy level of many audiences, and some critics might debate details of the recommendations, this comprehensive, modifiable mini curriculum provides specific steps necessary for the consumer to reduce sodium intakes. This translation of dietary guidance into actionable steps can serve as a model for development of materials on other nutrition-related topics.

People Eat Diets, Not Foods or Nutrients

Further complicating matters is that messages to promote dietary behaviors often address a singular focus. The environment is saturated with nutrition messages related to specific health conditions. People are told to consume a diet to reduce cardiovascular risk, or to promote bone health, or to prevent cancer, or of course, to lose weight. Other messages focus on one particular nutrient. Individuals are advised to eat for more vitamin C, vitamin D, or iron or to avoid trans fats or carbohydrates. These pointed messages, which appear on everything from printed public health materials to front-of-package food labels, neglect the fact that most individuals do not eat to reduce risk of one disease or another, but instead consume a group of foods commonly referred to as their "diet." With this in mind, nutrition communicators should as a general rule place information about individual foods or nutrients within the context of the total diet. The 2010 Dietary Guidelines Advisory Committee recently took steps in this regard, advocating for a "total diet approach to achieving dietary goals" and providing an evidence-based review of healthful eating patterns, such as the Dietary Approaches to Stop Hypertension (DASH) and Mediterranean patterns [1].

Everyone Is an Expert

The challenge of influencing eating behavior begins at the most fundamental level: everyone eats. Consciously or unconsciously, people draw on their vast reservoir of experiences with food each time they decide to buy, prepare, and consume food. Further, in their role as caregivers, many individuals draw on those experiences to make decisions about the foods that they serve to their families. When new information conflicts with what they "know" about food (that is, their preferences) they engage in the process of deciding whether that information should be used to modify their choices. For example, a common concern expressed by participants in *Sisters Together* focus groups was that substitution of healthier choices would not be acceptable to family members. Therefore, the campaign needed to address women's reluctance to modify certain food practices based on family preferences [23].

Despite years of attempts to regulate who can say what about nutrition, it remains generally true that almost anyone can set themselves up as an expert and dispense nutrition advice even to broad audiences. The problem has grown as more and more individuals turn to the Internet for nutrition information. As a result, it is more difficult than ever for consumers to identify sound, unbiased nutrition information.

A challenge related to this proliferation of unchecked nutrition advice is that, when it comes to health messages, we accept or reject nutrition information depending on our experiences, beliefs, and biases. In the current nutrition communication landscape, we can easily find sources that confirm what we want to believe. For example, one might find any number of communications that extol the health benefits of dark chocolate, red wine, or fast food diets. Stumbling upon a source that affirms a favorite food as healthful may, in turn, prompt a consumer to ignore the less attractive, but accurate, advice communicated by more reputable sources [24]. That said, while TV, magazines, and the Internet represent the most frequently used sources of nutrition information, consumers rank registered dietitians, doctors, and nurses as the most credible sources [25,26]. Clearly, one-on-one interactions with patients are an important opportunity for health professionals to cut through the noise and establish themselves as providers of sound, actionable nutrition guidance.

Social Networks

Social networks, "the web of social relationships that surround individuals" [27], provide another avenue for meaningful nutrition communication. The relationship between social networks and health gained attention in the 1970s when researchers demonstrated that less connected individuals had a higher risk of all-cause mortality than well-connected individuals [28–30]. Since then, social networks have been studied for their effect on health issues as varied as smoking cessation, sexual behaviors, and obesity. Maibach and colleagues highlight the importance of the size and connectedness of one's personal network; the social support and modeling provided by family members, peers, and mentors within that network; and the role of opinion leaders as key influences on health behaviors [3].

Personal Network and Social Support

While well-connected individuals are generally healthier than less connected individuals, extending the size of individuals' social networks seems beyond the scope of most nutrition communication efforts. However, health providers should be sensitive to the fact that an individual's level of social support and day-to-day influences can have a significant impact on whether or not they adopt or maintain healthy eating behaviors. More important for the nutrition communicator is understanding how to engage with the social networks that individuals occupy in order to promote healthful behaviors. Evidence shows that having a friend who becomes obese can significantly increase one's own risk of obesity, yet this research also suggests that these same social influences

could be used to slow the spread of obesity [31]. Formative research with the target audience is a key step in integrating social support and modeling into a nutrition communications strategy, particularly by identifying the people who have the most influence (positive or negative) on eating habits within a social network. For example, if formative research shows that members of the target audience are most influenced by their mothers, messaging can be designed to invoke a mother's voice. Alternatively, if research shows that spouses most frequently undermine healthy eating habits, messaging can specifically target spouses.

Opinion Leaders

Opinion leaders, sometimes called champions, are individuals who influence the opinions, attitudes, beliefs, motivations, and behaviors of others. They can act as gatekeepers for interventions, help change social norms, and accelerate behavior change. In public health, they have been used to gain support for and implement community health programs in at least four different ways. They provide access for and legitimize external change agents, serve as the communication link between communities and external agencies that implement programs, act as role models for behavior change within a community, convey health messages, and serve as the "capital" that institutionalizes program goals after an outside agency has left a community. In the diffusion of innovation model, it is the opinion leaders who tend to monitor the climate of opinion and use their influence when the advantages of a new idea is apparent or when it is clear that norms will change [32]. Community opinion leaders often include clergy, teachers, legislators, and physicians. However, it is important to assess the primary influencers within each target audience through formative research.

Population/Community

The attributes of groups, communities, and populations that influence health behaviors are perhaps less well understood than are other factors in the people and places framework [3]. However, a large body of work is beginning to clarify how racial and socioeconomic disparities negatively influence health. Furthermore, a growing number of interventions based on community-based participatory models incorporate community organization and coalition building to create sustainable change. Within this context, it is critical to understand factors such as social norms, culture, social cohesion, collective efficacy, social capital, and income disparities. Both interventions described in some detail in this chapter, *Sisters Together: Move More, Eat Better* and *Shape Up Somerville*, addressed these factors in the planning and execution stages.

PLACES

Place-based factors outlined by Maibach and colleagues include the availability of products and services, the physical structure of the environment, the social structures within the environment, and media and cultural messages to which the target population is exposed. At the local level, these include home, school, neighborhood, local stores, workplaces, and the city. At the distal level they include state, regional, national, and even international factors. Health practitioners working at the local level must familiarize themselves with the community in which they work, identifying supportive individuals and groups as well as gaps in available resources. For example, if the goal is to increase fruit and vegetable consumption, then it is essential to understand the availability of food markets and seasonal farmer's markets that provide high-quality fruits and vegetables at fair market prices, as well as to help organize advocacy efforts to bring such resources to underserved neighborhoods. If the goal is to insure that public schools are following the mandated wellness policies with respect to nutrition and physical activity, it is important to know what these policies are, to identify where progress is being made and where it has lagged, and to actively participate in efforts to ensure progress. In the *Sisters Together* campaign, beauty salons were identified as an important component of the social structure of the community, so those businesses were engaged as partners to promote healthy eating by providing materials developed by the campaign. While attention to such place-based resources can enhance the effectiveness of nutrition communications, the challenges of engaging such resources are considerable.

Shift in Communications Landscape

As Abroms and Maibach aptly note, "A communication revolution has blurred traditional distinctions between mass and interpersonal communication, and changed in many ways how we must think about using the media to promote the public's health" [33]. The rise of the Internet has radically altered the way that information flows through our society. In an earlier era, communication occurred largely on a one-on-one or one-to-few basis and flowed in a somewhat linear fashion through one of two pathways. In the "treatment model" pathway, information flowed from research to medical practitioners and then to consumers as patients. In the wellness domain, it flowed through media and health professionals to consumers. The arrival of next-generation technologies has enabled dramatic shifts in that process, providing individuals and organizations with dynamic and powerful new communication tools to spread their influence to thousands, if not millions, of people, independent of traditional media channels and their associated gatekeepers. Not only is the interested consumer receiving the latest research findings at the same time as the practitioner, but the consumer can also take on the role of "citizen journalist," actively engaging in the dialogue about nutrition and health issues. In short, there is a lack of clarity about who exactly are the experts, increasing the level of consumer confusion.

The proliferation of mass media channels has also led to a decline in the size of the audience captured by any individual channel. As a result, each channel now tends to focus narrowly on the interests of a specific audience,

decreasing the likelihood that a particular message will reach the intended audience with sufficient clarity and repetition to influence behavior. This shift in the nutrition communication landscape has led to a shift in Americans' sources for food and nutrition information. Two-thirds of Americans look to Internet articles, cooking shows/hosts, TV or radio news programs, magazine articles, newspapers, talk shows, public service announcements or ad campaigns on TV or radio, and blogs or social networking sites like Twitter and Facebook [8]. That Americans are increasingly connected with these media sources is both an opportunity and a challenge for communicating about nutrition. While communications campaigns can target specific populations from multiple angles, it has grown much more difficult to cut through the noise. On the other hand, it is extremely important to keep in mind that, while there has been a burgeoning of electronic resources to communicate all kinds of information, there is still a significant percentage of the population that still do not use such resources. In developing nutrition communications activities, it is critical to assess the types of channels the target population uses and the reasons why those channels are preferred, and then to tailor the intervention accordingly.

Other Challenges to Communication of Nutrition Messages for Behavior Change

While it is uncertain exactly how many nutrition-related messages the average American is exposed to each day, the number is undoubtedly extremely large, and growing given the proliferation of opportunities made available through Internet-based communications. These messages include information on food labels, in advertising, in print and electronic media of all types, and even on billboards at sporting events. The goal of much of the information that is provided is to persuade the individual to behave in way that is desired by the provider of that information. The behavior that is being advocated will depend on the agenda of those that are providing it.

In the case of the media, a chronic problem is that, more often than not, nutrition research is portrayed as revolutionary, with findings inappropriately described as breakthroughs that are ready to translate to actionable behaviors. For example, a 1995 epidemiologic study suggesting a potential inverse relationship between lycopene and prostate cancer led to widespread recommendations from mainstream media and food and supplement manufacturers to increase lycopene intakes [34]. By 2007, however, the media exposed the limitations of research on lycopene's protective effects: a headline in the *New York Times*, for example, read, "Lycopene as Cancer Blocker? Review Says Evidence Is Scant." That same year, new reports posited another nutritional panacea for prostate cancer prevention: an article in *Science Daily* asked, "Worried about prostate cancer? Tomato-broccoli combo shown to be effective." It went on to report that rats who had been implanted with prostate cancer cells and fed a combination of 10% of their diet as tomato powder and another 10% as broccoli powder had less growth of prostate tumors than rats fed one or the other, lycopene powder, or a drug given to men with enlarged prostates. Translating that advice to humans (an extrapolation, given that the effect was seen in rats who consumed 20% of their diet from two vegetables), a 55-year-old man concerned about prostate health should consume 1.4 cups of raw broccoli and 1 cup of tomato sauce or a half cup of tomato paste every day! Because new findings are so often framed as absolute truth rather within the context of a specific issue, it is understandable that consumers say they are confused when conflicting results appear.

Another problem that is particularly important in nutrition communication is the tendency among health professionals and the media to focus on dietary objectives that are *not* being met, rather than acknowledging progress that *is* being achieved. Such negative messaging can be discouraging. Further, even as the public falls short of meeting certain dietary guidelines, we continue to raise the bar, delivering guidance that many Americans may view as infeasible or impractical. To an individual who eats two servings of fruits and vegetables a day, for example, raising the guideline from five servings to nine may seem so lofty as to be counterproductive. Communicating achievable goals and celebrating incremental successes can enhance the success of nutrition communications.

Media Advocacy: Using Media to Get Behind Your Cause/Sway Public Opinion and Policymakers

In some cases the strategic use of media can help promote policy changes that support desired health behaviors. Advocacy is the process of using evidence to influence government-level policymakers and working with partners to elevate issues to decision-makers' agendas. (For readers interested in how to influence health policy, *Essentials of Public Health Communication* offers an excellent discussion.) If it is not possible to communicate with policymakers directly, an alternative is grassroots advocacy by a group of citizens interested in the same issue. In this situation, the key is to form an effective coalition that becomes informed about the problem and possible solutions to it, and then draws a focus to it through local events or work with the local media to frame the discussion according to the objectives of the group. Mothers Against Drunk Driving (MADD), for example, brings together individuals with a common concern and works to influence policy pertaining to that issue. At the local level, community members might use a media advocacy strategy to bring a supermarket to an underserved area. The effective use of media can raise the volume of their message to a level where it is heard by policymakers who have the power to influence environmental change. There are a number of resources available to help with the design of media advocacy campaigns, such as that published by the American Public Health Association (http://www.apha.org/advocacy).

ROLE OF NUTRITION COMMUNICATION IN CHANGING BEHAVIOR: COMMUNITY-LEVEL INTERVENTIONS

Mass media campaigns have been defined as "any planned effort that disseminates messages to produce awareness or behavior change among an intended population through channels that reach a broad audience" [33]. That definition can be readily applied to the design of nutrition communication efforts at the community level. The following two case studies illustrate the process. The first, *Sisters Together: Move More, Eat Better,* is a communications campaign that was accompanied by community-building efforts. The second, *Shape Up Somerville: Eat Smart, Play Hard,* was designed according to the principles of community-based participatory research (CBPR), and nutrition communications played a major role in many aspects of the intervention.

Sisters Together: Move More, Eat Better

Sisters Together: Move More, Eat Better was designed to prevent obesity through promotion of improved nutrition and increased physical activity in African American women between 18 and 35 years old in three inner city communities in Boston, MA. The overall framework for the campaign was drawn from the ecological model, as proposed by McLeroy et al. in 1988 [35].

People-Based Campaign Components

Defining and understanding a target population was the first step in developing *Sisters Together.* The contract from National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) for the development, implementation, and evaluation of the intervention mandated that the campaign focus on obesity prevention in a minority group, but did not further specify the target population. The population was defined through a series of steps. A literature review that documented higher prevalence of obesity in African American women than in the general population was confirmed by data from the behavioral risk factor surveillance study [36] in Massachusetts, which also showed that increased risk was associated with low income and living in an urban area. A search of peer-reviewed publications and popular literature, including magazines and newspapers, explored obesity treatment interventions and weight loss practices, target audience understanding of the link between disease and obesity, perceptions of body weight and image, and other cultural factors that would affect acceptance of campaign messages. In addition to helping identify a target population, this formative research uncovered insights that later informed the design of the campaign, and particularly to ensure that it addressed population-specific attributes.

The focus of the campaign was narrowed following a series of key informant interviews with nutritionists and other community health workers, who identified 18- to 35-year-old black women as an underserved population. To further understand culture, gender, social class issues, attitudes, and preferences, the campaign planning group was expanded to include experts in media, education, and nutrition who lived and/or worked in the communities and were familiar with the culture of the target population. This was a crucial step in creating a foundation for community building and community linkages.

Throughout the project, design of all new materials and activities were based on formative evaluation that addressed three fundamental questions:

- Do the materials address the themes, key information, and skills that are needed?
- Does the design reflect the culture and preferences of the target population?
- Is the language and style appropriate and understandable?

The campaign logo for *Sisters Together* (see Figure 14.2), for example, communicates the culturally relevant concept of sisterhood expressed repeatedly in lay literature. The shapes of the women reflect the acceptance of a heavier weight as ideal, hair styles and variations typical of the target population, and the sense of movement being promoted by the campaign. While the logo could be reproduced successfully in black and white, the green, red, and black used in the original design were recommended by campaign planning group members familiar with the community. The various features of the logo were tested in focus groups and, when that was not feasible, in intercept interviews to ensure that decisions were acceptable to the target population.

Beyond such campaign branding efforts, the messages and materials in *Sisters Together* were tailored to social and cultural characteristics of the target population. For example, formative research showed that one widely popular dish was macaroni and cheese, high in calories and saturated fat. The challenge was to create a version that would be significantly lower in calories and acceptable to the target population. The first step was to identify recipes that met the criteria. The second step was to show the recipes to women in the target

FIGURE 14.2 The logo for the *Sisters Together: Move More, Eat Better* campaign was developed from extensive formative research with the target population.

population to identify which ones might be acceptable, and to reject those that were not; with this population, it emerged that few of the women would prepare a recipe with cottage cheese, so the numerous calorie-reduced versions with this ingredient were removed from consideration. Once possible recipes were selected, the third step was a taste test, again with members of the target population, to determine the recipe that would be accepted most widely. This process was repeated for each of the 12 recipes used in a calendar, one of the materials designed for the communication campaign. In an evaluation of the calendar, many women reported that they liked and used the recipes, demonstrating the value of the formative research [37].

The campaign also included cooking demonstrations, which were held at as many community events as possible, with the goal of addressing key concerns for women in the community: cost, convenience, and self-efficacy with respect to preparation of food that tastes good and follows healthful criteria. Recipes used relatively less expensive ingredients and could be prepared quickly. Demonstrations emphasized basic kitchen skills, such as knife skills, frequently found to be a barrier to food preparation.

Place-Based Campaign Components

Sisters Together also incorporated place-based components, at both the local and distal levels. For example, the campaign's launch was publicized through local broadcast and print media, and promotion through these channels continued for the duration of the campaign. A coalition of community partners was also established to support and extend the campaign message. Attendance at partner events allowed not only the *Sisters* team but also its partners to cross promote their programs and events. In addition, events were used to compile a mailing list for a monthly newsletter. Each newsletter had a monthly theme, with a review of recent events held by partners, a description/promotion of partner organizations, and a detailed calendar of events for the next month.

At the distal level, *Sisters Together* remains a national initiative of the NIDDK Weight-Control Information Network, and has been and continues to be adapted to meet the needs of communities throughout the United States. The campaign workbook and other materials are available at http://win.niddk.nih.gov/publications/SisPrmGuide2.pdf. Ongoing reevaluation of the messages and materials is essential to identify adaptations that appear necessary and to ensure suitability for target populations.

Shape Up Somerville: Eat Smart, Play Hard

Shape Up Somerville: Eat Smart, Play Hard (SUS) was an intervention designed according to CBPR, a collaborative approach that combines systematic inquiry, participation, and action to address urban health problems. This approach aligns closely with the People and Places framework [3]. SUS was designed to bring the energy equation into balance by increasing physical activity options and availability of healthful foods for early elementary school children, within the before-, during-, and after-school environments, as well as the home and community. The goal was to prevent the expected weight gain in elementary school children through small changes in their diets and physical activity [38]. Nutrition communications, which grew out of formative research with the members of the target community, played a key role in virtually every aspect of the project.

People-Based Campaign Components

Similar to *Sisters Together,* the branding of SUS was developed based on formative research specific to the target population. The name for the campaign, "Shape Up Somerville: Eat Smart, Play Hard," came out of focus groups with children. (Coincidentally, "Eat Smart, Play Hard" was also adopted as the name of a national USDA campaign, so there was a logical synergy that strengthened the messaging.) A logo, designed to reflect physical activity and healthy eating behavior in both boys and girls, was derived from ideas suggested by the children in focus groups representative of the target population. Alternative designs, including different graphics and colors, were tested in formative research with the children. The final logo was a red and orange line drawing of a boy jumping rope and a girl eating a banana, with words in a font chosen and approved specifically for the project. This logo was used on all project communications, including written communications to families, promotional materials such as water bottles and T-shirts, window stickers that promoted *Shape Up Approved* restaurants in the community, and reflective tags for "Walk to School" day. This consistent branding was critical to increasing campaign recognition.

SUS also engaged families through newsletters that were developed based on information obtained in parent focus groups. In response to feedback from parents and caregivers, coupons for produce were solicited from a local vendor and included in the newsletters. Knowing that the newsletters contained coupons raised the likelihood that parents and caregivers would open and read them. In addition, newsletters provided information that would be of value to the target population, including recipes for foods that were being promoted, publicity about locations and times of farmers markets and local events, ideas for activities with their children, important food safety information, and research findings of particular relevance to the population.

Place-Based Campaign Components

Given SUS's focus on children, its place-based components logically included several school-based elements. For example, school lunches and a la carte offerings were adapted to include less energy-dense food and beverage options, with an emphasis on fruits and vegetables, whole grains, and low-fat dairy. Schools also adopted new wellness policies and were provided new play equipment to allow more active recess activities. Another program component specifically aimed to increase children's acceptance of dried beans, a nutrient-dense commodity food. Recipes were developed and tested to ensure that children would like them, and beans were promoted through a unique audio program broadcast through

the school public address system. In order to heighten interest in the program, students in the schools participated in the design and delivery of each of the 11 messages. Focus groups with children in the community informed message development, and content analysis of food advertisements to children was conducted to identify characteristics and persuasive techniques that might be used effectively [39].

Beyond the school setting, SUS also addressed issues of access to healthful foods through a program that certified restaurants as "SUS-approved" if they met specific healthy eating standards. To support physical activity in the context of an urban built environment, a "walking school bus" program was initiated, and a mandate was developed to paint crosswalks with more durable paint to make them safer for crossing. A column in the local newspaper, *The Somerville Journal*, featured regular articles to raise the visibility of the intervention and the many activities that were being conducted. For example, the *Journal* ran a series of articles titled "Where's Mayor Joe?" focusing the mayor's visits to restaurants that had adopted SUS healthy eating standards. The articles positioned Mayor Joseph Curtatone, an opinion leader in the community social network, as an individual who could promote the normative behavior being recommended in the environment. The success of this program component depended largely on the shared interests among SUS researchers and community stakeholders: SUS benefitted from the promotion of approved restaurants, the mayor gained favorable publicity, restaurants obtained a no-cost marketing opportunity, and the newspaper enhanced public relations through its promotion of community programs.

At the conclusion of the intervention, the SUS logo was signed over to the city, which has continued many aspects of the intervention. At the distal level, the success of SUS led to the development of the Balance Project, which has adapted and implemented the SUS model for other U.S. communities. National publicity, including a front-page feature of SUS in the *Wall Street Journal*, further extended the campaign's influence on nationwide policies surrounding child nutrition and physical activity.

General Nutrition Communication Recommendations

Nutrition communication, by itself, cannot be expected to influence eating behavior. Its greatest promise is as a component of a comprehensive intervention that begins with a definition and understanding of the target population, based on thorough formative research, and a clearly specified, measurable set of outcome objectives. Nutrition advice must be framed in the context of total diet and be consistent with the Dietary Guidelines for Americans. The information is complex for most consumers and is generally more effective when divided into digestible bits and actionable steps. Nutrition messages and materials should be accurate, actionable, and relevant to the target population.

Whether you are designing a nutrition communication intervention for a small group with very specific needs, or for a large, generalized group, a well-planned approach using specific strategies can help your message resonate with the target audience and drive the desired behavior change.

DEFINITION OF PHYSICAL FITNESS

The Centers for Disease Control and Prevention (CDC) and the American College of Sports Medicine (ACSM) define physical fitness as, "a set of physical attributes that people have or achieve that relates to the ability to perform physical activity" [1,2]. These attributes have important implications for overall health, including one's ability to perform recreational or occupational activities, the determination of disability, injury prevention, and skeletal muscle, bone, and cardiovascular health. Moreover, higher fitness is strongly associated with better long-term health outcomes [3,4]. Engaging in proper physical training leads to an improvement in these physical attributes and physical fitness. The degree of improvement is determined by several factors, including training, diet, rest, psychological factors, and genetics.

AEROBIC AND ANAEROBIC FITNESS

The energy necessary to sustain life and perform work is extracted by the cells in one of two ways: with the use of oxygen and without oxygen. Historically, the utilization of oxygen to extract energy has been referred to as aerobic metabolism, and extracting energy without utilizing oxygen has been referred to as anaerobic metabolism. However, it is important to note that muscle cells are never entirely aerobic or anaerobic. Rather, their energy requirements are met through the harmonious interaction of the two systems, with the energy contribution of each system depending largely on the intensity of activity. In general, high-intensity activities derive their energy mainly independent of oxygen, while low-intensity activities utilize oxygen to meet their energy requirements. Therefore, aerobic fitness refers to the ability to provide the required energy for a specific task in which the body's cardiopulmonary system adequately supplies the needed oxygen to the working muscle cells. Conversely, anaerobic fitness refers to the body's ability to provide the required energy for a specific task independent of oxygen. Aerobic activities consist of repetitive, low-resistance movements (e.g., walking or cycling) that last over a relatively extended period of time (generally 5 min or more). Anaerobic activities on the other hand are characterized by bursts of intense activity lasting a comparatively short period of time (sprinting, lifting of a heavy weight, jumping, etc.). It is important to emphasize that these two energy systems (aerobic and anaerobic) are almost always working together in a harmonious way, sharing the responsibility for providing the energy requirements for the working muscles and the entire body. However, one is likely to be the predominant system to provide most of the energy for the particular activity at hand [5].

DETERMINING EXERCISE CAPACITY: DIRECT METHOD-OPEN CIRCUIT SPIROMETRY

The "true" maximum aerobic capacity is the maximum amount of oxygen (referred to as maximal oxygen uptake or VO_2 max) the body can utilize during work. This is assessed in laboratories by *open circuit spirometry.* VO_2 max is usually determined by a graded exercise test (GXT). A brief description and rationale for this procedure is as follows.

The individual breathes room air via a mouth piece (nose occluded), connected to an automated system (often termed a metabolic cart) by plastic tubes. The mouth piece is designed in such a way that it allows the measurement of the volume of expired air, while a small sample of the expired air enters the metabolic cart and is analyzed for its oxygen and carbon dioxide (CO_2) content. Oxygen uptake is determined by the product of ventilation and the difference between the O_2 content of the ambient and expired air. After resting samples are taken, the individual is subjected to a standardized exercise protocol on a treadmill or stationary bike. The exercise begins at a very low workload and increases progressively until volitional fatigue or until a clinical indication for stopping is reached. The rate of increase in external work depends on the exercise protocol used, but it is typically recommended that the test be individualized to last between 8 and 12 min.

Since the relationship between the increase in workload and oxygen consumption is linear, oxygen requirements also increase. At some point the individual reaches a volitional fatigue endpoint, and the test is terminated. This level is referred to as the maximal aerobic capacity of the individual. The oxygen utilized by the body at the point of fatigue is referred to as the VO_2 max. The measurement of VO_2 max implies that an individual's physiological limit has been reached. True VO_2 max has historically been defined by a plateau in VO_2 between the final two exercise work rates and requires that maximal effort be achieved and sustained for a specified period. Because this determination is subjective, can be difficult to define, and is rarely observed when patients with cardiovascular or pulmonary disease are tested, the term *peak* VO_2 is more commonly used clinically to express exercise capacity. Conversely, the term VO_2 *max* is more often used to describe exercise capacity in apparently healthy individuals, in whom achievement of a maximal physiological response is more likely. VO_2 max is expressed in milliliters of oxygen per minute (mL/min) or milliliters of oxygen per kilogram (kg) of body weight per minute (mL/kg/min). The latter is usually the preferred expression since it allows comparisons between subjects of different weights.

The direct measurement of VO_2 max is most often used for research purposes and has a number of important clinical applications for patients with cardiovascular or pulmonary disease. However, it is not often practical for someone who simply wishes to know the appropriate exercise intensity during his or her training. For this purpose, exercise intensity can be easily determined by the heart rate that corresponds to the appropriate percentage of oxygen consumption. Since heart rate and oxygen uptake are continuously recorded during the metabolic test, one can easily match a desired percentage of heart rate to the corresponding oxygen consumption. The advantage of the direct method is that it is highly accurate. It allows an accurate assessment of the exercise intensity of an individual based on directly measured rather than estimated aerobic capacity. However, it is an elaborate method that requires expensive equipment and trained personal and is therefore cost-prohibitive for large populations. It is mostly used in individuals with specific clinical needs and for research purposes [5].

DETERMINING AEROBIC FITNESS BY STANDARDIZED TESTS USING INDIRECT METHODS

The need for more practical methods to assess aerobic capacity for large populations led to the development of standardized exercise tests and the common practice of estimating energy requirements from different workloads. An indirect method for estimating the fitness level of an individual is based on the same principle as that for the direct assessment of VO_2 max with one exception; oxygen consumption is not directly measured. Rather, it is estimated based on treadmill speed and grade utilizing equations derived from the direct assessment of VO_2 max. The actual procedure is similar to that described for the assessment of VO_2 max with the exception that the individual is not connected to a metabolic cart (no breathing apparatus). While an ECG is monitored, the individual undergoes a standardized exercise protocol on a treadmill or stationary cycle ergometer. The most commonly used exercise protocols in the United States are described in Table 15.1, and these are discussed as follows. Exercise begins at a very low workload and increases every 2–3 min depending on the exercise protocol. The maximal workload is determined from the speed and elevation of the treadmill, or the resistance if a cycle ergometer is used. Heart rate is continuously monitored and recorded during the entire test (photo), and blood pressure is recorded every 2–3 min.

The workload is estimated for each exercise stage based on the speed and elevation of the treadmill. This estimation is based on comparison studies in which the energy requirements (oxygen consumption) were measured directly with metabolic equipment. In general, the amount of oxygen used during resting conditions is approximately 3.5 mL of oxygen per kilogram of body weight per minute (3.5 mL O_2/kg/min). This value (the resting metabolic rate) is termed 1 metabolic equivalent or 1 MET. Naturally, any increase beyond the 1-MET level represents higher total body oxygen consumption. Based on this rationale, several standardized exercise protocols have been developed to assess the MET level of individuals for clinical and other reasons. The MET level achieved upon termination of the test (the individual reaches volitional fatigue) represents the peak aerobic capacity of the individual. Because each MET is equal to approximately 3.5 mL O_2/kg/min, VO_2 max can be estimated by multiplying the MET level achieved by 3.5 [5]. It is important to note that exercise capacity assessed by such exercise tests is associated

with physical activity status of the individual. However, the ability to perform aerobic work is also determined by age and gender, as well as an important genetic component [6,7].

PROTOCOLS

The purpose of the test and the person tested are important considerations in selecting the protocol. Exercise testing may be performed for diagnostic purposes, for functional assessment, or for risk stratification. An often ignored but nevertheless consistent recommendation in the recent exercise testing guidelines is that the protocol be individualized for the patient being tested [8–10]. For example, a maximal, symptom-limited test on a relatively demanding protocol would not be appropriate (or very informative) for a severely limited patient. Likewise, a very gradual protocol might not be useful for an apparently healthy, active person. Use of submaximal testing, gas exchange techniques, the presence of a physician, and the exercise mode and protocol should be determined by considering the person being tested and the goals of the test.

Commonly used exercise protocols, their stages, and the MET level for each stage are outlined in Table 15.1. The most suitable protocols for clinical testing should include a low-intensity warm-up phase followed by progressive, continuous exercise in which the demand is elevated to a patient's maximal level within a total duration of 8–12 min [8–13]. In the absence of gas exchange techniques, it is important to report exercise capacity in METs rather than exercise time, so that exercise capacity can be compared uniformly between protocols. METs can be estimated from any protocol using standardized equations that have been put into tabular form [8,9,14]. In general, 1 MET represents an increment on the treadmill

of approximately 1.0 mph or 2.5% grade. On a cycle ergometer, 1 MET represents an increment of approximately 20 W (120 kg m/min) for a 70-kg person. The assumptions necessary for predicting MET levels from treadmill or cycle ergometer work rates (including not holding the handrails, that oxygen uptake is constant [i.e., steady-state exercise is performed], that the subject is healthy, and that all people are similar in their walking efficiency) raise uncertainties as to the accuracy of estimating the work performed for an individual patient. For example, the steady-state requirement is rarely met for most patients on most exercise protocols; most clinical testing is performed among patients with varying degrees of cardiovascular or pulmonary disease; and people vary widely in their walking efficiency [14]. It has therefore been recommended that a patient be ascribed a MET level only for stages in which all or most of a given stage duration has been completed [15].

CYCLE ERGOMETER PROTOCOLS

Although there are specific bicycle protocols named for early researchers in Europe, such as Astrand [16], bicycle ergometer protocols tend to be more generalized than for the treadmill. For example, 15–25-W increments per 2-min stage are commonly used for patients with cardiovascular disease, whereas for apparently healthy adults or athletic individuals, appropriate work rate increments might typically be between 40 and 50 W/stage. Most modern, electronically braked cycle ergometers have controllers that permit ramp testing, in which the work rate increments can be individualized in continuous fashion (see next section).

RAMP TESTING

An approach to exercise testing that has gained interest in recent years is the ramp protocol, in which work increases constantly and continuously. In 1981, Whipp et al. [17] first described cardiopulmonary responses to a ramp test on a cycle ergometer, and many of the gas exchange equipment manufacturers now include ramp software. Treadmills have also been adapted to conduct ramp tests [13,18,19]. The ramp protocol uses a constant and continuous increase in metabolic demand that replaces the "staging" used in conventional exercise tests. The uniform increase in work allows for a steady increase in cardiopulmonary responses and permits a more accurate estimation of oxygen uptake [13]. The recent call for "optimizing" exercise testing [8,10,12,15] would appear to be facilitated by the ramp approach, because large work increments are avoided and increases in work are individualized, permitting test duration to be targeted. Because there are no stages per se, the errors associated with predicting exercise capacity alluded to previously are lessened [8,9,13].

SUBMAXIMAL TESTING

In general, maximal, symptom-limited tests are not considered appropriate until 1 month after myocardial infarction (MI) or cardiac surgery. Thus, submaximal exercise testing has an important role clinically for predischarge, post-MI, or postbypass surgery evaluations. Submaximal tests have been shown to be important in risk stratification [19–22] for making appropriate activity recommendations, for recognizing the need for modification of the medical regimen, or for further interventions in patients who have sustained a cardiac event. A submaximal, predischarge test appears to be as predictive for future events as a symptom-limited test among patients less than 1 month after MI. Submaximal testing is also appropriate for patients with a high probability of serious arrhythmias. The testing endpoints for submaximal testing have traditionally been arbitrary but should always be based on clinical judgment. A heart rate limit of 140 beats/min and a MET level of 7 are often used for patients younger than age 40 years, and limits of 130 beats/min and a MET level of 5 are often used for patients older than 40 years. For those using beta-blockers, a Borg perceived exertion level in the range of 7–8 (1–10 scale) or 15–16 (6–20 scale) are conservative endpoints. The initial onset of symptoms including fatigue, shortness of breath, or angina, is also indications to stop the test. A low-level protocol should be used, that is, one that uses no more than 1-MET increments per stage. The Naughton protocol [23] is commonly used for submaximal testing. Ramp testing is also ideal for this purpose because the ramp rate (such as 5 METs achieved over 10-min duration) can be individualized depending on the patient tested [13].

Submaximal testing can also be used to assess the capacity of apparently healthy individuals to exercise safely or to estimate VO_2 max by extrapolation. The premise of estimating VO_2 max from a submaximal test is based on the linear relationship between heart rate and oxygen consumption, provided that the work is aerobic in nature. In submaximal test protocols, the HR at each workload is plotted against the workload and extrapolated to VO_2 max at an age-predicted maximal heart rate (typically 220-age). VO_2 max can be calculated using prediction equations [2] or estimated from values obtained by commonly used exercise protocols if the following assumptions are met: (1) the workload is reproducible; (2) a steady-state heart rate is obtained during each stage; and (3) a linear relationship exists between heart rate and oxygen consumption over a wide range of values. Examples of submaximal tests used to estimate peak VO_2 include the YMCA test, the Astrand test, and others [16,24,25].

WALK TESTS FOR CARDIORESPIRATORY FITNESS ASSESSMENT

A number of walking tests have also been developed for estimating cardiorespiratory fitness or assessing functional status of patients with cardiovascular or pulmonary disease in clinical settings. Advantages of walk tests include the fact that they are easy to perform and are relatively inexpensive, and thus can be applied to large populations. These include (1) the 6-min walk test, (2) the Cooper 12-min test, (3) the 1.5 mile test, and the Rockport one-mile fitness walking test [2].

The 6-min walk test is popular for assessing functional status in clinical settings, and is mostly used among diseased populations such as patients with heart failure, stroke, and peripheral vascular disease. The objective of the test is to cover the greatest distance by walking in 6 min. Its obvious advantages are that it requires practically no equipment (other than a stop watch) and little time.

Although the association between the 6-min walk performance and exercise capacity is only modest, peak VO_2 can be estimated from the 6-min walk distance by the following multivariate equation along with other readily available information:

$$\begin{aligned} Peak\ VO_2 = {} & [0.02 * distance(\mathrm{m})] - [0.191 * age(\mathrm{yr})] \\ & - [0.07 * weight(\mathrm{kg})] + [0.09 * height(\mathrm{cm})] \\ & + [0.26 * RPP(*10^{-3})] \end{aligned}$$

where
- m is meter
- kg is kilogram
- cm is centimeters
- yr is year
- RPP is rate pressure product (systolic blood pressure [mm Hg]* heart rate)

The Cooper 12-min test is based on a similar concept (covering the greatest distance in 12 min), while the objective of the 1.5 mile test is to run the distance (1.5 miles) in the shortest period of time. Unlike the 6-min walk test, both of these tests are more suitable for healthy, younger individuals. They also require little or no additional equipment and can be administered to large populations.

The Rockport one-mile fitness walking test involves covering a 1-mile distance in the shortest period of time. However, in addition to the time required to cover the 1-mile distance, the test utilizes peak heart rate achieved during the last minute of the walk, and an estimate of peak VO_2 is derived. If heart rate monitoring is not an option during the test, a 10-s heart rate obtained immediately after the completion of the test can be used as an alternative. However, this is likely to overestimate peak VO_2 compared to that calculated when heart rate is obtained during the last minute of the walk.

MUSCULAR FITNESS

The ACSM defines *muscular fitness* as the ability of the muscle to perform tasks that require muscular strength or muscular endurance. Strength is an important component of fitness assessment since it has implications for an individual's functional capabilities, disability, bone health, and insulin resistance and has been shown to have a strong association with long-term outcomes [26].

MUSCULAR STRENGTH

Muscular strength is defined as the ability of the muscle or muscle groups to exert force during a voluntary contraction [1]. The maximal force a muscle or group of muscles can exert is traditionally assessed by tests that require maximum effort against the greatest resistance one can move through the full range of motion once. This is known as the 1-repetition maximum (1-RM). A percentage of the 1-RM is then used to determine the number of repetitions one should perform to enhance the strength for a specific muscle. Generally, 8–12 repetitions at 40%–60% of 1-RM are sufficient to enhance muscular strength. An appropriate resistance training regimen involves performing these 8–12 repetitions 1–3 times, 2–3 times per week. While intensities as much as 80% and relatively low repetitions (such as 3–5) have been shown to be quite effective for rapid strength gains, this approach is generally limited to athletes whose performance requires great amounts of force.

It is important to note that intensity for resistance exercise is not always easy to determine and the 1RM does not depict a true intensity. The number of repetitions and the percentage of resistance based on 1RM differ significantly between individuals and muscle groups. Thus, the 1RM should only be used as a general guideline [2].

MUSCULAR ENDURANCE

Muscular endurance is defined as the ability of the muscle or muscle groups to perform repetitive contractions over a period of time against resistance, such as lifting a set amount of weight several times [2]. Muscular endurance is assessed by tests requiring more than 12 repetitions. A simple test of muscular endurance is the maximum number of push-ups or sit-ups one can execute without rest [2].

TESTS OF ANAEROBIC POWER

Because *anaerobic* power is an important determinant of athletic performance requiring high levels of exertion over short periods, tests have been developed to measure the capacity of the anaerobic energy systems. One of the more common tests of this type is the *Wingate* test, which involves 30–120 s of high-intensity effort on a cycle ergometer. The resistance is based on body mass (originally 0.075 kp per kg body mass, though this may vary) and is applied after initial inertia and unloaded resistance are overcome. *Peak power* is considered to represent the highest mechanical power generated during any 3–5 s period during the test; *average power* is the average of the total power generated during the test. An underlying assumption of the Wingate test is that peak power reflects the energy-generating capacity of the oxygen-independent high-energy phosphates, whereas average power is a representation of one's glycolytic capacity [27,28]. In studies comparing the Wingate test results to athletic performance and laboratory findings, it has been demonstrated to be a good index of these energy systems, although studies are mixed in terms of its ability to predict success in events requiring high exercise intensity [28].

BODY COMPOSITION

In the United States and most of the industrialized world, obesity has reached epidemic proportions [29]. Overweight and obesity are not simply cosmetic problems, but serious health conditions. They are both considered to be leading risk factors for a number of chronic health conditions including diabetes, hypertension, coronary heart disease, and premature mortality in developed countries. Although the mechanisms and causes of obesity are poorly understood, experts agree that obesity is largely the result of a chronic imbalance between caloric intake and caloric expenditure. This imbalance is likely the outcome of a complex interaction between genetic and environmental factors [30].

DEFINITION, ASSESSMENT, AND CLASSIFICATION OF OVERWEIGHT AND OBESITY

Body composition is comprised of three major structural components: muscle, bone, and fat. Obesity is defined as the accumulation of excess body fat, usually ≥25% of the total body weight for men and ≥33% for women [31]. Assessing body fat is not a simple task. Several methods have been developed with mixed success. The most commonly used methods, the strengths and weaknesses are presented as follows.

HYDRODENSIOMETRY OR UNDERWATER WEIGHING

One of the most accurate assessments of body composition is hydrodensiometry or underwater weighing. This method is based on Archimedes' principle, which states that the weight an object loses when immersed in water is equal to the weight of the displaced water resulting from that immersion. Percent body fat is estimated from body density, knowing that lean mass (bone and muscle) is heavier than body fat. The following equations for estimating body composition from underwater weighing were developed in the late 1950s and early 1960s [32,33] and are still in common use:

$$\% \text{ Body fat} = (457/\text{Body density}) - 414.2 \text{ [34]}$$

$$\% \text{ Body fat} = (495/\text{Body density}) - 450 \text{ [35]}$$

A number of equations have also been developed over the years to address specific populations, gender, and different races.

OTHER METHODS

Direct assessment of body fat by densitometry is one of the most accurate methods, but it is generally not practical for large populations. Thus, several indirect techniques have been developed over the years to assess body composition. The most commonly used methods for estimating or assessing body composition, their advantages and disadvantages are described in Table 15.2 [5].

Because direct body fat assessment is impractical for large populations, the American Heart Association (AHA) and other health organizations have adopted body mass index (BMI) as a practical clinical indicator of adiposity [30]. BMI, calculated as weight [kg] divided by height [m] squared (kg/m^2), correlates well with total body fat and is related to cardiovascular and all-cause mortality [34–36]. The estimated BMI for different weights and heights is presented in Table 15.3.

A set of cut-points at five BMI intervals to classify overweight and obesity have been adapted by the National Heart, Lung, and Blood Institute and World Health Organization [31]. Based on this classification, men and women with a BMI ≥30 kg/m^2 are considered obese (Table 15.4). However, it is important to keep in mind that BMI may not accurately reflect true adiposity for some populations. For example, a relatively muscular male weighing 100 kg, 1.80 m in height and approximately 20% actual body fat, has a BMI of 30.86 (BMI = 100/1.8^2). Conversely, a male 1.80 m tall, weighing 80 kg, with 30% actual body fat, has a BMI of 24.7. According to the classification system commonly used (Table 15.4), these individuals will be misclassified as obese and not obese, respectively [5].

WAIST CIRCUMFERENCE

Evidence supports the concept that excess accumulation of adipose tissue in the abdomen, characteristic of male-type fat distribution (android, abdominal, or central obesity) is associated with a higher risk for mortality than peripheral distribution of body fat [38]. This is because fat that surrounds the internal organs, known as *visceral fat*, is most closely associated with metabolic disorders that increase cardiovascular risk, including insulin resistance, lipid abnormalities, and heightened markers of inflammation. Since BMI also fails to take body fat distribution into account, waist circumference provides a practical method for assessing mortality risk associated with central distribution of fat, if a direct body fat assessment is not available. Waist circumference correlates more strongly with abdominal fat than BMI. Waist circumferences >102 cm for men and >88 cm for women are associated with increased cardiovascular risk [39,40].

SKINFOLD ASSESSMENT

Body composition estimated by skinfold measurements is based on the premise that approximately one-third of the total body fat is subcutaneous fat and the remaining is visceral fat. Thus, skinfold thickness parallels total body fat and is another method often use to estimate body composition. Because proportionally more fat is deposited viscerally with advancing age, age-adjusted equations should be

TABLE 15.2
Various Methods of Assessing Body Composition

Method/ Techniques	Method of Assessment	Advantages	Disadvantages
Densitometry from underwater weighing	Subject exhales fully all air. Then he/she submersed in water for only a few seconds. Weight is assessed under water	It is based on Archimedes principle. This method computes percentage body fat from body density (body mass/body volume)	Expensive and time consuming. Requires a laboratory equipped with a water tank trained personnel. It also requires that individuals exhale forcefully to reduce all possible all air from lungs. Then they are submersed in water for several trials, each lasting several seconds. This may not be tolerated well by some subjects who will either not undergo the procedure or make it difficult to obtain an accurate reading
Dual-energy x-ray absorptiometry (DXA)	Uses two low-energy distinct x-ray beams that penetrate bone and soft tissue areas to the depth of 30 cm. Computer software reconstructs the attenuated beams and produces an image of the tissues and quantify muscle, and fat mass	Quick, takes approximately 12 min to complete and correlates very highly with densitometry. Total body mass or regional tissue mass can be assessed	Expensive, requires trained personnel
Bod-pod	Relatively new procedure that uses an elliptical-shaped box that the subject sits in. It is based on air displacement plethysmography	Quick, takes approximately 3–5 min and has high reproducibility. Does not require any special skills by technician	Expensive. Claustrophobia may be an issue with some participants
Magnetic resonance imaging (MRI)		Can distinguish between changes in muscle mass and fat. Good for studies designed to assess changes in muscle mass (i.e. resistance [weight] training)	Very expensive, requires highly trained technicians. Cost prohibitive for large cohort studies.
Bioelectrical impedance	A light current is introduced to the individual. Body fat is estimated by opposition to current flow	Quick, relatively inexpensive	Tends to over predict body fat. Requires trained personnel and standardized conditions (hydration, environmental temperature) that may not be possible in all situations
Skinfolds	Requires a caliper that measures body fat at standardized anatomical body sites	Relatively easy and inexpensive to perform (requires a caliper). No special laboratory required other than a room for some privacy. Time requirements are only a few minutes per subject, thus allowing large numbers of individuals to be processed	Skilled and experienced personnel are required
BMI	Weight and height are needed	The simplest and least expensive method, requiring only the weight (kg) and height (m) of the individual	It is only an index of body dimensions. It does not measure body fat, but only assumes that higher BMI translates to higher body fat content. This may or may not be true and can vary greatly for different populations
Waist circumference and waist–hip ratio	Measurements of waist and hip circumference	Simple, inexpensive and relatively quick to perform	Both waist circumference and the waist-to-hip ratio are indices of body composition. They do not measure body fat. However, they both provide an index of fat distribution

Note: Body mass index <18 is not recommended, and therefore these values are not represented in this table.

TABLE 15.4
Classification of Body Weight and Obesity Based on BMI and Waist Circumference

	Obesity Class	BMI (kg/m²)	Waist Circumference	Associated Health Risk
Underweight		<18.5		
Normal		18.5–24.9		Average
Overweight		25.0–29.9	Men: ≥94 cm Women: ≥80 cm	Increased
Obesity class	I	30.0–34.9	Men: ≥102 cm Women: ≥102 cm	Moderate
Moderate obesity	II	35.0–39.9		High
Severe obesity	III	≥40		Very high

used in older men and women. Assuming that the appropriate technique is used and factors that contribute to measurement error are controlled, the technique correlates fairly well with hydrodensiometry (r = 0.70–0.90). Accuracy is also compromised with extremely obese or extremely lean individuals.

Over the years, several sites and techniques have been identified and used to assess body composition via skinfolds. A thorough review of anthropometric assessments related to skinfolds is recommended for those interested in a more detailed description of this methodology [41]. These techniques are also reviewed in the *ACSM Guidelines for Exercise Testing and Prescription* [2].

Summary 220
References 220

More now than ever, increasing one's physical activity is recognized as an important means of improving one's health. Table 16.1 lists the currently documented health benefits of physical activity [1]. *Physical activity* is defined as "bodily movement that is produced by the contraction of skeletal muscle and that substantially increases energy expenditure" [2]. *Exercise*, on the other hand, is a more strictly defined subset of physical activity that is "planned, structured, and repetitive bodily movement done to improve or maintain one or more components of physical fitness" (e.g., cardiorespiratory endurance, muscular strength) [2]. Increases in both exercise and overall physical activity can maintain and improve health. Accordingly, this chapter will (1) review the current recommendations for physical activity, (2) discuss prescription of both formal exercise and overall physical activity, and (3) discuss prudent alterations to the normal exercise prescription in some of the more prevalent clinical populations.

TABLE 16.1
Health Benefits of Physical Activity: A Review of the Strength of Scientific Evidence

Adults and Older Adults

Strong Evidence

Lower risk of:
- Early death
- Heart disease
- Stroke
- Type 2 diabetes
- High blood pressure
- Adverse blood lipid profile
- Metabolic syndrome
- Colon and breast cancers

Prevention of weight gain

Weight loss when combined with diet

Improved cardiorespiratory and muscular fitness

Prevention of falls

Reduced depression

Better cognitive function (older adults)

Moderate to Strong Evidence

Better functional health (older adults)

Reduced abdominal obesity

Moderate Evidence

Weight management after weight loss

Lower risk of hip fracture

Increased bone density

Improved sleep quality

Lower risk of lung and endometrial cancers

Children and Adolescents

Strong Evidence

Improved cardiorespiratory endurance and muscular fitness

Favorable body composition

Improved bone health

Improved cardiovascular and metabolic health biomarkers

Moderate Evidence

Reduced symptoms of anxiety and depression

PHYSICAL ACTIVITY RECOMMENDATIONS

In 2008, the U.S. Department of Health and Human Services released its Physical Activity Guidelines for Americans [1]. The purpose of this document was both to summarize the scientific data related to physical activity published since the release of the 1996 Surgeon General's Report, Physical Activity and Health [2] and to resolve any confusion created through differing recommendations released after the Surgeon General's Report. For adults aged 18–64 years, the Guidelines recommend a minimum of 150 weekly minutes of moderate-intensity aerobic activity and recognize that increasing benefits are likely to accrue through at least 300 min/week. Alternatively, 75–150 min of vigorous-intensity aerobic activity can be performed to amass similar benefits (*moderate-* and *vigorous-intensity* aerobic activities are defined and discussed later). A combination of moderate- and vigorous-intensity activity may also be employed. In addition, resistance training involving all major muscle groups is recommended at least twice weekly. Additional recommendations for children, the elderly, and other special populations are discussed later in this chapter.

EXERCISE PRESCRIPTION

Physical Fitness Parameters

Physical fitness is "the ability to carry out daily tasks with vigor and alertness, without undue fatigue and with ample energy to enjoy leisure-time pursuits and to meet unforeseen emergencies" [3]. Elements of physical fitness have traditionally been categorized as either health related (cardiorespiratory endurance, muscular endurance, muscular strength, body composition, flexibility) or skill related (agility, balance, coordination, speed, power, reaction time) [4]. Definitions of the various physical fitness elements are listed in Table 16.2. The health-related fitness components are certainly important in chronic disease prevention and rehabilitation. However, particularly among the elderly and those with certain musculoskeletal diseases, maintenance of a certain level of skill-related fitness is also critical to independent function and quality of life. For example, the ability to drive a car or cross a busy street safely depends as much on *skill*-related and *health*-related fitness. Conversely, all of the health-related fitness parameters are key elements of various athletic and recreational activities. Therefore, while categorization of these elements may be helpful in developing fitness goals and an exercise plan, one should realize that training toward elements of *both* health-related and skill-related fitness may be prudent with some clients.

Exercise Training Principles

Although goals and responses to physical activity and exercise training can vary considerably from person to person, three general principles should be considered when developing an exercise plan: *progressive overload*, *specificity*, and *reversibility.*

Progressive Overload

Adaptations only occur in physiological systems when the systems are stressed at levels to which they are unaccustomed. In other words, for any physical fitness or health parameter, a *threshold* of physical activity exists that a person must exceed in order to experience improvement. This minimal amount of training needed depends upon both the baseline level of the variable to be changed and a person's genetic capacity to experience positive changes in the targeted physiological system(s).

Given a steady overload, physiological improvement will level off or plateau after a given period of time. The term *progressive* overload indicates that the training stimulus must continue to increase in order for further improvement to be recognized. The overall training stimulus can

TABLE 16.2
Health-Related and Skill-Related Physical Fitness Parameters[a]

Health Related	Skill Related
Cardiorespiratory endurance—The ability of the circulatory and respiratory systems to supply fuel during sustained physical activity and to eliminate fatigue products after supplying fuel	*Agility*—The ability to rapidly change the position of the entire body in space with speed and accuracy
Muscular endurance—The ability of muscle groups to exert external force for many repetitions or successive exertions	*Balance*—The maintenance of equilibrium while stationary or moving
Muscular strength—The amount of external force that a muscle can exert	*Coordination*—The ability to use the senses, such as sight and hearing, together with body parts in performing motor tasks smoothly and accurately
Body composition—The relative amounts of muscle, fat, bone, and other vital parts of the body	*Speed*—The ability to perform a movement within a short period of time
Flexibility—The range of motion available at a joint	*Power*—The rate at which one can perform work
	Reaction time—The time elapsed between stimulation and the beginning of the reaction to it

[a] Although physical fitness is dichotomized into health- and skill-related categories, overlap exists between the two (see text).

usually be augmented by increasing the *intensity*, *duration*, and/or *frequency* of physical activity.

Specificity

Overload will only result in an adaptation to the muscle groups and physiological systems that are stressed in training. Specificity of training applies to the motor units involved (e.g., muscles used, joint angle), speed of contraction, and the energy systems and primary substrates used (e.g., aerobic versus anaerobic metabolism, fat versus carbohydrate). Unless a person is severely untrained (e.g., frail elderly), strength training will do little to improve cardiorespiratory endurance and vice versa. Furthermore, although distance cycling and running are both aerobic activities using the legs, the carryover from training in one mode to performance improvement in the other is limited. Similarly, while squat training mainly improves quadriceps strength, this improvement may not be recognized when testing with another exercise (e.g., leg extension) that uses different motor unit recruitment and accessory muscles. Therefore, in addition to training specifically toward a person's goals, assessment of improvement should involve testing that is congruent with the training that has been employed. The more specific a person's training goals (e.g., athletic performance), the more important these issues become.

Reversibility

Just as the body adapts positively to increases in physical activity, it adapts negatively to inactivity. The rate of deconditioning varies depending on the previous training level and how much it is curtailed. For example, casting or extended bed rest can result in sharp rapid declines in strength and endurance performance. In a more practical sense, fitness levels tend to decline significantly after about 2 weeks of exercise cessation. Endurance training of 2–3 days/week and resistance training of at least once per week are generally necessary to maintain previously attained fitness levels.

Cardiorespiratory Endurance Training

Maximal oxygen consumption (VO_{2max}) is the most accurate measure of cardiorespiratory fitness. Although some health benefits may be recognized with the practice of moderate-intensity physical activity that is less likely to improve VO_{2max} [5], strong inverse relationship exists between VO_{2max} and overall mortality and most major chronic diseases [6]. As such, the American College of Sports Medicine has traditionally recommended the following frequency, intensity, time, and type (FITT) of exercise for the improvement of cardiorespiratory fitness [7].

Type (Mode) of Exercise

Activities that overload the cardiorespiratory system are repetitive (rhythmic) in nature and involve larger muscle groups. Examples include brisk walking, running, cycling, rowing, and exercising on an elliptical machine. Sports that constantly require intermittent bouts of vigorous body movement, such as basketball, soccer, and tennis, can also contribute to improved cardiorespiratory fitness. Unless medical conditions dictate otherwise, the majority of exercise should be weight-bearing in order to help prevent osteoporosis.

While specificity of training is very important for athletes, persons training more for overall health and fitness purposes will likely benefit from practicing a variety of exercise modes. Such practice will likely lead to fewer overuse injuries and will also add variety to the training regimen, possibly leading to better program compliance. For beginning exercisers, walking is generally a very good activity to include since it requires little skill and results in fewer overuse injuries than most other modalities.

Intensity of Exercise

Improvement in VO_{2max} can usually be attained by exercising regularly at 50%–85% of $VO_{2reserve}$ ($VO_{2reserve} = VO_{2max} - VO_{2rest}$). Obviously, this range is wide; the most effective

TABLE 16.3
Calculation of Target Oxygen Consumption ($VO_{2target}$) and Target Heart Rate (HR_{target}) by Reserve Method

$VO_{2target}$[a]	HR_{target}
Step 1: Calculate $VO_{2reserve}$ $VO_{2reserve} = VO_{2max} - VO_{2rest}$ *Step 2*: Multiply $VO_{2reserve}$ by the desired percentage $VO_{2fraction} = VO_{2reserve} \times$ target percentage *Step 3*: Calculate $VO_{2target}$ by adding VO_{2rest} to $VO_{2fraction}$ $VO_{2target} = VO_{2fraction} + VO_{2rest}$	*Step 1*: Estimate HR_{max}[b] $HR_{max} = 220 - age$[c] *Step 2*: Calculate $HR_{reserve}$ $HR_{reserve} = HR_{max} - HR_{rest}$ *Step 3*: Multiply $HR_{reserve}$ by the desired percentage $HR_{fraction} = HR_{reserve} \times$ target percentage *Step 4*: Calculate HR_{target} by adding HR_{rest} to $HR_{fraction}$ $HR_{target} = HR_{fraction} + HR_{rest}$
Example: You want a person with a VO_{2max} of 35 mL/kg/min to exercise at 65% $VO_{2reserve}$: *Step 1*: Calculate $VO_{2reserve}$ $VO_{2reserve} = 35.0 - 3.5 = 31.5$ mL/kg/min *Step 2*: Multiply $VO_{2reserve}$ by the desired percentage $VO_{2fraction} = 31.5 \times 0.65 = 20.5$ mL/kg/min *Step 3*: Calculate $VO_{2target}$ by adding VO_{2rest} to $VO_{2fraction}$ $VO_{2target} = 20.5 + 3.5 = 24.0$ mL/kg/min	**Example:** You want a 50-year-old person with a HR_{rest} of 70 bpm to exercise at 65% $HR_{reserve}$: *Step 1*: Estimate HR_{max}[b] $HR_{max} = 220 - 50 = 170$ bpm[c] *Step 2*: Calculate $HR_{reserve}$ $HR_{reserve} = 170 - 70 = 100$ bpm *Step 3*: Multiply $HR_{reserve}$ by the desired percentage $HR_{fraction} = 100 \times 0.65 = 65$ bpm *Step 4*: Calculate HR_{target} by adding HR_{rest} to $HR_{fraction}$ $HR_{target} = 65 + 70 = 135$ bpm

[a] MET values may be substituted for VO_2 (1 MET = 3.5 mL/kg/min).
[b] When possible, use HR_{max} from maximal graded exercise test instead of estimation.
[c] Alternatively, the formula "$HR_{max} = 206.9 - (0.67 \times age)$" may be used.

intensity will depend in part upon the duration and frequency of exercise. Nevertheless, larger improvements in VO_{2max} typically occur with higher intensities. However, higher volumes of exercise (to include intensity, duration, and frequency) are more likely to result in overtraining symptoms (e.g., fatigue, injury, decreased performance, suppressed immune function). Exercise training at 60%–80% $VO_{2reserve}$ generally results in improved VO_{2max}. Although intensities above this range may benefit certain athletic performances, they should be practiced sparingly.

As stated in this chapter's introduction, the Physical Activity Guidelines for Americans give recommendations for both moderate- and vigorous-intensity physical activity. In relative terms, *moderate-intensity* physical activity is defined as activity requiring 40%–60% of $VO_{2reserve}$ while *vigorous-intensity* physical activity is anything that requires above 60% $VO_{2reserve}$. While moderate-intensity physical activity may result in some fitness improvement for those starting at a low fitness level, the progressive overload necessary to elicit and maintain improvement lies in the vigorous-intensity range for many people, especially those who are younger and/or more fit.

If a person's VO_{2max} has been measured or estimated through exercise testing [7], exercise intensity may be prescribed as a given percentage of $VO_{2reserve}$. $VO_{2reserve}$ is calculated by subtracting the estimated value for VO_{2rest} (1 MET = 3.5 mL/kg/min) from VO_{2max}. $VO_{2reserve}$ is then multiplied by the target percentage and VO_{2rest} is then added back to the product to yield the target VO_2. An example of this procedure is presented in Table 16.3.

Knowing the MET ("metabolic equivalent") levels of various activities can be useful in prescribing physical activity after a target VO_2 range has been determined. One MET is an estimation of a person's energy expenditure when seated at rest (3.5 mL/kg/min). As an example, if a person performs an activity that requires six times the energy requirement of sitting at rest, that activity would carry a MET level of 6, requiring a VO_2 of approximately 21 mL/kg/min ($6 \times 3.5 = 21$). The Compendium of Physical Activities (http://sites.google.com/site/compendiumofphysicalactivities/) has been published to provide the MET requirements of more than 800 leisure-time and occupational activities [8]. Table 16.4 includes examples of MET levels for some more common activities. If a target MET range has been determined ($MET_{target} = VO_{2target}/3.5$), the Compendium can be used to identify activities of appropriate intensity.

Many professionals find it more practical to prescribe exercise intensity by heart rate rather than VO_2. Since heart rate and VO_2 have a linear relationship during graded exercise, a given percentage of heart rate reserve ($HR_{reserve}$) parallels the same percentage of $VO_{2reserve}$ and, therefore, may be used in its place. When available, it is preferable to use the maximal heart rate (HR_{max}) attained from a maximal graded exercise test. If a true HR_{max} is not available, an age-predicted value may be used. Just as with the $VO_{2reserve}$ method, HR_{rest} is subtracted from HR_{max} to obtain $HR_{reserve}$.

TABLE 16.4
Sample Metabolic Equivalent (MET) Levels of Common Physical Activities

Activity	METs	Activity	METs
Walking, 2 miles/h	2.8	Aerobic dancing	5.0–9.5
Walking, 3 miles/h	3.5	Golf, using power cart	3.5
Walking, 4 miles/h	5.0	Golf, walking, pulling/ carrying clubs	4.3–5.3
Running, 6 miles/h	9.8	Tennis	4.5–8.0
Running, 7.5 miles/h	11.5	Soccer	7.0–10.0
Running, 9 miles/h	12.8	Washing and waxing car	2.0
Bicycling, 5.5 miles/h	3.5	Most housecleaning activities	2.5–3.5
Bicycling, 9.4 miles/h	5.8	Gardening	2.3–5.8
Bicycling, 15 miles/h	10.0	Mowing lawn, riding mower	2.5
Swimming, sidestroke	7.0	Mowing lawn, walk, power mower	4.5–5.0
Swimming, crawl, ~50 yards/min	8.3	Mowing lawn, walk, hand mower	6.0
Swimming, crawl, ~75 yards/min	10.0	Shoveling dirt or snow	5.3–7.8

Source: Ainsworth, B.E. et al., *The Compendium of Physical Activities Tracking Guide*, Healthy Lifestyles Research Center, College of Nursing and Health Innovation, Arizona State University, Tempe, AZ, http://sites.google.com/site/compendiumofphysicalactivities/.

The target heart rate is then derived by multiplying $HR_{reserve}$ by the desired percentage and adding HR_{rest} to the product (Table 16.3).

The most common formula for estimating HR_{max} in adults is "HR_{max} = 220 − age." It is most accurate at the age of 40 years and over- and underestimates HR_{max} in younger and older people, respectively. A more accurate formula, "HR_{max} = 206.9 − (0.67 × age)," has recently been introduced [9]. While this formula is slightly more complicated, it may result in a more appropriate intensity prescription, particularly among the elderly. Regardless of the formula used, it is important to realize that HR_{max} has a standard deviation of 10–12 beats per minute (bpm) across the adult age span. This can obviously limit the value of using age-predicted HR_{max} in determining a target heart rate. As such, many professionals prescribe HR_{target} as a range of 10% $HR_{reserve}$ or so. A person's subjective feeling of effort should also be taken into account during exercise. On a scale of 0–10, where sitting is 0 and maximal effort is 10, moderate-intensity activity should yield a rating of 5 or 6 and vigorous-intensity activity of 7 or 8 [1]. Such ratings are particularly useful for people who have clinical conditions or take medications that affect the heart rate response to exercise.

Alternative to the $HR_{reserve}$ method, exercise intensity may be prescribed using a straight percentage of HR_{max} (65%–90% HR_{max} is approximately equivalent to 50%–85% $HR_{reserve}$). However, many professionals prefer the $HR_{reserve}$ method, as it is more individualized by taking HR_{rest} into account.

Time (Duration) of Exercise

For improvement in cardiorespiratory fitness, 20–60 min per session is recommended, with duration and intensity interacting with one another. For example, 20–30 min of exercise at a higher intensity can yield similar benefits to 50–60 min of exercise at a lower intensity. Similar health and fitness benefits are recognized regardless of whether exercise is performed continuously or intermittently throughout the day in bouts of 10 min or more.

Frequency of Exercise

Three to five days of exercise have traditionally been recommended for the improvement of cardiorespiratory fitness. While 6 or 7 days/week may be practiced to accumulate the moderate-intensity guidelines of 150–300 min/week, such a frequency of vigorous-intensity exercise will likely increase one's chance of injury while yielding few additional health or fitness benefits. Therefore, as with other exercise prescription parameters, exercise frequency should vary with goals. For example, daily or near-daily physical activity is advocated for weight loss or maintenance while "recovery days" of rest or lighter activity are usually necessary between more intense workouts.

Overall Exercise Volume

The 1996 Report of the Surgeon General recommended 1000 kcal as the minimum weekly energy expenditure necessary to accrue health benefits [2]. This recommendation is congruent with the 150 weekly minutes of moderate-intensity or 75 min of vigorous-intensity physical activity recommended in the Physical Activity Guidelines for Americans [1]. The concept of a dose–response relationship is more evident in the more recent recommendations, that is, a greater amount of physical activity will yield greater health and fitness benefits. Therefore, the Guidelines recognize that 300 weekly minutes of moderate-intensity physical activity is superior to 150 min for most people (and 150 weekly minutes of vigorous-intensity physical activity may be superior to 75 min). Further health benefits from physical activity quantities above those recommended in the Guidelines are not well documented. In addition, while greater fitness benefits may result from higher volumes of exercise, the risk of overtraining symptoms also increases.

On the other end of the continuum, some people may be deconditioned to the extent that they have difficulty in attaining the minimal physical activity recommendations. Such people should do as much physical activity as they can without undue fatigue, with the goal of progressing into the range recommended in the Guidelines, which state "For all individuals, some activity is better than none" [1].

Rate of Progression

Training volume can be increased through alteration of exercise frequency, intensity, and/or duration. Many professionals first choose to implement small changes in exercise duration (5–10 min per session), as they are usually well tolerated

and may be less likely to negatively affect exercise adherence. Depending upon a person's beginning exercise volume and his/her goals, frequency and/or intensity may then be increased. Although somewhat anecdotal, the "ten percent rule" is a good rule of thumb; exercise volume (usually quantified by distance or time) should not be increased by more than 10% per week. In addition, overtraining symptoms (e.g., upper respiratory infection, muscle/joint pain) should be recognized and a reduction of training volume and/or a change of exercise modality should be implemented.

Resistance Training

The Physical Activity Guidelines for Americans recommend that muscle-strengthening (resistance) activities that involve all major muscle groups be performed on two or more days per week [1]. Benefits of resistance training include maintenance or increases in bone mass, insulin sensitivity, and skeletal muscle mass, the latter being important for those attempting to lose weight. Maintenance or gain in strength can also be important in preserving physical function in the elderly and persons with certain disabilities.

Type of Resistance

Dynamic resistance exercises alternately overcome (*concentric* contractions) and accommodate (*eccentric* contractions) a given force. This force is often in the form of weights (either "free" weights or stacked weights on various machines), but can also exist in other forms, such as elastic bands or one's own body weight. The type of resistance to be used in training depends largely upon the goals of the participant and a combination of resistance modes is often employed. More "controlled" modes (e.g., weight machines, resistance bands) are generally safer and less likely to require a spotter, while less controlled modes (e.g., free weights) require more balance and tend to mimic real-life movement more. For the purposes of safety and effectiveness (i.e., specificity), proper technique (e.g., keeping back straight, controlling eccentric portion of exercise) should be stressed with any type of exercise. In addition, unless the development of isometric (static) strength is a specific training goal, resistance exercises should be dynamic, generally taking the involved joints through the fullest range of motion possible. This allows a greater number of motors units to be trained, creating more functional benefits.

Regardless of the mode(s) of resistance used, all major muscle groups should be exercised. At least 8–10 different exercises are generally required to target all of the major muscle groups. Accordingly, to encompass the entire body and lessen the chances of strength imbalances, opposing (antagonistic) muscles groups should be exercised. For example, if the abdominal muscles are focused upon in one exercise, another exercise should target the lower back muscles; both the biceps and triceps should be targeted in separate exercises, etc. For practical purposes, multi-joint exercises (e.g., bench press, squat) that simultaneously train more than one muscle group are preferred over single-joint exercises (e.g., triceps extension, leg extension) because they are more time efficient and tend to represent real-life movements more. However, single-joint exercises can still serve as useful adjuncts, particularly if they mimic a particular movement in a sport or other activity for which a person is training.

Amount of Resistance, Repetitions, and Sets

To achieve improvements in both muscular endurance and strength, completion of 8–12 repetitions of each exercise to a point of *fatigue* (not necessarily *failure*) is recommended. Lifting to fatigue infers that an additional repetition would be difficult to perform without help [1]. Performing 8–12 repetitions to fatigue generally requires a resistance of 60%–80% of a person's 1-repetition maximum (1RM; the maximum amount of weight that can be lifted in a single effort in that same exercise) [7]. Performing fewer than 8–12 repetitions to fatigue (which would employ a greater resistance) will result in more strength gain than gain in endurance, while performing more than 8–12 repetitions (requiring less resistance) will result in more improvement in muscular endurance.

The compilation of repetitions of an exercise performed at one time (e.g., 8–12) is termed a *set*. Multiple sets of an exercise may be performed with 2–3 min rest in between being recommended. For beginners, performing a single set of an exercise for 8–12 repetitions to fatigue on a regular basis will almost always result in strength gains. In time, additional sets will likely be necessary for further improvement [1]. ACSM recommends that —two to four sets be performed with each muscle group. However, more than one exercise may be employed for a given muscle group. For example both the bench press and dips involve the pectoralis and triceps muscles, but require different movement patterns. Therefore, completing a single set of both of these exercises would satisfy this recommendation for these muscle groups [7]. In short, the number of sets to be performed depends upon the goals of the participant. Health and functional benefits can be recognized with a minimum number of sets while athletes commonly exceed the number of sets recommended by health organizations.

Frequency of Training

To allow sufficient recovery, resistance training sessions should be spaced at least 48 h apart from one another [7]. Therefore, 2–3 days/week of resistance training is recommended. If time constraints do not permit all exercises to be performed in a given day, then the same muscle groups should not be exercised on consecutive days (e.g., train the upper body one day and the lower body the next).

Rate of Progression

As mentioned earlier, resistance training sets should be performed to fatigue in order for muscular fitness gains to be achieved. A person should increase the resistance of an exercise when he or she can perform one or two extra repetitions with good form. To remain in the desired repetition range (e.g., 8–12), increases of 2.5–5 lb are generally appropriate for smaller muscle groups and increases of 5–10 lb are generally appropriate for larger ones.

Even when the earlier criteria are followed, people training for larger gains in muscle size and strength often *plateau* or fail to experience continued improvement after many months. In this case, *periodization*, the frequent alteration of training intensity, repetitions, sets, and/or resistance mode, can be useful. While beyond the scope of this chapter, ACSM has published a position stand addressing this topic [10].

Flexibility Training

Maintenance of flexibility, the range of motion around a joint, can be important for the prevention of low back pain and for the maintenance of activities of daily living. While stretching might help prevent injury in activities where one's range of motion is taken to its limits (e.g., gymnastics), there is no conclusive evidence that stretching prevents injury in activities requiring less range of motion (e.g., jogging) or that it prevents muscle soreness [11,12].

Nevertheless, since flexibility decreases with aging, stretching is an important component of a well-rounded fitness program. Unless ballistic (bouncing) movement is part of an activity for which a person is training, static stretching, where a person holds a stretch for an extended period (15 s or more), is recommended. Stretching is more effective, and possibly safer, after a person has gone through a warm-up period. In fact, unless a person is getting ready to perform activities that challenge their range of motion, stretching is usually most effective at the end of an exercise session rather than at the beginning. If stretching before exercise, a person should still warm up first (see next section). ACSM recommends that stretching exercises be performed at least four repetitions per stretch for at least 15 s each on at least 2–3 days weekly [7].

Warm-Up and Cooldown

Both before (*warm-up*) and after (*cooldown*) the conditioning phase of an exercise session, at least 5–10 min of low-intensity physical activity should be performed. The increased blood flow and body temperature resulting from the warm-up period allows the muscle and connective tissue to become more pliable, reducing the chance of injury during vigorous activities. It also allows a more gradual cardiovascular adaptation to the stress of exercise, which is particularly important for people who are more likely to experience cardiac events. Similarly, a proper cooldown period helps prevent venous pooling in the lower extremities, thereby facilitating venous return to the heart and brain. Muscular endurance activities, such as abdominal exercises, and stretching may also be better performed during the cooldown phase.

Physical Activity Adherence

Specific strategies for enhancing physical activity participation are detailed elsewhere in this book. In general terms, the clinician should recognize that a good bit of flexibility exists in how a person can choose to meet physical activity guidelines (i.e., wide ranges exist in the components of FITT) and that physical activity may be practiced in a variety of settings (at home, outside, in a fitness facility, etc.). In addition, leisure-time physical activity may be practiced alone, with a partner, or in a group setting. Everyone should be encouraged to experiment with a variety of exercise regimens and to continue to practice the one(s) they enjoy the most.

Approximately 56% of American adults fail to meet current physical activity recommendations [13]. As patients are more likely to be physically active when such behavior is endorsed by their physicians, an initiative of Healthy People 2020 is to "increase the proportion of physician office visits that include counseling or education related to physical activity" [14]. However, most physicians have received little education on physical activity counseling as part of their medical training. Appropriately, in order to facilitate delivery of prudent physical activity information by health care providers, ACSM and the American Medical Association launched an educational website, Exercise is Medicine, in 2007 (http://exerciseismedicine.org) [15].

EXERCISE PRESCRIPTION FOR SPECIAL POPULATIONS

With rare exception, everyone should be physically active. However, physical limitations and safety issues sometimes necessitate that the "normal" exercise prescription described earlier be altered. As such, this next section discusses recommendations for children and older adults, pregnant women, and people with some of the more prevalent chronic diseases. This discussion is only introductory in nature; other sources dedicated to the subject of clinical exercise physiology are available and cover a wider variety of chronic conditions in greater detail [16–18]. Exercise prescription for individuals with cardiovascular disease (CVD) and obesity is detailed elsewhere in this book.

Children and Adolescents

Proper physical activity can help develop and maintain a healthy body weight and cardiometabolic risk profile, can reduce symptoms of anxiety and depression, and can instill positive habits that may carry over into adulthood. The Physical Activity Guidelines for Americans recommend that youth accumulate at least 60 min of moderate- and vigorous-intensity physical activity daily [1]. These 60 min should include a combination of aerobic activities (e.g., bicycling, dancing) and short bursts of activity (e.g., playing tag, soccer) as well as activities that promote muscular fitness (e.g., climbing trees or playground equipment) and bone health (impact activities such as running or jumping rope). The Guidelines can be met through structured sports, games, and exercise classes and/or unstructured play.

Adults can facilitate physical activity among youth by providing ample opportunity for participation. Two examples of how to do this are by limiting screen time (television, video games, and computers) and increasing the amount of

time dedicated to physical activity during the school day. Academic performance is not sacrificed when students are provided with opportunities for daily physical activity in school, such as daily recess, physical education classes, or implementation of physically active learning opportunities in other classes [19]. Many youth will choose to be active when given ample opportunity. However, some cohorts that tend to be less active (adolescent girls, obese) may benefit from structured exercise programs that include like peers and focus on a variety of activities that are popular within a given gender and age group (e.g., dance for adolescent girls).

Compared to adults, a couple of physiological differences in children are worth noting. First of all, children sweat less than adults and do not acclimatize to heat exposure as quickly. They also possess a delayed thirst response. Therefore, it is important to gradually expose children to exercise in warmer environments and to emphasize frequent fluid intake (every 15–20 min). Second, adult formulas for maximal heart rate do not apply to children and adolescents, who typically have maximal heart rates of approximately 200–205 bpm. For exercise prescription purposes, however, RPE scales tend to work well with older children (>8 years old) [20].

Older Adults

Among older adults, proper physical activity can increase and maintain physical function, improve and maintain body composition, promote psychological and cognitive well-being, and assist in primary and secondary prevention of chronic diseases. Keeping in mind that exercise intensity is relative (e.g., a given walking speed may be considered light for one person and vigorous for another), the physical activity guidelines are essentially the same for adults over the age of 65 years as they are for middle-aged and younger adults [1]. Frail persons, who may have difficulty meeting the guidelines, should practice as much physical activity as they can tolerate with the goal of safely advancing their physical activity into the range recommended for the general population.

In addition to the same endurance and resistance exercise advocated for the general population, older adults at risk for falling should add exercises 2–3 days/week that focus on balance. While a wide variety of such activities exist, the ones performed should focus on a person's particular needs. Examples include walking sideways and backward, repetitively standing and sitting, standing with eyes closed, tai chi, etc. Previously inactive seniors, in particular, may benefit from the services of a properly credentialed personal trainer or exercise class in the beginning stages of an exercise program.

Pregnancy and Postpartum

Proper physical activity during pregnancy may help prevent excessive weight gain, gestational diabetes, and pregnancy-induced hypertension. When proper precautions are followed, very little risk is associated with exercise. On average, women who exercise throughout pregnancy may deliver a few days earlier and have babies that are a few ounces lighter. However, there is no evidence that properly practiced exercise leads to preterm deliveries or low-birth-weight babies. Absolute (exercise under no circumstances) and relative (exercise only when benefits outweigh risks) contraindications and warning signs to terminate exercise as published by the American College of Obstetricians and Gynecologists (ACOG) are listed in Tables 16.5 and 16.6, respectively [21].

TABLE 16.5
Absolute and Relative Contraindications to Aerobic Exercise during Pregnancy

Absolute Contraindications

- Hemodynamically significant heart disease
- Restrictive lung disease
- Incompetent cervix/cerclage
- Multiple gestation at risk for premature labor
- Persistent second- or third-trimester bleeding
- Placenta previa after 26 week gestation
- Premature labor during the current pregnancy
- Ruptured membranes
- Preeclampsia/pregnancy-induced hypertension

Relative Contraindications

- Severe anemia
- Unevaluated maternal cardiac dysrhythmia
- Chronic bronchitis
- Poorly controlled type 1 diabetes
- Extreme morbid obesity
- Extreme underweight (BMI < 12)
- History of extremely sedentary lifestyle
- Intrauterine growth restriction in current pregnancy
- Poorly controlled hypertension
- Orthopedic limitations
- Poorly controlled seizure disorder
- Poorly controlled hyperthyroidism
- Heavy smoker

TABLE 16.6
Warning Signs to Terminate Exercise while Pregnant

- Vaginal bleeding
- Dyspnea prior to exertion
- Dizziness
- Headache
- Chest pain
- Muscle weakness
- Calf pain or swelling (need to rule out thrombophlebitis)
- Preterm labor
- Decreased fetal movement
- Amniotic fluid leakage

The Physical Activity Guidelines for Americans [1] recommend that previously inactive women progress to at least 150 weekly minutes of moderate-intensity physical activity. In addition, within reason and in consultation with their physician, women who are already practicing vigorous-intensity aerobic activity may continue to do so during pregnancy as long as no warning signs occur (e.g., vaginal spotting). Although vigorous-intensity physical activity is safe for most previously active women, fetal effects of severe hyperthermia or repeated bouts of hypoglycemia that may result from more prolonged or competitive exercise are unknown. Hence, competitive training during pregnancy requires more precaution and close physician supervision [21].

Due to potential decompression sickness, ACOG recommends that scuba diving not be practiced during pregnancy. In addition, women who plan to expose themselves to higher altitudes (>6000 ft) should be made aware of the signs of altitude sickness at which they should terminate exercise, descend from the altitude, and seek medical attention. Sports and other activities with the potential for contact or falling should be avoided, especially as the pregnancy progresses. Also, supine exercise can inhibit venous return and is contraindicated after the first trimester. Women at risk or with a history of preterm delivery should reduce their physical activity during the third trimester [21].

The American College of Sports Medicine advocates resistance training during pregnancy to a point of moderate fatigue [7]. Such training has been shown to reduce insulin requirements in women with gestational diabetes [22,23]. However, little research has been performed to determine the effects of more intense resistance exercise, particularly practicing of the Valsalva maneuver (holding one's breath during exertion) or prolonged or intense contractions involving the abdominal muscles. ACSM recommends avoidance of the Valsalva maneuver after the first trimester [7].

During the postpartum period, regularly practiced physical activity may reduce excessive weight gain and/or lessen depressive symptoms. In lactating mothers, moderate-intensity exercise does not significantly affect breast milk content or volume or their infants' weight gain [24]. In addition, a combined aerobic and resistance training program was shown to decrease bone mineral loss in lactating mothers [25].

Nearly all women without postpartum complications are able to resume leisure-time physical activity by 6 weeks following delivery, if not much sooner. However, earlier physical activity should begin at a low intensity and duration and should progress gradually, particularly in women who deliver via caesarian section.

Diabetes Mellitus

Both type 1 and type 2 diabetes mellitus are characterized by abnormally high blood glucose levels. Since physical activity facilitates glucose uptake by skeletal muscle, it can serve as an important mechanism of managing glucose concentration in either disease. In addition, through its effect on weight management, an adequate amount of physical activity (combined with a prudent diet) may assist in partial or, more rarely, full reversal of type 2 diabetes. Proper physical activity can also improve one's CVD risk profile. Exercise can also be an effective means of preventing diabetes onset in people with impaired glucose tolerance [26].

TABLE 16.7
Criteria for Electrocardiographic Stress Testing before Exercise Training Participation in Diabetes Patients

1. Age >40 years, with or without cardiovascular disease risk factors other than diabetes
2. Age >30 years and
   a. Type 1 or 2 diabetes of >10 years in duration
   b. Hypertension
   c. Cigarette Smoking
   d. Dyslipidemia
   e. Proliferative or preproliferative retinopathy
   f. Nephropathy including microalbuminuria
3. Any of the following, regardless of age
   a. Known or suspected coronary artery disease, cerebrovascular disease, and/or peripheral artery disease
   b. Autonomic neuropathy
   c. Advanced nephropathy with renal failure

Since diabetics are at increased risk for CVD, they should undergo a physical examination before engaging in vigorous-intensity exercise. Recommended criteria for electrocardiographic stress testing before exercise training [27] are listed in Table 16.7. Although many type 1 and 2 diabetics participate independently in exercise and sports, it is recommended that novices begin training with a qualified exercise specialist, particularly when resistance training is involved, in order to avoid injury and blood glucose abnormalities that are more likely to occur in persons with diabetes [27].

Chronic hyperglycemia can lead to neural, retinal, and circulatory damage that can present special problems during and as a result of exercise in persons with more advanced diabetes. Silent ischemia may be present in persons with underlying CVD. In addition to having proper screening for CVD, such patients need to be aware of other warning signs of CVD (e.g., dizziness, unusual shortness of breath). In addition, advanced neuropathy may cause a diabetic patient to be oblivious to foot ulcerations, which are more common due to microcirculatory damage. Therefore, diabetic patients should always exercise with clean, dry socks and proper fitting footwear. In addition, they should check their feet daily for blisters and ulcerations. Non-weight-bearing exercises should be practiced in persons with foot injuries or open sores [27]. Thermoregulation can also be impaired in persons with advanced diabetes, so particular precaution (e.g., keeping extremities warm, proper hydration) should be practiced in cold and hot weather.

Due to the risk of intraocular hemorrhage, diabetic patients with retinopathies should be carefully screened before participating in exercise. High impact activities (including running)

and high-intensity activities are not recommended. In addition, although it can be very beneficial in helping manage blood glucose, higher intensity resistance training that causes straining on the participant's part is contraindicated due to high increases in blood pressure [27].

Maintenance of a proper blood glucose concentration is important during and following exercise. As long as they are feeling well, type 2 diabetics may exercise with elevated glucose levels (>300 mg/dL) [27]. However, type 1 diabetics should not exercise in this condition (or with glucose >250 mg/dL and presence of ketone bodies), as this represents insulin deficiency and exercise will likely exacerbate the hyperglycemia.

Hypoglycemia is a more common incident during and following exercise. As such, proper balance and timing of exercise, diet, and medication is important. Due to increased glucose uptake during exercise, insulin or insulin secretagogue doses may need to be decreased in both type 1 and 2 diabetes patients, particularly in the hours preceding exercise. Exercise should not be practiced during times of peak insulin uptake and insulin injections during the hours before exercise should not be in the vicinity of the exercising muscles. To avoid nocturnal hypoglycemia, it is best not to exercise within a few hours before bedtime. However, if this must be done, a carbohydrate snack should be ingested before going to sleep. In addition, carbohydrates (5–30 g) should be consumed following intense or prolonged exercise. Persons taking insulin or insulin secretagogue should consume a carbohydrate snack before participating in physical activity if their glucose level is <100 mg/dL [27]. Regardless of medication type, all diabetic patients should be aware of hypoglycemic symptoms (weakness, nervousness, etc.).

With some important alterations, the exercise prescription for persons with diabetes should be very similar to that for healthy adults. Overall volume of physical activity should be 150 min/week or greater, recognizing the importance of a dose–response relationship, especially as far as weight management is concerned. Although previous inactive persons should begin exercise at a moderate intensity, progression to mostly vigorous-intensity exercise may lead to a greater improvement in blood glucose concentration [28]. Since exercise-induced alterations in insulin sensitivity can begin to reverse within a few days on inactivity, it is recommended that no more than 2 days of inactivity be allowed between exercise bouts [27]. In fact, daily, or near-daily, physical activity of similar intensity and duration can be useful in maintaining a balance among the glycemic effects of physical activity, diet, and medications. Due to beneficial effects on insulin sensitivity, resistance training is recommended at least 2, and preferably 3, days/week in patients without retinopathies [27]. With both aerobic and resistance training, increases in exercise volume should occur gradually to avoid disruptions in glycemic control.

Finally, although cardiac reactivity to physical activity should be normal in most diabetics, autonomic neuropathy may result in a blunted heart rate response in some patients. Unless a maximal heart rate has been obtained through graded exercise testing, calculation of a target heart rate using an age-predicted maximum is inappropriate in patients with known or suspected neuropathy. Use of subjective feelings of exertion should be employed instead.

Cancer

Whether currently undergoing treatment or in remission, regular physical activity can yield both physiological and psychological benefits for most cancer patients. Physical activity can help reduce the decline of functional capacity during treatment. Even during palliative care, properly practiced physical activity may prolong independent function and can reduce depressive symptoms and generate a greater sense of control. During recovery, in addition to contributing to a faster and more complete restoration of physical function, proper physical activity can reduce the chances of the reoccurrence of certain cancers, particularly those of the breast and colon. Additionally, since some cancer treatments increase the likelihood of future CVD and diabetes, the practice of physical activity is important in the management of cardiometabolic risk.

Exercise prescription should vary based on the type and severity of cancer. Since the side effects of cancer treatments can in some cases be nearly as severe as the disease itself, the type and time course of treatment should be taken into account as well. Similarly, during recovery, a person's capacity to exercise will be affected by any tissue damage they encountered due to the cancer and treatments and how far they are into remission.

McNeely et al. have published a list of suggested contraindications to exercise testing and training that has been adopted by ACSM [7,29]. In summary, these contraindications include platelet counts <50,000, white blood cells <3000, hemoglobin <10 g/dL, fever >100°F (38°C), resting heart rate >100 or <50 bpm, resting systolic blood pressure >145 or <85 mm Hg, and resting diastolic blood pressure >95 mm Hg. Also included as contraindications are more severe subjective side effects of cancer and its treatments, including severe cachexia, bone/joint pain (particularly in spinal region), declines in functional status (strength, balance, etc.), gastrointestinal disorders (vomiting, diarrhea, severe nausea, etc.), and cardiovascular and pulmonary symptoms (chest pain, severe dyspnea, etc.). Exercise should also be avoided on the day of intravenous chemotherapy and within 24 h after treatment. A more complete list of these contraindications appears in the referenced sources [7,29].

Due to a wide variety of cancers and treatments, there are numerous potential precautions to take when prescribing exercise. In general terms, exercise prescription and progression needs to be highly individualized and should vary day-to-day as the patient deals with the side effects of their treatments and the disease itself. Fatigue will commonly persist for days, and often for weeks or more, following chemotherapy and radiation. Although exercise is generally good for bone health, bone of cancer patients may be more susceptible to fracture due to radiation therapy and/or cancer metastases.

As such, higher impact activities should be avoided during cancer treatment and, if desired, should be introduced very gradually during recovery. Due to the risk of contamination, bone-transplant patients and patients with low white blood cell counts should take care to exercise in a clean environment. Also, although water exercise can be very beneficial to some patients, it should be avoided in those with indwelling catheters or central lines and feeding tubes and for those receiving radiation. In addition, patients undergoing radiation therapy may develop severe skin irritations. Therefore, comfortable clothing should be worn and the skin should be kept dry and clean during and after exercise [7].

ACSM recommends that cancer patients perform aerobic physical activity at 3–5 days/week for 20–60 min. Although a moderate-intensity of 40%–60% $VO_{2reserve}$ or $HR_{reserve}$ is recommended, some patients will find this difficult and should adjust their intensity accordingly. One to three sets of 10–15 repetitions of resistance exercise at 40%–60% 1RM are recommended on two to three nonconsecutive days per week. Flexibility training, which can be particularly beneficial following some surgeries, is recommended 2–7 days/week. Four repetitions of 10–30 s are suggested [7]. With the exception of high-impact activities, a wide range of exercise types can be used to meet a patient's goals. In addition, some exercise modalities, such as tai chi, offer the opportunity to complete moderate-intensity exercise in a supportive group atmosphere.

Arthritis

Both osteoarthritis and rheumatoid arthritis result in pain with movement. This often sets up a vicious cycle in which a person moves less due to pain. In turn, stamina and neuromuscular conditioning decline, which can eventually result in a decreased ability to perform activities of daily living. As functional tolerance deteriorates and arthritic pain increases, physical activity levels will most likely decline further, making the individual less functionally tolerant and more susceptible to hypokinetic diseases. As such, a major objective of exercise in individuals with arthritis is to increase and preserve physical function. Although physical activity may acutely cause pain, chronically practiced physical activity can actually reduce joint pain and stiffness, resulting in a higher quality of life. Also, as arthritis is common in overweight and obese individuals, physical activity can also serve as a means of weight control and cardiometabolic disease risk factor management.

Exercise levels recommended for the general population also increase physical fitness and produce health benefits in persons with arthritis [7]. However, certain adaptations may make physical activity more tolerable and increase compliance. While adequate warm-up is important in all cases, it is particularly important with arthritis as the increased blood flow warms the joints and makes movement easier and less painful. Since many arthritic patients experience more stiffness and pain in the morning, exercise later in the day is often wise, especially after morning medications have had time to reach their peak effects. In addition, many patients find warm water (83°F–88°F, 28°C–31°C) exercise to be more comfortable than other environments. Out of the water, proper fitting shoes with adequate stability and cushioning may help prevent excessive knee, hip, and/or back pain. Custom-made orthotics may be beneficial for persons with biomechanical abnormalities.

To increase and maintain functional ranges of motion, flexibility exercises are particularly important for patients with arthritis. Although resistance training can increase strength and stability around affected joints, maximal isometric contractions, practiced at a few angles per joint, may be preferable to dynamic contractions in persons who experience higher levels of joint pain. As this becomes less painful, patients can then advance to dynamic exercise with lighter resistance, increasing the resistance as tolerated. With aerobic training, people with more pain and/or less functional tolerance may need to exercise intermittently in the beginning, but should be able to progress to more continuous activity.

Some pain during exercise is to be expected with arthritis. However, if joint pain persists more than 2 h following exercise, the volume of training should be reduced [7]. Pain makes physical activity less enjoyable and is likely to negatively affect exercise compliance. Therefore, patients should not be pushed to a point where they are less likely to continue to stay active.

Disabilities

Depending on the type and extent of disability, proper physical activity may improve physical fitness and functional abilities and may reduce a person's risk for cardiometabolic diseases. The range of disabilities (cerebral palsy, spinal cord injury, stroke, etc.) is too wide to permit a thorough discussion of exercise prescription for each in this chapter. However, a few points are important to remember across many conditions. For example, disabilities resulting in autonomic impairment will yield abnormal cardiovascular responses to exercise and impaired thermoregulation. Therefore, perceived exertion may be a better gauge of exercise intensity and special precaution should be taken to prevent hyper- or hypothermia. In addition, adaptions in equipment or clothing may be needed to help persons with particular disabilities perform common exercises. For example, persons with impaired gripping ability may benefit from Velcro gloves when performing resistance exercises or arm ergometry. Shorter bouts of physical activity spread throughout the day may be necessary for persons with very low physical tolerance.

When possible, persons with disabilities should perform the same physical activity recommended for more able-bodied adults [1]. When this is not possible, they should perform as much physical activity as they are able to accomplish without undue fatigue. Aerobic, resistance, and flexibility exercise should all be practiced. Even when exercise tolerance is very low, physical inactivity should be avoided to maintain as much functional independence as possible and to avoid hypokinetic diseases.

SUMMARY

Current physical activity guidelines advocate a well-balanced exercise program to include aerobic, resistance, and flexibility training. To allow for individual preferences and abilities, these guidelines allow a good bit of flexibility among frequency, intensity, and duration of physical activity, as long as a critical overall volume is met. Health and fitness-related benefits can also be obtained with a variety of exercise modalities. The chosen modalities should be safe for a given individual and should be enjoyable to enhance program adherence.

In addition, disease or disability should not inhibit anyone from being physically active. Individuals who are not able to meet the physical activity levels recommended for the general public should still strive to be as active as possible within the confines of any disease or disability. *Everyone* can benefit from physical activity.

The application of psychological theories and models to health behavior change research, program development, and policy has soared in popularity over the past few decades. Desired outcomes are most likely achieved within the context of health behavior change programs that are based on an objective understanding of the target health behaviors and the variables that influence them; theories and models enable researchers and other program developers to organize these variables to achieve these outcomes [1]. Theories and models provide structures for identifying and examining problems, choosing or developing appropriate interventions, and assessing results. They fall within the parameters of the current emphasis on employing evidence-based interventions in the public health, behavioral medicine, and medicine fields [1].

Comprehensive lists and descriptions of theories and models that have been utilized to guide health behavior research have been described extensively elsewhere (refs). We focus here on a select few that have consistently received attention in the health behavior literature, including the following: Health Belief Model (HBM), Theory of Reasoned Action (TRA)/Planned Behavior (TBP), Social Cognitive Theory (SCT), Transtheoretical Model (TTM), and Socioecological Model (SEM). The main components and structures of these theories and models, along with examples of their use in the literature, are described in the sections later.

Many of these theories share some similar or even identical constructs, including the widely adopted concept of self-efficacy, which was coined by the famous psychologist Albert Bandura [2,3]. This construct refers to confidence in one's abilities to successfully perform a particular behavior (i.e., walk 1 mile) despite barriers such as bad weather or a busy schedule. Most incorporate static individual differences (e.g., demographic variables), dynamic individual differences (e.g., mood/affect), and interpersonal factors (e.g., social support), but the degree to which each of these variables is highlighted varies widely from one theory or model to another. Although similarities among the models and theories are clearly apparent, their differences set them apart from one another and make them more or less useful as frameworks through which to understand and/or modify different types of health behaviors. For example, some are more applicable to one-time or short-term health behaviors (e.g., HBM), while others are better suited for longer-term ones (e.g., TTM). An overarching characteristic that differentiates models and theories is their relative focus on the primary force(s) influencing behavior change. Thus, we organize the selected models and theories into three broader levels: individual, interpersonal, and ecological.

INDIVIDUAL LEVEL

Health Belief Model

The HBM [4–6], depicted in Figure 17.1, was initially developed in the 1950s in attempt to understand and explain why many individuals were not participating in preventive health services, even when they were offered at no cost. The HBM proposes that the likelihood that individuals will engage in any given health behavior largely depends on their *perceptions* of the following variables: severity of the illness(es) it helps prevent, their susceptibility to the illness(es), benefits of engaging in the behavior, and barriers to engaging in the behavior. According to the HBM, individuals are more likely to adopt the target health behavior if they believe the potential illness is serious, that they are highly susceptible to it, and that the benefits of engaging in the behavior outweigh

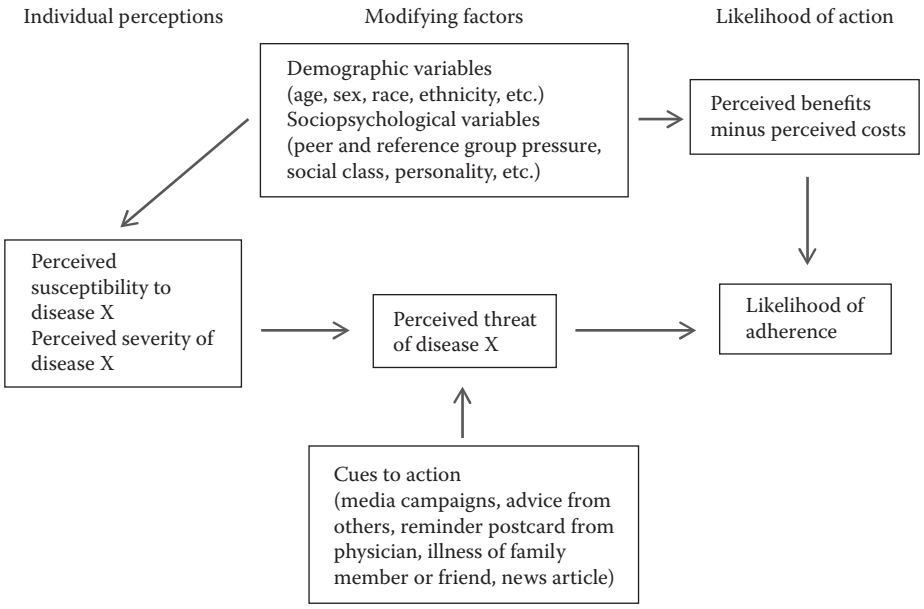

FIGURE 17.1 Health Belief Model.

the associated barriers. The construct "cues to action," which are factors that prompt action (e.g., media campaigns, physician reminders), was later added to the model to increase its explanatory power. Other factors, such as demographic characteristics (e.g., age, race, ethnicity, gender) and psychosocial variables (e.g., peer influence, mood/affect) also exert considerable influence over individuals' decisions to engage in a specific health behavior according to the HBM. Self-efficacy, described as behavior-specific self-confidence [2,3], was also later added to the HBM in attempt to increase its ability to accurately predict health behavior [7]. Self-efficacy was not initially included as an HBM construct because the model was primarily used to predict one-time or short-term health behaviors, such as getting a vaccination or health screening, for which self-efficacy is not particularly relevant. Nevertheless, these modified or extended versions of the HBM have been utilized in relatively recent research examining the model's ability to predict short-term behaviors such as breast self-examination among women with a family history of breast cancer [8] and HPV vaccination initiation among adolescent girls in high risk communities [9].

The HBM has since been applied to longer-term health behaviors and habits, such as exercise, smoking cessation, and dieting, with some success, but it has received significant criticism and has not held up to rigorous scientific examination in these contexts. Indeed, a recent meta-analysis of studies using HBM constructs to longitudinally predict health behavior concluded that utilizing the direct effects model may not be useful because the two primary constructs (perceived severity and perceived susceptibility) only weakly predicted behavior [10].

Although the HBM has been one of the most utilized models in health behavior research [11], many concerns about the model remain. For example, the relationships among the model's constructs are not clearly delineated; measurements of some HBM constructs are not standardized; and some of its constructs (especially "cues to action") are difficult to empirically test [10,12]. Furthermore, other models have exhibited stronger predictive ability of health behavior than the HBM [13]. Thus, although some HBM constructs may be helpful to consider in the prediction of health behavior, the model as a whole may not be particularly useful except in the context of single or short-term behaviors [10].

Theory of Reasoned Action and Theory of Planned Behavior

The TRA, developed by Ajzen and Fishbein [14,15], stems from premises of cognitive and social psychology. The TRA posits that individuals' likelihood of engaging in a particular health behavior can be predicted by the strength of their *intentions* to engage in that behavior. Intentions represent a combination of their own attitudes toward the behavior and their "subjective norms." According to the TRA, attitudes are formed by individuals' beliefs about the consequences of the health behavior and the weight they place on those consequences. Likewise, subjective norms are products of individuals' beliefs about others' expectations of them regarding the behavior and their motivation to comply with those expectations. The TRA is depicted in Figure 17.2.

Research examining the TRA has demonstrated that it is most useful at predicting behaviors under volitional control; however, most behaviors are not completely within an individual's control. Therefore, Ajzen [16] proposed an extension of the TRA called the TPB in attempt to better predict health behaviors. The TPB incorporates TRA constructs and adds a construct called perceived behavioral control, which is defined as individuals' perceptions of their ability to perform a given behavior [16]. The TPB's perceived behavioral control construct is similar to the concept of self-efficacy

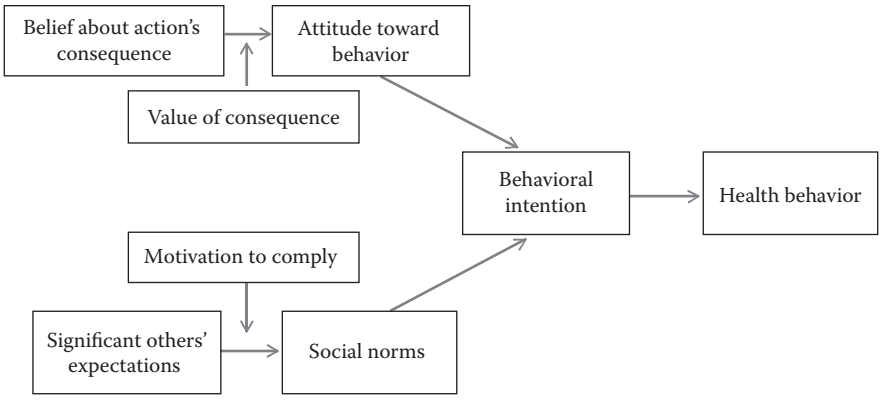

FIGURE 17.2 Theory of Reasoned Action.

[2,3] and defined in terms of control beliefs (the presence or absence of perceived facilitators and barriers associated with a given behavior) and perceived power (the impact of these facilitators and barriers).

Unlike the HBM, the TRA and TPB models clearly delineate the relationships between their individual constructs. As a result, research examining the predictive abilities of these models has generally supported each of them as a whole [13]. However, a major concern about the models is that they do not incorporate any constructs that allow for affective/emotional or psychosocial variability [17], which has also been a noted concern with the HBM [18]. Some have proposed extended version of the TPB to more thoroughly account for the components that are missing from the model, including past behavior, self-identity, and the additional social influence variables of group norms, family social support, friends' social support, and social provisions, without much greater success in the results [19]. Furthermore, the models do not take into account the fact that some behaviors are so habitual that they are not subject to planning or reasoning; in these cases, even the strongest of intentions are not likely powerful enough to overcome the automatic nature of well-established habits [17].

Although the TRA and TPB have received less attention in health behavior research than some of the newer models in recent years, they consistently rank among the most utilized theories in the field and demonstrate considerable predictive value [20]. The TRA and/or TPB have been used as guiding frameworks for assessing, understanding, and influencing behavior change in diverse populations with a variety of health behaviors, such as female condom use among Chinese sex workers [21], safer sex intentions and protected sex among heterosexual, HIV-negative methamphetamine users [22], family meal frequency among adolescents [23], fruit and vegetable consumption [24], and physical activity maintenance [25], among others.

INTERPERSONAL LEVEL

Social Cognitive Theory

SCT is one of the most robust health behavior change theories [26,27]. It evolved from Social Learning Theory [26,28], and originally focused on observational learning, or learning by watching others' behavior (also called modeling) and the reinforcements (both positive and negative, internal and external) that help determine whether or not one will repeat the behavior. Updated by Bandura and colleagues, SCT posits that behavior change is influenced by internal individual factors (e.g., cognitive, affective, biological) as well as the social and physical environment. The model is reciprocal in that each of these factors affects the others in a continuous, dynamic feedback loop (Figure 17.3) [26].

Self-efficacy is the main construct of SCT [29] and, as mentioned previously in this chapter, a powerful predictor of behavior change that has been incorporated into numerous social and behavior science theories [26,27]. Self-efficacy beliefs have been strongly associated with actual performance of a diverse range of health behaviors [30,31]. According to Bandura, self-efficacy can be increased through mastery experiences, social modeling, improving physical and emotional states, and verbal persuasion [27]. Mastery experience is gained through succeeding in attainable, yet increasingly challenging health behavior change goals and is considered to have the strongest influence on self-efficacy beliefs [26,27,32]. Modeling, as previously discussed, can be

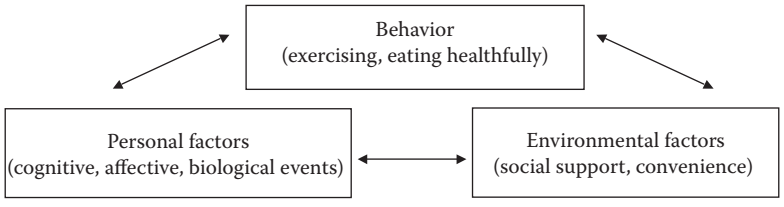

FIGURE 17.3 Reciprocal determinism.

accomplished by watching others perform the desired behavior; it is especially effective when relatable peer(s) perform the behavior. Finally, maintaining an optimal level of physiological intensity (i.e., excited but not too anxious) for performing the behavior, which can be accomplished by using relaxation techniques and positive self-talk as well as receiving encouragement from others, can increase self-efficacy [26,27,32].

Self-regulation strategies are also used to enhance confidence for behavior change and typically begin with self-monitoring, or systematically observing, one's current health behaviors [27]. Data are collected with pedometers, food diaries, smoking logs, or other tools, depending on the health behavior(s) being targeted. These objective data can then be reviewed to determine how specific health behaviors might be improved and to identify incremental and long-term behavior change goals. Overlapping to a degree with the concept of mastery experience, self-regulation can also include establishing rewards for meeting behavior change goals and enlisting social support from family and friends for performing target behaviors [27].

Another important determinant of behavior according to the SCT is outcome expectancies [26]. This construct, defined as the influence that the outcomes anticipated from a health behavior exert on one's willingness to perform this behavior, makes intuitive sense and has been supported in numerous research studies [33]. SCT posits that a health behavior is more likely to be performed if positive outcome expectancies are present, whereas negative outcome expectancies reduce the likelihood of the health behavior. For example, individuals will be much more inclined to run a mile if they anticipate that doing so will energize them rather than cause them to feel sore. The relative value of the anticipated outcome also plays an important role in this decision-making process. For example, an individual may view a positive anticipated outcome of smoking a cigarette (feeling more relaxed) as less important than a negative anticipated outcome (smelling like smoke) and thus decide accordingly to forgo the cigarette.

SCT offers a comprehensive model of the behavior change process. Some critics suggest that this model is overly broad and has not been tested as a whole in the way other theories are routinely examined [27]. Rather, studies have shown that specific SCT concepts (e.g., self-efficacy) are associated with behaviors, but such research does not confirm the entire theory. Nevertheless, the SCT provides a strong foundation for health promotion research and practice, using numerous strategies to address diverse public health issues. Furthermore, SCT has been successfully applied to a variety of health behaviors (e.g., cardiovascular disease [34–38], cancer screening [39], tobacco use [40–43], alcohol use [28,44–46], diet [47,48], obesity [49], physical activity [33,47,48,50,51], diabetes prevention [52], condom use [53,54]) in a wide range of ages (including children [48], teens [45], and elderly [51]) and underserved populations (e.g., African Americans [41], Latinas [49,52], low-income individuals [48,49]), and in several different countries (mostly in the United States, but also in China [53], Sweden [48], and Australia [51]).

Transtheoretical Model

The TTM is an integrative model of behavior change developed from many different psychological theories, such as SCT [55] and Learning Theory [28,56]. Prochaska and colleagues first described this model after noting that people vary in terms of motivational readiness to quit smoking [57] and move through specific stages of motivational readiness along the path to behavior change [58]. The five stages of change that form the core of the TTM are

- Precontemplation, in which change is not being considered
- Contemplation, in which change is being considered
- Preparation, in which an individual takes small steps toward change
- Action, in which the health habit has been recently adopted
- Maintenance, in which the change has been sustained for ≥6 months

This model is considered cyclical, accounting for people's tendency to move back and forth through these stages of change. Individuals may lose resolve and abandon new behavior patterns, feel guilty, lose confidence, and revert to their previous routines, with probable recycling through the earlier stages of precontemplation or contemplation. Thus, numerous cycles through the stages often happen before an adopted health behavior becomes a habit [59,60].

The cognitive and behavioral strategies and techniques that people use to advance through these stages of change are described as processes of change (see Table 17.1). The TTM posits that people use different processes of change at different stages in the change process and are likely to benefit from interventions developed specifically for their level of motivational readiness and most relevant to their current information needs [26,60]. For example, to help move individuals from precontemplation to contemplation, processes such as consciousness raising and dramatic relief should be attempted, whereas people in the action stage are more likely to find contingency management, counterconditioning, and stimulus control helpful [59].

TABLE 17.1
Pros (Advantages) and Cons (Disadvantages) of a Health-Related Behavior: The Example of Exercise

Pros

- I would be healthier if I exercised more regularly.
- I would feel better about myself if I exercised more regularly.
- Other people would respect me more if I exercised more regularly.

Cons

- I would probably be sore and uncomfortable if I exercised more regularly.
- If I exercised more regularly, my family and friends would get to spend less time with me.
- I would feel that I was wasting my time if I exercised more regularly.

TABLE 17.2
Processes of Change within the Transtheoretical Model

Process	Definition
Consciousness raising	Increasing information about self and problem
Self-reevaluation	Assessing how one feels and thinks about oneself with respect to a problem
Self-liberation	Choosing and commitment to act or belief in ability to change
Counterconditioning	Substituting alternatives for problem behaviors
Stimulus control	Avoiding or countering stimuli that elicit problem behaviors
Reinforcement management	Rewarding oneself or being rewarded by others for making changes
Helping relationships	Being open and trusting about problems with someone who cares
Dramatic relief	Experiencing and expressing feelings about one's problems and solutions
Environmental reevaluation	Assessing how one's problem affects physical environment
Social liberation	Increasing alternatives for nonproblem behaviors available in society

Theoretical constructs, such as self-efficacy and decisional balance, also play important roles in the adoption and maintenance of health behaviors according to the TTM [26,59,60]. The decisional balance construct comes from Janis and Mann's Decision-Making Theory [61] and involves weighing the perceived advantages and disadvantages of behavior change when deciding whether to adopt a new health behavior. Table 17.2 lists examples of perceived benefits (the "pros") and perceived costs (the "cons") of physical activity. A standardized "decisional balance" score may be derived by subtracting total standardized cons scores from total standardized pros scores [62]. Decisional balance has been shown to vary as a function of stage [58,62,63]. Early stages (precontemplation and contemplation) are associated with higher ratings of disadvantages (cons) and lower ratings of advantages (pros) of change, whereas later stages (action and maintenance) are associated with lower ratings of disadvantages (cons) and higher ratings of advantages (pros) of change [59].

Although the TTM originated in the addictions research field, it has since been applied to numerous health behaviors (e.g., fruit and vegetable consumption [64], weight control [65], condom and oral contraceptive use [66,67], sunscreen use [68], medical compliance [69], cervical cancer and mammography screening [70,71], stress management [72], intimate partner violence [73,74], and exercise [75,76]), in diverse populations (e.g., college students [77], African American adolescents [64], and patients with severe mental illness [78], tuberculosis [79], HIV [80], and multiple sclerosis [69]), and in many countries (e.g., Taiwan [71], Nepal [80], Malaysia [79]).

However, several criticisms of this model have been raised [81,82]. For example, the complexity of health behaviors is an issue when considering stage-based behavior change theories. Staging algorithms typically ask about physical activity or diet in general, but motivational readiness for change may vary for subcategories not fully captured by these algorithms (e.g., interested in walking and vegetable consumption but not strength training or reducing fat intake). The TTM also focuses on stage progression as a significant outcome but this is not always associated with actual behavior change [83,84]. Nevertheless, the TTM has been a highly influential theoretical framework comprised of a number of useful organizing constructs that have been shown to be meaningfully related in empirical data and psychometric studies.

ECOLOGICAL LEVEL

Socioecological Model

In more recent years, psychological theories and models have increasingly incorporated the broader contexts that affect health behaviors, recognizing that these external factors are often as influential as internal factors [85–87]. Social ecological models are based on four fundamental principles that are critical to understanding their application to health behavior change [88–90]: (1) the environmental and personal factors that influence health behavior dynamically interact with each other; (2) environments are multidimensional and complex; (3) people are multidimensional and complex, and intervention designs should consider both the individual and the groups with which the individual is affiliated; and (4) people–environment interactions exert multiple levels of influence, such that individuals often modify their settings, and social features of settings influence individuals. The social ecological framework suggests that both person-focused and environment-focused strategies can be applied to health behavior change [89]. For example, person-focused strategies may include preventive screening programs, individual counseling, or participation in lifestyle interventions. Environmental strategies include both geographic (e.g., mixed use communities) and sociocultural (e.g., integrating target health behaviors into organizational structures/cultures) aspects.

The SEM has recently grown tremendously in popularity, particularly in the public health realm. The SEM differs from more traditional psychological models in that it explicitly incorporates not only the individual's immediate external influences (e.g., interpersonal relationships) but also more peripheral factors (e.g., community, environment). Furthermore, rather than predicting a specific order or direction in which influences exert themselves, the SEM depicts the individual in the center of increasingly broader circles of influence, which interact with one another in an ongoing process (see Figure 17.4).

The SEM has been applied in assessment and intervention research on a variety of health behaviors and/or in diverse populations, including fruit and vegetable consumption among low-income African Americans [91], church-based health promotion interventions [92], physical activity

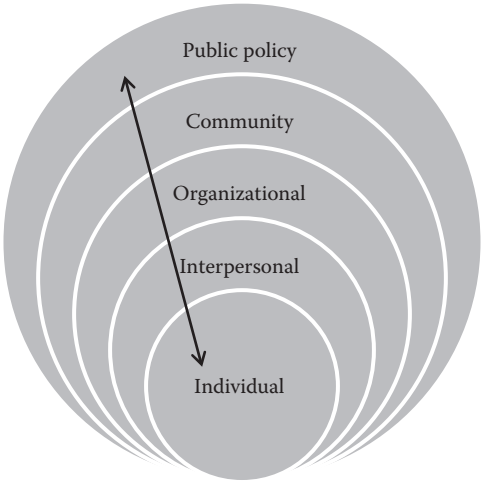

FIGURE 17.4 Socioecological Model.

promotion and fruit and vegetable intake [93], and physical activity assessment within a variety of different populations [94–96], among others.

As with all of the aforementioned models and theories, some challenges arise in the application of the SEM to health behavior change interventions. Because the model is exceptionally comprehensive, its application is inherently complex. For example, addressing the SEM's multiple levels of influence, including regional (e.g., neighborhoods), structural (e.g., the physical environment), and institutional (e.g., government, worksite, family) factors, on health behaviors is challenging due in large part to limitations on control over these external variables. In addition, additional research is required to help determine which of the model's multiple components are critical in the behavior change process. Despite its complexity, the SEM appears to be a promising model for an increasingly multidisciplinary scientific community.

SUMMARY

In this chapter, we summarized only a few of the numerous psychological models and theories that guide health behavior change interventions. We chose to focus on some of the most frequently utilized models and theories in the literature as well as to represent the range of general categories by which they are organized (i.e., individual, interpersonal, ecological). Over the past few decades, the fields of behavioral medicine, public health, and medicine (among others) have been gradually shifting from a sole focus on the individual to a progressively greater focus on the local and, to a growing extent, global environment in which the individual resides [1,88]. Although this shift recognizes and better accounts for the increasingly globalized world that undoubtedly influences individuals' behavior more than ever before, these new ecological models and theories are quite complex and somewhat generic [88–90]. Their numerous and relatively broadly defined variables are often difficult to measure, rendering these models as a whole difficult to assess. However, they relieve individuals of at least some of the overwhelming amount of personal responsibility placed on them by the individual and, to a somewhat lesser but still significant extent, interpersonal models and theories, which explicitly or implicitly assert that individuals should engage in target health behaviors regardless of the external barriers they may face. Moreover, the health problems and challenges for which health behavior change interventions are designed have also shifted from primarily acute and/or short-term illnesses (e.g., deadly viruses and infections) to predominantly chronic diseases (e.g., cardiovascular disease and diabetes). As mentioned previously, one-time or short-term problems appear to be adequately addressed by the individual-focused theories and models, whereas interventions for longer-term problems are more appropriately designed using interpersonal (and presumably ecological) ones.

Many other theories not included in this chapter also incorporate key concepts that help explain and predict health behaviors. Perhaps the two biggest challenges facing the various disciplines involved in health behavior change research are (1) to match specific goal health behaviors with the models and theories that incorporate the most relevant and appropriate constructs in order to design and implement effective interventions and (2) to systematically incorporate and account for the wide range of ecological factors that clearly influence health behavior to an increasingly greater extent in the modern, global world.

Physical activity research has led to many developments in the understanding of the benefits of activity in prevention, risk reduction, and improvements in health. By the end of the twentieth century, progress had been made in understanding correlates of regular activity; numerous randomized clinical trials (RCTs) had compared theoretically based interventions, particularly those based on cognitive and behavioral approaches with control conditions; and programmatic and lifestyle-based activity had been integrated into public health guidelines. Despite this compelling evidence for the benefits of physical activity and progress in research approaches, physical activity levels typically remained low in most population subgroups [1,2].

Over the past decade, much work has been done to extend the understanding of optimal approaches to physical activity promotion. Numerous reviews [3–6], meta-analyses [7,8], and well-controlled individual studies have enhanced understanding of intervention components that appear to be consistently effective in promoting physical activity participation. Since the publication of the previous version of this chapter, nearly 40 reviews and multiple meta-analyses related to exercise interventions have been published. Randomized trials have been extended to clinical populations and real-world community settings.

In this chapter, we will provide an overview of the findings reflected in these reviews and seminal studies. The aim of this chapter is to describe the domains of exercise intervention that have emerged in the past 10 years and describe their translation in real-world settings. When conclusions may be reached from the existing literature, we will highlight for whom the approaches work and in what circumstances. Novel and emerging approaches will also be described, including the use of technology, expanding approaches to conceptualizing physical activity evaluation, dissemination of interventions by peer leaders, and recent applications of newer frameworks to enhance outreach. Our purpose is to illustrate the intervention approaches that have had demonstrated efficacy in promoting exercise and physical activity in clinical and health-promoting settings and summarize the conclusions of key quantitative and qualitative reviews. We focus on interventions that are based on scientific studies of behavior and cognition. These interventions emphasize the manipulation of observable environmental and person characteristics, but they also include internal states and

cognitions that, although not directly measureable, can be inferred from observations and self-reported by individuals. We do not attempt to provide another critical review of the literature, since timely reviews are already available for the interested reader.

OVERVIEW OF EMPIRICALLY SUPPORTED BEHAVIORAL AND COGNITIVE INTERVENTIONS FOR PROMOTING PHYSICAL ACTIVITY

A 2011 systematic review was conducted of existing reviews of intervention components associated with increased effectiveness in diet and physical activity interventions [5]. Of several thousand articles identified, 30 met the stringent criteria for detailed review. In this review, outcome measures included weight, weight loss, and diet in addition to physical activity. Evidence grades were assigned to each reported analysis, using the Scottish Intercollegiate Guidelines Network (SIGN) system to take methodological quality into account. The physical activity outcomes examined were quantified changes, as measured by objective means such as accelerometer or by self-report or by changes in cardiorespiratory fitness. Consistent with previous reviews [2] and with behavioral theory [9], *self-monitoring*, *specific goal setting*, *feedback on performance*, and *goal review* were found to be associated with greater intervention effectiveness. *Prompting* practice of activity and *individual tailoring* via provision of information or counseling on intervention content were supported as specific intervention behavior change techniques resulting in increased activity.

An additional recent review of physical activity interventions [7] utilized meta-analysis with a focus on activity outcomes in healthy adults. This review was unique because it was not limited to randomized trials and thereby avoided publication bias (some limitations of this approach are evident in our later discussion). Thus, this meta-analysis included diverse interventions, ranging from group education focused sessions to supervised activity sessions, and inclusion of a variety of experimental designs and both published and nonpublished studies. Notably, nearly 100,000 activity intervention study participants' data were examined. The vast majority of participants were middle-aged (median of the mean age was 44 years), were predominantly women (74%), and were rarely ethnic minority (14% among studies that reported this information). The inclusive nature of this review highlighted the wide array of intervention approaches being undertaken—interventions ranged from very brief (a single motivational contact) to intensive supervised activity sessions spanning many weeks. Examination of effect sizes generally supported the conclusions of the previously described review [5], that is, behavioral strategies such as *goal setting*, *contracting*, *self-monitoring*, and *using cues or rewards* were effective in increasing physical activity. Contrary to other study summaries, the review concluded that use of the Social Cognitive Theory [10,11] and Transtheoretical Model [12] and cognitive strategies were ineffective in promoting activity. However, it should be noted that the authors' approach to grouping cognitive interventions probably differed from the cognitive approaches subsumed under this category by including basic health education and provision of information. Health education did not increase effect size. *Face-to-face delivery* of interventions had better effect size than did *mail and phone delivery*. The presence of *supervised exercise* in the intervention was associated with better physical activity outcomes in dichotomous moderator analyses, but this finding was not supported in supplemental analyses that examined multiple moderators. Interventions delivered by *dedicated project staff* (vs. *train-the-trainer* models), *modeling of the activity* by research staff, and *standardized interventions* (vs. individually tailored interventions) were also supported.

EXTENDING WORK ON BEHAVIORAL APPROACHES TO PHYSICAL ACTIVITY PROMOTION

Expanding Self-Monitoring to Include Imagery and Motivation

Studies have consistently documented the important role that goal setting and self-monitoring can play in physical activity interventions. A challenge to current studies utilizing this and related behavioral strategies is to learn how to further optimize the process of self-regulation in order to maximize intervention approaches. A recent study provides an example of using theory to create novel monitoring intervention approaches. Using self-regulation theory as a guide, Chan and Cameron used mental imagery related to physical activity to promote physical activity goal-directed behaviors in 182 sedentary adults [13]. In this RCT, participants received training in one of two types of activity-related imagery or neutral imagery over a 4 week period and were assigned daily practice. The physical activity imagery consisted of approach imagery (attainment of desired goal states) or process imagery (steps for enacting behavior). Approach imagery was associated with increased approach motivations for physical activity at Week 4 as well as greater intentions for activity and more action planning and facilitated more physical activity at Week 4 via action planning. These findings offer promise for novel low-cost approaches to enhancing self-monitoring and goal setting.

Including Sedentary Behavior as an Intervention Target

An additional behavioral approach to physical activity intervention that has emerged is a focus on reduction of sedentary behavior as a target outcome. Time watching television (TV), time sitting in cars, and general sitting have all been found to be associated with premature mortality and compromised metabolic function, even in physically active

adults [14]. It has been recommended that interventions target breaking-up periods of sedentary time in order to reduce health risks [14]. An intervention study aimed at reducing sedentary time was conducted with older adults since this age group has the highest level of sedentary behaviors and exhibited associations between overall sitting and television time and metabolic syndrome in previous research [15]. Participants were 59 men and women age 60 years and older, who reported watching TV for at least 2 h/day, were not currently employed for pay, and were ambulatory. A pre/post-experimental design was used. The intervention had a key message to stand up and move after 30 min of uninterrupted sitting. Intervention approaches included aspects of Behavioral and Social Cognitive Theory [10,11] (goal setting to reduce sedentary time and increase the number of breaks in prolonged sedentary time, self-monitoring of sedentary time and goals, enhancing self-efficacy and outcome expectancies, formulation of a behaviorally specific action plan, rewards for behavior change) as well as identifying alternative preferred nonsedentary activities. Participants used an activity workbook and sedentary time was assessed with accelerometers and sedentary time feedback provided along with comparison to a normative sample of similar age and gender. Results indicated that reach was 87.5% of those screened and met inclusion criteria. Participants reported high satisfaction with the intervention on a single-item rating. Findings highlight the feasibility of this brief approach and the compatibility of integrating behavioral and cognitive strategies into interventions targeting sedentary behavior.

NEW APPROACHES TO ENHANCING BEHAVIORAL ASSESSMENT AND INTERVENTION

Using Emerging Technology to Enhance Self-Monitoring

Self-monitoring theory has developed alongside various techniques to facilitate its implementation in physical activity assessment and intervention. The traditional use of activity self-management techniques such as activity session diary keeping has given way to electronic monitors. Pedometers, accelerometers, and handheld (palmtop) computers have been widely used to assess physical activity levels in research and clinical interventions, often to assess the feasibility of the now-heuristic recommended exercise dose of 10,000 steps/day. A review by Choi et al. noted that it is often difficult to accrue this level of activity with routine daily activity and that pre-intervention deficits of approximately 4000 steps/day (typical range of 3000–6000) are observed [16]. The systematic review of existing literature reviews of intervention components referenced earlier [5] noted three reviews that examined activity interventions that incorporated pedometers. Causal evidence supported their role in increasing walking. Reviews indicated that the median weeks of study were 11, with an average increase of 2004 steps/day and median walk time increase of 54 min/week. It is noted in this systematic review that most of the interventions reviewed in meta-analysis articles also included goals related to steps and/or diaries in addition to pedometers, highlighting the self-monitoring aspect of pedometer use. A meta-analysis by Bohannon reaffirmed the utility of pedometer-based physical activity assessment, citing the immediate feedback for exercisers and readily available normative values as primary benefits [17]. Bennett et al. sought to explore the feasibility of pedometer use in a randomized controlled trial of a multiethnic sample of adults residing in public housing [18]. Participants were 433 black, Hispanic, predominantly female participants of low socioeconomic status. The study demonstrated the utility of pedometer-based methodology among lower income population-based samples. Findings were consistent with other pedometer-assessed activity levels in community samples and indicated a largely sedentary lifestyle of an average of 5300 steps/day. Studies using this approach to assessment of activity have been primarily restricted to walking and lifestyle behavior. Findings suggest that pedometers may play a role in enhancing monitoring and may also be a convenient approach that may circumvent difficulties inherent in reliance on self-reported physical activity information.

While the past decade has seen an increase in the use of activity pedometers and their efficacy has largely been supported, this methodology has limitations—most importantly, the inability to measure intensity or duration in an account of accumulated physical activity [18]. Accelerometry offers the benefits of accounting for amount, frequency, and duration of physical activity, along with estimates of energy expense and exercise schedule. This may be used to enhance exercise participation, if integrated into the interventionist's approach in a way that resembles pedometer use. However, a review by Murphy notes that the approximations made by accelerometers do not account for various walking conditions and placement [19]. In addition, the data produced by accelerometers can take more time to analyze and relay to the exerciser than that produced by pedometers. Other methodologies circumvent these limitations by coupling self-report techniques with handheld computer technologies (often called palmtop computers, or personal digital assistants). A small randomized controlled trial by King et al. demonstrated the efficacy of this technique in an 8 week intervention in which 19 participants were provided with digital physical activity monitors, as well as palmtop delivered personalized feedback, goal setting, and support [20]. Compared with 18 control participants who received written support and educational materials, the intervention participants reported significantly greater calorie expenditure and moderate to vigorous physical activity. The benefits of accelerometers and palmtop computers must be examined within the context of their comparatively high cost. Both accelerometers and pedometers may be used to enhance both assessment and intervention. Pedometer usage is feasible, particularly with population-based work; accelerometers offer detailed feedback for participants across multiple activity domains.

Coupling Behavioral and Cognitive Interventions with Technology Using Ecological Momentary Assessment

As clinicians and researchers strive to obtain a comprehensive understanding of physical activity behavior change, integrative approaches offer benefits as they span multiple methodologies. Recent strides in this approach have been made with Ecological Momentary Assessment or EMA (often referred to within clinical contexts as Ecological Momentary Intervention). The diverse techniques of EMA include diary keeping, self-monitoring systems, physiological monitoring, and behavioral observation—all within the context of the exerciser's environment. These methods can be integrated with unstructured clinical visits or with more regimented exercise prescriptions. A review by Heron and Smyth examined 27 studies that utilized the EMA framework [21]. In the small RCT by King et al., previously described [20], those participants who were provided with instructions and used a palmtop computer to facilitate activity monitoring twice a day and were provided personalized feedback and support had higher levels of physical activity and pedometer-based steps than did the control group, which received written materials.

While this study is indicative of EMA usage with limited clinician involvement, Heron and Smyth note that several of the examined weight loss intervention trials demonstrated similar efficacy and outcomes to cognitive behavior therapy treatments, and suggest that coupling behavioral and cognitive interventions with EMA has the potential to enhance positive outcomes. Another study by Pellegrini et al. separated 51 participants into three conditions: standard behavioral weight loss, a standard behavioral weight loss plus technology-based system, and technology-based system only [22]. Those in the technology-based conditions received an energy-monitoring armband and accelerometer, access to a tailored physical activity website, and telephone information sessions. When paired with standard behavioral weight loss treatment consisting of in-person sessions and paper diaries, the technology-based approach yielded significant improvements in self-reported physical activity, cardiorespiratory fitness, and body fat percentage. The statistical increase in physical activity present in this study is higher than other studies incorporating Internet-based programs within a similar methodology.

ADVANCES IN PHYSICAL ACTIVITY INTERVENTIONS THROUGH VARIED CHANNELS OF COMMUNICATION

Another additional aspect of physical activity intervention that has been evaluated in the past decade is the communication channel through which the intervention has been delivered. In order to avoid the outreach limitations and costs associated with face-to-face delivery, print materials as well as telephone outreach have been explored as modalities for activity intervention delivery.

Phone- and Print-Based Interventions

Direct comparisons of phone- and print-based physical activity intervention approaches with one another and with face-to-face intervention have yielded mixed results. Conn et al.'s meta-analysis [7] noted that both mail and phone physical activity intervention delivery approaches had smaller effect sizes relative to face-to-face delivery in single-variable analyses but these differences were not observed in supplemental analyses that examined multiple moderators.

Phone- and print-based methods are often integrated in actual physical activity interventions, as in Marcus et al.'s study of individualized and tailored physical activity promotion within Project STRIDE [23]. In this randomized controlled trial, 239 participants were assigned to either a print or telephone condition in which they received individually tailored messages drawn from Social Cognitive Theory [10,11] and the Transtheoretical Model [12]. These messages included prompts to reinforce goal-seeking behavior and a computer-generated system for assessing stages of change and motivational readiness. As measured by a 7 day Physical Activity Recall Interview, both the print- and phone-based interventions were similarly efficacious compared to the control condition. Other trials have replicated these congruent outcomes: a randomized controlled trial by van Keulen et al. distributed 1629 participants among conditions of tailored print letters, motivational telephone calls, and control interventions [24]. Tailored print communication and tailored motivational interviewing via phone were found to be equally effective in promoting self-reported physical activity compared to control groups. This finding applied to middle-aged adults, as well as participants with low education levels.

Peer Support Telephone Calls

Peer support for behavior change has been championed by those aiming to improve health outcomes by extending the outreach of available behavior change approaches beyond the reach of intervention staff [25]. The increase in studies examining the effects of peer support telephone calls led to a Cochrane review publication in 2008 [26]. At the time of this review, controlled studies were limited, and methodological issues limited the existing evidence base, leading the authors to call for well-designed trials to examine the clinical effectiveness and cost of peer supported phone contacts aimed at improving health behavior and health outcomes. The results of a well-controlled physical activity program that compared the delivery of a physical activity program delivered by program staff to delivery by trained peer volunteers using telephone contacts help to bridge the gap between understanding of the efficacy of professional interventionist phone contact and peer phone outreach. Participants were 181 sedentary adults age 50 years and older who participated in a year-long controlled activity trial. Telephone activity interventionists were 12 volunteer peer mentors and professional staff. Participants were randomly assigned to phone-based activity advice from the professional staff, peer mentors, or

a staff-delivered phone nutrition support attention control condition. This well-controlled study examined treatment fidelity for the phone interventions. Moderate intensity or vigorous activity was assessed with self-report, with accelerometry validation in a subsample. At 6 and 12 months, both physical activity phone contact arms significantly increased activity relative to the control condition. Notably, both professional and peer phone contact groups showed comparable quantity of intervention delivery in fidelity analyses, while the peer mentor interventionists demonstrated more versatility and comprehensiveness in quality of intervention content.

This study demonstrates the efficacy of peer telephone modality of physical activity intervention delivery and highlights its potential for community outreach.

Computer- and Web-Based Interventions

Computer- and web-based dissemination of physical activity-related information has vastly increased within the past decade, but is still in a state of infancy. Some work has explored the efficacy of computer-tailored interventions in comparison with other avenues of health behavior change—a meta-analysis by Krebs et al. examined the effects of 88 computer-based health interventions published between 1988 and 2009, finding no significant differences between print-, computer-, or phone-based methodologies [27]. A 2009 report on Internet-based physical activity interventions among adults [28] found more than 20 studies. Studies yielded encouraging results with response to an Internet-based physical activity intervention similar to response to other more established, effective interventions. An Australian study examined attitudes toward Internet-based physical activity behavior change content and delivery as part of a program evaluation of a randomized trial that compared face-to-face exercise intervention, Internet only, and combined Internet and face-to-face groups [29]. Face-to-face exercise delivery group participants were more satisfied with their group allocation relative to the Internet groups. Internet groups reported liking the home-based access of materials and self-paced nature of the website. Internet groups reported that time and motivation were barriers to use. No differences were found regarding acceptability or credibility of content. Website usability was high for both groups. These studies suggest that web-based formats are useful; however, they may benefit from supplementation.

A review by Bennett and Glasgow cited a variety of improvements that need to be made for the platform to be effective, as well as many signs of promise [30]. While the potential reach of web-based interventions is high—nearly 75% of adult Americas regularly use the Internet—promoting utilization, tailoring, and minimizing attrition rates are challenges that face the field. However, the authors reaffirm that the convenience and engaging anonymity of web-based interventions are strong advantages of the method. Within the context of community interventions, web-based techniques are gaining a foothold, but are underutilized: a 2011 Cochrane review by Baker et al. reported that web-based communication strategies for increasing physical activities were among six primary goals for community health interventions [4], yet very few Internet trials have been conducted with multiethnic samples.

The studies available to date indicate that computer/Internet approaches can be successfully integrated into physical activity intervention efforts. However, the advent of integrative technological approaches does not negate the relevance of more traditional phone- and print-based methodologies to increase physical activity. Within the past decade, these modalities have been just as prominent, if not more so, than their often more expensive counterparts. While these technologies are not new, the communication they enable continues to be optimized in order to facilitate the dissemination of physical activity interventions.

ADVANCES IN CHANNELS OF ACTIVITY INTERVENTION AND IMPLICATIONS FOR PROMOTION OF COMMUNITY-WIDE PHYSICAL ACTIVITY

As described in the earlier sections, print, telephone, and peer delivery modalities offer opportunities for reaching a wide variety of individuals who may benefit from these extended intervention approaches. In addition to these delivery modalities, activity interventions may be aimed at even more broad sets of participant via community-wide interventions.

A 2011 Cochrane review examined community-wide interventions aimed at increasing physical activity in order to evaluate their influence on population-level health [4]. Twenty-five studies of interventions that directed their intervention at the community level and used multiple identifiable components were identified. Of these, 19 were conducted in high-income countries; 11 of these were described as aimed to reach low, socioeconomic, or disadvantaged communities. Six studies were conducted in low-income countries. The review authors concluded that methodological issues precluded reaching clear conclusions regarding the effectiveness of community interventions; however, the methodological review offers instructive information about the types of community interventions that have been conducted and suggestions for future intervention programs and research. A major concern identified in the community-wide physical activity intervention literature was selection bias, particularly limited use of community comparisons and randomization, and the quality and validity of assessments used to measure outcomes. Despite these limitations, it is encouraging to see that the majority of interventions included establishing partnerships with local government or nongovernment local organizations. Community strategies generally involved planning initiatives with the aim of producing long-lasting benefits for the community. They also operated at a series of levels to attempt to influence activity, such as environmental changes, policy changes, and use of the media. The review also provides a description of community-level strategies for outreach to many types of disadvantaged groups: (1) social marketing

through local mass media (television, radio, newspaper); (2) other communication outreach (posters, flyers, information booklets, websites, maps) to raise awareness of the intervention program and provide specific information; (3) individual behavior change counseling by health professionals such as the use of physical activity prescriptions; (4) working with voluntary, government, and nongovernment organizations, such as sport organizations, to promote events and activities such as walking; (5) working within specific settings that may facilitate contact with individuals who have social disadvantages such as lack of transportation and might otherwise be missed by traditional outreach, for example, schools, senior centers, workplaces, community centers, homeless shelters, and shopping malls; and (6) environmental change strategies such as creation of walking trails and partnering with legislative and fiscal leaders to promote planning for outreach to the broader population.

Despite the identified methodological limitations precluding a clear understanding of the influence of community-wide interventions or the unique contributions of specific aspect of such interventions, the Cochrane review provides a useful overview of the types of approaches that have been undertaken in the last decade. Of the studies reviewed, many incorporated theory-based intervention models into their intervention methods. Of the 25 studies described, 6 focused on ecological approaches to increase activity, 4 interventions developed community interventions using the Transtheoretical Model [12] as the behavior change framework, 4 community interventions were based on Social Cognitive Theory [10,11], and 2 based their interventions on adaptations of a Community Empowerment Model [31–35]. Some community-wide interventions targeted specific social cognitive constructs such as self-efficacy or addressed the use of persuasive communications theory or emphasized principles of and community organization. In some cases, multiple models informed interventions. This highlights the challenges inherent in attempting to identify key components of effective community-based physical activity interventions.

Given the findings of previously described reviews of physical activity interventions with adult based on controlled studies indicated that the majority of participants are middle-aged, female, and nonminority, these types of community-wide intervention approaches offer tremendous potential to promote activity. More well-controlled evaluations of these approaches are needed and offer challenges for future programmatic evaluations.

Community-Wide Physical Activity and the Role of Built Environment

An additional approach to addressing the needs of the broader community when developing physical activity interventions is to consider the role of the built environment. An emerging body of studies indicates that the physical environment plays an influential role in physical activity [36,37]. Reviews have found that neighborhoods that are characterized as walkable (those with mixed land use such as having homes, schools, workplaces, and areas to shops accessible) can encourage walking to multiple destinations [36,38,39]. Reviews of the evidence to date indicate that the majority of studies of the relationship between physical activity and the built environment are cross-sectional [36,39], which limits the evidence regarding the effectiveness of changing the environment on physical activity. However, several studies have facilitated understanding of how the built environment might impact activity and how neighborhood environments might moderate the effect of activity interventions. A 2006 review of evidence to date identified several projects that evaluated the development of new walking and bicycle paths and found that this increased activity [40]. However, path use was optimized by promotional campaigns and mediated by the user's pre-existing physical activity levels, proximity of user's homes from the paths, and safety concerns, highlighting the complexity of evaluating specific effectiveness of these environmental changes. King et al. evaluated both social and built environment influences in the context of physical activity interventions across five intervention trials [37]. Features of the built environment were assessed with a Neighborhood Walkability Scale. Activity guidelines were more likely to be met by participants living in neighborhoods with more attractive scenery and ease of walking. Analyses examining within site variables also indicated that seeing others when walking and encountering dogs that impeded efforts made it more difficult to walk.

Additional analyses suggested that traffic safety was related to both facilitating and impeding activity. To explore the interactions between changes in walking over time, lifestyle physical activity intervention conditions, and the walkability of participants' neighborhoods, Kerr et al. examined data from two randomized activity intervention trials [39]. Both trials were conducted by the same researchers and used similar methodologies and geographic recruitment regions in the same county. One of the activity trials was with women with BMIs between 25 and 39 who were randomized to either a "Patient-Centered Assessment and Counseling for Exercise and Nutrition via the Internet (PACEi)" or an "enhanced" standard care comparison group. The PACEi intervention consisted of computerized assessment with a staged action plan followed by brief counseling from their primary care provider. The women were also encouraged to use a study website for activity and nutrition information, tips, and skills and to set monthly behavior change goals. They received monthly support and tailored feedback by e-mail and quarterly telephone calls. The standard care comparison group received basic print materials on the topics of physical activity and nutrition. The other activity trial was with men with BMIs between 25 and 39 who were recruited from the community through newspaper advertisements. They were randomly assigned to either the PACEi intervention with content designed for men or a general health information website. The RCT with men also provided participants with pedometers to track their daily steps. They were encouraged to access the website weekly to report goal progress, weight, and set new

goals. They also had occasional telephone and e-mail contact with project staff to assist them with the website and any technical difficulties. In examining the interactions between the built environment and interventions, it was found that men who resided in less walkable neighborhoods (as assessed with a walkability index) who were in the intervention group significantly increased their walking time (daily walking time was increased by 29 min from baseline to 1 year) while men who resided in high walkable neighborhoods decreased their walking over the course of the study (a decrease by 10 min from baseline to 1 year). Men in the control condition did not increase their walking time. For women, results showed similar trends, with women living in low walkable neighborhoods who were in the intervention group increasing their walking the most (7 min increase from baseline to 1 year), although results did not reach statistical significance. Women who perceived an unsafe volume or speed of traffic had decreased walking time (22 min daily decrease), while women who perceived that the traffic in their neighborhood was safer had increased walking time (increased by 17 min) over the course of the study. Findings of this study suggest a possible ceiling effect of living in a highly walkable neighborhood. The authors discuss the possibility of other nonwalking behaviors and focus on dietary factors. The gender differences in interactions between built environment issues and activity outcomes from the activity RCTs are intriguing and suggest that men and women may have different perceptions of and responses to changes at the built environment level. Gender difference findings may also be accounted for by the differences in frequency of goal setting and use of pedometers as a monitoring aid between the gender-specific RCTs. As reviewed in previous sections of this chapter, these basic behavioral strategies are known to enhance physical activity interventions. The study authors concluded that the pattern of results indicate that behavior change interventions can encourage walking behavior, even in less supportive and walkable neighborhood environments.

PHYSICAL ACTIVITY INTERVENTIONS IN RACIAL/ETHNIC UNDERSERVED SAMPLES

Ten years ago, reviews of physical activity intervention consistently called for additional studies that included racial and ethnic minority and underserved samples [1]. While additional studies have been conducted, the optimal approaches to providing activity interventions that reach minorities and result in the most effective level of change remain unclear.

Pekmezi et al. conducted a feasibility and efficacy study of computer- and Internet-based physical activity interventions as part of a 1-year intervention comparing three communication modalities—motivationally tailored print, motivationally tailored Internet (matched to Stage of Change), and standard Internet [41]. Participants were part of a large study sample of 249 sedentary adults in good health who had access to a computer with a modem (Step Into Motion Trial [42]). As a part of this study, these investigators were able to examine the feasibility and efficacy of the varied communication modalities in a subsample of 38 African American participants. The larger trial did not specifically include cultural tailoring [42]. Both motivationally tailored activity intervention communication conditions included provision of individualized computer expert system feedback which was delivered using either print materials (mailed to participants) or Internet. The motivationally tailored feedback was related to participant questionnaire responses and was based on constructs underlying the Transtheoretical Model [12] and Social Cognitive Theory [10,11]. The standard Internet condition provided online access to six websites about physical activity that were available at the time of the study (American Heart Association, Shape Up America, Mayo Clinic Fitness and Sports Medicine Center, American Academy of Family Physicians, American Council on Exercise, American College of Sports Medicine). Of note, participants in each of the three groups completed physical activity–monitoring logs and were provided with incentives for log completion. Findings indicated that as a group, these African American participants significantly increased their activity from baseline to 6 months post-baseline and remained more active relative to baseline and less active relative to 6 months at the 1-year follow-up. Satisfaction ratings were available for 30 participants, with 70% reporting that they read "most or all" of the activity-related information that was provided by print or Internet. The Internet and print programs were rated as "somewhat" or "very" helpful by 80% and enjoyable by 87% of those providing this post-intervention feedback. These findings suggest that computer and Internet communication approaches are acceptable to African Americans and can produce adoption and maintenance of physical activity. Additional programs and controlled studies are needed to involve larger numbers of African Americans and other minority participants in order to further evaluate the best ways to provide computer-concluded based communication and outreach in diverse populations.

Whitt-Glover and Kumanyika conducted a systematic review of interventions to increase activity and fitness in African Americans [6]. This review included studies published between 1985 and 2006. Interventions included adult and child samples. Effective programs were identified for adults; however, most of the studies conducted with children yielded null findings. Of interest, the majority of studies were conducted with women. Interventions included community-based approaches such as delivering the intervention in community settings such as the YMCA, community centers, church, worksites, and public housing projects. Cultural adaptations were included in a number of studies. For example, several physical activity interventions with African American participants were conducted in a church setting and included activity instructors from the African American community, gospel our "soul" music and incorporated prayer. Hip-hop dancing was also represented. Resnicow et al. involved African American celebrities from the local community and, in a church-based program, included video of pastors giving sermons addressing the importance and value of physical activity [43]. As highlighted in the Whitt-Glover et al. review [6], the culturally adaptive methods

of intervention were frequently paired with other behavior change approaches, including monitoring, use of pedometers, peer phone contacts, supervised exercise sessions, and social support via group walks in the local neighborhood. The multiple approaches and study design limitations make it difficult to evaluate the specific influences of these culturally tailored approaches. However, examination of findings from individual studies showing significant group differences led the authors to look for trends associated with "best practices." Common factors associated with the effectiveness of individual studies of physical activity interventions in African Americans were use of randomized controlled trial design, assessing physical activity using an objective measure, providing specific physical activity goals to participants, and including structured activity programs. These trends are consistent with other general reviews of activity intervention studies. Carefully controlled intervention studies are needed to more thoroughly examine the specific influences of culturally adapted intervention approaches.

TRANSLATING BEHAVIORAL AND COGNITIVE APPROACHES INTO REAL-WORLD INTERVENTIONS TO PROMOTE PHYSICAL ACTIVITY INTERVENTION OUTREACH

The findings of the past decade have reinforced previous research on the efficacy of behavioral and cognitive interventions to promote physical activity, but the limitations in the study designs and results highlight the need for outreach to diverse individuals and settings as well as the complexity of physical activity intervention efforts in a community context. A useful framework has been developed to enhance the impact of health interventions by addressing issues of real-world implementation of evidence-based approaches to be sure that they actually reach diverse and underserved populations and varied settings and are adopted and maintained over time. The RE-AIM framework (Reach, Effectiveness, Adoption, Implementation, Maintenance) [44] proposes five steps for translating what is known from research studies into actual intervention action in the real world [44–46]:

1. Reach the target population—Interventions reach large groups of individuals in need, including those from characteristically underserved or hard to reach settings.
2. Effective impact of the intervention (also referred to as efficacy of the intervention)—Interventions make an impact on important outcomes and consider both positive and negative influences, unanticipated outcomes, quality of life, and even economic outcomes.
3. Adoption of the intervention approach in the real-world setting—Interventions are adopted by different settings and the number, proportion, and representativeness of the settings, and people who deliver the program are representative of those who would benefit from the program.
4. Implementation of the intervention is consistent—Intervention protocol is consistently delivered as intended in the real-world setting.
5. Maintenance of the intervention at the setting and individual levels so that it is delivered and results in benefits over the long run—Intervention becomes sustainable and a part of the routine within the programs or organizations delivering it, the health-related behaviors and benefits are maintained, and when appropriate, policies are maintained.

The RE-AIM approach has been widely adopted and since its development there have been over 100 publications spanning diverse disciplines and settings [46]. King et al. have made recommendations for applying the RE-AIM approach to the built environment [45]. They argue that by using a RE-AIM approach in which the physical location of proposed interventions is considered, interventionists can greatly influence who is reached and how frequently and how environmental changes might have positive, negative, or neutral influences on the outcomes. They cite an approach called Transit Orienting Design (TOD) as an example of considering redesigning communities to promote walking, bicycling, and decreasing car dependence. In this approach, mixed-use residential and commercial areas are placed near public transportation stops to make public transportation more attractive than driving [47]. However, the economic, environmental, housing, and equity goals intended with such approaches may not always be achieved. By using a RE-AIM approach for strategic planning, the plans for built environment intervention could have the potential for impact on all aspects of the community setting, including unintended consequences such as gentrification and displacement of low-income residents [48]. The authors recommend careful strategic planning in advance of developing community interventions including interactions with varied disciplines and agencies, using relevant information already available readily from public sources such as crime, traffic, and accident data and identifying practical approaches in the community to track behavior—for example, walkability audit tools [49] to promote greater community involvement and enhance maintenance.

A 2011 review evaluated theory-based physical activity interventions from a RE-AIM perspective. Theoretically guided interventions published between 1996 and mid-2009 were included; 57 studies met criteria for review [50]. Few of the physical activity studies included in this review reported on the specific intended target population for the intervention. Most did not report on the representativeness of the study sample relative to the target population. Many studies had small sample sizes and most included motivated, healthy participants, minimizing Reach. Adoption was the least reported dimension of the intervention studies, precluding evaluation of the representativeness of sites that did adopt the intervention. Approximately one-third of the studies reported implementation information via process evaluation. It was noted that this could be a consequence of journal page limits. More than half of the studies reported information

in individual maintenance of activity levels. However, only three reported on maintenance at the organizational level. Overall, the physical activity intervention studies reviewed with the RE-AIM framework were more likely to address individual rather than organizational, level. From a practical standpoint, this impedes the translation of many of the physical activity interventions into actual practice in real-world settings with diverse populations.

MAINTENANCE OF PHYSICAL ACTIVITY FOLLOWING INTERVENTION

In this section, we turn to a problem that has been recognized since the earliest efforts to promote exercise and physical activity in clinical and community populations. Adoption of an active lifestyle for a few weeks or months is not sufficient for the health-promoting benefits of activity. We now turn to an update on approaches to the challenge of effective promotion of ongoing activity, or maintenance of the activity, over time.

A recent systematic review of maintenance of physical activity following participation in a physical activity or diet intervention (defined as at least 3 months posttreatment) found that of 157 studies reporting behavioral outcomes, 35% included follow-up data of 3 months or longer [51]. When a comparison group was also included, there were 18% reporting follow-up (29 trials). This review identified a number of behavioral strategies that were common to randomized trials that showed maintenance of physical activity behavior change for at least 3 months after an intervention. Characteristics of trials showing activity maintenance were pretrial screening based on behavioral criteria, interventions that lasted longer than 24 weeks, had face-to-face contact, used multiple intervention strategies (more than six), and used follow-up prompts. The most common strategies in trials achieving maintenance were providing instruction on how to achieve behavior change (81%), prompting to identify behaviors (71%), and providing opportunities for making social comparisons (67%). The 2011 systematic review of reviews of intervention components associated with increased effectiveness in diet and activity interventions [5] noted that maintenance in physical activity is also associated with use of time management techniques and positive, encouraging self-talk.

A recent study is informative in its use of a sophisticated approach to prospectively examining dynamic changes in data to study changes in health cognitions and physical activity following intervention. The intervention was a lifestyle change program aimed at preventing type 2 diabetes in a sample of 389 Finnish adults. Participants' cognitions and activity were measured prior to the lifestyle intervention and 3 months and 1 year post-intervention. Using growth curve modeling, the researchers were able to examine how changes in cognitions influenced exercise adoption and maintenance. They found that health-related cognitions were amenable to change and that these changes in cognitions facilitated both physical activity adoption and maintenance [52]. Use of these new approaches to examining longitudinal data offers exciting opportunities for understanding how the process of activity adoption and maintenance unfold.

Advancing Understanding of Activity Maintenance by Examining Exercise Lapse

Several studies have promoted understanding of the process of exercise behavior over time not only by examining frequency/intensity/duration of exercise accrued within a session or time frame such as weeks or longer, but also by examining missed exercise sessions or omissions of exercise over time, sometimes referred to as exercise lapses. In a study of 508 postmenopausal women ages 52–62 years, lapses in physical activity were examined over the course of a randomized trial [53]. Lapses were associated with lower levels of activity, including a relapse (inactivity) following the lapse for many women. Of interest, relapse following a lapse was greater in participants who had higher anxiety and depressive symptoms and less frequent use of behavioral exercise processes of change. Lapses were less likely to lead to a relapse in women reporting more frequent use of behavioral processes of change related to activity. This highlights the previously identified benefits of behavioral strategies in physical activity as well as the potential role of affect in activity maintenance following intervention. Lapses in exercise didn't seem to be related to decreased exercise self-efficacy and health-related quality of life, which may suggest that women can lapse and at least accrue benefits. An additional study of activity on lapse and relapse provides some additional perspective on the context of lapses and relapse. Specifically, in a study of youth activity, Shields et al. noted that contextual factors are important in determining whether lapses occur and whether these lapses spiral into unhealthy behaviors such as inactivity [54]. It was proposed that the context of activity patterns include the social influence of others. Using a prospective, longitudinal approach, the study provided some support for the suggestion that interventions may be effective at preventing an activity lapse from becoming a relapse to inactivity by increasing the social influences of the family. Findings indicated that self-efficacy for self-regulation partially mediated associations between physical activity and family social influence. Further studies of the process of activity lapses may provide useful information about the types of factors associated with lapses in physical activity behavior and how such lapses might influence the maintenance of activity over time.

CONCLUSION

At the time of the first version of this chapter, in 1999, there was growing evidence supporting the benefits of using behavior change theory to inform physical activity interventions. Evaluation of interventions utilizing approaches driven by Social Cognitive Theory [10,11], the Transtheoretical Model [12], and other frameworks supported the use of behavioral approaches, such as those that focused on specific behaviors and factors that can be manipulated to influence physical

activity behavior. Examples included using behavioral contracting and reinforcement, modeling, provision of cues and prompts. Findings highlighted the effectiveness of behavioral strategies for enhancing exercise adoption and participation. In addition, at the time of the previous version of this chapter, cognitive interventions addressing thoughts related to facilitating or hindering physical activity and incorporated methods such as guidelines and instructions aimed at enhancing motivation for behavior change and monitoring and altering self-statements were supported.

Ten years later, the earlier work in understanding the utility of cognitive and behavioral approaches to enhancing exercise participation has been extended by exciting developments in research approaches. Technology has greatly enhanced the methods available for physical activity monitoring and communications between interventionists and program participants. The use of written diaries and logs is now often accompanied by palmtop handheld computers, accelerometers, and step counters. Activity program participants may access interventions through peers, the Internet, and various types of structured telephone contact approaches in addition to—or instead of—face-to-face contacts and printed materials. Efforts to improve intervention approaches to encourage adoption of exercise are now more strongly enhanced by a renewed emphasis on the importance of interventions that promote maintenance of activity once it has been established. Recent advances in statistical methodologies have allowed for longitudinal examination of the usefulness of specific aspects of theoretically based intervention approaches, aiding in efforts to longitudinally examine the process of activity maintenance and relationship to intervention components. In addition to a focus on enhancing physical activity behaviors pre- and post-intervention, studies have examined other approaches to assessment of the exercise process, including short-term slips from planned activity. Recent intervention studies have also addressed not only activity per se but changes in the sedentary behaviors that are encouraged, if not enforced, by our modern lifestyles.

Technological changes continue to introduce new ways of replacing active living with sedentary behavior and suppress opportunities for physical activity in almost every domain of modern life. The obesity epidemic now threatens almost all population subgroups and even less technologically advanced cultures. Although these public health challenges that motivate physical activity research are undoubtedly powerful adversaries, new discoveries of the benefits of physical activity are a continuing source of inspiration to researchers, health care providers, and others committed to find more effective ways of encouraging all people to be physically active and healthy.

The advances and limitations highlighted in this review of behavioral and cognitive interventions for promoting physical activity suggest some of the directions for future work. In particular, we expect to see more studies that translate findings of efficacious interventions into a wide variety of settings and populations. New technologies are likely to make monitoring of the spectrum of activity, from complete rest to the most vigorous exertion, more accurate, and less expensive. Telecommunications and Internet communications will provide new opportunities to connect people to physical activity promotion interventions, and we need to learn how to effectively and efficiently combine the technology with the personal contacts that many people still desire. Genetic studies may help us understand why some people enjoy and get more benefit from physical activity than others, and point the way toward biological as well as behavioral and cultural tailoring of interventions to individuals. There will also be unexpected challenges, but the scientific and creative advances of the past decade suggest that there will be exciting new progress to report in future years.

In the twentieth century, tobacco killed 100 million people worldwide [1]. Unless urgent action is taken, it will kill 1 billion in the twenty-first century [1]. In the United States, significant strides have been made to reduce the smoking prevalence among certain segments of the population, but there are important areas where gains have been minimal. The purpose of this chapter is to provide a brief overview of the health consequences of smoking and to review key behavioral approaches and strategies that have been used to enhance smoking cessation. This is not a comprehensive review, but rather a summary of the most effective treatments and promising research initiatives that are currently underway.

HEALTH CONSEQUENCES OF SMOKING

Worldwide, tobacco use remains the leading preventable cause of death, and it is a risk factor for six of the eight of leading causes of death [2]. Evidence shows that any exposure to tobacco smoke, even an occasional cigarette or exposure to secondhand smoke, is harmful because it contains more than 7000 chemicals and compounds [3]. Indeed, smoking harms nearly every organ of the body and can cause cardiovascular disease, stroke, periodontitis, aneurysms, pneumonia, chronic obstructive pulmonary disease (COPD), asthma, and low bone mineral density [2]. Cigarette smoking can also cause cancer of the lung, bladder, cervix, esophagus, oral cavity, larynx, stomach, kidney, uterus, and pharynx [4].

In the United States, the negative health effects from smoking account for an estimated 443,000 deaths annually (approximately 20% of all deaths) and $193 billion in direct health care expenditures and productivity losses each year [4]. In fact, more deaths are caused by tobacco use than by all deaths from illegal drug use, alcohol use, human immunodeficiency virus (HIV), motor vehicle injuries, murders, and suicides combined [4]. Lastly, smoking has additional adverse effects on early childhood and reproductive health, including infertility, preterm delivery, stillbirth, low birth weight, and sudden infant death syndrome (SIDS) [4].

SMOKING PREVALENCE AND EPIDEMIOLOGY

It is currently estimated that more than 1 billion people smoke cigarettes worldwide, with smoking rates growing fastest in low-income countries [1]. In the United States, previous declines in smoking prevalence have stalled. For the past 3 years, the proportion of adults who were cigarette smokers did not significantly change. Specifically, 19.4% of adults aged 18 years and over [5] and 10.7% of youths aged 12–17 years [6] are current smokers. Smoking and tobacco use overall is higher in males (33.7%) than in females (21.5%) and differs by various other demographics [6]. For example, American Indians and Alaskan Natives report the highest rates of tobacco use (35.8%), followed by 29.5% of whites, 27.3% of blacks, 21.9% of Hispanics, and 12.5% of Asians [7]. Cigarette smoking is most prevalent among those who had not completed high school (34.3%), and least prevalent (12.8%) among those with a college degree. The most recent reports indicate that smoking is more common among unemployed adults than among adults who were working full time or part time (39.9% vs. 24.9% and 24.4%, respectively). Finally, smoking rates are currently highest in the Midwest (24.8%), followed by the South (21.4%), Northeast (22.2%), and the West (20.0%), and this predominately occurs in nonmetropolitan areas (26.0%), as opposed to small (23.5%) and large (21.7%) metropolitan areas [7].

PREVALENCE OF SMOKING CESSATION

Both the risk and the severity of many diseases caused by smoking are directly related to how long the smoker has smoked and the number of cigarettes smoked per day. It is beneficial to quit smoking at any age, and smokers who quit before the age of 35 years have mortality rates similar to those who never smoked [7]. More specifically, after quitting, the risk for a heart attack drops sharply after just 1 year; stroke risk can fall to about the same as a nonsmoker's after 2–5 years; risks for cancer of the mouth, throat, esophagus, and bladder are cut in half after 5 years; and the risk for dying of lung cancer drops by half after 10 years [3]. Since 2002, the number of former U.S. smokers has exceeded the number of current smokers [7]. The most recent estimates indicate that almost 70% of current smokers would like to stop smoking, but less than 5% are able to maintain abstinence for more than 12 months [7,8]. Overall, cessation rates are initially much higher among those who participate in smoking cessation programs than those who quit without assistance. However, the different rate of abstinence between these groups narrows over time, particularly after 6 months [9]. Interest in quitting and attempting to quit has been reported to be higher among certain demographic groups, such as females, non-Hispanic black smokers, those aged <65 years, and those with a post-high school education [10]. A recent report indicated that 6.2% of smokers were able to quit in the past year for ≥6 months [7]. Cessation was also found to be more likely among non-Hispanic whites, those with a higher level of education, and those with private health care plans [7].

PHARMACOLOGICAL AIDS FOR SMOKING CESSATION

The earliest studies on smoking cessation did not recognize the addictive nature of cigarette smoking. Modern day approaches now take into account that the nicotine in cigarettes is a highly addictive drug, and this has led to a wealth of research on using medication to help smokers quit. The combination of behavioral counseling and medication has been shown to be more effective than either treatment alone [11]. Therefore, prior to describing several different behavioral approaches to enhancing smoking cessation, a clarification of the medications that often accompany treatment is needed.

Currently, there are seven U.S. Food and Drug Administration (FDA) approved first-line medications shown to be helpful for increasing long-term smoking abstinence rates. These include over-the-counter (OTC) products (nicotine gum, nicotine lozenge, and the nicotine patch) and prescription-only medications (nicotine nasal spray, nicotine inhaler, sustained-release bupropion, and varenicline). When used properly, the nicotine replacement therapies (NTRs) can relieve nicotine withdrawal and have been shown to nearly double the success rate of smoking cessation when compared to a placebo [11,12]. Bupropion, an antidepressant, has also been shown to double quit rates [13]. It reduces nicotine's rewarding effects by blocking the reuptake of norepinephrine and dopamine in the mesolimbic system and nucleus accumbens, a key area for nicotine reinforcement [12]. Varenicline, the newest medication, has been shown to triple abstinence rates in smokers when compared to a placebo [11–13]. Like buproprion, varenicline attenuates the rewarding effects of nicotine. In addition, varenicline operates as a partial agonist for the $\alpha_4\beta_2$ subtype of the nicotinic acetylcholine receptors, which are associated with the addictive effects of nicotine [12]. Importantly, all of these medications can have side effects that range from dry mouth to suicidal ideation, and many of them are not appropriate or have not been studied in special population of smokers (e.g., individuals with psychiatric comorbidities, adolescents, postpartum women) [12]. Given that the combination of behavioral counseling and medication is ideal, more studies on how to best use these strategies for all smokers are urgently needed.

BEHAVIORAL SMOKING CESSATION STRATEGIES

Extensive scientific and community resources have been used to examine ways to reduce tobacco use and increase smoking cessation. Strategies that have been used range from government-based initiatives to media-based campaigns to independently run interventions targeting a wide array of smokers. The following review covers the various types of behavioral smoking cessation interventions that vary from minimal contact to intensive counseling. The programs described later can be classified based on the type of approach used, the population targeted, and the setting in which it is delivered. Regardless of their classification, all of the programs attempt to provide smokers with the information and behavioral skills thought to be necessary for achieving initial cessation and sustained abstinence.

COUNSELING AND THERAPY-BASED APPROACHES

Group Therapy

Delivering a smoking cessation intervention in a group format has been used for more than 20 years, and it remains popular [14,15]. Using a group format is particularly helpful for certain therapeutic approaches such as cognitive behavioral therapy and contingency management. Overall, the group format can provide smokers with a unique opportunity to learn about the challenges other smokers face when trying to quit, which might result in increased quit rates when compared to self-help methods [15]. While it is not yet clear whether group therapy is more effective than individual counseling, it appears that smokers motivated to quit can increase their likelihood of success if they participate in a group [15]. Given that group-based smoking cessation interventions are often less costly than other methods, group therapy may be the one of the most cost-effective behavioral approaches for smoking cessation.

Individual Counseling

Individual or face-to-face counseling is a well-established method for delivering smoking cessation treatment. The treatment can be delivered by practitioners with varying levels of education and training (e.g., smoking treatment specialists, psychologists), and it can be done in different formats, for varying lengths of time (e.g., 10–60 min sessions), and across a wide-ranging number of sessions. Individual counseling can also be combined with self-help components, medication, group counseling, and/or telephone assistance [16]. Currently, there is sufficient evidence to support using individual counseling, as it has been shown to increase the likelihood of quitting smoking when compared to less intensive treatment (e.g., self-help) [16]. Going forward, it will be important to identify the most effective and cost-effective intensity and duration of individual counseling for diverse and hard-to-reach population.

Telephone Counseling

A clear benefit of telephone counseling is that it can be used as a substitute for face-to-face contact to reach a large number of smokers at a much lower cost. There are two approaches to telephone counseling: proactive and reactive. Counselors use a proactive approach when they call smokers in attempt to support a quit attempt or prevent relapse. These calls are typically made as part of a larger effort to expand the level of support given to the smoker, which may have initially included smoking cessation counseling or the provision of self-help materials or pharmacotherapy. Reactive counseling occurs when a smoker calls a quit-line, such as 1-800- QUIT-NOW [17]. Quit-lines may be regional or national and may provide the caller with counseling at the time of the call, a future (proactive) call, mailed materials, access to pharmacotherapy, a recorded message, or a mixture of these components [18]. Recent research has shown that proactive telephone counseling can significantly increase abstinence for up to 9 months among smokers interested in quitting; however, the long-term (12 months or longer) effect is less clear [18,19]. In addition, there is some evidence for a dose–response relationship with the number of proactive calls, with three or more calls increasing the chances of quitting over other minimal interventions such as self-help materials or pharmacotherapy alone [18]. New research will need to determine how to extend the effects of proactive calls for long-term cessation and how to capitalize on reactive counseling [18,19].

Motivational Interviewing

Motivational interviewing (MI) was originally developed in the early 1980s as a treatment for substance abuse [20]. It is an individually administered, client-centered counseling approach to elicit behavior change by helping individuals explore and resolve ambivalence [21]. MI seeks to reduce resistance to change by developing a discrepancy between an individual's current behavior and his/her values and goals. Four general principles underlie this approach: (1) express empathy, (2) develop discrepancy, (3) roll with resistance, and (4) support self-efficacy. The first study to use MI for nicotine dependence was published in 1998 [22], and just over 30 trials are currently published [23,24]. Overall, MI seems to be an efficacious treatment for smoking cessation across a wide array of patients, and it is within the range of other behavioral treatments for nicotine dependence [11,23,24]. MI appears to be the most effective when delivered by trained counselors in two or more 20–60 min sessions [23,25]. In addition, MI may be more ideal for those with low levels of motivation to quit, individuals living outside the United States, adolescents, and those with medical comorbidities [23,24]. Future research will need to more rigorously test standardized MI protocols, include fidelity assessments, and determine the independent effects of MI when compared to other cessation treatments [24].

SMOKING CESSATION IN MEDICAL SETTINGS

Considering that smoking contributes to a myriad of medical problems, it is not surprising that smoking is more common in a variety of medical population. For example, smoking rates among heart disease, COPD, and stroke patients are at least 10% greater than the general population [26]. Cessation after such problems are diagnosed can still reduce morbidity and mortality. For example, patients who stop smoking after a myocardial infarction decrease risk of another MI and mortality by about one-third [27]. Likewise, cessation after being diagnosed with lung cancer reduces cancer recurrence by 46%–77% and total mortality by 46%–66% [28]. Thus, smoking cessation in medical patients can function as an important secondary prevention intervention.

The "5 As" smoking cessation framework (*Ask*, *Advise*, *Assess*, *Assist*, and *Arrange*) is specifically designed to be applicable to brief medical visits [11]. This framework calls for all clinicians to assess smoking status at each visit (i.e., *Ask*). The identification of smokers can be increased by treating smoking status as a "vital sign" [29] and building prompts into electronic medical records [30]. Having such an identification system increases the likelihood that clinicians will provide cessation interventions [11,31]. Some clinicians may worry that repeatedly bringing up smoking cessation during visits will decrease patient satisfaction; however, this does not seem to be the case [32,33].

Providing strong, personal advice to quit (i.e., *Advise*) only takes a few minutes and has clear empirical support. Specifically, physicians providing strong advice to quit can increase the likelihood of quitting even when relatively little time is spent (e.g., <3 min) [11]. Although the absolute increase in quit rates due to brief advice may only be 1%–3% [34], the cost of advice is low and the reach is high, so its potential public health impact is great.

Discussion of a patient's willingness to make a cessation attempt at this time (i.e., *Assess*) will identify patients who are currently interested in quitting and those who are not, so clinicians should be ready to use treatment techniques for both groups [35]. For those who are ready to quit, the clinician can *Assist*. Assistance strategies include developing a quit plan (including setting a quit date); recommending and/or prescribing pharmacotherapy; referring the patient to additional counseling, quit-lines, or web support; providing practical counseling (e.g., problem-solving barriers to cessation); and providing social support. It is notable that quit rates increase as time spent counseling increases [11]. Finally, following up in person or by phone (*Arrange*) provides an opportunity to reinforce cessation or encourage another quit attempt if the patient has relapsed. Ideally, a first follow-up contact would occur within a week of the quit date and a second within a month of the quit date [11].

For smokers currently uninterested in quitting, the "5 Rs" (*Relevance*, *Risks*, *Rewards*, *Roadblocks*, and *Repetition*) provide a framework for increasing motivation and are consistent with the MI approach described earlier [11]. In this framework, patients are asked (not told) about the personal *Relevance* of smoking, perceived personal *Risks* of smoking and *Rewards* of quitting, and perceived *Roadblocks* to successful cessation (for which the clinician can suggest solutions). These steps can be repeated at each visit (*Repetition*). Studies have shown that the 5 Rs approach increases the likelihood of future quit attempts in those with initially low motivation to quit smoking [36].

Integrating smoking cessation services into regular systems of medical care is ideal because when treatment is delayed or in another location, fewer patients follow through on referrals than when treatment is easily assessable [35]. Although cessation services could be integrated into almost any medical encounter (including some nontraditional contexts such as pharmacies and dental offices) [37,38], we review two of the most important in the following sections: primary care visits and inpatient hospital stays.

Primary Care Visits

In the United States, 70% of smokers see some type of a primary care provider (PCP) each year [39]. Thus, primary care–based cessation interventions can reach most smokers. In addition, PCP providers have long-standing relationships with their patients and may be in a unique position as a trusted clinician to provide influential advice that will lead to a quit attempt. It may be frustrating for the provider to repeatedly spend time discussing smoking cessation with the same patient; however, because intentions to quit can fluctuate on a week-to-week basis [40], assessing motivation to quit at every contact will catch more patients when they are ready to make an attempt. An additional advantage of conducting a smoking cessation intervention in primary care is that pharmacotherapy options can also be discussed and prescribed on the spot.

About 20% of smokers in primary care are willing to make a serious quit attempt [41]. PCPs may be concerned that intervening with smokers who are not ready to quit would be alienating. However, the opposite seems to be true; patients who receive the 5 As during primary care visits are more satisfied with their tobacco-specific and overall care, even smokers who are not ready to quit [32]. Further, there is evidence that primary care interventions that target all smokers (regardless of readiness to quit) can be effective [42].

Due to time and logistical constraints, many PCPs may be limited in the amount of follow-up support they can provide for a quit attempt. However, recent evidence suggests that referral to a proactive quit-line (e.g., service that proactively calls the patient) following brief cessation treatment during a primary care visit can approximately double quit rates [43]. Such quit-line referrals have also been successfully integrated with primary care–based pharmacological interventions [41]. Thus, referral to a quit-line may provide a viable option for follow-up care (*Arrange* in the 5 As) when primary care resources are unavailable.

Inpatient Hospitalization

Hospitalization can be considered a "Teachable Moment" when the health effects of smoking are salient and patients

are more likely to accept cessation treatment [11]. In addition, U.S. hospitals are now smoke-free, so inpatients will likely experience temporary abstinence regardless of their desire to quit [44]. Clinical guidelines [11] indicate that smoking status should be assessed upon hospital admission and documented on the problem list and discharge summary. Smokers should be offered NRT while in the hospital even if they are not considering quitting, as a positive experience with NRT relieving withdrawal symptoms may increase NRT use during future attempts [11,35].

The advice and brief counseling interventions described earlier should also be used during the inpatient stay. However, a recent meta-analysis indicates that cessation programs that do not provide cessation support for at least 1 month post-discharge are not efficacious, whereas treatments that begin during an inpatient hospitalization and continue contacts for at least 1 month after discharge increase the odds of cessation by 65% [44].

In line with these findings, starting in January 2012, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) will begin tracking the rate at which hospitals offer and provide inpatient and post-discharge cessation treatment to all hospitalized tobacco users, regardless of medical diagnosis [45].

Given that hospitalized patients are acutely ill, it is particularly important to consider possible contraindications for psychopharmacology in this setting. For example, the FDA package inserts recommend that nicotine replacement should be "used with caution" for 2 weeks following an MI [11]. The cardiac risk of varenicline has also been called into question [46]. Thus, with certain patients, inpatient providers must weigh the medical risk of prescribing pharmacological cessation aids with the benefit of an increased likelihood of cessation.

COMMUNITY-BASED APPROACHES

Mass Media Campaigns

Despite the overwhelming evidence supporting the dangers of smoking, many smokers worldwide underestimate the full extent of the risk to themselves and others [47]. Mass media, which includes television, film, the Internet, radio, newspapers, magazines, billboards, and packaging, can play a key role in shaping smoking-related knowledge, attitudes, and behaviors [47]. Mass media campaigns can be designed either to directly target individuals' behavior or to influence the social and political landscape, which can lead to a change in social norms around smoking [48]. Theoretically based campaign messages broadcasted at a sufficient intensity, frequency, and duration have been associated with an increase in the number of calls to telephone quit-lines [49], a reduction in adult and youth smoking prevalence [50–53], an increase in adult cessation rates and youth abstinence rates [54,55], and sustained positive changes in attitudes, beliefs, and intentions to smoke among youth [56]. As such, theoretically based mass media campaigns can be cost-effective when compared to other smoking cessation interventions, given that they can positively influence behavior and reach large populations quickly and efficiently [57]. Future research will need to investigate the benefits of using newer types of communication such as social media (e.g., Twitter, Facebook), as they are becoming increasingly more effective in reaching a wider cross section of the population, particularly adolescents.

Worksite Programs

Although smoking is more common among unemployed adults, nearly 25% of full- and part-time workers smoke [11]. There are numerous adverse effects associated with employees that smoke, such as increased health care costs and disability, greater absenteeism, poorer job performance, and an increased risk of injury [58]. As a result, employers may be motivated to provide support for effective worksite smoking cessation programs as a way to offset the potential costs related to the negative health consequences of smoking [59]. There are several advantages to conducting a cessation program in such an environment, including (1) access to a large, stable population; (2) the potential for high participation and compliance; (3) a socially reinforcing network and positive atmosphere; (4) an opportunity to include a diverse or hard-to-reach population; and (5) the ability to run a program that can be tailored to the interests, challenges, and needs of a particular group [60]. To date, research has shown that when individual and group counseling, pharmacological treatment, and competitions and incentives for participation in these programs are offered, employees who smoke are likely to quit at rates that are at least comparable to off-site programs [60,61]. However, more studies are needed, as participation in worksite interventions has been lower than expected, and most of the research has been conducted in traditionally stable worksites, which are becoming less common with advancing technology and increasingly mobile employees. Lastly, there is a lack of data detailing the specific costs of worksite smoking cessation programs and the relevant associated potential economic outcomes such as reduced absenteeism and increased productivity [60].

TECHNOLOGY-DRIVEN APPROACHES

Internet-Based Interventions

Almost one-third of the world's entire population (i.e., over 2 billion people) actively uses the Internet [62]. In the United States, 78% of the population uses the Internet, with rates of use equal between genders and relatively consistent across other demographic variables (e.g., age, race/ethnicity) [63]. Internet-based interventions are emerging as potential channels for smoking cessation intervention [64,65]. Internet-based services can potentially provide smokers with the option of finding information at any day or time they choose, unlike real-time counseling via telephone and individual or group counseling [64,66,67]. To date, interactive, web-based smoking cessation programs appear to be acceptable by users and more effective for cessation than control comparisons.

For example, Swartz et al. [68] used a fully automated website intervention composed of video segments and audio-targeted to users by age, sex, and race/ethnicity and found significantly higher 3 month abstinence rates (12.3%) relative to the wait-list control group (5.0%). Future research efforts need to use rigorous evaluation methods to determine the effectiveness of Internet-based components, such as e-mails, chat rooms, and other ways of engaging users and providing support during the quitting process. More information on factors, such as usability and sociability, that make people spend more time on sites or return to the sites more often is also important.

Text Message Interventions

Currently, more than two-thirds of the world's population own a mobile phone, and approximately 6.2 trillion text messages were sent in 2010 [69]. In the United States, it is estimated that 82% of the population owns a mobile phone, with 72% of adult and 87% of adolescent cell phone users sending and receiving text messages daily [70]. As such, researchers have begun examining the efficacy of using text message interventions for smoking cessation. Messages typically used during face-to-face smoking cessation support are modified for delivery via mobile phones with the content tailored to the age, sex, and ethnic group of the quitter [71]. Such an intervention allows for the smoking treatment to be delivered directly to the patient with minimal direct contact and to a large number of smokers at a low cost. Additionally, smokers can also receive messages anywhere, at the most appropriate or convenient times, and without threats to confidentiality [72]. To date, there have been just a few randomized controlled trials testing text-based smoking cessation interventions, but preliminary evidence is positive for short-term smoking outcomes (6 weeks) [72]. Future research is needed to determine if sustained effects can be achieved over longer periods of time (e.g., greater than 6 months).

SMOKING CESSATION IN SPECIAL POPULATION

Young Adult and Adolescent Smokers

More than 3000 children and adolescents become daily smokers every day [73], resulting in approximately 1.23 million new smokers under the age of 18 years each year. The prevalence of smoking among young adults aged 18–25 years remains the highest rate of all age groups [6]. To date, studies utilizing behavioral interventions with this population result in significant short-term results (7 day point-prevalence abstinence or continuous abstinence at 48 h to 3 months post-treatment). However, simply adapting adult interventions may not be effective in reducing young adult tobacco use [74]. Some of the key features of these interventions include recruiting participants through high schools and following them postgraduation as well as personalizing content to meet the specific interests of individual patients [74]. These strategies may allow for increased follow-up time and address issues related to intervention reach and effectiveness.

Racial and Ethnic Minority Smokers

Behavioral smoking cessation interventions have been shown to be effective across different racial and ethnic minorities [75]; however, treatments should be modified or tailored for the ethnic or racial population which will be used whenever possible [11]. Understanding smoking characteristics of the population is important when developing interventions for the community. Behavioral interventions alone may be more appropriate for Hispanic smokers as they consume fewer cigarettes than non-Hispanic whites [76,77] and are less likely to choose cessation aids when quit attempts are made [78]. However, given the significant heterogeneity within the nationalities in the United States, researchers should address the challenges of message framing and asking the appropriate questions for the target group [79]. In the United States, approximately 36% of Alaskan Natives and American Indians report smoking compared to about 23% of nonindigenous population [7]. Research indicates that the needs of this group are much greater given challenges including access to resources and acceptance of smoking in families and communities [80,81]. Finally, smoking in the African American community remains a major contributor to negative health consequences. Efforts to increase African Americans' participation in clinical research may aid in the development of culturally acceptable and efficacious interventions [79]. Interventions that aim to address the barriers of racial and ethnic minorities will allow researchers to develop treatments that can meet each group's specific needs.

Pregnant Smokers

Behavioral support is the most widely used smoking cessation intervention for pregnant smokers. Providing behavioral support for cessation during pregnancy increases rates of cessation by up to 6% [82]. In a review of behavior smoking cessation interventions for pregnant smokers, the authors concluded that smoking cessation programs in pregnancy are effective both in reducing the proportion of women who continue to smoke in late pregnancy and in reducing low birth weight and preterm birth [83]. Recent reviews concur that evidence regarding smoking cessation interventions are effective; few studies examine the long-term efficacy of these interventions in preventing relapse [84,85]. Approximately 75% of women who quit smoking due to pregnancy (women who quit smoking prior to becoming pregnant or during pregnancy) return to smoking by 6 months postpartum [86]. This highlights the need for continued development of interventions that address factors associated with postpartum relapse (weight concern, stress, negative affect) to increase cessation maintenance [87].

Mentally Ill Smokers

Cigarette smoking among individuals with mental illness (e.g., depression, schizophrenia) is more common than in the general population, and this can be attributed to complex neurobiological, psychological, and pharmacotherapeutic

mechanisms [88,89]. Current clinical guidelines recommend that smokers with mental health problems should be treated with the same smoking cessation strategies as those used for the general population, even though most of the research on cessation has been conducted in the general population and not in smokers with psychiatric comorbidities. Although the health risks of smoking are the same among those with mental illness, nicotine may have certain beneficial effects across a range of mental health domains, including improved concentration and cognition, relief of stress and depressive affect, and enhanced pleasurable sensations [88]. As a result, smoking cessation programs for this population should carefully consider the dynamic relationships among nicotine dependence, nicotine withdrawal symptoms, and mental illness. Current evidence suggests that flexible and individualized treatment programs (e.g., smoking reduction) may be the most successful; however, larger randomized controlled trials are needed to confirm these initial findings [90,91].

OTHER BEHAVIORAL APPROACHES

Exercise

The U.S. Department of Health and Human Services currently promotes using exercise as an aid for quitting smoking [11], and a wealth of clinical trial and acute laboratory-based research has examined the use of exercise as an adjunct to treatment. Overall, it appears that exercise is helpful for managing smoking cessation because it can reduce nicotine cravings and many of the withdrawal symptoms that often accompany quitting, such as negative affect and weight gain [92,93]. To date, however, the majority of studies conducted have only focused on females and light- or moderate-intensity aerobic exercise [93]. More recent research has begun to examine the benefits of other types of exercise such as resistance training (i.e., weight lifting) and yoga, and has included males [93–95]. Going forward, more research, with larger sample sizes, sufficiently intense interventions, equal contact control conditions, and measures of exercise adherence and change in physical activity in both exercise and comparison groups, is needed [93].

Abrupt Quitting and Gradual Reduction

The traditional behavioral method used to quit smoking is to smoke as normal until a predetermined "quit day" and then abruptly stop using all cigarettes. An alternative approach beginning to gain support is to gradually reduce the number of cigarettes smoked prior to quitting completely [96,97]. The value of this approach is somewhat controversial because there is concern that short-term decreases in smoking will not be maintained and that future quit attempts and motivation to quit will ultimately be undermined [96]. However, recent research shows that smokers using the reduction method have been able to maintain abstinence [98], and this technique may be more attractive to smokers less motivated to quit [96,99,100]. When comparing the effects of abrupt quitting versus gradual reduction, studies have found no difference in quit rates, and these effects held whether or not behavioral support, self-help materials, or NTR was used [98]. Although more studies are needed in this area, the most current research suggests that smokers should be given a choice of quitting methods, either reducing smoking before quitting or abruptly quitting [96,98].

SUMMARY AND CONCLUSIONS

Worldwide, there is an urgent need to reduce cigarette smoking. This chapter has described a range of approaches and strategies that have shown promise for changing smoking behavior in various settings and across several population. Overall, targeted behavioral interventions that build on smokers' current needs and skills are the most effective. Smokers should be matched with a cessation program based on their motivational level and previous experience with quitting. This includes strategies ranging from low intensity (brief advice) to high intensity (medication with individual counseling). Given the clear role that cultural and socioeconomic factors play in smoking status, future cessation programs need to focus on the social and contextual issues that support cigarette smoking. Ideally, smoking cessation programs will be regularly incorporated into existing community-based organizations, increasing the likelihood that these strategies will be disseminated to, and effectively used by, the population with the highest level of smoking prevalence and greatest need for help.

The prevalence of obesity in this country has increased at an alarming rate, creating a major public health concern. The most recent National Health and Nutrition Examination Survey (NHANES) data indicate that more than two-thirds of U.S. adults are considered either obese or overweight [1]. Indeed, one-third of Americans (32.2% of men and 35.5% of women) are considered obese, defined as a body mass index of 30 or greater. The excess body fat associated with overweight and obesity is associated with a host of adverse outcomes. For example, obesity is an independent risk factor for cardiovascular disease, negatively affects cardiac function, and increases the risk factors for heart disease such as type 2 diabetes mellitus, dyslipidemia, pulmonary disease, and hypertension [2]. The entrenchment of the obesity epidemic constitutes a significant public health issue, with dramatic state-by-state increases in obesity documented over the past 20 years (see data from the Centers for Disease Control documenting these changes; [3]). This resulting pattern of increasing prevalence of obesity has led to tremendous costs to our health care system, and if it continues, "total health care costs attributable to obesity could reach $861 to $957 billion by 2030, which would account for 16%–18% of U.S. health expenditures" [4].

The factors that contribute to the prevalence of obesity in our society (a bountiful supply of inexpensive and highly appealing food, less reliance on manual labor at home and work, and sedentary leisure activities) appear rooted in our society, thus obesity levels are likely to remain at epidemic levels. Weight loss, even as modest as 5% of initial weight, can improve many of the obesity-related risk factors for heart disease [5]. Thus, effective intervention strategies designed to reduce body weight have never been more important.

BEHAVIORAL STRATEGIES FOR WEIGHT LOSS

Behavior modification approaches to obesity have been applied and researched for more than 40 years. Consisting of a set of approaches drawn from the principles of social learning theory, behavioral modification emphasizes alteration of eating and activity habits by manipulation of eating-related environmental cues. It postulates that maladaptive behaviors are learned through classical conditioning, instrumental conditioning, or modeling, and emphasizes (1) the contribution of environmental factors that precede behavior (antecedents), through intervention strategies such as stimulus control, as well as (2) the consequences of eating and exercise behaviors, through intervention tactics such as contingency management and incentives [6]. Individuals who successfully utilize these strategies often reduce their initial body weight by 8%–10% within 4–6 months of treatment [7]. It should be noted that behavior modification is currently the most widely used formal treatment for those with mild to moderate obesity and

has led to improvements in the magnitude and stability of weight loss maintenance [8]. Even with the advent of other medical or dietary treatments for obesity, including various low- and very-low-calorie diets, pharmacotherapy, or surgical approaches, the majority of these are commonly implemented in combination with behavioral approaches, thus improving the effectiveness of these interventions for weight loss success [9–11].

The purpose of this chapter is to review several key behavioral approaches to weight loss and maintenance. For each approach, we describe how the intervention was developed; that is, we present the behavioral principles that guided its conceptualization, describe how the strategy is utilized, and review research on its effectiveness. It should be noted that most of the research examining the effectiveness of these strategies for weight loss has focused on altering eating habits, rather than exercise behaviors. Exercise by itself is not a particularly effective weight loss strategy with typical weight losses less than 3% of initial body weight [12]. However, it is clear that greater weight loss occurs when weight loss treatment includes both dietary and exercise components.

SELF-MONITORING

Self-monitoring, defined as the systematic observation and recording of one's own specific target behaviors [13], is a critical component of any behavioral treatment for obesity [14]. Self-monitoring for weight management most often focuses on dietary intake, but is also used to observe physical activity patterns, and changes in body weight. Through daily recording of dietary intake, and the circumstances under which eating occurs, critical information is obtained that allows the health care provider to tailor more accurate, specific intervention strategies [8,15]. Additionally, self-monitoring not only has been found useful in both assessment and treatment phases of weight management, but several studies have documented spontaneous reduction in caloric intake upon initiation of self-monitoring, presumably due to the increased awareness of food intake [16,17]. Studies consistently show that individuals who self-monitor eating and exercise behaviors more consistency and completely (e.g., all food consumed, time of eating, quantity of food eaten, or grams of fat consumed) have the greatest weight loss [18,19]. Sperduto et al. [20] found that behavioral weight loss groups that incorporated self-monitoring experienced greater weight reduction, as well as better attendance, than control groups not monitoring their eating and activity levels. Burke et al. recently published a systematic literature review on self-monitoring of food intake, physical activity, and body weight in behavioral weight loss studies [21]. They concluded that there is a consistent finding between adherence to self-monitoring and greater weight loss. While the studies reviewed covered a wide array of self-monitoring methods, the paper diary was used most often. Adherence to self-monitoring was reported most frequently as the number of diaries completed. The authors noted that the most significant limitations of the research in this area are the reliance on self-report for measuring self-monitoring and a lack of diversity in the samples [21]. The use of technological devices, such as smartphone applications, to aid in self-monitoring has improved the convenience of self-monitoring and perhaps the reliability of data gathered in real time. Whether this leads to improved weight loss outcomes remains unclear.

While most research on self-monitoring and weight loss has examined the monitoring of food intake or the monitoring of food intake with physical activity, there is some evidence to suggest that monitoring exercise alone increases physical activity levels and can result in modest weight loss even without a dietary intervention. In a study conducted by Carels et al., participants recorded daily the type and duration of their physical activity. Individuals who were the most consistent monitors of physical activity (turned in the most exercise diaries) exercised more often, experienced fewer difficulties with exercise, and achieved significantly greater weight loss [22]. In a review of the literature examining the effectiveness of pedometers, Bravata et al. found that using a pedometer increased physical activity by 27% and reduced BMI by 0.38 [23]. A recent meta-analysis of pedometer-based walking studies without a dietary intervention found that pedometer usage resulted in an average weight loss of about 0.05 kg/week and that longer interventions were associated with greater weight change [24]. Consistent with this, Polzien et al. [25] found that continuous use of an energy expenditure armband body monitor (Sensewear Pro Armband; Bodymedia, Pittsburgh, PA) during a 12 week behavioral weight control program led to a slightly better weight loss than either standard behavioral weight loss or using the armband body monitor only intermittently. Given that pedometers are quite inexpensive, easy to use, and lead to increased physical activity and weight loss (albeit modest), pedometer usage combined with self-monitoring is a useful tool for the weight loss interventionist.

Frequency of self-monitoring of body weight has recently been called into question. Previously, weekly weigh-ins were widely held to be most effective for optimal weight loss, providing weekly feedback on weight loss success, while not allowing success to be entirely defined by the number on a scale. However, this assumption has been challenged recently, given the argument that more frequent self-monitoring of body weight serves to increase awareness of weight and its relation to recent behaviors engaged in (e.g., food intake and lifestyle activity). Recent research suggests that more frequent weighing (daily) is associated with greater weight loss and less frequent weighing is associated with weight gain [21]. For example, Butryn et al. [26] investigated self-weighing and weight loss maintenance in individuals who had successfully maintained a weight loss, and found that more frequent weighing (once per day) was associated with lower BMI. Weight gain at 1 year follow-up was significantly greater for participants whose self-weighing frequency decreased compared with those whose frequency increased or remained the same. Consistent daily self-weighing may help individuals maintain their weight loss by alerting them to small increases in body weight so that they can

make the appropriate adjustments in their behaviors to prevent additional weight gain. Nevertheless, among those few individuals who weigh themselves multiple times a day, it is our clinical impression that this frequency may become anxiety provoking and may lead to weight regain. In sum, these findings suggest that daily self-weighing should be stressed in clinical practice.

Research confirms the need for consistent self-monitoring in behavioral weight reduction programs, not only to produce benefits such as increased awareness of eating behaviors, physical activity patterns, and greater weight loss, but also to prevent failure in self-awareness and self-regulation [19,27]. Although there is no doubt that self-monitoring is an effective strategy, adherence can be a problem. Research is needed to uncover effective strategies for maintaining this self-monitoring. One strategy may be to reduce the level of detail required for the self-monitoring record as participants may find detailed self-monitoring to be too time-consuming to maintain over the long run. Helsel et al. found that transitioning to a simplified approach to self-monitoring did not negatively affect short-term weight loss in overweight adults [28]. Advances in technology can also offer suggestions that may ease the burden of dietary self-monitoring. For example, a study by Burak and King compared traditional paper diaries to digital photos and found that the individuals using photos to record intake were more successful at losing weight [29]. Given that so many cell phones are equipped with cameras, taking a photo of the food consumed may be an easier and more accurate way of recording intake than writing in a paper diary. Yon et al. compared traditional paper diaries to personal digital assistants (PDA) for dietary self-monitoring in overweight adults enrolled in a behavioral weight control program for overweight adults [30]. This study found no significant differences in weight loss or dietary self-monitoring. Both methods were effective at producing weight loss suggesting that matching individuals to a mode of self-monitoring that is fitting to their lifestyle and skills may lead to greater adherence. In summary, overweight individuals should be encouraged to self-monitor their food intake and physical activity using the mode (paper diary, photos, PDA, pedometer, smartphone) they find most acceptable and to weigh themselves daily.

STIMULUS CONTROL

Stimulus control is a term used to describe a set of procedures that seek to alter the antecedent stimuli that control behavior [31]. Stimulus control applied to weight management is directed toward modifying factors that serve as cues for inappropriate eating [32] or physical inactivity. Cues are often environmental (e.g., driving by a favorite fast food restaurant on the way home from work), but can be derived from internal factors as well, including cognitive (e.g., conveniently placed reminders to exercise) or physiological (e.g., cravings to eat when under stress) cues [33]. Indeed, obese individuals are more likely to be distracted by food-related cues than are normal weight individuals or those who have lost and maintained their weight [34]. Consistent with this, research utilizing functional brain imaging has shown overweight to be related to a hyperresponsivity of dopamine-based reward circuitry in the brain and a greater attentional bias to food cues among adolescents, leading to an increased risk for weight gain [35]. Targeting and altering an individual's triggers for eating, as well as the consequences of eating, remain integral components of most behavioral weight loss programs for adults, as well as for children [8,32,36].

Stimulus control strategies may be divided into several categories: limiting the times and places associated with eating, reducing exposure to food by storing it out of sight, limiting activities associated with eating, and reducing the purchase of problematic foods, thereby breaking "automatic" eating responses [8,16,37]. In one study [38], participants were randomly assigned to one of several behavioral interventions. Importantly, the stimulus control strategies taught—and used by participants (specifically, eating in one place only, shopping from a list, storing food out of sight, and deciding ahead what to eat)—were the only variables that predicted weight loss. Additionally, when combined with positive eating behaviors, such as making healthy food choices and limiting portion sizes, stimulus control strategies were the only factors that predicted weight loss and successful maintenance. Stimulus control strategies incorporated within standard behavioral weight loss treatments have also been shown to facilitate weight loss [39]. In a brief, 8 week weight loss study, those who received the active intervention, consisting of a "Ten Top Tips" brochure of 10 stimulus control strategies for reducing calorie consumption, promoting healthy routines, and increasing self-monitoring, were more likely to have lost 5% or more of their body weight than those in the no-treatment control condition [40]. By encouraging basic changes in these daily behaviors, new healthier behaviors may be learned and substituted for previously entrenched, unhealthy behavior chains.

GOAL SETTING, CONTINGENCY CONTRACTING, AND REINFORCEMENT

The process of setting small, realistic goals allows the complex task of losing weight to be broken down into meaningful, simple steps that are achievable [33]. Contingency contracting builds upon the notion of goal setting, asking an individual to identify the target behavior needed to be changed, the consequences for meeting—and not meeting—the target behavior goal, the time frame for completion of goals, and the proposed reinforcement for achieving the goal. Based upon the learning principle of shaping [41], goal setting and contingency management can be useful and powerful tools in delineating specific target behaviors for change, as well as establishing criteria for success and consequences for both desirable and undesirable outcomes [42,43]. Weight loss programs incorporating behavioral contracting have resulted in greater weight loss and lower attrition rates than programs not incorporating these elements [42,44]. Inherent in the use of contingency management are the processes of self-monitoring, self-evaluation, and reward for goals obtained.

Several methods of direct reinforcement of weight loss have been investigated in the literature, including monetary contracts for weight loss, dietary compliance, or physical activity; refundable deposit contracts; or lottery incentive programs. Early research by Mahoney [14] investigated the contribution of self-reward for short-term weight loss, comparing treatment conditions of self-reward for weight loss, self-reward for habit improvement, self-monitoring without specific instruction in self-reward, and a delayed treatment control group. Results suggested that when self-reward, in the form of a refundable deposit, was added to the process of self-monitoring and self-evaluation, greater weight loss was obtained.

More recently, there is mixed support for the use of economic incentives, in the form of deposit contracts or lottery incentive programs, in producing significant short-term weight loss, with some studies yielding significantly improved weight losses in those receiving economic incentives [45,46], and other studies finding incentives yield no differences in weight loss program enrollment or weight loss [47]. Interestingly, one study investigating a behavioral intervention with direct reinforcement (monetary compensation) as compared with a behavioral intervention combined with free prepackaged, portion-controlled meals found that adding this food provision, but not the monetary compensation, was associated with significantly improved weight loss, as well as improved treatment attendance and quality of diet [6]. The authors speculate that, in addition to the economic incentive of free meals being offered, the packaging of food and portion-controlled meals may have also significantly affected antecedent eating cues. Similarly, Rock et al. found that those receiving a structured weight loss program that included free prepared meals lost significantly more weight than those assigned to a usual care group (two visits with a study dietician), with these weight losses largely maintained through 2 year follow-up [48].

At the present time, there is great variation in the types of direct reinforcement incentive programs being utilized in behavioral weight management programs, as well as variability in the behaviors targeted for change. While results are mixed, it is clear that contingency management and the role of direct reinforcement will continue to be explored for their effectiveness in improving weight loss outcomes. Most studies of direct reinforcement have included incentives within the active treatment phase (average 12–20 weeks), although have yet to explore the longer-term use of economic incentives. This research may have significant implications for managed health care programs in the future.

COGNITIVE RESTRUCTURING

Cognitive restructuring techniques focus on changing the errors in thinking that contribute to maladaptive, unhealthy behaviors [49]. Behavioral treatment programs for obesity have long incorporated cognitive strategies for changing the maladaptive thought processes that are likely to hinder weight loss success [8,50,51]. Based upon Mahoney and Mahoney's [52] early work describing maladaptive cognitions frequently experienced by dieters, common irrational beliefs are identified and modified in order to improve success at weight loss and long-term maintenance. Common irrational beliefs held by overweight individuals include: self-doubt over weight loss ("I've never been able to do it, why would I succeed now?"), establishment of unrealistic goals ("I'll never overeat again"), and punitive self-statements ("I'm a failure because I can't lose weight"). Individuals that hold more of these maladaptive cognitions and disparaging views of self are more likely to experience greater emotional distress and unhealthy eating patterns, which contributes to difficulty losing weight and maintaining weight loss [16,52,53].

Research suggests that cognitive factors play a critical role in weight regulation [54], with alteration of maladaptive cognitions particularly important in developing greater control overeating, preventing relapse, and thus, improving long-term success. Although cognitive distortions may be commonly experienced among overweight and obese individuals, research supporting the utility-specific cognitive restructuring techniques in weight management interventions has been mixed. In a comparison of cognitive-behavioral treatment (CBT) for obesity, behavioral therapy, and minimally guided self-help, Cooper et al. found that the CBT and behavior therapy conditions resulted in average weight losses of 10% of initial body weight [55]. However, at 3 year follow-up, the large majority of participants in all three conditions had regained nearly all of the weight lost, leading the authors to suggest that the long-term management of obesity is resistant to psychological methods of treatment [55]. However, Werrij et al. found that the addition of cognitive therapy to a group dietary intervention led to a greater weight loss at end of 10 week intervention, which was sustained at 1 year follow-up [56]. Although research to date highlights the importance of cognitive factors in obesity and weight control, identification of specific, clinically effective cognitive techniques is needed. Focusing on development of appropriate cognitive outcome measures that shed light on the specific cognitive processes involved in weight loss treatment may be worthwhile.

SOCIAL SUPPORT

Social support is commonly included in behavioral weight management protocols in one of three capacities: (1) teaching skills to participants in order to elicit and further enhance their social support networks, (2) actively involving significant family members in the weight loss process with the participant, or (3) eliciting social support as part of the group process. While there are many instances in the scientific literature of increased social support leading to improved weight loss and maintenance [57], questions remain about the amount of support needed in order to maximize success, the type of support most effective at eliciting weight loss, and whether supports also need to lose weight in order to be an effective source of support. While it has been well documented that having social support is associated with

successful weight loss, how to enhance an individual's support for healthy living is not well understood.

The presence of a cooperative spouse, or family member, does not guarantee improved weight loss [58]. Brownell et al. [59] found that participants whose spouses attended weight loss sessions and were trained in the specific techniques of modeling, self-monitoring, and reinforcement lost significantly more weight than either participants with a cooperative spouse who did not attend sessions or participants with a noncooperative spouse who refused to participate in sessions. These results are consistent with a study by Gorin et al., which found that participants who had at least one successful partner (defined as at least 10% weight loss) lost significantly more weight at all follow-up time points through 18 months, as compared with those with no successful partners or those without participating partners [60]. As would be expected, weight loss behaviors of participants and their partners were highly related, such as completion of food diaries. Thus, support partners appear to be beneficial in obesity treatment when the partners themselves lose weight, perhaps due to increased instrumental support offered during the process of weight loss.

Further research is needed to discover which types of social support are most helpful for successful weight loss. Recent research has explored the role of autonomy support and autonomous self-regulation on short-term weight loss [61], which suggests that receiving autonomy support (e.g., "My family and friends listened to how I would like to do things regarding my weight") in the naturally existing social environment of family and friends is more effective at yielding weight loss, as opposed to well-meaning, directive support. Qualitative interviews examining the social support needs of overweight/obese African American women are consistent with the earlier text, with women interested in receiving support through co-participation in exercise, using positive reinforcement and incentives, and avoiding criticism [62].

With the increased use of technology-driven weight loss interventions, the issue of how social support fits into these interventions is raised. A review of the literature on technology-based weight loss interventions finds that social support remains a critical aspect of successful Internet-delivered weight loss programs [63]. Indeed, use of online supportive counseling, whether via chat rooms or e-coaches, may be an alternative to face-to-face meetings [64]. A recent study conducted by Gabriele et al. [65] evaluated three different forms of support included in a 12 week Internet-delivered weight loss intervention: minimal e-coach support (involving a weekly lesson e-mail and no individualized support), nondirective e-coach support (individualized feedback, with goals selected by participant), and directive e-coach support (specific advice on weight loss provided, with goals and topics of discussion chosen by e-coach). Females in the directive support condition lost more weight than females in the nondirective and minimal support conditions, suggesting that a directive support approach for weight loss may be particularly useful for those participants who are motivated to lose weight, but perhaps feel they lack the skills necessary to overcome obstacles. Research such as this illustrates how the various dimensions of social support (e.g., directive and nondirective) can be manipulated in order to explore how to best incorporate support into a weight loss program for a given individual, whether delivered face-to-face or over the Internet.

USE OF eHEALTH TECHNOLOGIES TO CHANGE WEIGHT LOSS BEHAVIORS

The past decade has seen tremendous growth in the area of eHealth technology, defined as "the use of emerging information and communication technology, especially the internet, to improve or enable health and health care" [66]. While initial eHealth technology facilitated tailoring of intervention print materials, the current generation of eHealth technology, such as smartphones, digital cameras, personal data assistants (PDA), and tablets, continues to expand what is possible in receiving timely, tailored psych-educational information; reporting on physical activity and dietary behavior goals and tracking daily progress; and providing and receiving individualized social support via synchronous chat rooms or e-coaches [67]. Smartphones, now carried by over 80% of U.S. adults, have become pervasive in our society [68]. There are countless smartphone software applications (apps) available for calorie counting, meal planning, exercise tracking, calorie expenditure, etc. These include such apps as *myfitnesspal.com*, which allows a person to track their eating and exercise behaviors on their smartphone and automatically synchronize this information to the web, or *mealsnap.com*, which allows a person to use their smartphone to take a picture of any food or drink, with the system automatically identifying and providing estimated calories. Indeed, it is estimated that nearly one-third of the 1.4 billion smartphone users in 2015 will be using mobile health care apps [69]. Needless to say, there is a growing literature on the use of smartphones in improving health behaviors [70]. Indeed, the concept of ecological momentary assessment (EMA), or the use of personal computing devices to enhance accurate reporting of real-time, self-reported data, can now also be applied to an ecological momentary intervention paradigm [67]. Future empirical studies and clinical applications will need to consider how to best marry the convenience of eHealth technologies with further improving the quality and outcomes of the interventions provided.

WEIGHT MAINTENANCE STRATEGIES

It has been well documented that recidivism following weight loss is a serious problem [71]. Some estimate that most patients regain all of their weight within 3–5 years [72]. Although numerous studies have documented high relapse rates for weight control, few investigations have identified effective maintenance strategies. This section reviews the relevant research on behavioral strategies for weight maintenance.

MAINTENANCE GROUPS

In the 1980s, Perri et al. established the foundation of current knowledge of effective maintenance strategies. In a series of studies [73–75], the effects of professional contact, telephone contact, relapse prevention training, social support, exercise, and problem-solving skills were investigated. Perri et al. [75] examined 26 men and 97 women who were 20%–100% overweight and who participated in a 20 week group behavior therapy weight management program. During the 20 week program, participants were taught numerous behavioral strategies: self-monitoring, stimulus control, self-reinforcement, cognitive restructuring, and slowing the rate of eating. After 20 weeks, subjects were randomly assigned to follow-up only or to four different 6 month biweekly maintenance programs:

1. A posttreatment contact condition that included weigh-ins, self-monitoring, and therapist-led problem solving of difficulties in maintaining habit changes in eating and exercise behavior. The problem-solving training included four steps: problem identification, brainstorming, decision making, and solution implementation and verification.
2. Posttreatment contact and a social influence program. The social influence program included monetary group contingencies for adherence, participation in lectures, and instructions in peer telephone contact.
3. A posttreatment contact and an aerobic exercise program that combined a new set of exercise goals and therapist-led exercise sessions.
4. A posttreatment contact and a social influence and an aerobic exercise program.

Participation in these behavioral maintenance groups proved highly beneficial. At the 18 month follow-up, the participants in the four posttreatment programs maintained 82.7% of their weight loss compared to an average sustained weight loss of only 33.3% for the participants in the no-posttreatment contact condition. Participants in the combined maintenance condition maintained 99% of their weight loss, suggesting that the combination of high-frequency exercise, coupled with support and problem solving, holds great promise in improving the long-term management of obesity. With increase use of telemedicine, these results have been applied to a telephone-based maintenance program. The researchers found that extended care, delivered either by telephone or in face-to-face sessions, was equally effective in preventing weight regain [76]. Since the Internet has the potential to reach a greater percent of the population than face-to-face clinic visits, this technology has recently been examined. However, investigators found that monthly personal contact was more beneficial in maintaining weight loss compared to a web-based intervention [77]. Finally, in terms of maintenance innovations, motivational interviewing counseling techniques have been widely used in the addictions field for many years. Recent research has applied these techniques in a weight loss maintenance program, finding them to be as effective as an approach focused on weight loss skill building [78].

STRATEGIES USED BY SUCCESSFUL MAINTAINERS

In a national survey, researchers at the University of Pittsburgh School of Medicine [79] created a National Weight Control Registry (NWCR) of 629 women and 155 men who lost an average of 30 kg and had maintained a weight loss of at least 13.6 kg for 5 years. The researchers were interested in learning more about the participants' weight loss and weight maintenance strategies and about what types of behavioral approaches people used. Fifty-five percent of the sample used a formal weight loss program, and 45% lost weight on their own. Most of the individuals (89%) modified both their dietary intake and their physical activity level to lose weight. The three most commonly used strategies to change diet were to limit the intake of certain foods, limit the quantities of food, and count calories.

During their 5 years of maintenance, most individuals (92%) reported limiting their intake of certain foods. Many also reported relying on self-monitoring techniques for limiting quantities of foods (49%), restricting fat intake (38%), counting calories (36%), or counting fat grams (30%). Participants also reported using stimulus control techniques. They ate most of their meals at home where food choices are more restricted. Subjects reported engaging in a high level of physical activity, averaging an equivalent of walking 28 miles/week. Participants engaged in cycling, aerobics, walking, running, and hiking. Thus, these maintainers participated in the type of physical activity that is recommended for weight loss, but the amount of time they reported exercising is more than double what is typically recommended.

A great deal continues to be learned from participants in the ongoing NWCR. Nevertheless, it is possible that this group of highly successful weight loss maintainers may not be representative of all individuals who have worked to maintain their weight losses. Later, we outline some of the key characteristics of weight loss maintenance that are consistent across the majority of research conducted.

PHYSICAL ACTIVITY LEVEL

While self-monitoring is the cornerstone of successful weight loss, exercise is the key to maintenance. As discussed earlier, successful maintainers tend to engage in a high level of physical activity [79]. Kayman et al. [80] found that maintainers were far more likely than regainers to exercise at least three times per week for 30 min or more. Maintainers also engaged in more lifestyle activity than relapsers.

Since exercise clearly facilitates weight maintenance, research is now focused on how to facilitate the adoption and maintenance of an active lifestyle. One promising approach is home-based exercise programs. Researchers have found that instructing patients in home-based exercise rather than in

group-based exercise over a 12 month intervention facilitated weight maintenance at a 3 month follow-up [81]. According to the authors, the greater convenience and flexibility of home-based exercise probably contributed to higher exercise adherence. During months 7 through 12, subjects in the home-based condition completed 78% of their exercise sessions compared to 48% in the group condition. Interestingly, participants in the home-based conditions attended more weight loss group sessions and were more likely to complete food records. A subsequent 4 year weight loss study yielded similar results—physical activity level related to weight loss maintenance and maintainers attended more treatment sessions and reported more favorable food intake [82]. Thus, the investigators speculate that exercise adherence may promote adherence to other strategies such as group attendance and self-monitoring of eating behavior, both of which facilitate maintenance.

More recently, clinicians and investigators have been closely examining lifestyle activities. Sedentary behaviors, such as watching television, are associated with elevated risk for obesity and type 2 diabetes [83]. Others researchers have found that obese individuals sit 2 h longer per day compared to lean individuals, thus leading to a difference of about 350 kcal/day, which could contribute to a weight gain of over 10 kg/year [84]. These findings have led some practitioners to focus on increasing physical activity level, both aerobic and strength training, and on decreasing sedentary behaviors, such as screen time [85].

COGNITIVE RESTRUCTURING STRATEGIES

As in active weight loss efforts, cognitive restructuring strategies also appear important during the maintenance phase of weight loss. For example, it has been proposed that unrealistic weight loss expectations may contribute to relapse [86]. If individuals are disappointed in their ability to reach their goal weight or discouraged with their rate of weight loss, these negative cognitions and emotions may reduce motivation and/or trigger overeating episodes. Research examining outcome expectations reveals the importance of challenging unrealistic outcome expectations [87]. In a study of 60 obese women, participants were asked prior to weight loss to identify their goal weight and four other weights: "dream weight" ("a weight you would choose if you could weigh whatever you wanted"); "happy weight" ("this weight is not as ideal as the first one; it is a weight, however, that you would be happy to achieve"); "acceptable weight" ("a weight that you would not be particularly happy with, but one that you could accept, since it is less than your current weight"); and "disappointed weight" ("a weight that is less than your current weight, but one that you could not view as successful in any way; you would be disappointed if this were your final weight"). Participants' goal weight averaged a 32% reduction in body weight. Despite a 16 kg weight loss during a 48 week treatment program, only 9% of subjects achieved a "happy weight." Furthermore, although they reported achieving numerous positive physical and psychological effects of weight loss, 47% still had not yet even reached their "disappointed" weight. Cognitive strategies to promote the adoption of a reasonable weight goal need to be identified by future research.

More evidence for the importance of cognitive strategies during the maintenance phase is provided by a study conducted by Kayman et al. [80]. These investigators found that maintainers incorporated a new eating style but to avoid feelings of deprivation did not completely restrict their intake of problem foods. In contrast, regainers also dieted but did not permit themselves any of their favorite foods, and they viewed their weight loss foods as special foods, different from the foods their family would have and different from the foods they wanted. Thus, classifying foods as "good" and "bad" probably promoted dichotomous thinking and may have contributed to relapse.

Confidence and attributions of success are other important cognitions to address in maintenance treatment. A recent study examining the relation between method of weight loss (VLCD, commercial program, self-guided approach) and weight loss maintenance found that the individuals who had used a self-guided approach were the most successful at maintaining their weight loss, leading the authors to speculate that confidence in one's ability to lose weight may have affected the choice of weight loss method [88]. In other words, individuals who chose to lose weight without outside assistance may have greater confidence in their ability to lose weight than those who selected a very intensive treatment such as a VLCD. Additionally, individuals who lose weight on their own may be more likely to attribute their success to their own efforts rather than attribute their success to a weight loss program.

STRESS MANAGEMENT

Having a high stress level is associated with health problems and unhealthy behaviors. Adults with high stress are more likely to be overweight and sedentary and have low confidence [89]. Therefore, stress reduction strategies continue to be important as individuals move from the weight loss phase to the weight maintenance phase of weight control. Kayman et al. [80] found that regainers and maintainers reported experiencing stressful events at the same rate; however, the two groups differed in how they responded to stress. Maintainers used problem-solving skills or confrontive ways of coping with stress. In contrast, relapsers used emotion-focused or escape-avoidance strategies such as eating, sleeping, or just hoping the problem would go away. A basic component of most stress management interventions is training in problem-solving skills, in which individuals are taught to identify problems, generate solutions, evaluate solutions, implement a solution, and then evaluate the results. More recently stress reduction programs have incorporated yoga, tai chi, and mediation, and how these interventions may impact weight maintenance should be examined [90]. Research continues to identify that problem-solving skills are important for weight loss outcomes [91]. Thus stress management strategies, in particular problem-solving skills, may be important for weight maintenance.

Social support has also been identified as a weight maintenance facilitator [59]. A support system can help one to solve problems, offer emotional support, or be available for practical assistance. Maintainers identify more support systems [92] and are more likely than regainers to seek support when dealing with stress [80]. This finding was recently replicated in a study of 1869 overweight and obese younger adults that determined increased emotional support to be a key predictor of weight loss maintenance [93].

In summary, continued contact with a professional, consistent physical activity, social support, and maintaining dietary intake changes all facilitate weight maintenance. Behavioral strategies that have garnered support for their role in weight maintenance include self-monitoring, stress management and problem solving, stimulus control, and cognitive restructuring. Although it is clear that there is a relationship between physical activity level and weight maintenance, we need to discover more effective intervention strategies for adoption of a more active lifestyle. Preparing participants and practitioners for adopting a continuous care model of obesity should also be beneficial.

EFFORTS TO MATCH TREATMENT TO A PARTICULAR INDIVIDUAL

There remains movement within the field of obesity treatment to consider individual characteristics when recommending treatments. Thus, rather than using a single approach with all obese individuals, effort is made to tailor or match treatments to individuals. For example, individuals may be matched to treatment based upon their percentage overweight. Treatment recommendations are determined by their likely effectiveness and a risk-benefit analysis [94]. Clark et al. [95] found greater attrition from a low-intensity weight loss program among individuals with higher levels of obesity. Factors other than level of obesity are also considered important when making treatment decisions. Schwartz et al. [96] surveyed experts in weight loss treatment to identify client characteristics important for treatment matching. Five factors were identified by a majority of the experts as important when making treatment decisions: weight, weight loss history, medical condition, eating disorders, and psychiatric comorbidity. Additional matching characteristics worth considering include a history of being the victim of sexual trauma [97], in particular, being the victim of childhood sexual abuse [98], and a negative body image [99] since both of these factors have been shown to impact obesity treatment outcome. Intuitively, the idea of treatment matching makes sense; however, there has been very little empirical validation of treatment matching models. Future research is needed that examines the validity and utility of treatment matching models for obesity.

SUMMARY

It is clear that the United States is experiencing an obesity epidemic, with a critical need for the development of effective strategies for weight loss and maintenance. Fortunately, the research literature provides empirical support for the effectiveness of several behavioral approaches for weight management (see Table 20.1). There is clear support for the effectiveness of self-monitoring dietary intake, physical activity levels, and body weight. Advances in technology, such as smart phones and their applications, as well as use of pedometers and accelerometers, have made monitoring these behaviors simpler and more accurate. It is also important to target and alter triggers for eating. Goal setting and contingency management have proven to be valuable tools in improving monitoring and altering overeating triggers. Recent research suggests that meal provision may be a particularly effective incentive for weight loss. Cognitive factors play a critical role in weight management, with alteration of maladaptive cognitions particularly important in developing more control over eating, preventing relapse and, improving long-term success. Social support can also be beneficial, particularly when provided in an empathic versus critical manner. Consistently engaging in high levels of physical activity appears key to maintaining a weight loss. Further research is warranted that examines the adoption and maintenance of an active lifestyle in an obese population. Although self-control procedures are still an integral part of most weight management programs, the focus has begun to shift to a lifestyle modification approach that recognizes that in order to successfully lose weight, the obese individual needs to establish a new—and improved—lifestyle that supports the maintenance of a healthier and thinner physique [92,100].

TABLE 20.1
Weight Management Strategies

Weight Loss	Maintenance
Decrease caloric intake	Physical activity
Increase caloric expenditure	Low-fat diet
Self-monitoring	Coping skills
Weigh daily	Extended treatment
Stimulus control	Social support
Cognitive restructuring	Reasonable goal weight
Social support	Self-monitoring

21 Women's Health
Challenges and Opportunities

Pamela M. Peeke, MD, MPH, FACP

There is a picture that frequently appears in PowerPoint presentations when gender differences are to be discussed. It's entitled "the gender-specific control panel." The top part of the panel shows a single on-and-off switch humorously depicting the stereotypic male view of life. Below, the panel is densely populated by countless, colorful knobs and switches reflecting the broad spectrum of influences over a woman's well-being. Despite the witty tongue in cheek pictorial, there is wisdom to be shared. In their comprehensive role as caregivers, women more often than not neglect their own self-care. Wading through the "knobs" of responsibilities, obligations, and deference to the welfare of others, women are prone to lose focus on their own health maintenance needs. However, even in the face of this age-old feminine challenge, the status of women's health care is changing for the better. Women can now access more credible information about the critical importance of health prevention. And they're feeling more free to discuss these issues with their medical provider. This includes establishing rituals of breast checks, monitoring bone mineral density, consuming a nutrient-rich diet of whole foods, and incorporating aerobic activities and strength training into daily life routines. This chapter will provide clinicians with the knowledge, tools, and tips to help them better communicate with and guide their female patients to optimal health and wellness.

With a projected doubling in the overall incidence of breast cancer by 2040, including an alarming rise in young women, there is an important need for prevention as well as treatment strategies. Beth Dupree outlines the epidemiology of breast cancer with particular focus on the history and controversy surrounding the role of hormonal replacement therapy (HRT). Clinicians will also enjoy an illuminating discussion of breast development through the hormonal milestones of a woman's life. Clarifying the roles of genetics and screening as it relates to breast cancer are kernel elements of this chapter. The protective effect of healthy lifestyle choices for both pre- and postmenopausal women is covered in depth, including the ability to prevent breast disease through positive behaviors beginning in youth. Acknowledging that 75%–80% of breast cancers occur in women with no family history, clinicians are tasked to help their patients decrease personal risk through healthy lifestyle behaviors.

Sobia Khan and Holly Thacker outline the medical as well as socioeconomic costs born by the diagnosis of osteoporosis. Worldwide osteoporosis affects over 75 million people, and causes more than 8.9 million fractures annually. The National Osteoporosis Foundation notes that currently over 10 million Americans carry the diagnosis of osteoporosis with another 34 million at risk, all occurring at a cost of $20 billion. With over half of all women over 50 years predicted to incur an osteoporosis-related fracture, the need for prevention is imperative. What is often overlooked is the level of serious disability associated with fractures, as well as life-threatening complications related to treatment and immobility. Of paramount importance is an understanding of the risk factors for bone loss and fracture, including age, genetics, lifestyle choices, menopausal status, prior incidence of a low trauma fracture, parental history of hip fracture, present tobacco smoking history, and long-term glucocorticoid use. In this chapter, clinicians will become familiar with the state of the art of screening for osteoporosis, noting that current evidence suggests that it is most effective in determining which postmenopausal women have low bone mineral density and how to prevent fractures in this population in particular. First detailing a host of therapeutic pharmacological options once a diagnosis of osteoporosis is confirmed, a strong case is then made for the incorporation of critical lifestyle elements including diet, vitamin D, and calcium supplementation as well as weight-bearing and strength training exercise. Clinicians will find the case studies useful models for their own daily decision making in patient care.

Inherent to any discussion about women's health is the issue of menopause. As close to 50 million women transition through this milestone stage of life, there are a constellation of challenges and endless questions about how to navigate the often stormy waters of hormonal fluctuations. Margery Gass provides the blueprint for comprehending the often complex physiology behind these endocrine fluxes, from causation to genetics. Clinicians are provided with a look into the psychosocial and cultural influences that shape a woman's perception of aging, beauty, and self-esteem during this watershed period. Menopause provides women a unique opportunity to stop and reassess their life goals and whether their current lifestyle habits support the achievement of these objectives. From weight control to sexual function, strategies are detailed to optimize quality of life from pre- to postmenopause. Clinicians are shown how to help a woman make the connection between her mental and physical fitness and how menopausal symptoms may manifest themselves. Complementary and alternative modalities are a constant source of inquiry

by women seeking options to traditional pharmacological modalities, to include nonhormonal prescription therapies such as selective serotonin reuptake inhibitors and selective norepinephrine reuptake inhibitors. However, the single most important discussion a woman will have with her physician is if and when HRT should be used and for how long. Since the tumult surrounding the early results from the Women's Health Initiative (WHI) trial, subsequent investigations have led to greater clarity about the actual benefits of HRT. When the WHI was first conceived, it was not yet known that the effects of estrogen therapy (ET) and the estrogen and progesterone theory (EPT) combination would vary so much by age. After comprehensive analysis of the WHI data, it became apparent that both ET and EPT are options that clinicians can recommend for most symptomatic younger postmenopausal but not older postmenopausal women. In this chapter, clinicians will understand that women today can and should have an open conversation with their physician about hormonal status and that many options are available to facilitate an optimal transition as they age.

In order to manage the constant incoming stresses and pressures in a woman's life while also striving to practice healthy lifestyle habits, it has become apparent that women need to master new life skills to achieve health and wellness in the face of these challenges. Witness then the emergence of credentialed professional health and wellness coaches providing the expert competency to help women achieve and sustain personal focus, responsibility, and motivation as they adapt and adjust to the dramas and traumas of daily life without resorting to self-destruction. In this chapter, Beth Frates and Margaret Moore present the case that although most women know the fundamental things they need to do to achieve mental and physical well-being, they're struggling with how to implement what appear to be simple strategies when they feel psychologically overwhelmed and technically disorganized. Social and behavioral scientists have developed a new approach—the psychology of healthy lifestyle—to guiding an individual through their daily personal and work-related mazes. Clinicians will learn how to empower their female patients with coaching competencies that help women learn how to become more mindful and focused, practice self-acceptance and self-efficacy, and maintain a positive inner dialogue of motivation. All clinicians will benefit from improved communication and coaching skills as they promote sustainable behavioral change leading to healthier lifestyle habits with their patients.

Shari Bassuk and JoAnn Manson provide clinicians with an overview of the epidemiological evidence on the relationship between physical activity and health outcomes in women. In doing so, they tease apart methodological challenges presented by the plethora of observational studies and lack of randomized clinical trials. That being said, there is convincing evidence of the significant impact of regular physical activity on morbidity and mortality. In this chapter, prospective studies are presented that show an inverse relationship between physical activity and all-cause mortality. As well, there is a dose–response relationship between women who exercise and their risk for coronary heart disease. Drawing upon data from the Nurses' Health Study, simply walking for 2.5 h/week was associated with a striking 25% risk reduction in type 2 diabetes. Similar disease risks are seen in a variety of cancers as well. Being more physically active and engaging in resistance training can strengthen bones, helping to reduce fracture occurrence, as well as prevent falls through improvements in flexibility, balance, and strength. Clinicians will appreciate the value of telling their female patients about the power of that 30 min walk every day to improve a woman's overall health status and maintain an active and vibrant life.

A discussion of body composition is a game-changer in the world of weight management. Pam Peeke describes why the prior reliance on body weight with no consideration of the quality of body components has led to consumer confusion and clinician frustration as both strive to achieve optimal physical fitness and health. Many women may share the same age, height, and weight, but their body composition will determine their ultimate physical fitness, shape, size, and disease risk. What begins as a description of the evolution of body composition throughout a woman's life span is followed by a discussion of the relationship between body fat and disease risk, and specifically the metabolic syndrome. Female sex steroid hormones affect body fat distribution and may regulate overall fat mass. Clinicians will learn about the various modalities for body composition measurement including accessible tools for use in routine clinical practice. The clinician will understand the importance of assessing body composition for purposes that include its use: (1) as a motivational tool, (2) in monitoring changes in body composition due to medical or age-related influences, (3) in identifying patients with increased disease risk, and (4) in evaluating the effectiveness of nutrition and exercise programs. In this chapter, the relationship between a woman's lifestyle habits and the status of her fat and lean body mass are presented so that clinicians may see the significant improvement in a woman's physical strength and independence along with a decrease in disease risk and disability. It is hoped that clinicians will monitor both body weight as well as composition as they recommend healthy lifestyle strategies.

INTRODUCTION

Menopause is an important milestone in a woman's life. It heralds the end of her reproductive years. Naturally occurring menopause is characterized by amenorrhea and marked diminution of estrogen/progesterone production resulting from the depletion of viable follicles in the ovary. Clinically, it is officially diagnosed after 1 year of amenorrhea not due to other causes.

Menopause can be spontaneous or the result of an intervention. Spontaneous menopause usually occurs between ages 40 and 55 years, with an average age of 51 years. In a study that enrolled students at the University of Minnesota in the 1930s and followed them through menopause, the age range of the 393 cases of spontaneously occurring menopause was 41–59 years with a mean of 50.7 years.[1] The Massachusetts' Health Study reported the average age of menopause to be 51 years.[2] More recently, the Study of Women's Health Across the Nation (SWAN) reported a mean age of menopause of 51.4 years for a multiracial/multiethnic group of women in the United States.[3] The study also reported that smoking, lower education, and nonemployment were associated with an earlier menopause.[3] Women who smoke reach menopause 1–2 years earlier than their nonsmoking counterparts.[3–6] Japanese race/ethnicity was associated with a later menopause compared to other ethnic groups in the United States.

There is some concordance of age at menopause within families, but both genetics and environmental factors play a role in determining when menopause will occur. Candidate genes have been identified but further research is required to understand the interplay between genes and the environment.[7]

Many women experience a surgical menopause as the result of having both ovaries removed. Hysterectomy is the second most common surgical procedure in women in the United States. Below age 45 years, approximately one-third of women undergo bilateral oophorectomy at the time of hysterectomy. Between ages 45 and 54 years, ~75% of women have a concurrent bilateral oophorectomy (Figure 22.1).[8] Other medical interventions that can lead to iatrogenic menopause include chemotherapy and radiation treatments, both of which can deplete the pool of viable follicles in the ovaries.

Perimenopause

Perimenopause is a defined period around the time of menopause. It includes the year after the final menses plus a variable amount of time leading to the final menstrual period (FMP). The perimenopausal time before menopause is variable because there can be a large difference in the number of months or years women spend with irregular menses and transient menopausal symptoms. The perimenopause construct is important because it is typically the most symptomatic time for women.

Perimenopause is one of several stages of reproductive aging defined by the 2012 Stages of Reproductive Aging Workshop (STRAW).[9] Achieving a consensus on the stages of the reproductive years and menopause as seen in Figure 22.2 provided a basis for standardizing scientific research in addition to serving as a clinical guide.

Women who experience menopause before age 40 years as a result of bilateral oophorectomy, or as a result of irreparable damage to the ovaries from radiation or chemotherapy, are said to have a premature menopause. Until recently, all women who experienced menopause spontaneously prior to age 40 years were considered to have premature menopause or premature ovarian failure. However, these terms are misnomers for a subgroup of these women who are not completely and permanently

menopausal. The proposed new terminology for women in this category is primary ovarian insufficiency (POI).[10,11]

Primary Ovarian Insufficiency

POI, also descriptively called hypergonadotropic amenorrhea, is a poorly understood condition that affects <1% of women. It is characterized by loss of menses for ≥4 months and a follicle-stimulating hormone (FSH) level in the menopausal range on two separate occasions at least 1 month apart.[10] The condition is distinguished from premature menopause by intermittent ovarian function. The variable estrogen levels can be borderline menopausal and may keep many of these women from having typical menopausal symptoms. From 5% to 10% of women with the diagnosis have conceived and delivered a child.[12–14]

Most women who receive this diagnosis are stunned to learn they have entered a menopause-like state, and they often benefit from social and psychological support. The term "primary ovarian insufficiency" is a more accurate description of the condition, and affected women seem to prefer it to "premature menopause."

Causes of POI have not been completely delineated. Two broad mechanistic categories are follicle dysfunction and follicle depletion. In the former, some follicles still remain in the ovaries, but an aberrant process prevents them from functioning normally. Follicle depletion can result from an inadequate original pool of follicles, accelerated depletion/apoptosis of a normal pool of follicles, or damage to the follicles by a toxin or an autoimmune condition. A cause is identified in ~10% of cases.[12] Table 22.1 gives a list of conditions that have been associated with POI.

TABLE 22.1
Causes of Premature Ovarian Failure/Primary Ovarian Insufficiency[a]

I. X Chromosomal causes
  A. Structural alterations or mutations in or absence of an X chromosome
    1. With the stigmata of Turner syndrome (45,X or mosaic)
    2. Without the stigmata of Turner syndrome
      a. Mutations in premature ovarian failure 1 (Xq26-q28)
      b. Mutations in premature ovarian failure 1 in association with fragile X premutation (Xq27.3)
      c. Mutations in premature ovarian failure 2A (Xq22)
      d. Mutations in premature ovarian failure 2B (Xq21)
      e. Mutations in premature ovarian failure 4 in association with mutations in bone morphogenetic protein 15 (Xp11.2)
  B. Trisomy X with or without mosaicism
II. Mutations associated with a 46,XY karyotype
  A. Mutations in Xp22.11-p21.2 (Swyer syndrome)
  B. Mutations in 5 cen
III. Autosomal causes
  A. Mutations involving enzymes important for reproduction
    1. Galactosemia (galactose-1-phosphate uridyltransferase deficiency) (9p13)
    2. 17α-Hydroxylase deficiency (CPY17A1) (10q24.3)
  B. Mutations involving reproductive hormones, their receptors, and action
    1. Mutations of luteinizing hormone or follicle-stimulating hormone or both rendering them biologically inactive (theoretical)
    2. Mutations of inhibin (theoretical)
    3. Receptor mutations
      a. Follicle-stimulating hormone receptor (2p21-p16)
      b. Luteinizing hormone/human chorionic gonadotropin receptor (2p21)
    4. Mutations in the hormone action pathways
  C. Other mutations
    1. Blepharophimosis, ptosis, and epicanthus inversus, type 1 (BPES) (premature ovarian failure 3) (3q23)
    2. Premature ovarian failure 5 (newborn ovary homeobox) (7q35)
    3. Autoimmune polyendocrine syndrome, type 1 (APS1) (autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy, APECED) (autoimmune regulator gene, AIRE) (21q22.3)
    4. Vanishing white matter leukodystrophy with ovarian failure (genes encoding the translation initiation factor E1F2B) (14q24, Chr 12, 1p34.1, 3q27, 2p23.3)
    5. Congenital disorders of glycosylation, type 1a (CDG1a) (genes encoding phosphomannomutase-2, PMM2) (16p13.3-p13.2)
IV. Environmental insults
  A. Chemotherapeutic (especially alkylating) agents
  B. Ionizing radiation
  C. Viral infection (documented for mumps)
  D. Surgical injury or extirpation
V. Immune disturbances
  A. In association with other autoimmune diseases
  B. Isolated
  C. In association with congenital thymic aplasia
VI. Idiopathic causes

Paradigms

Cultural beliefs play a role in how menopause is perceived and experienced. In some cultures in Africa, women gain respect equal to men when they become menopausal. Childless women may become depressed with menopause.[15] In cultures where the focus is on youth, beauty, and antiaging strategies, older women may perceive less respect and experience lower self-esteem.

Until recently, menopause was not discussed in public and sometimes not even in the home. SWAN interviewed 16,065 women from various ethnic groups in the United States and found generally neutral to positive attitudes toward menopause with some ethnic differences. Among African American, Caucasian, Chinese American, Hispanic, and Japanese American women in the study, the Hispanic women were most positive and the two Asian ethnic groups were the least positive (Figure 22.3).[16]

The medical community can influence how women perceive their menopause. In some professional circles, menopause has been labeled an endocrine deficiency disease and in others it has been described as a natural, normal phase in a woman's life. Researchers have debated whether women were prepared from an evolutionary perspective to live beyond menopause, pointing to the animal kingdom where females of most species die after reproduction. They also cite diseases of aging that become more common after menopause. However, others counter with examples of nonhuman female primates that live beyond their reproductive phase[17,18] and note that chronic diseases of later life are more related to aging than to menopause. Anthropologists report that menopause evolved very early in human history, millennia ago.[19]

Paradigms about menopause are shifting. Risk factors for cardiovascular disease (CVD), for example, may cause earlier menopause instead of the reverse hypothesis that an early menopause leads to CVD.[20,21] With regard to osteoporosis, the short-term accelerated loss of bone density associated with menopause parallels a short-term accelerated gain in bone density at puberty that is greater in girls than in boys.[22,23] The proposed hypothesis for the increased gain in bone mineral content at puberty and greater loss at menopause is the benefit this additional amount of calcium would supply for pregnancy and lactation.[22] In this paradigm, the short-term loss of bone at menopause is physiological, not pathological (Figure 22.4).

On an individual level, menopause conveys different meanings to different women. Just as different cultures have different views toward aging, individual women also have different

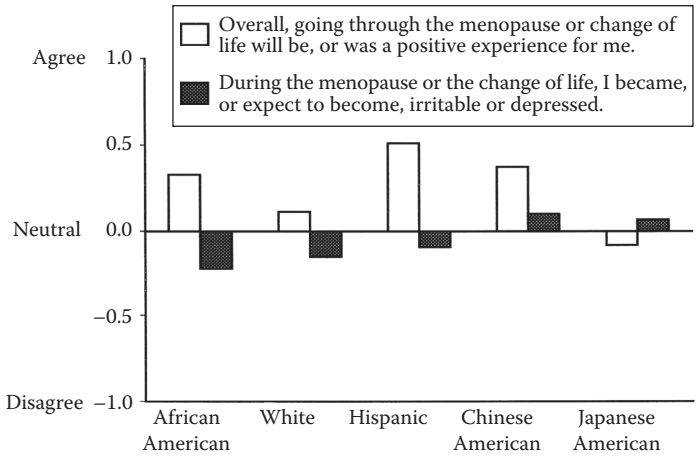

FIGURE 22.3 Degree of agreement and disagreement with affective items by ethnic group (means). (From Sommer, B. et al., *Psychosom. Med*., 61, 868, 1999. With permission.)

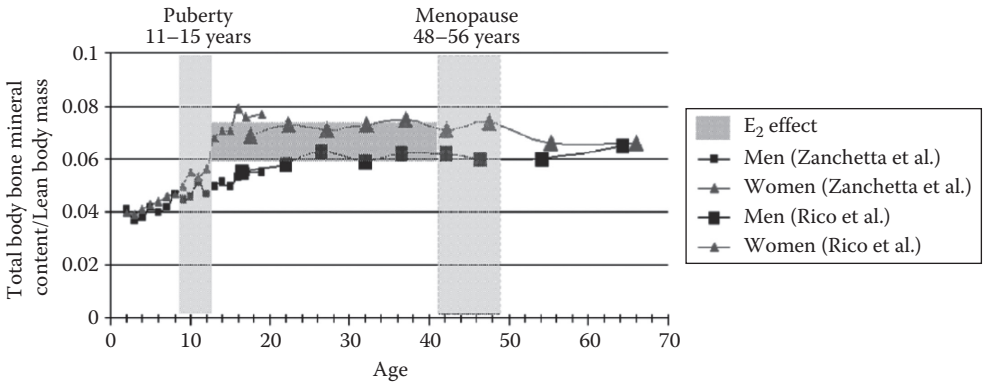

FIGURE 22.4 The ratio of total body bone mineral content to lean body mass plotted against age. views on aging. Menopause is a clear message that the reproductive phase of life has been completed. Loss of reproductive capacity may bring joy to some and sadness to others.

ENDOCRINOLOGY AND PHYSIOLOGY

The decline in the number of ovarian follicles that leads to menopause commences during fetal life. Halfway through the gestation, the female reaches her peak number of follicles, 2–6 million.[24] The decline in the number of follicles begins in utero. By the time of birth, the female infant has ~1 to 2 million and by the time of puberty, the approximate number of follicles is 400,000. Fewer than 500 follicles are used for ovulation with the rest being lost through the process of atresia. This process appears to occur at an ever accelerating rate of decline until menopause (Figure 22.5).[25]

Despite the decline in follicles and the decline in fertility (after a peak in the mid-20s), the ovaries continue to produce normal levels of steroid hormones until 2–3 years before menopause.[26] The irregular cycles that characterize perimenopause clearly signal a phase of markedly compromised fertility.[27] The consistently cycling hormone levels characteristic of the premenopausal years give way to higher-than-normal levels of estradiol resulting from higher FSH levels. These occasional very high levels of estradiol have been reported to occur in what has been called a luteal out-of-phase (LOOP) cycle.[28] In brief, this phenomenon involves the capacity of the elevated FSH levels to recruit a second dominant follicle during the luteal phase of a menstrual cycle, thereby producing the unusually high estradiol levels (Figure 22.6).

A primary cause of the gradual increase in FSH is the decreased production of inhibin B, which is one of two peptides (inhibin A and inhibin B) produced by the granulosa cells of the follicle. Inhibin A is produced by the dominant ovarian follicle in parallel with estradiol, and inhibin B is produced by the small antral follicles. The latter inhibits the production of FSH. The rise in FSH in the early follicular phase of the menstrual cycle that results from the decline in inhibin B is often seen in women over a mean age of 37–38 years.[29–31] The shrinking pool of follicles is related to both decreased fecundity and menopause.[32]

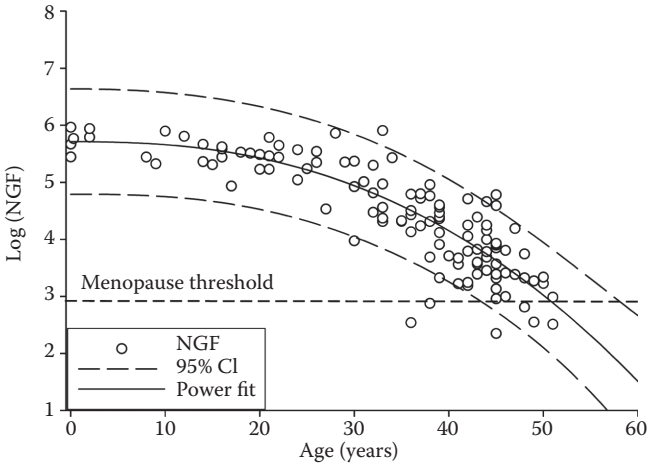

FIGURE 22.5 Power model of ovarian nongrowing follicle (NGF) decay. The log of the ovarian NGF number is plotted versus age (years). (From Hansen, K.R., Knowlton, N.S., Thyer, A.C., Charleston, J.S., Soules, M.R., and Klein, N.A., A new model of reproductive aging: The decline in ovarian non-growing follicle number from birth to menopause. *Hum Reprod* 23, 699, 2008. Reprinted by permission Oxford University Press. Copyright European Society of Human Reproduction and Embryology.)

Anti-Müllerian hormone (AMH), also produced by the granulosa cells, is another biomarker of menopause. This hormone has been found to be predictive of the age at menopause.[33–36] Unlike FSH and inhibin B, which vary across the menstrual cycle, AMH has been reported to be relatively stable in normally cycling women.[37,38] Further, the (log)AMH appears to be linear while the (log)FSH and (log)inhibin B are curvilinear and vary inversely with each other.[35] However, Robertson et al. reported intra-cycle variability in AMH levels in the late reproductive phase when levels were already extremely low.[39]

After menopause, estradiol and progesterone plateau at very low levels, <20 pg/mL and <1 ng/mL, respectively. AMH and inhibin B remain low; FSH peaks in the year after the FMP and may decline slightly thereafter.

Testosterone and dehydroepiandrosterone also decline after a peak in the 20s. There is no abrupt change in androgen levels at the time of menopause. In fact, androgen levels appear to be rather stable across the menopause transition. Two longitudinal studies have reported a rise in testosterone in the seventh and eighth decades.[40,41] In the Rancho Bernardo Study, testosterone levels returned to premenopausal levels in women in their 70s.[41]

The first physical sign of approaching menopause for most women is a change in their menstrual pattern. The most common trend in cycle length across the reproductive years is for the cycles to become shorter. The median length of the cycle in adolescent years is 29 days, and by age of 40 years, it is 26 days. The change occurs in the length of the follicular phase with the luteal phase remaining a relatively constant 14 days. Not all women experience irregular bleeding, but the majority do.

The female reproductive organs are particularly affected by the presence or absence of estrogen. The ovaries enlarge with puberty and after menopause they decrease in size. The uterus, and any leiomyomas therein, also decrease in size after menopause. The cervix typically decreases in size and may become stenotic. In some cases, it effaces to the point of becoming flush with the vault of the vagina.

The labia and the mons pubis tend to lose adipose tissue after menopause, a change that may be related to aging. Vaginal and vulvar mucosa become thinner as a result of low estrogen levels, especially the epithelial layer (Figure 22.7). There is loss of vaginal rugae and elasticity. Color tends to change from red to pale pink. In the absence of vaginal sexual activity, the vagina may constrict.

Breast tissue is also affected by the decrease in estrogen and by aging. There is loss of both the glandular and adipose components of the breast causing them to be less full and firm. Combined with the loss of elastic fibers associated with aging skin, breasts and many skin structures begin to sag. Skin turgor decreases.

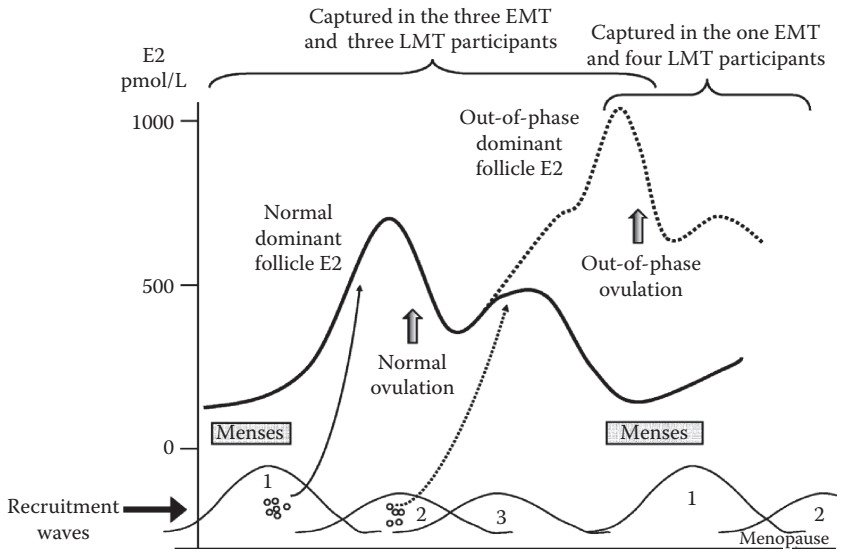

FIGURE 22.6 A luteal out-of-phase (LOOP) event. (From Hale, G.E. et al., *Menopause*, 16, 50, 2009. With permission.)

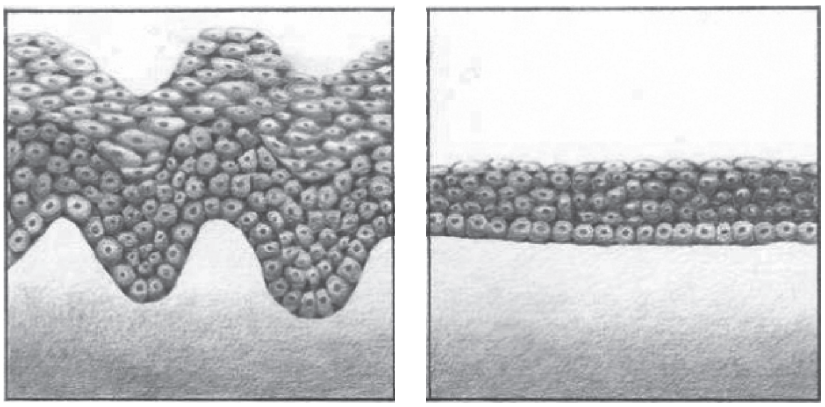

FIGURE 22.7 Illustration of microscopic view of vaginal lining before and after menopause. (a) Vaginal lining with estrogen. (b) Vaginal lining in low-estrogen state. Changes in hair distribution and amount are highly variable. Multiple factors control body hair including health and nutrition status, age, genetics/ethnicity, and hormones. Some women experience generalized hair loss and thinning that can involve a loss of all arm and leg hair along with thinning of scalp and pubic hair. Some women experience changes similar to male pattern hair loss such as receding hairline at the temples and thinning on the crown. Endocrine evaluation of hormone levels rarely finds a cause of hair changes. Products such as minoxidil and finasteride may help, but a catch-up hair loss is often observed when the treatment is discontinued.

SYMPTOMS

The classic symptoms of menopause in the United States are vasomotor symptoms (VMS) and symptomatic vaginal atrophy. The latter usually translates clinically to vaginal dryness, atrophic vaginitis, and dyspareunia. Hot flashes (or flushes) and night sweats are synonymous with VMS. Other symptoms that have variably been included in the list are moodiness; anxiety; irritability; sleep disruption; musculoskeletal discomfort, particularly joint pains; and cognitive concerns such as memory loss, word recall, and forgetfulness. The list of symptoms varies among cultures and in some cultures, VMS are not on the list. In Japan, for example, musculoskeletal symptoms such as shoulder stiffness predominate.[42] Even within the United States, different cultural subgroups rank common symptoms differently. A survey from SWAN indicated that more African American women reported VMS than Caucasian women, while Chinese American and Japanese American women had a much lower incidence of VMS than Caucasian women. It has been suggested that there is no universal menopausal syndrome.[43]

VMS are classified as mild, moderate, or severe with specific definitions provided by the Food and Drug Administration (FDA) for research purposes (Table 22.2).[44] Approximately 75% of women experience VMS and of these women, ~25% report severe symptoms. A drop in the estrogen level of an estrogen-primed individual is an important trigger. Lifelong low estrogen levels, as in Turner syndrome,

TABLE 22.2
Classification of Hot Flashes according to Food and Drug Administration Guidance for Hormone Therapy Research Studies

Severity	Description
Mild	Sensation of heat without perspiration
Moderate	Sensation of heat with perspiration, able to continue activity
Severe	Sensation of heat with sweating, causing the woman to stop activity

Source: U.S. Department of Health and Human Services. Guidance for industry: Estrogen and estrogen/progestin drug products to treat vasomotor symptoms and vulvar and vaginal atrophy symptoms—Recommendations for clinical evaluation. 2003.

are not associated with VMS. Both natural and iatrogenic (castration, aromatase inhibitors, GnRH agonists) reductions in gonadal hormone levels can result in VMS in both women and men.[45] Treatment with estrogen, progesterone, or androgen therapy can eliminate most of the VMS.[46,47]

There is great variability in how long a woman experiences VMS. In SWAN, women with an onset of VMS earlier in the perimenopause transition tended to experience them for a longer time.[48] Those with the earliest onset of VMS reported them for a median of 11.75 years. Those with onset in the middle of the perimenopause transition reported VMS a median of 7.5 years, and those with late onset of VMS during the transition had a median duration of 3.84 years.[48]

The current understanding of the mechanism of menopausal VMS is based on the concept of a narrowing of the core body thermoneutral zone, which is the core body temperature range within which women are comfortable.[49] Below the lower limit of the thermoneutral comfort zone, the body shivers, and above the upper limit, the body sweats. In the woman with VMS, this zone is very narrow. An increase of 0.1°F in core body temperature can trigger a hot flash in the research laboratory. What produces this change in sensitivity of the thermoregulatory zone of the hypothalamus is not known, nor is it known why some women do not experience this thermoregulatory change. Estrogen is reported to raise the sweating threshold in those women with VMS.[50] An α_2-adrenergic mechanism appears to be involved in triggering VMS.[51]

While menopause is known to cause specific symptoms, it can also eliminate other bothersome symptoms from the premenopausal years such as breast discomfort related to fibrocystic breast condition and cyclic premenstrual engorgement. Women who experienced pelvic pain related to dysmenorrhea, endometriosis, fibroids, ovarian cysts, and Mittelschmerz often have complete resolution of their pain. Menorrhagia disappears and any associated anemia improves. The woman who suffered with menstrual migraines enjoys a complete cure, and contraception is no longer an issue.

With regard to the vagina, there are both positive and negative effects from menopause. Some women appreciate the decrease in vaginal discharge that occurs with menopause. Others find the resulting vaginal dryness a source of dyspareunia. In one perimenopause study, ~20% of women reported vaginal dryness in the preceding 2 weeks.[52] Among postmenopausal women ages 50–59 years in the Women's Health Initiative (WHI) not taking estrogen, ~11% reported moderate to severe vaginal dryness.[53] These figures will vary with the population studied. Vaginal atrophy in and of itself does not usually cause symptoms, especially in the absence of vaginal sexual activity.[54] However, when a postmenopausal woman with vaginal atrophy begins sexual activity or undergoes a speculum examination after a long period of no vaginal activity, she is likely to experience dryness and tightness.

In SWAN, vaginal dryness correlated with vaginal/pelvic pain and with lower arousal, physical pleasure, and emotional satisfaction. However, VMS and the menopause transition were generally not related to arousal, physical pleasure, frequency of sexual activity, or satisfaction with a partner. Sexual function was found to be highly related to health, age, and social and psychological factors.[52]

VMS and symptoms related to vaginal atrophy are the most widely recognized symptoms of menopause in the United States. Other symptoms such as depression, anxiety, cognitive issues, and musculoskeletal aches and pains are reported with variable frequency from study to study. There has been some controversy over the years about the relationship of depression to menopause. A report from the Penn Ovarian Aging Study suggested a slightly higher occurrence of depressive symptoms and depressive disorder around the time of menopause,[55] while a report from SWAN found that women were 2–4 times more likely to experience a depression around the time of menopause compared to premenopause.[56] There is a growing consensus that women have increased vulnerability for depression during the menopause transition.

Memory complaints are common during the menopause transition but perception may be worse than reality. Results from midlife cohort studies suggest that memory is generally unaffected by natural menopause and that there is no link between serum levels of estradiol and objective memory test scores.[57–59] One report from the SWAN study indicated that any small decline in memory or cognition appeared to resolve after the menopause transition.[60]

DIAGNOSIS

An official diagnosis of naturally occurring menopause requires 1 year of no menses and the absence of other causes of amenorrhea. Thus, establishing the FMP as the date of menopause is a retrospective diagnosis. By then, a woman usually knows she is menopausal. Diagnosing perimenopause is based on clinical signs and symptoms. A woman who is over age of 40 years, skipping menstrual cycles, and reporting bothersome VMS is most likely in perimenopause. If there is the possibility of pregnancy, a urine pregnancy test should be performed to be sure that pregnancy is not the cause of amenorrhea. The unintended pregnancy rate among pregnant women in this age group is 38%.[61]

If a woman's presentation is not clearly perimenopausal (e.g., skipping menses without any menopausal symptoms), other

diagnoses should be considered. Pregnancy, thyroid disorder, hypothalamic amenorrhea, and hyperprolactinemia can be eliminated from the differential diagnosis by simple blood tests.

An FSH level is the test most often used to confirm menopause. However, one FSH level in the menopausal range does not assure that a woman will have no more menstrual cycles. It is not uncommon for a woman to have several months of amenorrhea, VMS, and an elevated FSH (>40 mIU/mL qualifies as menopausal in many laboratories), only to resume menstrual cycles again. This meandering course of perimenopause is what necessitates the definition of 1 year of no menses.

Another hormone that may contribute information about the timing of menopause is AMH. Recent publications suggest that AMH levels may predict the approximate age of a woman's menopause years ahead of time.[34] This test could be useful for women whose mother had an early menopause. These women may want to know if they need to complete childbearing sooner rather than later. A history of extensive ovarian surgery is another clinical scenario where this test might be useful. One report suggested that AMH levels could give indication of how much ovarian function remains after ovarian surgery.[62]

The phases of menopause as defined by STRAW in 2012 (Figure 22.2)[9] can provide guidance for determining where a woman is in the menopausal transition, but cannot be used prior to the onset of irregular cycles to predict menopause. AMH, on the other hand, might be useful throughout the reproductive years to estimate approximate age at which menopause will occur.

INTERVENTIONS

Menopause is an ideal time for a woman to reassess her goals and lifestyle, especially with regard to health and well-being. Lifestyle plays a significant role. Each woman chooses whether she will eat healthy food or unhealthy food, exercise or be sedentary, and on what pursuits she will spend her time.

Lifestyle Changes

Healthy food and physical activity are key components of weight control. Women of normal weight have fewer VMS than obese women.[63] Women who smoke have more VMS as well.[64] These two risk factors for VMS could be modified by lifestyle interventions. Exercise has many benefits besides weight control. Paradoxically, women who exercise have more energy. Exercise is reported to increase the sense of well-being.[65] In addition, aerobic exercise produces benefits for cardiovascular health, and weight-bearing exercise preserves and builds muscle mass which in turn helps preserve bone mineral content. Better muscles and bones may help prevent frailty, falls, and fractures.[66] The risks of smoking are well known. Both weight reduction and cessation of smoking could lead to fewer VMS, but data are sparse.[67] Data for a direct effect of aerobic exercise on VMS are less clear.[68]

With a wide variety of food in the diet, supplements may not be needed, but to be sure the basic nutrients are obtained, a multivitamin, along with calcium and vitamin D supplementation, is often recommended. The 2010 Institute of Medicine report recommends calcium intake (through food and/or supplements) of 1200 mg/day and vitamin D intake of 600 IU/day for women ages 51–70 years.[69] Both vitamin D and calcium are vital to bone health. Normal levels of vitamin D (20–60 ng/dL) are required for absorption of calcium from the gastrointestinal tract. Inadequate levels of vitamin D can lead to secondary hyperparathyroidism and osteomalacia. The IOM report recommends a minimum serum level of 20 ng/dL for bone health.[69] A myriad of other benefits have been attributed to vitamin D, but most lack confirmation from randomized controlled trials.

Sexual function requires more attention and nurturing with age. Libido generally diminishes for both partners. A first consideration is whether the couple wants to maintain their sexual relationship. Second, vaginal dryness associated with low levels of estrogen can lead to dyspareunia or pain with any vaginal sexual activity. If not addressed, this discomfort becomes a disincentive for vaginal sexual activity. Elimination of soap on the vulva (clean water is sufficient for hygiene) and elimination of fabric softeners and anticling products on underwear may reduce dryness and irritation. Adequate foreplay is important. Use of a vaginal moisturizer once or twice a week can be beneficial. If these measures are not sufficient, lubricants will often solve the problem. In more severe cases, it may be necessary to use vaginal estrogen until sexual activity becomes comfortable again. Vaginal estrogen is available in several forms: cream, tablet, or ring (Tables 22.3 through 22.7). The most effective

TABLE 22.3
Oral Estrogen Products for Postmenopausal Use in the United States and Canada

Composition	Product Name	Available Dosages/Day (mg)
Conjugated estrogens	Premarin	0.3, 0.45,[a] 0.625, 0.9,[a] 1.25
Synthetic conjugated estrogens, A	Cenestin[a]	0.3. 0.45, 0.625, 0.9, 1.25
	Congest[b]	0.3, 0.625, 0.9, 1.25, 2.5
	C.E.S[b]	0.3, 0.625, 0.9, 1.25
	PMS-Conjugated[b]	0.3, 0.625, 0.9, 1.25
Synthetic conjugated estrogens, B	Enjuvia[a]	0.3, 0.45, 0.625, 0.9, 1.25
Esterified estrogens	Menest[a]	0.3, 0.625, 1.25, 2.5
	Neo-Estrone[b]	0.3, 0.625
17β-Estradiol	Estrace	0.5, 1.0, 2.0
	Various generics	0.5, 1.0, 2.0
Estradiol acetate	Femtrace[a]	0.45, 0.9, 1.8
Estropipate	Ortho-Est[a]	0.625 (0.75 estropipate, calculated as sodium estrone sulfate 0.625), 1.25 (1.5), 2.5 (3.0), 5.0 (6.0)
	Ogen[b]	0.625 (0.75), 1.25 (1.5), 2.5 (3.0)
	Various generics	0.625 (0.75), 1.5 (3.0), 5.0 (6.0)

TABLE 22.4
Transdermal/Topical Estrogen Products for Postmenopausal Use in the United States and Canada

Composition	Product Name	Delivery Rate (mg/Day)	Dosage/Day
17β-Estradiol matrix patch	Alora[a]	0.025, 0.05, 0.075, 0.1	Twice weekly
	Climara	0.025, 0.0375,[a] 0.05, 0.075, 0.1	Once weekly
	Esclim[a]	0.025, 0.0375, 0.05, 0.075, 0.1	Twice weekly
	Estradot[b]	0.025, 0.0375, 0.05, 0.075, 0.1	Twice weekly
	Fempatch	0.025	Once weekly
	Menostar[a]	0.014	Once weekly
	Oesclim[b]	0.05, 0.1	Twice weekly
	Vivelle[a]	0.025, 0.0375, 0.05, 0.075, 0.1[a]	Twice weekly
	Vivelle-Dot[a]	0.025, 0.0375, 0.05, 0.075, 0.1	Twice weekly
	Generics	0.1, 0.05	Once or twice weekly
17β-Estradiol	Estraderm	0.025,[b] 0.05,[a] 0.1	Twice weekly reservoir patch (patch cannot be cut)
17β-Estradiol transdermal gel	EstroGel[a]	0.06%, 0.035	Daily application; 1 metered pump delivers 1.25 g of gel containing 0.75 mg 17β-estradiol
	Estrogel[b]	0.06%	
	Elestrin[a]	0.06%, 0.0375	Daily application; 1 metered pump delivers 0.87 g of gel containing 0.52 mg 17β-estradiol
	Divigel[a]	0.1%[a], 0.003, 0.009, 0.027	Daily application; 3 strengths of packets provide 0.25, 0.5, or 1.0 g of gel
17β-Estradiol topical emulsion	Estrasorb[a]	0.05 (2 packets)	Daily application of 2 packets; 1 packet = 1.74 g of emulsion
17β-Estradiol transdermal spray	Evamist[a]	0.021 mg/90 μL spray (metered-dose pump) 1.5 mg estradiol/90 μL spray	Initial: 1 spray/day of 1.7% solution, increasing to 2–3 sprays/day if needed

TABLE 22.5
Vaginal Estrogen Products for Postmenopausal Use in the United States and Canada

Composition	Product Name	Dosage/Day
Vaginal creams		
17β-Estradiol	Estrace Vaginal Cream[a]	Initial: 2–4 g/day for 1–2 week Maintenance: 1 g/day (0.1 mg active ingredient/g)
Conjugated estrogens	Premarin Vaginal Cream	0.5–2 g/day (0.625 mg active ingredient/g)
Esterified estrogens	Neo-Estrone Vaginal Cream[b]	2–4 g/day (1 mg active ingredient/g)
Vaginal rings		
17β-Estradiol	Estring	Device containing 2 mg releases 7.5 μg/day for 90 days (local vaginal with minimal systemic amount)
Estradiol acetate	Femring[a]	Device containing 12.4 or 24.8 mg estradiol acetate releases 0.05 or 0.10 mg/day estradiol for 90 days (systemic levels)
Vaginal tablet		
Estradiol hemihydrate	Vagifem	Initial: 1 tablet/day for 2 week Maintenance: 1 tablet twice/week (tablet containing 25.8 μg or 10 μg of estradiol hemihydrates, equivalent to 25 or 10 μg of estradiol)
	Vagifem LD	10 μg estradiol hemihydrates
Injectable estrogens		
Estradiol valerate	Delestrogen[a]	10–20 mg IM q 4 weeks
Estradiol cypionate	Depo-estradiol[a]	1–5 mg IM q 3–4 weeks
Estrogens-conjugated (dose for excessive bleeding)	Premarin[c]	25 mg IV/IM

TABLE 22.6
Combination Estrogen/Progestogen Products for Postmenopausal Use in the United States and Canada

Composition	Product Name	Dosage/day (mg)
Oral continuous-cyclic regimen		
Conjugated estrogens (E) + medroxyprogesterone acetate (P) (E alone for days 1–14, followed by E + P on days 15–28)	Premphase[a]	0.625 mg E + 5.0 mg P (2 tablets: E and E + P)
Oral continuous-combined regimen		
Conjugated estrogens (E) + medroxyprogesterone acetate (P)	Prempro[a]	0.625 mg E + 2.5 or 5.0 mg P (1 tablet); 0.3 or 0.45 mg E + 1.5 mg P (1 tablet)
	Premplus[b]	0.625 mg E + 2.5 or 5.0 mg P (2 tablets: E and P)
	Premplus Cycle[b] Oral	0.625 mg E daily with 10 mg P taken for the last 14 days each month
Ethinyl estradiol (E) + norethindrone acetate (P)	femhrt[a]	2.5 µg E + 0.5 mg P (1 tablet); 5 µg E + 1 mg P (1 tablet)
	femHRT[b]	2.5 µg E + 0.5 µg P (1 tablet); 5 µg E + 1 mg P (1 tablet)
17β-Estradiol (E) + norethindrone acetate (P)	Activella,[a] Activelle[b]	0.5 mg E + 0.1 mg P (1 tablet);
	Activelle LD[b]	1 mg E + 0.5 mg P (1 tablet)
17β-Estradiol (E) + drospirenone (P)	Angeliq	1 mg E + 0.5 mg P (1 tablet)[a]; 1 mg E + 1 mg P (1 tablet)[b]
Oral intermittent-combined regimen		
17β-Estradiol (E) + norgestimate (P) (E alone for 3 days, followed by E + P for 3 days, repeated continuously)	Prefest[a]	1 mg E + 0.09 mg P (2 tablets: E and E + P)
Transdermal continuous-combined regimen		
17β-Estradiol (E) + norethindrone acetate (P)	CombiPatch[a]	0.05 mg E + 0.14 mg P (9 cm^2 patch, twice/week)
	Estalis[b]	0.05 mg E + 0.25 mg P (16 cm^2 patch, twice/week)
17β-Estradiol (E) + levonorgestrel (P)	Climara Pro	0.045 mg E + 0.015 mg P (22 cm^2 patch, once/week)

TABLE 22.7
Progestogens Available in the United States and Canada

Composition	Product Name	Dosage/Day
Oral tablet: progestin		
Medroxyprogesterone acetate	Provera, various generics	2.5, 5, 10 mg
Norethindrone	Micronor,[a] Nor-QD,[a,b] various generics	0.35 mg
Norethindrone acetate	Aygestin,[a,b] various generics	5 mg
Megestrol acetate	Megace,[a] various generics	20[b], 40, 40 mg suspension
Oral capsule: progesterone		
Micronized progesterone (in peanut oil)	Prometrium	100, 200[b] mg
Intrauterine system: progestin		
Levonorgestrel	Mirena[a]	20 µg/day approximately release rate (52 mg IUS has 5 year use)
Vaginal gel: progesterone		
Progesterone	Crinone 4%,[a,b] 8%	45 or 90 mg applicator

[a] Not approved by the FDA for menopausal hormone therapy.

[b] Available in the United States but not Canada.

way to maintain vaginal sexual function with menopause is to continue to have regular sexual activity throughout the menopause transition and thereafter. This is an important lifestyle consideration and option that should be discussed early in the menopause transition.

Other lifestyle changes may also be beneficial in managing symptoms of menopause. VMS are aggravated by heat. Dressing in layers allows one to adjust clothing to the environment. Open-neck clothing is particularly suited to women with VMS because the upper chest, neck, and face are most often affected by a hot flash. Women with VMS should avoid turtle neck shirts and sitting in direct sunlight. Even bright lights or spot lights in the ceiling can trigger hot flashes or red ears.

Becoming too warm while sleeping is a common cause of night sweats. Comforters are major offenders because they trap body heat too well. There are many practical measures for easing night sweats. Switching to a lighter, more loosely woven blanket allows body heat to dissipate. Bed linens and pillows designed to have a cooling effect are available commercially. Some women chose to sleep in exercise clothing designed to wick away perspiration. A gentle overhead fan or bedside fan can be helpful. Often women feel chilled or have cold feet by the time they are ready to get into bed. Rather than piling on blankets that will later create an oven effect, it may be better to don a comfortable pair of socks that can easily be removed later as needed.

Emotional responses to situations are also triggers for hot flashes. It is not easy to avert emotional reactions, but learning a few behavioral techniques can be effective in addition to moving to a cooler environment. A desk fan and commercially available cool neck packs and/or cloths are other options.

Paced respiration has been demonstrated to decrease hot flashes.[70] This breathing technique involves inhaling slowly and exhaling slowly in a controlled fashion. Engaging in this practice on a daily basis was found to decrease VMS by ~50%. In this same study, exercise was not found to be beneficial for VMS.

Complementary and Alternative Medicine

Many studies on complementary and alternative medicine (CAM) products for the treatment of VMS have yielded mixed results. Black cohosh, red clover, and other CAM products have been found to lack strong evidence of benefit.[71] One randomized controlled trial enrolled 351 women for 1 year and randomized them to black cohosh, black cohosh combined with multi-botanicals, black cohosh and dietary soy counseling, conjugated estrogens 0.625 mg, or placebo. Black cohosh in any of the combinations was no better than placebo at any time point.[72] There has been some concern about possible liver damage with use of black cohosh. A review of 69 cases found "little, if any," evidence of causality.[73] Studies on the effect of acupuncture for VMS have also produced mixed results.[74,75] The National Center for Complementary and Alternative Medicine (NCCAM) has a website for clinicians with information on the safety and efficacy of CAM products.[76]

Soy has been the focus of much research because of constituents in the plant that resemble the chemical structure of estradiol. These phytoestrogens or plant estrogens include genistein and daidzein, two isoflavones that are considered to be very weak estrogens. Some prefer to use the term mixed estrogen agonists/antagonists. Studies using soy foods and soy extracts abound. Recently, the focus has been on S-equol.[77] This metabolite of daidzein and daidzin is produced in the intestines of some, but not all, people. The S(–)-equol enantiomer has selective affinity for estrogen receptor-β. It is being investigated as a potentially therapeutic agent for menopausal symptoms. In a comprehensive review of the scientific research, soy-based isoflavones were found to be modestly effective in treating symptoms of menopause, and the supplements with higher levels of genistein or S(–)-equol were thought to provide more benefits.[78]

Nonhormonal Medicines

Nonhormonal prescription therapies for VMS have focused on selective serotonin reuptake inhibitors (SSRIs) and selective norepinephrine reuptake inhibitors (SNRIs). Serotonin and norepinephrine are involved in thermoregulation via central and peripheral mechanisms. Studies of the SSRIs citalopram and escitalopram significantly reduced the frequency and severity of VMS.[79,80] The SNRI desvenlafaxine has been extensively investigated and has been found to reduce VMS by 64%, significantly better than placebo.[81] These drugs improved mood as well as VMS.

Another neuroactive drug, gabapentin, has also been found to have a beneficial effect on VMS.[82–84] Gabapentin was approved by the FDA as an adjunct therapy for partial seizures and as a treatment for neuropathic pain. It has been used off-label for many other conditions including VMS. Most studies on the effect of gabapentin on hot flashes have used 900 mg/day and reported an ~20% greater reduction in hot flashes than placebo. Reddy et al. used 2400 mg of gabapentin and also an estrogen comparator. Both estrogen and gabapentin had an ~25% greater reduction in hot flashes than placebo, but there were more side effects with gabapentin, namely dizziness, headaches, and disorientation.[83] This anticonvulsant should be titrated starting at 300 mg (100 mg if the patient is older or sensitive to medication) taken at night in order to minimize the common side effect of dizziness. Similarly, the drug should be tapered slowly to avoid withdrawal symptoms after prolonged use or after use of high doses.[85]

Hormone Therapy

Hormone therapy (HT) is the most effective treatment for menopausal symptoms. The two general categories of HT are estrogen therapy (ET) and combined estrogen/progestogen therapy (EPT).

A summary of HT terminology is listed in Table 22.8. The choice between ET and EPT is based on the presence or absence of the uterus. Women with a uterus should be advised to take a regimen that contains a progestogen in order to protect the endometrium from the development of adenocarcinoma. Prolonged use of unopposed ET can increase the risk of endometrial

TABLE 22.8
Hormone Therapy Terminology

HT	Hormone therapy (encompassing both ET and EPT)
ET	Estrogen therapy
EPT	Combined estrogen/progestogen therapy
Progestogen	Encompassing both progesterone and progestin
Systemic therapy	HT administration that results in absorption in the blood high enough to provide clinically significant effects
Local therapy	Vaginal ET administration that does not result in clinically significant systemic absorption

Source: North American Menopause Society. Estrogen and progestogen use in postmenopausal women: 2010 Position statement of The North American Menopause Society. Menopause 17, 242–255, 2010. With permission.

adenocarcinoma 2- to 10-fold depending on estrogen dose and duration.[86,87] The addition of a progestogen offsets this risk.

Most brands of HT are approved by the FDA for treatment of moderate to severe VMS and symptomatic vaginal atrophy. Some ET products are also approved for prevention of osteoporosis and some are approved for dyspareunia. See Tables 22.3 through 22.7 for an extensive list of hormone products available in the United States and Canada. Menopausal symptoms usually resolve completely with use of HT. Women should be informed that symptoms recur in ~40% of women upon discontinuation of HT.[88]

Benefits and risks are similar across estrogen products, especially with regard to alleviating menopausal symptoms. The risk of venous thrombosis, however, may vary by route of administration. Observational data from Europe suggest that parenteral administration of estrogen may have a lower risk of venous thrombosis, but there have been no direct comparisons of oral and parenteral therapies.[89,90] Personal history of venous thrombosis is generally considered a contraindication to HT.

The WHI Hormone Therapy Trial, a randomized controlled trial that enrolled ~27,000 healthy women ages 50–79 years, was a prevention trial; i.e., healthy women were randomized to an HT intervention to determine if HT would keep them healthier than those women who were randomized to placebo. Both EPT and ET were stopped earlier than planned when signs of harm were seen in the absence of an overriding benefit. The mean duration of intervention in the two groups was 5.2 and 6.8 years, respectively, of an expected 8.5 years. Mean duration of adherence (defined as taking ≥80% of study drug) to EPT and ET was much shorter because at the time of terminating the interventions, 42% of EPT users had already discontinued the drug and 54% of ET users had already discontinued.[91,92]

The EPT intervention was stopped because the incidence of invasive breast cancer in the hormone users reached a predetermined safety limit. In the case of ET, a rising rate of stroke with no obvious benefit for cardiac health prompted the discontinuation of ET. The women continued to be followed, however, and it was noted that most of the benefit (fracture reduction) and risk (thrombosis, stroke, cardiac events) disappeared quickly after treatment was stopped. Two hormone effects persisted in analyses that continued for 3 years after intervention termination. In the EPT arm of the study, more deaths were attributed to breast cancer in those women randomized to EPT compared to those women randomized to placebo (HR, 1.96; 95% CI, 1.00–4.04; $P = 0.049$). New diagnoses of breast cancer were no longer elevated in the former EPT group in the 3 years post-intervention.[93] In the ET arm, the lower breast cancer incidence seen in the ET group during the intervention phase persisted through the follow-up period.[94]

When the WHI was designed, it was not anticipated that the effects of EPT and ET would vary by age.[95] The post hoc analyses by age group yielded results that suggested that most of the risks of HT occur more frequently in older postmenopausal women compared to younger postmenopausal women. For example, using a global index of chronic diseases, the analysis by age revealed a statistically significant increased risk in the global index for women ages 70–79 years assigned to ET (HR 1.15; 95% CI, 1.01–1.32) and a possible statistically significant reduction in the global index risk in women ages 50–59 years (HR 0.85, 95% CI, 0.70–1.03; $P = .009$) for interaction.[94] The exception to this generalization is that breast cancer risk appears to be less in postmenopausal women who have had a few years without use of HT prior to initiating it. In the EPT arm, it was the women who had been using EPT prior to WHI who had the increased risk when they continued EPT in the WHI.[91] In the ET arm, women who had not been taking ET prior to WHI actually had a decrease in breast cancer incidence after starting ET in the WHI.[96,97] These findings suggest that risk of breast cancer, unlike the other adverse outcomes, may be greater in the younger postmenopausal women who have continuous exposure to HT, but further analyses are required to confirm this concept.[98]

Overall, women taking EPT had more adverse events than the women assigned to estrogen alone. In the entire EPT cohort, there were increased risks of cardiovascular events, stroke, and breast cancer along with decreased risks of colorectal cancer and hip fracture.[91] Considering only the 50–59 year olds, there were only four more strokes and five more cases each of breast cancer and coronary heart disease among 10,000 women per year.[99–101] These are small risks. Both the ET and the EPT groups had a decreased risk of hip fracture overall.[91,92] Besides venous thrombosis, the only other statistically significant risk in the entire ET cohort was stroke: 12 additional cases per 10,000 women per year and only one additional stroke in the 50–59 year old group.[92] Fewer deaths occurred in both the EPT and ET arms in the younger group, 11 and 12 fewer deaths, respectively (Table 22.9).[102–110]

After years of analyzing the WHI data from different perspectives, it has become apparent that both ET and EPT are viable options for most symptomatic younger postmenopausal but not older postmenopausal women. ET is acceptably safe for symptomatic women who have had a hysterectomy and no history of venous thrombosis or breast cancer. EPT carries slightly more risk because of the breast cancer cases with EPT that were not seen with relatively short-term use of ET. The elevated risk of breast cancer seen with EPT in the WHI was consistent with findings from observational studies, but the decreased risk of breast cancer among the women assigned to ET in WHI differed

TABLE 22.9
Absolute Risks of Hormone Therapy Ages 50–59 per 10,000 Women per Year, Women's Health Initiative

Event	Estrogen Progestogen Therapy (n = 5522)	Estrogen Therapy (n = 3310)
Venous thromboembolism	+11	+2
Coronary heart disease rate	+5	−10
Stroke	+4	0
Breast cancer	+5	−8
Hip fracture	−2	+3
Death	−11	−10

markedly from the findings of many large observational studies where ET use also conveyed an increased risk of breast cancer, albeit a smaller risk than with EPT.[96,100,111–115]

Hypotheses have been proposed to explain the conflicting findings related to the effect of ET on breast cancer incidence rates. One hypothesis suggests that there is a mammogram screening bias in favor of women using ET that results in more regular use of mammograms which in turn leads to more ET users being diagnosed with breast cancer. The second hypothesis has been called the "gap hypothesis" because it states that the only women who experienced a reduction in breast cancer while using ET were those who had a "gap" in their estrogen exposure after menopause; i.e., these women experienced several years after menopause without taking ET prior to being randomized to it in the study. Certain analyses of the WHI data appear to support this hypothesis.[96,97]

With the abrupt decline in HT use following the published reports of the risks associated with EPT in 2002,[91] many women found themselves symptomatic again and seeking relief. HT in the form of compounded "bioidentical" hormones began to fill the void because these products were being promoted as natural and safe in spite of the absence of scientific evidence supporting such claims. Many clinicians prescribing compounded hormones were also recommending salivary hormone testing to tailor the dose of HT. Medical entities such as The North American Menopause Society, The Endocrine Society, the American Congress of Obstetrics and Gynecology, Nurse Practitioners in Women's Health, and the FDA have published information online regarding the lack of evidence for this approach.

Controversy regarding HT is nothing new. HT has fallen in and out of favor for decades. The more recent emphasis on evidence-based medicine and the emphasis on the superiority of randomized, controlled trials have raised the standards for decision making. Detailed practical guidance for interpreting the many scientific findings related to the use of HT has been published by The North American Menopause Society and The Endocrine Society.[116,117]

Dramatic advances have been made in the understanding of menopause and HT over the last 10 years. More advances are needed to completely understand the complex effects of hormones in different women at different ages. In the meanwhile, women have many choices for alleviating their symptoms and for staying healthy at midlife.

INTRODUCTION

Breast cancer is the most prevalent cancer in women worldwide and holds a very visible place in society with the pink ribbon awareness campaigns. Technological advances in the diagnosis and treatment of breast cancer have led to a decline in death from breast cancer[1,2]; however, the disease prevalence is increasing. After the Women's Health Initiative (WHI) study was released in 2003, we experienced an initial decrease in the incidence of breast cancer. This was likely due to a rapid discontinuation of hormone replacement therapy.[3] We are now seeing a leveling off and actual increase in the incidence of breast cancer in certain subgroups of women.[4] An even greater concern is in the projected risk: the overall incidence of breast cancer is projected to double by the year 2040 and occur more frequently in younger women.[5,6] This projected risk requires a shift of our focus from simply better treatments and early detection to overall prevention of a disease that currently affects one in eight women. Educating and empowering women to modify their lifestyle can decrease their overall risk of developing breast cancer. This needs to

become a priority in our fast paced society. Positive changes made early in a woman's life can impact her individual risk as well as her children's future risk.[2]

Li et al. studied the modifiable risk factors in women who had been treated for and estrogen receptor–positive breast cancer. They found that women who exhibited poor lifestyle choices (smoked, were obese, and drank more than seven alcoholic beverages per week) had a 7.2-fold elevated risk of contralateral breast cancer than matched counterparts who never smoked, were not obese, and drank less than seven cocktails per week.[7] These data lead us to believe that lifestyle choices and changes can significantly impact not only the risk of a woman who has had breast cancer but also the risk in the average woman.

EPIDEMIOLOGY

Breast cancer is the leading cause of cancer in women worldwide and the most common cause of cancer death in U.S. women between the ages of 20 and 59 years. It accounted for 23% (1.38 million) of the cancers diagnosed in women and accounted for 14% (485,400) of all cancer deaths in 2008.[8] An increased incidence is observed in countries as they become "Westernized." The risk of developing breast cancer is very dependent upon where a woman lives in the world. Nearly half of the total individuals diagnosed and ~60% of the breast cancer deaths occur in economically developed countries, and North America, Western and Northern Europe, New Zealand, and Australia are the high-risk regions. The lowest risk regions are Sub-Saharan Africa and Asia.[8]

Several factors have played a significant role in the increased incidence of breast cancer in Westernized cultures. They include early menarche, delayed childbearing, late menopause, oral contraception, hormone replacement therapy, alcohol consumption, and obesity.[9]

Combined estrogen and progesterone therapy was shown to increase the risk of breast cancer as reported by the WHI in 2003. Since 2004, incidence rates of breast cancer decreased sharply in the United States, United Kingdom, France, and Australia. This decrease in incidence was due to a rapid discontinuation of combined postmenopausal hormone therapy when the study results were released.[10] Recent follow-up data from the same WHI study show that the declining incidence has reached a plateau and may even be increasing in certain populations.[2]

BREAST DEVELOPMENT

The breast is an amazing organ as it has the capability to extract nutrients from the body's circulation and produce a fluid so rich that it can completely and totally sustain an infant from the day of birth well into the second year of life. Understanding breast development and function, we can gain insight into how the breasts are affected by known risk factors and potential breast cancer risk factors.

Breast development can be viewed as several distinguishable phases. Each individual stage is sensitive to environmental factors. Unlike other organs that develop fully in utero, the breast has only completed the first stage of development at the completion of gestation. Breast maturity continues over the course of 10–15 years once they begin to develop.

The breasts develop throughout adolescence and do not reach full maturation and size until a woman reaches her early 20s. The DNA replication process must occur to create new breast cells and therefore they are susceptible to genetic mutations. Radiation exposure in adolescence, for example, is a significant risk factor for developing breast cancer later in life. Even though the breast may appear fully developed externally, it is not until a full-term pregnancy that this maturation process is completed. Immature breast cells are more sensitive to hormonal factors than mature breast cells; therefore, a delay in a woman's first pregnancy can impact her future breast cancer risk.[10]

The breast is fully matured when the first full-term pregnancy comes to fruition and the breasts begin to produce milk. The final maturation of the breasts occurs during the breast-feeding process.[11] Any delay in a woman's first full-term pregnancy can increase her breast cancer risk later in life. Women living in an industrialized nation often delay childbearing to their fourth and sometimes fifth decade of life. This delay allows breast cells to continue to be influenced by the cyclic estrogen and exogenous estrogen (oral contraceptives). Long-term exposure to internal or external estrogen sources can act as a "fuel" on a potential fire.[10]

Breast-feeding has long been evaluated in the role that it plays in breast cancer risk reduction. The true benefits have been likely underestimated and underreported. Women, who were breast-fed when they were infants, were found to have a decreased incidence of premenopausal breast cancer in a meta-analysis.[12] Women who themselves breast-feed their infants, cumulatively over their lifetime for 12–24 months, had a 66% reduction in breast cancer. There is a direct relationship established between the duration of breast-feeding and decreased risk.[13] Young women, who were at high risk due to family history, were found to have a decreased incidence of breast cancer when they breast-fed their children.[14] Recent studies from Brigham and Women's hospital support these findings of breast cancer risk reduction from breast-feeding.[15]

The final phase in the cycle of breast changes occurs in menopause. The dense fibrous tissue of the breasts involutes and is replaced by fat. This enhances the ability of mammography to detect subtle changes in the breasts and represents the final transition that the breasts make in their life cycle. After menopause, breasts are no longer under the cyclic influence of the ovaries; however, they are influenced by estrogen from other internal and external sources.

Many women fail to recognize that the largest source of estrogen after menopause is related to her body fat, particularly fat that is found surrounding her waist. Higher levels of body fat may be the detrimental factor, since estrogen precursors are converted into active estrogens in adipose tissue. This process occurs through the enzyme aromatase, which is

produced in the adrenal gland. Several factors are known to increase aromatase activity. They include age, obesity, insulin, gonadotropins, and alcohol. A woman's basal metabolic index (BMI) has long been associated with an increased risk of cardiovascular disease, diabetes, and estrogen-driven breast cancers.[16] Recent data reveal that higher BMI/obesity has also been linked with the development of a more aggressive subtype of breast cancer that is known as a triple negative or ER–, PR–, Her 2 neu– cancer.[17]

HORMONE REPLACEMENT IN MENOPAUSE

Hormone replacement therapy has been used for years to treat the "symptoms" of menopause, such as hot flashes, mood swings, vaginal dryness, and loss of libido. In a groundbreaking study released in 2003, the WHI's findings brought to light the fact that breast cancer incidence was increased when estrogen and progesterone were taken in combination. Almost immediately after the studies initial findings were released, there was a marked decline in the use of hormone replacement therapy. As a result, there was a decline in the incidence of breast cancer. It was proposed that the breast cancers were found earlier, were more treatable, and were better prognosis tumors, still many women discontinued the use or the combined hormones at that time as they were concerned that the risks were greater than the benefits.[10] In 2010, the follow-up to the study showed that the cancers were more aggressive, higher nodal status with a decrease in survival.[18] A concurrent study of unopposed estrogen revealed that there was actually a slight decrease in the incidence of breast cancer in postmenopausal women who did not have a uterus and were on estrogen only without the progesterone. The combination of estrogen and progesterone appears to be the culprit.[19]

Menopause is a normally occurring process in a woman's life cycle. There are symptoms of menopause that can greatly affect a women's quality of life, but we need to carefully consider the consequences to her overall health and well-being before beginning exogenous estrogen.

GENETICS

Many women are under the mistaken impression that they are not at significant risk if they have no family members with breast cancer. On the contrary, 75%–80% of all breast cancers occur in women who have no prior family history whatsoever. This far too often underemphasized fact is precisely why we need to carefully evaluate how our lifestyle choices impact breast cancer risk. The greatest risk factor for developing breast cancer is being born female. One man for every 100 women is diagnosed with breast cancer. Women, who have either a maternal or paternal family history of breast and/or ovarian cancer, are at a high risk for developing breast cancer and need to clearly understand their lifetime risk. Familial breast cancer can be of environmental or genetic origin. Only 4%–6% of all breast cancers occur as a result of a currently recognized breast cancer mutation.

Risk factors for carrying a known breast and ovarian cancer gene are

- Breast cancer diagnosed before age of 50 years
- Ovarian cancer at any age
- Two primary breast cancers in an individual
- Both breast and ovarian cancer in an individual
- Male breast cancer at any age
- Two or more breast cancers in a family, one under age of 50 years
- Women of Ashkenazi Jewish descent with breast or ovarian cancer at any age
- A previously identified BRCA mutation in the family[20]

Carriers of the BRCA I or II gene mutation have a 56%–87% chance of developing breast cancer and a 27%–44% risk of developing ovarian cancer by the age of 70 years.

Most breast cancer risk assessment models underestimate a woman's risk; therefore, it is important for a woman to discuss her personal individual risk with a health care professional.

There are steps that can be taken to reduce the risk of developing breast cancer.[21] Antiestrogen therapy with tamoxifen or raloxifene has been demonstrated in the STAR trial to reduce the risk of estrogen receptor–positive breast cancers by 48%.[22,23] Surgical removal of the breasts known as prophylactic mastectomies in this high-risk population can reduce the risk of developing breast cancer to ~2%.

Women, who carry the BRCA mutations, need to understand that the cancers they are likely to develop have a higher chance of being a triple negative cancer (BRCA I 67% and BRCA II 35%, general population 11%).[24] Triple negative breast cancers are typically fast growing, aggressive, and are not prevented by blocking the estrogen receptors as these cancers do not have estrogen receptors.

SCREENING

Mammograms do not prevent breast cancer but they prevent death from breast cancer. Population screening studies have shown that with early detection we can experience a 60% reduction in death from breast cancer.[25] While we work to create healthy lifestyle changes globally, we need to remain diligent about screening women for breast cancer to diagnose this disease as early as possible in order to effect mortality.

Digital mammography is the main tool for early detection. On February 11, 2011, the FDA approved 3-D tomosynthesis as an adjunct screening modality in dense breasted women. Tomosynthesis can more readily detect cancers in mammographically dense breasted women and also decrease the rate of recall (false positives) for benign findings on screening mammography.[26]

Magnetic resonance imaging (MRI) of the breasts is also used to screen high-risk populations including BRCA-positive individuals and women with a cumulative lifetime risk of >20% as calculated by the GAIL risk model.[27]

Additional radiological studies are under FDA investigation for use in screening. Ultrasound systems for automated breast ultrasound (ABUS) scanning are in development and show great promise, but not yet considered a standard in screening.

Gamma imaging is also being used in dense breasted patients and patients with a breast cancer diagnosis. Due to the radiation exposure, it is not available as a routine screening tool.

Thermography has received significant interest as an alternative to mammography, but has not been proven in clinical trials to have the sensitivity, specificity of mammography.

The American College of Radiology, American Society of Breast Surgeons, American Cancer Society, and The American College of Surgeons recommend screening mammography annually for women over the age of 40 years unless there is a significant family history of premenopausal breast cancer in which case screening schedules should be individualized and may include breast MRI.[28,29]

LIFESTYLE MODIFICATION

Lifestyle modification can greatly impact a woman's risk of developing breast cancer. A population-based case–control study from Mexico found that a healthy lifestyle, defined as moderate- and/or vigorous-intensity physical activity; low consumption of fat, processed foods, refined cereals, and complex sugars; and the avoidance of tobacco smoking and alcohol consumption, was associated with a reduction in the risk of a woman developing breast cancer. The results showed a protective effect in both pre- and postmenopausal women.[30]

Regardless of a woman's age, there are certain risk factors that cannot be altered such as family history and age of her menarche. If a woman becomes aware of the impact of her life choices while she is young, she has the ability to alter her life's course. She may choose to have her children at a younger age, avoid exogenous estrogen, maintain a healthy BMI with diet and exercise, as well as choose to breast-feed her children.

Our daughters and granddaughters should be empowered to make positive choices early on in their lives so that they can potentially decrease their breast cancer risk profile.

Early puberty and lack of physical activity in adolescence can lead to early menarche and increased risk of developing breast cancer. Studies have found that underweight girls have a delay in menarche, thus decreasing the years of cyclical estrogen stimulation to the breasts. Conversely, being overweight and having an increased BMI leads to a premature menarche and early breast development. This causes estrogen stimulation to those breasts in these young girls whose breasts are still maturing. Young women who are physically active and maintain a healthy BMI have a delay in their menarche.[31,32] This is an opportunity to modify behavior in young girls. Parents need to understand that action, or lack of their action, and influence on their children's lifestyle choices can have significant long-term consequences.

In industrialized nations, for many reasons, women are delaying childbirth to their fourth and fifth decade, creating a delay in the final phase of breast development that occurs after completion of a woman's first full-term pregnancy. Delaying pregnancy or never giving birth increases a woman's risk of developing breast cancer. A woman who delays childbirth until she is 30 years has approximately the same risk of developing breast cancer as a woman who is nulliparous. The more children that you have at a younger age, the less likely you are to develop breast cancer.[33]

A major protective effect of pregnancy, as it relates to breast cancer risk, is breast-feeding. Using the breasts for their intended purpose, feeding our offspring, has also been shown to decrease a woman's risk of breast cancer. The risk reduction gained by breast-feeding is proportional to amount of time that she breast-feeds cumulatively in her life.[13]

We know that having a first-degree relative with breast cancer increases a woman's risk of developing the disease herself. Women who have a first-degree relative who had breast cancer and who breast-fed their own children were found to have a 59% reduction in breast cancer development. This finding strongly suggests a significant protective effect of breast-feeding. In addition, breast-feeding can help to cancel out the effect of delaying childbirth and needs to be embraced by women as an opportunity to decrease their risk profile.

When women are deeply imbedded in their career path, childbearing is often delayed. Understanding that when they do decide to conceive, they should strongly consider building a plan to breast-feed. This act will not only benefit their newborn child, but also benefit their breast health.[33] Every choice we make in life has consequences, and the decision to breast-feed has a positive effect on breast cancer risk reduction.

According to the American Cancer Society and the National Cancer Institute, "The preponderance of observational studies have associated combined hormone therapy use with an increase in breast cancers that have favorable characteristics, lower stage and longer survival compared with breast cancers diagnosed in nonusers of hormone therapy."[34] Despite the initial fall in the incidence of breast cancer that was experienced, we are now back to a plateau and possibly the incidence is on the rise. This supports the thought that the cancer risk was always there and that the estrogen acts to stimulant or promote cancer cell growth.

In the fall of 2010, the second phase of the WHI's follow-up study revealed that the cancers that are occurring on the combined estrogen/progesterone hormone replacement therapy are diagnosed higher stage, have a worse prognosis, and suggests that they have a higher mortality.[9,18]

After the initial decline in breast cancer incidence as a result of the discontinuation of combined estrogen and progestin, we are now seeing a plateau and even an increased incidence of breast cancers in certain subgroups. There is an increase in estrogen receptor–positive cancers and a decrease in estrogen receptor–negative cancers in non-Hispanic white women of age 40–49 years. There was also an annual 5.2% increase in ER+ cancers in black women of age 40–49 years.[35]

The use of exogenous estrogen and progesterone has been clearly shown to increase a woman's risk of developing breast cancer. Oral contraceptives have been associated with as high as 44% increased risk of developing premenopausal breast cancer when they are taken prior to the completion of a woman's first pregnancy.[35] It appears as though these women would likely have developed breast cancer and that the estrogen and progesterone acted as "fuel" for the fire.

These studies beg the question: why are we treating a normal evolutionary process of menopause as a disease that requires pharmacological intervention? The symptoms of menopause can be treated individually with far less risk to women.

LIFESTYLE EVALUATION AND MODIFICATION

The good news is that population studies show that we are living longer. The bad news is that we are unprepared for this longevity. We care for our bodies as if life is short and then still have decades remaining to live in our bodies.

With 75%–80% of breast cancers occurring in women who have no family history, we have to make a change in how we view our personal risk. Changes need to be made in our everyday lives to decrease our individual and global risk.[36] Personal accountability is needed to initiate this shift in thinking. We can no longer wait for the wake-up call of cancer to shift our thinking. We need to be proactive in our lives and empower our sisters, daughters, granddaughter's friends, and colleagues to make these changes NOW.

The best defense is a good offense. We need to begin to empower women and young girls to make tough choices and create healthy changes in their lives. These choices and changes can greatly impact their overall breast cancer risk. A woman cannot change her family history, but she can choose to make conscious choices in her lifetime and do everything in her power to lessen her risk.

PREVENTION

There are pharmacological means of decreasing breast cancer risk. First and foremost is avoiding exogenous estrogen in any form. Oral contraceptives, hormone replacement therapy, and any form of estrogen should be prescribed based upon severity of symptoms being treated and at the lowest dose to achieve relief.

For women at high risk, >20% lifetime or >1.7% 5 years (GAIL risk), tamoxifen and Evista have been proven to decrease the risk of developing breast cancer by 48%. raloxifene (Evista) cannot be used in premenopausal women as it can cause birth defects but is an excellent choice in high-risk postmenopausal women with osteopenia as it can also increase bone density. Tamoxifen is approved for prevention in premenopausal women at high risk. Women who take tamoxifen need to be informed that there is an associated risk of developing uterine cancer of ~2.5%.[37]

Surgical options for risk reduction in high-risk women including women who carry the BRCA I and II mutation include prophylactic oopharectomy and prophylactic mastectomies. A 90% reduction in breast cancer can be achieved; for a BRCA mutation carrier that translates into a *reduction in* risk from 87% to ~2%. Two thousand and five hundred BRCA mutation carriers were followed after prophylactic mastectomy or intensive screening. In the follow-up study reviewing breast cancer development after prophylactic surgery in BRCA I and II carriers, no one had developed breast cancer in the 3 years postmastectomy where 7% of the women who had chosen intensive screening had developed breast cancer. This once again reinforces that intensive surveillance is not equivalent to prevention.[38]

Of significant importance is knowledge of the aggressive subtypes of breast cancer BRCA I and II carriers are likely to develop. In 67% of BRCA I carriers and 35% of BRCA II carriers, the cancers that develop are triple negative or ER–, PR–, Her 2 neu–. Estrogen reduction from oopharectomy does not help to prevent these breast cancers, as the cancers are not responsive to estrogen stimulation.[24]

Cigarette smoking has been clearly associated with the development of lung cancer and heart disease. Smoking has also been shown to increase the breast cancer incidence in postmenopausal women in current and past smokers.[39] A higher incidence of breast cancer has been associated with past and current smokers (16% higher in current smokers, 10% higher in former smokers, and passive smoke exposure is suggestive of a link). An increased risk was also noted in women who began smoking before their breasts had completely developed through their first full-term pregnancy. The breast tissue is particularly vulnerable prior to its complete maturation at childbirth.[40]

Women with a 20 pack-years history after menopause had a slight decrease in risk (HR 0.93, 95% CI, 0.85–1.02). Researchers explained that this may have reflected an antiestrogenic effect from smoking. This supports a decreased incidence in estrogen receptor–positive breast cancers in long-time smokers, but the other health risks of smoking far outweigh any possible benefit.[41]

Alcohol use has become widespread in our society. It is viewed as a normal part of our social lives and few women realize the implications of over indulgence. Rarely do I encounter a patient that understands that the National Cancer Institute considers alcohol in any form a breast cancer carcinogen.[40] The amount of alcohol consumed is directly proportional to the increased risk of developing breast cancer. The alcohol, regardless of what type, not only increases empty caloric intake, but also interferes with the degradation of estrogen. Therefore, alcohol consumption increases a woman's circulating estrogen. We know that estrogen does not cause breast cancer but can act as fuel on a fire that is already burning. Three cocktails per week increases a woman's risk by 6% and more than three cocktails per day increases a postmenopausal woman's risk by 40%.[42] Moderation is the key to success and education of our young women is mandatory.

Obesity in the United States is epidemic. It is a well-established breast cancer risk factor. There has been a threefold increase in obesity in our fast-paced society in

the last 30 years. Body composition plays a significant role in several factors regarding breast cancer occurrence and recurrence. It has been well documented that women who have a BMI > 30% have a significant risk of breast cancer recurrence once they have been diagnosed. This is related to two specific factors. Increased body fat leads to increased estrogen production through the conversion of steroids to estradiol via the enzyme aromatase. This process occurs in fat cells and increased body fat leads to increased estrogen production. The second mechanism is related to insulin resistance. Insulin resistance is a condition where the body does not respond to insulin appropriately. According to a 2009 study in the International Journal of Cancer, high levels of insulin in the bloodstream are related to the development of postmenopausal breast cancer.[43] The Albert Einstein College of Medicine of Yeshiva University as part of the WHI has substantiated these results. Researchers found that the women with the highest levels of insulin, which suggests insulin resistance, have twice the risk of developing breast cancer than women with the lowest insulin production.[44]

A woman's goal should be to achieve and maintain a healthy weight and body composition throughout their lifetime.[45]

When it comes to treating women with estrogen-sensitive breast cancer, percentage body fat is also of concern.

Recent research suggests that obese women may have higher estrogen levels. A study of estrogen suppression by aromatase inhibitors according to basal metabolic levels (BMI) is needed to determine if dosing needs to be adjusted based upon BMI.[46] A BMI < 25% from childhood throughout their lives should be their goal.

Obesity is also associated with chronic inflammation in our body's tissues and inhibition of cellular repair.[47] Obesity in youth can lead to early menarche and the beginning of lifelong poor eating habits.

Studies conducted to evaluate diet are often difficult to interpret and control, as recall and honesty of the participants is mandatory. Dr. Carlo La Vecchia presented data for the International Agency for Research on Cancer in March 2010. This study revealed data that one-third of all breast cancers can likely be prevented with lifestyle modification.[48,49] The European data on the effect of lifestyle are very powerful. Sustainability of diet and exercise habits is required for the long-term lifestyle changes.

We live in a society where instant gratification and quick fixes are the norm. Modifying one's lifestyle requires each individual to look not only at the foods that we eat but also where and how the foods we eat are grown.

LIFESTYLE CHANGES THAT CAN DECREASE RISK AND PREVENT BREAST CANCER

How can we begin to create a healthier lifestyle? There is no reason to spend time lamenting over the risk factors that are out of our control. First and foremost, we need to change the risk factors that we can control.

#1. Do Not Smoke

Smoking is the leading cause of lung cancer and is associated with the increased incidence of many other cancers including breast cancer. It is also associated with heart disease and stroke. Choosing to smoke is choosing to invite cancer into your life.

#2. Maintain a Healthy BMI < 25%

Women who are overweight produce and store more estrogen. After menopause, the fat deposited between a woman's breasts and her hips is estrogen waiting to happen. Increased exposure to estrogen and risk of breast cancer are directly related. Since estrogen receptor–positive breast cancer is the most common subtype of breast cancer diagnosed after menopause, controlling obesity needs to be a priority. Obese women tend to have a larger breasts' potentially making it more difficult to detect palpable breast tumors in obese women, as compared to lean women.

#3. Avoid Exogenous Estrogen

Given all of the data on estrogen and its relationship to the development of breast cancer, women and girls need to carefully weigh the potential risks with the benefits before beginning any form of hormone therapy. If hormones are needed, go for the lowest dose for the shortest time period.

#4. Alcohol Moderation

Women who have a family history of breast cancer should consider avoiding alcohol altogether or drink it sparingly. Women in general should limit their alcohol intake to less than one drink per day.

#5. Modify the Foods We Eat

By looking at the foods we eat, we can make simple sustainable changes for a healthier tomorrow. We know that certain fruits and vegetables are more susceptible to pesticides, and therefore organically grown varieties are considered superior.

"THE DIRTY DOZEN." The fruits and vegetables that should be considered as safer when they are organic are cherries, grapes, blueberries, strawberries, apples, nectarines, peaches, peppers, celery, spinach kale, and potatoes.

Fruits and vegetables with thick skin are acceptable to buy nonorganic, as pesticides are less likely to penetrate the skin.[50] Eating a diet high in fruits and vegetables makes up the majority of the nutrients in your diet. Eating small meals can also enhance your ability to maintain a healthy weight and fuel your body appropriately. Fiber is also associated with a decreased risk of breast cancer. This is a direct result of the fiber escorting estrogen substrates out of the body via the colon.

#6. Exercise

Exercise and physical activity have been documented to decrease a woman's risk of developing breast cancer. Three to

five hours of physical exercise weekly decreases a woman's risk of breast cancer by 18%. The more lean muscle mass you have the more fat you burn and the less fat remains to be a substrate for estrogen production.[51] Exercise should be varied and include cardiovascular and strength training. Making a sustainable plan and having physical activity be a part of a plan for success is essential.[52] Before beginning any exercise program, a woman should consult with her physician to determine if there are specific limitations and then get to it.

Regular exercise also improves mood, increases self-esteem, and creates a positive body image. Doing regular exercise improves muscle tone, strength, and endurance. Exercise has the protective effect of decreasing heart disease and diabetes risk. It can help lower body weight, which in turn, reduces risk of breast cancer due to obesity.

#7. Stress Reduction

Stress is a major factor in the production of cortisol and inflammatory factors. Managing stress in our overscheduled and technological word can be a challenge. If you fail to plan, then plan to fail. Creating opportunities for you to organize and manage stress before it takes its toll is essential.[53]

#8. Reproductive Education

Young women need to be educated about the choices they can make in their lives that can significantly impact their risk. As a society, over the past 50 years, women have moved into the workforce and delayed childbearing. This change has had a negative impact upon our breast cancer risk. Choosing to have their children younger completes their breast development, which can significantly decrease their risk.

#9. Breast-Feeding

Breast-feeding is directly related to risk reduction. The reduction of the risk is proportional to amount of time breast-feeding occurs (>12 months of breast-feeding is associated with a 60% decreased risk).

#10. Vitamins and Antioxidants

There are several vitamins and antioxidants that can have a significant impact on breast cancer development and risk. The best source of vitamins comes directly from the food that we eat with rare exception. Before beginning a regimen of vitamins and supplements, a woman should discuss the plans with her physician.

Vitamin D

Vitamin D modulates cell growth, neuromuscular and immune function, and reduction of inflammation.[54–56]

Vitamin D deficiencies have been linked to an increased risk for breast cancer. A healthy level of 25-OH vitamin D should be maintained above 40 ng/mL. Women who do not have significant sun exposure (15 min/day) are oftentimes deficient. In addition, sunscreens that protect us from UV sunburn can impair our body's ability to produce vitamin D, leading to low levels. Women should understand the significance of being deficient. Vitamin D3 supplements can be taken to attain a normal level. Antioxidants may play a role in risk reduction by blocking the formation of free radicals and protecting cells from free radical damage.[57] The FDA recommends 1000 IU/day of vitamin D3 or sun exposure of 10 min/day.[58]

CoQ10

Coenzyme Q10 (CoQ10) is considered an important cellular antioxidant, as it is a component of the mitochondrial electron transport chain. A recent multiethnic cohort study found that higher CoQ10 levels in postmenopausal women may be associated with increased breast cancer risk.[59,60] Conversely, low circulating levels of CoQ10 have been associated with an increased incidence of a number of cancers as well as poor prognosis for a number of cancer types. In the Shanghai Women's Health Study, a prospective evaluation of CoQ10 levels was assessed. Circulating levels of CoQ10 were generally low in this population. The observed association with breast cancer risk may be limited to those women with exceptionally low values.[61] Lower levels of CoQ10 in the SWHS population suggest that the two studies may not be contradictory, actually suggesting a nonlinear (U-shaped) association of CoQ10 with risk. Clearly more research on CoQ10 is needed. CoQ10 has not been carefully tested in combination with chemotherapy to see if it is safe and effective. Because CoQ10 is sold as a dietary supplement, the FDA does not regulate it.[62]

Vitamin A

Retinol and β-Carotene

Vitamin A plays an important role in immune surveillance, cell differentiation, and cell division as well as many other functions. The genetic expression of inflammatory mediators in women with breast cancer was evaluated in a case–control study looking at levels of α-tocopherol, retinol, and β-carotene. A study published in the *European Journal of Cancer Prevention* (2011) showed that antioxidant nutrients have a possible biological effect in preventing breast cancer. It also supports the belief that immune response is activated in the course of breast cancer.[63] A large population-based case–control study of women residing in the states of Massachusetts, New Hampshire, and Wisconsin was performed. Five thousand seven hundred women with breast cancer and 6300 controls were interviewed regarding their intake of carotenoid-rich fruits and vegetables for the five previous years. Among premenopausal women who reported ever smoking, these results were stronger than among never smokers, although tests for interaction were not statistically significant. Results from this study are comparable to previous prospective studies. Findings suggested that a high consumption of carotenoids may reduce the risk of premenopausal breast cancer, but not postmenopausal breast cancer. The benefit was greatest in women who smoke.[64]

Daily vitamin A requirements should be obtained from a diet rich in vitamin A. The best food sources are liver, beef, carrots, spinach, kale cantaloupes, apricots, papaya, and mango to name a few of the richest sources.

Folate and Vitamin B

Folate and vitamin B play important roles in the production and maintenance of new cells. They are also needed to make DNA and RNA. In the midst of a cardiac study of folic acid, vitamin B6, and vitamin B12 treatment, a side study revealed that there was no significant effect on overall risk of total invasive cancer or breast cancer among women during the folic acid fortification era.[65] In contrast, the Shanghi Women's Study suggests that vitamins E and B supplements may confer protection against breast cancer among women who have low dietary intake of those vitamins.[66]

High folate intake in a prospective study of 62,000 French women was associated with decreased postmenopausal breast cancer risk.[67] In a study of 19,000 Japanese women of age 40–64 years, folate was found to have a protective effect on women who drink alcohol. In the women who had low folate intake and drank alcohol, there was an increased incidence of breast cancer observed.[68] This suggests a protective effect of folate.

Dietary sources of vitamin B are liver, beef, and many breakfast cereals. Excellent sources of folate include romaine lettuce, spinach, asparagus, turnip greens, mustard greens, calf's liver, parsley, collard greens, broccoli, cauliflower, beets, and lentils.

Vitamins C and E

Vitamins C and E are powerful antioxidants that also play a role in immune surveillance. There have been numerous case–control studies as well as prospective trials looking at the potential protective effect of vitamin C and breast cancer risk with no significant effect.[69] The Nurses' Health Study found no correlation between vitamins E and C with breast cancer prevention, but did find a protective correlation with vitamin A. Vitamin E may confer protection against breast cancer as indicated by the Shanghi Women's Study.[66]

More recently, the University of Rochester looked at the role of α-tocopherol (vitamin E)-associated protein. It is coexpressed with estrogen receptor in the luminal cells of normal/benign breast tissue. They found α-tocopherol-associated protein acting as an antiproliferative factor in estrogen receptor–positive luminal cells in normal/benign breast tissue, which serves as indirect evidence to support a role for vitamin E in breast cancer prevention.[70] More research is needed in the vitamins E and C breast cancer prevention arena.

Nuts, sunflower seeds, and many vegetable oils are the best dietary sources of vitamin E. Citrus fruits are the best source of vitamin C.

Zinc

Zinc is essential for all highly proliferating cells in the human body, especially the immune system. It is advertised on many websites as a breast cancer prevention supplement, but the data to support this are limited. Low levels of zinc impair immune function of many cells. This gives credence to the theoretical anticancer benefit.[71]

Zinc is found in meat, seafood, liver, eggs, milk, and whole-grain products.

Selenium

Selenium helps to produce selenoproteins, which are important antioxidant enzymes that prevent cell damage from free radicals.[72,73] The Nurses' Health Study, a prospective analysis, previously had found no association with selenium levels and breast cancer risk. In this study, the selenium concentrations were assessed through nail clippings.[74] In contrast, McConnell et al. identified a statistically significant inverse relationship between dietary selenium concentrations in the blood and the incidence of human breast cancer. Low selenium levels in the blood were identified in women with breast cancer.[75]

Tissue analysis of selenium and CEA levels correlated with serum levels revealed that the tissue concentrations in tumors had statistically higher concentrations compared to controls.

There was no correlation between serum/tissue selenium concentration and stage of the disease. The decrease in serum selenium combined with the increase level in the neoplastic breast tissue may reflect part of the defense mechanisms against the carcinogenetic process in the development of breast cancer.[76]

In a study of selenium and glutathione peroxidase activity, Moradi et al. found no difference in the levels of selenium in healthy controls compared to breast cancer patients, but did show an increased glutathione peroxidase activity that may have a protective effect against oxidative damage.[77] The relationship between serum selenium levels and breast cancer risk is still not completely delineated.

The best source of selenium is through the diet. Sources include brazil nuts, tuna, cod, turkey, and beef.

Caffeine

Coffee is a major source of antioxidants in the American diet. Previous studies have indicated that high coffee consumption might modestly reduce breast cancer risk; however, a meta-analysis of more than 500 reports about coffee's relationship to several types of cancer showed no association with breast cancer.[78] In a recent study, coffee consumption was found to be associated with a strong reduction in breast cancer risk for the ER–tumor subtype by up to 50% odds reduction. This effect was independent of hormone replacement therapy, smoking, highest education level attained, and average daily alcohol consumption.[79] The good news is that coffee consumption is not associated with any increased risk of breast cancer. The data are looking favorable for risk reduction in certain breast cancer subtypes.

#11. Pharmacologic Risk Reduction

There are two medications known as selective estrogen receptor modulators or SERMs. SERMs act like estrogen in some tissues but behave as antiestrogen in others. Tamoxifen

(Nolvadex) and raloxifene (Evista) are approved for breast cancer prevention for high-risk women (GAIL risk >1.7% 5 years and >20% lifetime risk). Tamoxifen and raloxifene are not recommended as prevention for women at low risk for breast cancer or its recurrence. Women with a history of current risk factors for stroke or heart disease should discuss with their doctors whether raloxifene is an appropriate choice. Raloxifene can cause birth defects and is approved only for postmenopausal women. Women at high risk for breast cancer should discuss the risks and benefits of antiestrogen therapy with their personal physician.

#12. Environmental Choices

In your daily life, make conscious choices to improve how you purchase, store, and cook your food. Limit the use of canned foods and plastic containers as chemicals can leach out of them. Use plastics with the recycling codes #1, #2, #4, and #5.[80–82] Prepare your foods to maintain the nutrients you need to remain healthy. Steaming, poaching, stir-frying, roasting, broiling, grilling, and sautéing will give you your best opportunity to retain the nutrients. Microwaving is acceptable but do not microwave in plastic.[81] Avoid using nonstick pans at high heat as they can release harmful chemicals.[83] The choice is yours on a daily basis to create positive changes in your life.

FUTURE

The only constant thing in life is change.

Despite significant advances in screening and treatment, breast cancer incidence is on the rise. Family history cannot be changed, but there remain many lifestyle modifications that can greatly impact individual breast cancer risk and ultimately the global breast cancer risk. If we as a society are going to impact the overall incidence of breast cancer, we need to get to work now. We need to create positive changes in our lives and increase personal accountability. Young women and girls need to be encouraged to make sustainable healthy choices and changes in their lives that will reduce their risk of developing breast cancer.

INTRODUCTION

Osteoporosis, from the Greek words *osteon* for bone and *poros* for pore, is a skeletal system disorder characterized by decreased bone strength leading to increased susceptibility to fracture [1]. The peak bone mass that is achieved by the third decade of woman's life is a major determinant of future bone health and osteoporosis risk. The process of bone loss also begins at that time and accelerates at menopause. By age of 80 years, many women have lost, on average, ~30% of their peak bone mass [2]. Bone strength (and hence, fracture risk) depends on many qualities of bone, of which bone mineral density (BMD) is the most commonly measured [1]. The World Health Organization (WHO) and the International Society of Clinical Densitometry have defined osteoporosis in a postmenopausal woman or a man over age of 50 years as a BMD that lies 2.5 standard deviations or more below the average value of less than or equal to *T*-score of −2.5 at the total hip, femoral neck, or lumbar spine (Table 24.1). If anatomic factors such as obesity or arthritis make measurements invalid, the distal one-third radius bone density may be measured [3]. Microarchitectural changes result in less bone mass, which causes decreased bone density, thus predisposing the skeleton to fractures that may occur with minor force or trauma [1]. Fractures that are secondary to osteoporosis are called fragility (low-trauma) fractures, because they result from trivial trauma commonly involving vertebrae, the hip, and the distal radius but in general they can affect any bone of the skeletal system. The diagnosis of osteoporosis can be made clinically by the presence of a fragility (low-trauma) fracture regardless of the *T*-score.

Osteopenia is a state of low bone density, which is a precursor of actual bone disease, that is, osteoporosis. Osteopenia is defined by WHO as a *T*-score between −1.1 and −2.4 standard deviations below the mean [4]. It has been identified as an independent risk factor for future fracture, yet it remains underdiagnosed and undertreated in postmenopausal women. If early intervention with preventive measures is incorporated among the osteopenic population, it may significantly minimize future morbidity, mortality, and health care costs.

TABLE 24.1
World Health Organization and National Osteoporosis Foundation Criteria for Classification of Osteoporosis and Osteopenia

Category	*T*-Score
Normal	−1.0 or more
Osteopenia	−1.1 to −2.4
Osteoporosis	−2.5 or less or fragility fracture
Severe osteoporosis	−2.5 or less and fragility fracture

EPIDEMIOLOGY

Osteoporosis has been recognized as an established and well-defined disease that affects more than 75 million people in the United States, Europe, and Japan [5]. Osteoporosis causes more than 8.9 million fractures annually worldwide, of which more than 4.5 million occur in United States and Europe. According to the National Osteoporosis Foundation, it has been diagnosed in 10 million Americans, and another 34 million are at risk. In 2005, osteoporosis was responsible for an estimated 2 million fractures and $19 billion in cost. By 2025, experts predict that osteoporosis will be responsible for ~3 million fractures and $25.3 billion in cost each year. Estimates suggest that about half of all women older than 50 years will break a bone because of osteoporosis [4]. Many more women have osteoporotic fractures (1.4 million) [6] than new strokes (373,000) [7], heart attacks (345,000) [7], or invasive breast cancer (213,000) [8] combined, according to recent statistics (2004–2006).

Osteoporosis not only is a major cause of fractures but also ranks high among diseases that cause disability with serious complications. These complications may be life-threatening in elderly people. In the United States and Europe, osteoporotic fractures account for 2.8 million disability-adjusted life years annually, somewhat more than accounted for by hypertension and rheumatoid arthritis [5], but less than diabetes mellitus or chronic obstructive pulmonary diseases.

GENETICS OF OSTEOPOROSIS

Bone mass is a complex trait that is affected by multiple hereditary, physiological, and environmental factors. Osteoporosis is often a multifactorial disease and has a strong genetic component. Twin studies have shown that genetic factors play a role in determining BMD, skeletal geometry, and bone turnover markers. Peak bone mass and rate of bone loss have separately been shown to be under genetic control [9,10]. In the search for genes responsible for bone strength, linkage studies in humans and animals have developed to map chromosomal regions that may be involved in the bone mass and skeletal geometry.

Linkage studies involve genotyping large number of polymorphic markers throughout the genome and relating them to the inheritance of a phenotype among members of a family. This technique has localized genes for various Mendelian inheritances and has identified components of complex (i.e., non-Mendelian) traits [11]. Genome-wide linkage studies in humans have identified foci on several chromosomes associated with BMD. To date, the genes that regulate bone mass are only partially characterized [10]. In order to determine their known or hypothetical effect on bone metabolism, candidate gene evaluation is performed. Approximately 20 candidate genes have been shown to be associated with BMD; most important are the vitamin D receptor (VDR), type I collagen alpha (COL1A1 and COL1A2), estrogen receptor alpha (ER-α), and transforming growth factor beta (TGF-β) [10].

The demonstration of association with these genes does not prove a cause-and-effect relationship; instead, multiple genes affect bone mass and each individual gene has a relatively small effect.

PATHOPHYSIOLOGY OF OSTEOPOROSIS

The skeleton is composed of two types of bones: cortical bone constituting the long bones and providing structure and stability, and trabecular bone found in the spine, both involved in calcium homeostasis. Our bones are in a dynamic state of remodeling throughout life, in which the old bone is destroyed by osteoclasts and new bone is formed osteoblasts. Osteoclasts are multinucleated giant cells that develop from hematopoietic stem cell precursors. Activated osteoclasts bind along the ruffled borders of internal bone surfaces and secrete acid proteolytic enzymes and free radicals, which dissolve the underlying bone, leaving resorption pits [12]. As osteoclasts migrate along bone surfaces, they also release cytokines that activate nearby osteoblasts, which develop from mesenchymal cell precursors. Multiple osteoblasts are recruited in the recently excavated resorption pits and fill these cavities by secreting osteoid, a bone-specific collagen. If the calcium and phosphate concentration in the circulation and extracellular fluid are adequate, calcium phosphate (hydroxyapatite) crystals precipitate into the new osteoid, causing it to harden and mature. Osteoblasts then develop into mature osteocytes and reside in the crypts within bone tissue. These cells act as mechanoreceptors that sense developing areas of skeletal stress and then orchestrate local bone remodeling by sending signals to the other bone cells to activate or suppress new bone remodeling units in the appropriate areas.

Peak bone mass is the major determinant of future osteoporosis risk, and optimal achievement is usually multifactorial [12]. Uncoupling of bone turnover, leading to either increase or decrease formation, may result in either net bone gain, as occurs in Paget's disease of bone, or net bone loss, as occurs in postmenopausal women, primary hyperparathyroidism, glucocorticoid use, estrogen deficiency, and rheumatoid arthritis [13,14]. Bone resorption occurs by two main biochemical pathways: the cathepsin K and the metalloproteinase-dependent pathways, leading to increased osteoclastic activity.

Recently, the receptor activator of nuclear factor-κb (nuclear factor kappa-light-chain-enhancer of activated B cells) (RANK), its ligand RANKL, and a decoy receptor, osteoprotegerin (OPG), have emerged as major local regulators of bone remodeling [15]. RANKL, synthesized by osteoblasts and stromal cells and present in the bone microenvironment, binds to RANK, expressed in osteoclast progenitor cells in the bone marrow, and promotes osteoclastogenesis. OPG is also synthesized by osteoblasts and stromal cells and serves as a decoy receptor for RANKL, preventing the binding of RANKL to RANK. Regulation of osteoclast activity depends, at least in part, on the balance between RANKL and OPG. The relative amount of these two molecules is governed, in turn, by systemic hormones (e.g., estrogen), local factors (such as interleukin-6 and tumor necrosis factor), and perhaps other factors as well [15,16].

RISK FACTORS FOR OSTEOPOROSIS

Potential risk factors should be classified into two broad categories: risk factors for *osteoporosis* as defined by BMD (both primary and secondary causes) and risk factors for *osteoporotic fracture*. For BMD-defined osteoporosis, common risk factors in women are advanced age, genetics, lifestyle factors, and menopause status.

Among risk factors for osteoporotic fractures, the most common ones are prior fragility (low trauma) fracture, parental history of hip fracture, current tobacco smoking, and long-term glucocorticoid use.

Women with multiple risk factors are at greater risk of fracture if they also have lower BMD. The use of BMD *T*-scores to assess fracture risk can be markedly improved by combining it with other significant risk factors [17], as used in the FRAX model.

Physiological Risk Factors

Age has been identified as a nonmodifiable risk factor for osteoporosis and hip fracture. After age of 50 years, risk of osteoporotic fracture doubles every 7–8 years. In women, the median age of vertebral fractures is calculated to be in the 70s; and the median age for hip fractures is 82 years [18].

Heritable Risk Factors

Heredity has the most basic influence on a woman's peak bone mass, that is, the maximum BMD gained during the skeletal development and maturation phase is determined by their genetic makeup. Studies have suggested that up to 80% of the variability in peak BMD might be attributable to genetic factors [19,20]. Daughters of women who have osteoporotic fractures have lower BMD than would be expected for their age [21,22]. First-degree relatives of women with osteoporosis also tend to have lower BMD than those with no family history of osteoporosis [23]. In a recent meta-analysis, hip fracture risks were 50%–127% higher if a hip fracture had occurred in a parent [24]. The importance of occurrence of hip fracture in parents is highlighted further by taking it into consideration in the FRAX score.

Pathological Risk Factors

Certain pathological causes have a severe impact on attainment of peak bone mass. Anorexia nervosa, hyperthyroidism, hyperparathyroidism, cystic fibrosis, malabsorption syndromes (e.g., celiac disease), and inflammatory arthritis are associated with lower bone mass compared to age-matched controls (Table 24.2).

Medications as Risk Factors

Many life-saving medications pose a threat to bone health. The most notorious of them all are glucocorticoids. A dose-dependent effect was noted with a dose of prednisolone of ≥7.5 mg/day (relative risk of vertebral fracture 5.2), whereas

Neurofibromatosis
Congenital porphyria

Medications
Glucocorticoids
Aromatase inhibitors
Heparin
Cytotoxic agents
Chronic depo-MPA
Anticonvulsants
GnRH agonists
Thyroxin
Selective serotonin reuptake inhibitors
Lithium

with 5.0–7.5 mg/day, the risk was lower (relative risk 2.6). Ever-use of glucocorticoids has been associated with significantly increased risk of any fracture at all ages compared with the risk faced by people with no glucocorticoid exposure [25]. Among other medications, aromatase inhibitors, excess thyroid hormones, unfractionated (high-molecular-weight) heparin, cyclosporine, gonadotropin-releasing hormone agonists, chronic depo-medroxyprogesterone acetate (depo-MPA), methotrexate, phenobarbital, phenothiazines, phenytoin, and tamoxifen rank high in lowering BMD and increasing the risk of fractures.

Lifestyle Risk Factors

Several randomized controlled trials have demonstrated that brisk walking increases the bone density of both the spine and the hip in postmenopausal women. Physical activities, specifically weight-bearing exercises, increase the bone density of the spine. Moreover, several epidemiologic studies have demonstrated that smoking decreases bone density and increases the risk of fractures in both men and women. Drinking alcohol heavily also poses a risk to bone health. An increased tendency to fall, due to many factors (such as impaired vision and poor body balance), may be reduced effectively by doing Tai'Chi exercises, muscle and balance training, and reducing psychopharmacological therapies. Making healthy choices in diet that can provide optimum calcium and vitamin D in the most natural way or facilitate its absorption, if taken in the form of supplements, is pivotal.

SCREENING RECOMMENDATIONS FOR OSTEOPOROSIS

There is no convincing direct evidence that screening for osteoporosis reduces fractures. However, there is good indirect evidence that screening is effective in identifying postmenopausal women with low BMD and that treating osteoporosis can reduce the risk of fractures of the wrist and spine in this population.

The January *2011 USPSTF Guidelines* state that any woman younger than age of 65 years whose fracture risk is equal to or greater than that of a 65-year-old white woman should be screened with dual-energy x-ray absorptiometry (DXA). The USPSTF also reinforced its existing guidelines calling for all women 65 years of age and older to receive regular screening [26].

The North American Menopause Society (NAMS) recommends that BMD be measured in the following populations [27]:

- All women age of 65 years and over, regardless of clinical risk factors
- Postmenopausal women with medical causes of bone loss (e.g., steroid use, hyperparathyroidism), regardless of age

- Postmenopausal women age of 50 years and over with additional risk factors
- Postmenopausal women with a fragility (low trauma) fracture (e.g., fracture from a fall from standing height)

BMD testing should be considered for postmenopausal women age of 50 years and older who have one or more of the following risk factors:

- Previous fracture (other than skull, facial bone, ankle, finger, and toe) after menopause
- Thinness (body weight ≤127 lb [57.7 kg] or BMI ≤21 kg/m^2)
- History of hip fracture in a parent
- Current smoking
- Rheumatoid arthritis
- Excessive alcohol intake

There are no recommendations for a specific age at which screening should no longer be offered because the risk of fracture continues to increase with age and the evidence indicates that benefits can be realized within 6–24 months after starting treatment.

EVALUATION AND DIAGNOSIS OF OSTEOPOROSIS

Like any medical evaluation of a pathological cause, *history taking* is the cornerstone in risk-stratifying the patients for the screening of osteoporosis. Medical, surgical, family, menopause, social, and medication histories all facilitate the early screening, timely diagnosis, and prevention/treatment of osteopenia/osteoporosis among high-risk populations. Determining the number and the severity of existing vertebral fractures can help predict the risk of future fracture as well.

The *physical examination* should include an annual measurement of height and weight, along with an assessment for acute or chronic back pain, kyphosis, and clinical risk factors. Height should be measured annually with an accurate method, such as a wall-mounted ruler or a stadiometer. Loss of 1.5 in. (3.8 cm) or more calls for evaluation by a lateral thoracolumbar radiograph or vertebral fracture assessment (VFA) by DXA to identify vertebral fractures [27]. Grading of vertebral fractures and percentage of height reduction (grade 1, mild, 20%–25%; grade 2, moderate, 25%–40%; grade 3, severe, over 40%) by a Genant semiquantitative methodology or equivalent are most important in the evaluation of height loss in the patient with severe osteoporosis [27]. Weight should be measured annually and BMI calculated to identify patients with a low BMI and to be aware of weight changes, as it may interfere with the interpretation of BMD changes overtime [27].

Various methods of imaging exist for the assessment of low BMD. The gold standard for densitometry today is DXA.

TABLE 24.3
Indications for Bone Mineral Density Screening

Age 65 years and older in female patients
Prior fragility fracture, defined as occurrence after 40 years of age
History of hip fracture among first-degree relatives
Low body mass index, i.e., <21 kg/m^2, or low body weight, i.e., <127 lb
Corticosteroid use of 7.5 mg daily for ≥3 months ever in lifetime
Personal history of smoking
Alcohol intake more than three drinks per day
Estrogen-deficient or postmenopausal state in female patients
Monitoring of treatment with agents to prevent or treat osteoporosis

Quantitative computed tomography (QCT) identifies individuals with low bone density as well. Quantitative ultrasonography (QUS), radiodensitometry, peripheral DXA (pDXA), peripheral QCT (pQCT), and single-energy x-ray absorptiometry (SXA) are less commonly used to determine risk of fracture in the United States [28]. Bone architecture can be assessed to determine trabecular connectivity and trabecular volume using magnetic resonance and micro-CT [29]. When BMD testing is indicated (Table 24.3), central DXA is the preferred technique. The total hip, femoral neck, and posterior anterior lumbar spine should be measured, using the lowest of the three BMD scores.

The prediction of hip fracture and other osteoporotic fractures has been based on assessment algorithms [30] that include clinical risk factors alone, or the combination of clinical risk factors plus BMD at the femoral neck (available at www.shef.ac.uk/FRAX). The FRAX algorithms are suitable for men and postmenopausal women.

The FRAX models have been developed by WHO from studying population-based cohorts from Europe, North America, Asia, and Australia. The FRAX algorithms give the output as a 10-year probability of hip fracture and the 10-year probability of a major osteoporotic fracture (clinical spine, forearm, hip, or shoulder fracture). By utilizing the FRAX model, treatment is indicated if the 10-year risk of hip fracture is greater than 3% or the 10-year risk of any osteoporotic fracture is greater than 20%.

The routine use of biochemical markers of bone turnover (Table 24.4) is not generally recommended in clinical practice and not used for diagnosis of osteoporosis.

Identifying Causes of Secondary Osteoporosis

It is important to identify and treat the potential underlying disorders that may be the basic etiology of osteopenia or osteoporosis. To date, there are no guidelines for the initiation of a workup for secondary causes. However, it is intuitive to screen women who have very low age-matched score *Z*-scores. The ISCD recommends screening for secondary causes in those with a low *Z*-score (–2 or less), men with osteoporosis, unexplained fracture (i.e., low trauma fracture with a normal BMD), poor response to treatment, or a high index of clinical suspicion based on the history and physical examination [31].

TABLE 24.4
Commonly Used Bone Turnover Markers

Bone Marker	Formation	Resorption	Measured
Bone-specific alkaline phosphatase (SPAP)	Yes	—	Serum
Amino-terminal propeptide of type I collagen (PINP)	Yes	—	Serum
Osteocalcin	Yes	—	Serum
Amino-terminal cross-linked telopeptide of type I collagen (NTX1)	—	Yes	Serum or urine
Carboxy-terminal cross-linked telopeptide of type I collagen (CTX1)	—	Yes	Serum or urine
Carboxy-terminal propeptide of type I collagen (PICP)	Yes	—	Serum
Pyridinoline cross-linked carboxy-terminal telopeptide of type I collagen (ICTP)	—	Yes	Serum
Tartrate-resistant acid phosphatase (TRAP-5β)	—	Yes	Serum
Deoxypyridinoline cross-linked carboxy-terminal of collagen (DPD)	—	Yes	Serum

There are various endocrine/metabolic, gastrointestinal, renal, hematologic, genetic, and hormonal disorders that can lead to osteoporosis (Table 24.2). Malignancy, organ transplantation, and various medications such as glucocorticoids, anticonvulsants, aromatase inhibitors (e.g., Arimidex, Femara, Aromasin), chronic depo-MPA (Depo-Provera) use for contraception for more than 2 years, GnRH agonists like Lupron, high doses of thyroxine, and cytotoxic drugs are also recognized to cause secondary osteoporosis.

Patients with *Z*-scores of −2 or less or with the clinical suspicion of secondary bone disease should have a minimum workup including a complete blood count, blood urea nitrogen, serum creatinine, serum calcium, phosphorous, thyroid-stimulating hormone, 25-OH vitamin D, intact parathyroid hormone (PTH; if the calcium level is normal), and 24 h urine calcium/creatinine (Table 24.5; [32]).

TABLE 24.5
Laboratory Workup to Evaluate the Causes of Secondary Osteoporosis

In all cases	Complete blood count (CBC)
	Comprehensive metabolic profile (CMP)
	Serum calcium
	Serum phosphorous
	Serum parathyroid hormone (PTH)
	Thyroid-stimulating hormone (TSH)
	25-OH vitamin D
In some cases	24 h urine calcium/creatinine
	Spot urine NTX/Cr
	SPEP/UPEP if anemic
	ESR/CRP if anemic
	Testosterone
	Urine cortisol
	Transglutaminase IgA and total IgA if anemic and vitamin D deficiency

OSTEOPOROSIS IN PREMENOPAUSAL WOMEN

Peak bone density is achieved between the ages of 20 and 39 years. During the reproductive years of a woman's life, various hormonal, physical, and biochemical factors influence the attainment and preservation of bone mass. Dietary habits, physical activity, hormonal breast cancer treatment, gonadotropin-releasing hormone agonists, pregnancy, and lactation are few important factors that may contribute to BMD gain or loss during young age [28].

Low bone density in a premenopausal woman on a single study should be interpreted with extreme caution, as it is only a single snapshot of bone health and does not demonstrate that patient has attained peak bone density. It should always be correlated to the present physical, clinical, social, and environmental condition, and the secondary causes (Table 24.2) should be explored before starting treatment.

It has been reported that GnRH agonist and norethindrone acetate alone or combined with low-dose conjugated equine estrogens administered to symptomatic endometriosis patients for 12 months provides extended pain relief and BMD preservation after completion of therapy [33].

PREVENTION AND TREATMENT OF OSTEOPOROSIS

Lifestyle

Prevention of a disease process always begins with lifestyle modifications, as they form the foundation of healthy living. Regardless of their bone density or clinical risk factors for osteoporosis, everyone should be encouraged to eat a balanced diet, optimize their intake of calcium and vitamin D, participate in weight-bearing exercises for at least 30 min daily, avoid cigarette smoke and excessive caffeine and alcohol consumption, and institute fall-prevention measures. The success of these approaches is heavily dependent on patient education and motivation to institute them [27].

Nonpharmacological Treatment

Calcium Supplementation

Adequate calcium intake is a simple and inexpensive strategy to prevent osteoporotic fractures. In a consensus statement, the United States National Institutes of Health claimed that the intake of high levels of calcium—for example, from milk and cheese—reduces the risk of osteoporosis. Furthermore, various clinical trials have demonstrated that combination of calcium and vitamin D intake is more effective than vitamin D alone.

A recent cohort study of 36,282 women showed that women older than 60 years who receive calcium plus vitamin D supplements have a significantly reduced risk of hip fractures (about 30% less risk) if they adhere to treatment.

Lifelong adequate calcium intake is pivotal for the acquisition of peak bone mass and subsequent maintenance of bone health. Our skeleton stores 99% of the body's calcium; when the exogenous supply is inadequate, resorption of calcium from bone tissue begins in order to maintain serum calcium within normal range. The National Osteoporosis Foundation [34] supports the National Academy of Sciences recommendation (1997) that women older than age of 50 years consume at least 1200 mg/day of elemental calcium. Intakes in excess of 1200–1500 mg/day have limited potential for benefit and may increase the risk of developing kidney stones or cardiovascular disease [34].

A small, nonstatistically significant increase in myocardial infarction (hazard ratio 1.31, 95% CI 1.02–1.67, $P = 0.35$) in patients taking elemental calcium supplements >500 mg/day was reported in a meta-analysis [35]. However, there was no increase in mortality seen among the calcium supplementation group. This study excluded patients taking a multivitamin containing calcium and patients taking a combination calcium and vitamin D supplement. Observational studies comparing calcium obtained from dietary sources versus supplements in postmenopausal females showed that the former group had a 30%–40% lower risk of cardiovascular mortality if they consumed more than 1400 mg of calcium in their diet [36].

Vitamin D or Vitamin D Analogs

Vitamin D is the sunshine vitamin synthesized in the skin in response to ultraviolet B radiation. It exists in two biochemical forms: vitamin D3 (cholecalciferol) and vitamin D2 (ergocalciferol). The source of vitamin D3 is from skin exposure to sunlight, animal sources (salmon, sardines, cod liver oil, egg yolks), or supplements. Vitamin D2 is found in some plants and produced commercially by irradiation of yeast for food fortification and vitamin supplements. Both forms of vitamin D are converted to 25-OH vitamin D in the liver, and its serum levels are measured to determine the clinical adequacy [37]. It is essential for the absorption of calcium from the gut, mineralization of the skeleton, muscle strength, balance, and prevention of falls [37–39]. The National Academy of Sciences recommends 400 IU of vitamin D in normal adults 51–70 years old and 600 IU/day for those above 70 years of age. Many experts now believe that these recommendations are too low [15,16]. For adults 50 years old or older, the National Osteoporosis Foundation recommends 800–1000 IU of vitamin D per day, but many experts recommend more—1000–2000 IU/day (see http://www.aace.com/alert/alert11302010.php); 4000 IU/day is the "safe upper limit"—and some patients require considerably more supplementation to achieve desirable levels [40]. Homebound individuals with limited mobility, patients who have intestinal malabsorption, or those who are receiving long-term anticonvulsant or glucocorticoid therapy are particularly at risk for vitamin D deficiency. The currently accepted minimal level for 25-OH vitamin D adequacy is 30–32 ng/mL, on the basis of a growing body of evidence indicating that secondary hyperparathyroidism is increasingly common as 25(OH) D levels decline below 30 ng/mL [41] and that fractional calcium absorption improves with vitamin D supplementation in patients with levels below 30 ng/mL. A reasonable upper limit, based on levels in sun-exposed healthy young adults, is 60 ng/mL [42].

Vitamin K

Dark green vegetables are rich in vitamin K, which is also produced by the body. Some epidemiologic studies have found that low intake of vitamin K is associated with low bone density and increased prevalence of fractures. This association is difficult to verify, since deficiency of vitamin K also is a marker of poor dietary intake.

Prevention of Fractures by Use of Hip Protectors

A hip protector usually consists of specially designed underwear with a built-in plastic shield for the hip protection. Several trials of hip protectors found both positive and no effects. A recent systematic review of 15 trials pooled data from 11 of these and showed evidence of a marginally significant reduction in the incidence of hip fracture. The authors of the review point to the great heterogeneity of the patients studied in the different trials, which were included in this meta-analysis. In reviewing data from three individually randomized trials, involving 5135 community-dwelling participants provided with hip protectors, no reduction in the incidence of hip fractures was demonstrated [43].

Pharmacological Treatment

The AACE categorizes the pharmacological treatment of osteoporosis in two groups:

First priority: Agents approved by the U.S. Food and Drug Administration (FDA) for the prevention or treatment (or both) of osteoporosis (Table 24.6).

Second priority: Agents not approved by the FDA but for which level 1 or level 2 evidence for efficacy and safety is available. These agents may be appropriate for patients who are unable to take approved agents.

Adherence and persistence are poor for osteoporosis therapies [44], as they are for other silent diseases such as hypertension and hyperlipidemia. Compliance with therapy

TABLE 24.6
FDA-Approved Drugs for Preventing and Treating Osteoporosis

Generic Name and Relative Cost	Brand Name	Dosing Method	Dosing Interval	Postmenopausal Osteoporosis		Glucocorticoid-Induced Osteoporosis	
				Prevention	Treatment	Prevention	Treatment
Alendronate $	Fosamax, Fosamax Plus D, generic	Pill liquid (in weekly dose only)	Daily, weekly	Yes 5 mg daily 35 mg weekly	Yes 10 mg daily 70 mg weekly	No	Yes

As the number of $ signs increases it means the medication is more costly.
$, least expensive.
$$$$, most expensive.

should be reinforced by educating the patients, addressing their concerns, and scheduling periodic follow-up visits to ensure appropriate intake of medication and check for any possible side effects [16]. Correction of disorders of mineral metabolism such as calcium and/or vitamin D deficiency is mandatory before initiating therapy.

Bisphosphonates

This class of drugs works by inhibiting the activity of osteoclasts and shortening osteoclast lifespan, thereby reducing bone resorption. The most common adverse effect of oral bisphosphonate therapy is esophageal and gastric irritation, particularly affecting individuals who dose inappropriately. Serum creatinine should be used to estimate the glomerular filtration rate; treatment may be initiated only if the rate is 30 mL/min or greater (35 mL/min with IV zoledronic acid [Reclast]) [16,45].

Clinical trials have demonstrated that bisphosphonates significantly increase BMD at the spine and hip in a dose-dependent manner in both younger and older postmenopausal women. In women with osteoporosis, bisphosphonates have been shown to reduce the risk of vertebral fractures by 40%–70% and reduced the incidence of nonvertebral fractures, including hip fracture, by about 20%–35%.[88,191] Most of the bisphosphonates approved for osteoporosis therapy in both the United States (alendronate, ibandronate, and risedronate) and Canada (alendronate, etidronate, and risedronate) are available in oral formulations for daily and intermittent dosing regimens. Zoledronic acid (Reclast) is available only as an IV injection 5 mg yearly (Table 24.6).

Alendronate

Alendronate (marketed as Fosamax) is FDA approved as an oral tablet in the United States for postmenopausal osteoporosis prevention (5 mg/day or 35 mg/week) and treatment

(10 mg/day or 70 mg/week). It is also available in a single weekly oral tablet of 70 mg with 5600 IU of vitamin D (Fosamax Plus D; Fosavance). It is also approved for treatment of osteoporosis in men and for glucocorticoid-induced osteoporosis. In the Fracture Intervention Trial (FIT), daily alendronate therapy for 2.9 years significantly reduced the risk of vertebral fracture by 47% and of hip fracture by 51% in women with low BMD and previous vertebral fracture [46].

Risedronate

Risedronate, marketed as Actonel, is FDA approved in the United States for the prevention and treatment of postmenopausal osteoporosis. It is available in oral tablet doses of 5 mg/day, 35 mg/week, and 150 mg/month. Atelvia is a new formulation that is taken on a full stomach after breakfast and is dosed as 35 mg/week.

Risedronate is also approved for osteoporosis in men and glucocorticoid-induced osteoporosis. Its efficacy has been studied in clinical trials for up to 7 years, but clinical experience of its use extends to 9 years. It is recommended to offer a 1-year drug holiday after 3 years of use. After 1 year of drug holiday, it should be resumed [16].

Ibandronate

Ibandronate has been FDA approved for the prevention and treatment of osteoporosis in postmenopausal women. It reduces the vertebral fractures but not proven to reduce the risk of nonvertebral or hip fractures. It is available as an oral dose of 2.5 mg daily, 150 mg monthly, and 3 mg monthly given intravenously. Its efficacy has been studied in the clinical trials for 3 years duration [16].

Zoledronic Acid

Zoledronic acid (Reclast) is given intravenously as 5-mg infusion over a minimum of 15 min every year for treatment and every other year for prevention of osteoporosis. It has been approved for prevention and treatment of glucocorticoid-induced osteoporosis, osteoporosis in postmenopausal women, in men, and in patients after surgical repair of hip fracture [47]. Patients should have their serum calcium and creatinine levels checked and be appropriately hydrated before each infusion. It has been shown to reduce hip, vertebral and nonvertebral fractures. Its efficacy has been studied for 3–6 years in clinical trials [16].

Controversies in Treatment with Bisphosphonates

Duration of Treatment with Bisphosphonates

The Fracture Intervention Trial long-term extension (FLEX) was the largest study done in this regard. In this trial, 1099 patients from the FIT trial [46] who had received alendronate for 3 years were randomized to receive alendronate 10 mg/day, alendronate 5 mg/day, or placebo for another 5 years. In comparison to those treated for 8 years, those treated for 3 years showed significant declines in BMD at total hip (−2.4%, 95% CI −2.9% to −1.8%, $P < 0.001$) and spine (−3.7%, 95% CI −4.5 to −3.0, $P < 0.001$). There was a reduction in clinically recognized vertebral fractures for those receiving 8 years of alendronate (RR 0.45, 95% CI 0.24–0.85) but no significant reduction in fracture at other sites. Interestingly, bone turnover markers (which signal bone resorption) increased in those taken off treatment, 56% for C-telopeptide and 60% for serum *N*-propeptide of type I collagen but sill remained lower than pretreatment levels [48].

However, patients on alendronate for 3–5 years also maintained BMD and showed reduction in turnover markers. No increased rate of fracture was seen over 5 or 10 years. From the best current evidence, patients at low risk who are well supplemented with calcium and vitamin D can be monitored off bisphosphonates after completing 3–5 years of bisphosphonate treatment. Patients at high risk can go on a 1–2-year drug holiday after completion of 10 years of treatment. The therapy should be reinitiated if a substantial decrease in BMD, increase in bone turnover markers, or fracture occur [16].

Bisphosphonates and Risk of Osteonecrosis of the Jaw

Osteonecrosis of the jaw (ONJ) has been defined as a delay in healing of an oral lesion after surgery or tooth extraction for more than 6–8 weeks. This may be a rare side effect (risk is 0.7–1.5/100,000) associated with the use of high doses of bisphosphonates. This possible association was first recognized in multiple myeloma patients undergoing treatment with IV pamidronate and zolendronate for hypercalcemia due to malignancy. These patients had poor dental hygiene at baseline and active cancer; these high-risk conditions are not consistent with the typical presentation of the postmenopausal osteoporotic patient. The American Dental Association does not discourage use of bisphosphonates, and routine dental checks are recommended for all patients. Research shows that estrogen deficiency may trigger periodontal disease and that risedronate use for at least 3 months had less clinical attachment loss and better soft tissue periodontal health [49].

The following are recommended to prevent ONJ when patients are on bisphosphonates [27,49]:

1. Regular dental assessment
2. Removal of abscessed and nonrestorable teeth and teeth with severe periodontal disease involvement before beginning the therapy
3. Avoidance of invasive dental procedures unless absolutely necessary
4. Ensure good fit of dentures
5. Aggressive nonsurgical management of dental infections

Bisphosphonates and Subtrochanteric Fractures of Femur

There are limited data to suggest atypical femoral fractures, secondary to microcracks in the bone (due to suspected suppressed bone turnover), occur from prolonged bisphosphonate use. An analysis of the three randomized controlled trials (the FIT, FLEX, and HORIZON trials) showed that the incidence of subtrochanteric or diaphyseal femur fractures associated with 10 years of bisphosphonate treatment in osteoporotic

patients is very low and not statistically significant [50]. It is postulated that specific population of patients (i.e., those with glucocorticoid-induced osteoporosis) may be at increased risk for these atypical fractures, but this remains to be validated. A recent large case–control study in older postmenopausal women (age > 68 years) on bisphosphonates found that 0.35% sustained a subtrochanteric fracture. Bisphosphonate treatment for more than 5 years may carry a low risk of atypical fracture (OR 2.74, 95% CI 1.25–6.02) [51]. However, the minimal risk is outweighed by the benefits achieved from the treatment of osteoporosis and subsequent reduction in risk of hip fractures.

Estrogen Agonists and Antagonists

These nonsteroidal agents of various chemical structures act as estrogen agonists and/or antagonists [27]. Raloxifene (marketed as Evista oral tablets) is FDA approved for the prevention and treatment of postmenopausal osteoporosis at a dose of 60 mg/day and is also approved to reduce breast cancer risk among high-risk postmenopausal women. It is contraindicated in childbearing women and those at risk of venous thromboembolic disease. It has been proven to decrease risk of vertebral fractures. Its clinical efficacy has been studied for up to 4 years.

Teriparatide

Teriparatide (recombinant human PTH 1–34), marketed as Forteo, is FDA approved for the treatment of osteoporosis in postmenopausal women who are at high risk for fracture or who have failed or are intolerant of other forms of therapy. It is also approved in men with idiopathic and hypogonadal osteoporosis, at high risk of fractures, and who have failed or are intolerant of other therapies. It is given as a 20-µg subcutaneous injection once daily via a disposable multiple dose pen device designed to provide 28 doses. It is an anabolic agent that directly stimulates osteoblastic bone formation, resulting in substantial increases in trabecular bone density and connectivity in women with postmenopausal osteoporosis. In postmenopausal women with prior vertebral fracture [52], 19 months of teriparatide treatment (20 µg/day) significantly increased bone density in the spine by 8.6% and in the femoral neck by 3.5% compared with placebo. The incidence of new vertebral fractures was reduced by 65% and new nonvertebral fragility fractures by 53%, although the study was not designed to examine the effect on hip fractures [27].

Drug-related adverse effects include muscle cramps, infrequent hypercalcemia, nausea, and dizziness. High-dose teriparatide treatment has caused bone tumors (osteosarcoma) in a rat model at doses ranging from 3 to 60 times the 20 µg/day dose in humans, although the significance of this finding in humans is uncertain [53]. Teriparatide should not be administered to postmenopausal women with hypercalcemia, bone metastases, disorders that predispose them to bone tumors such as Paget's disease, or those who received prior skeletal irradiation. It is approved for no longer than 24 months in the United States and for no longer than 18 months in Canada. After its discontinuation, there is abrupt decrease in BMD but prevention of fracture risk may persist for 1–2 years. Use of alendronate after teriparatide is discontinued may prevent this bone loss and maintain or improve BMD [54,55].

Estrogens

Systemic estrogen products (estrogen plus progestogen [EPT] for women with a uterus or estrogen therapy [ET] for women without a uterus) are government approved in the United States and Canada for prevention, but not treatment, of postmenopausal osteoporosis [27]. The beneficial effects of systemic oral or transdermal ET/EPT at standard doses on BMD preservation are well established. A 2002 meta-analysis [56] of 57 randomized controlled trials comparing ET/EPT against placebo in postmenopausal women found consistent BMD increases with ET/EPT at all sites. In trials of 2 years duration, the mean difference in BMD after ET/EPT was 6.8% at the lumbar spine and 4.1% at the femoral neck. The two largest and best controlled trials support these findings. In the Postmenopausal Estrogen/Progestin Interventions trial ($N = 875$), standard daily doses of 0.625 mg conjugated estrogens (CE), with or without a progestogen (either medroxyprogesterone acetate [MPA] or micronized progesterone), for 3 years significantly increased spinal BMD by 3.5%–5.0%, with a 1.7% increase in hip BMD [57]. The Womens' Health Initiative [58], a 5-year randomized controlled trial in postmenopausal women ages 50–79 years ($N = 16{,}608$), reported that standard doses of daily EPT (0.625 mg CE plus 2.5 mg MPA) significantly increased spine and total hip BMD by 4.5% and 3.7%, respectively, relative to placebo [27]. As soon as the ET/EPT treatment is discontinued, the antifracture benefit is gone and there is 5% decrease in BMD in the first year after that.

Calcitonin

Salmon calcitonin is government approved for postmenopausal osteoporosis treatment but not for prevention. It is available in the United States as a 200 IU nasal spray (marketed as Miacalcin Nasal Spray, Fortical Nasal Spray) and a 100 IU subcutaneous or intramuscular injection (marketed as Miacalcin Injection). Calcitonin is an inhibitor of bone resorption. In clinical use, the reduction in bone turnover with calcitonin is much less than with other antiresorptive agents. A small, dose-finding study of intranasal calcitonin in postmenopausal women with osteoporosis showed significant increases in spinal BMD of 3% relative to baseline [59]. Calcitonin has been shown to reduce bone pain from osteoporotic vertebral compression fractures more quickly than placebo immediately after a fracture. Intranasal calcitonin can cause allergic rhinitis or epistaxis. Parental administration can cause nausea, local inflammatory reaction, or vasomotor symptoms like flushing or sweating. Its safety and efficacy data are available through 5 years.

Combination Therapies

Combining potent antiresorptive agents results in small additional increments in bone density. In postmenopausal women (mean age 61–62 years) with low bone mass, BMD

improvements in the spine and hip with combined alendronate and ET were significantly greater (8.3%) than results for either agent alone (6.0%) [60]. Combined risedronate and ET/EPT also has shown favorable, although modest, BMD effects compared with either agent alone [61]. Whether increases in BMD result in better fracture protection is not known, the long-term safety of combination therapies has not been evaluated. One concern is that combining two antiresorptive therapies might oversuppress bone turnover, adversely affect bone quality, and thereby increase the likelihood of fracture. Combining antiresorptive agents is not generally recommended. Combining an anabolic agent such as teriparatide with an antiresorptive agent has been considered but is usually done sequentially [27].

Tibolone

Tibolone is approved in many countries for the prevention of osteoporosis, but not in the United States or Canada. In the Long-term Intervention on Fractures with Tibolone (LIFT) study [62], tibolone reduced the risk of vertebral and nonvertebral fracture, breast cancer, and possibly colon cancer, but increased the risk of stroke in older postmenopausal women with osteoporosis.

Denosumab

Denosumab, marketed as Prolia, is a fully human monoclonal antibody against receptor activator of nuclear factor-JB ligand (RANKL), a member of the tumor necrosis factor superfamily expressed on the surface of osteoblasts. RANKL binding to its receptor RANK on the surface of osteoclast precursors promotes the proliferation and differentiation of osteoclasts. By blocking the interaction between RANKL and RANK, denosumab inhibits bone resorption by osteoclasts. Denosumab is dosed as a subcutaneous 60-mg injection every 6 months for postmenopausal women at high risk for fractures. It decreases the risk of spine, hip, and other nonvertebral fractures by improving the BMD. Its efficacy has been studied for 6 years [63]. It does not require dose adjustments needed for patients with renal disease. Side effects reported are skin infections, eczema, and dermatitis.

New Horizons for Treatment

Several new drugs show promise for the treatment and/or prevention of osteoporosis. Some are now available outside North America, and others are in clinical development. These include strontium ranelate, PTH 1–84 (PreOs), additional Ea/EAg (bazedoxifene, lasofoxifene), oral calcitonin, and odanacatib, an inhibitor of cathepsin K [27].

Strontium Ranelate

Oral strontium ranelate (marketed as Protelos) is approved for the prevention and treatment of osteoporosis in many countries outside North America. Dosing involves dissolving 2 g of strontium ranelate in water and drinking it before bedtime.

A large randomized controlled trial in postmenopausal women in Europe and Australia with the primary end point of vertebral fractures demonstrated that 3 years of therapy significantly increased bone density at the spine (14%) and femoral neck (8%) [64]. Compared with placebo, the risk of spine fractures in strontium-treated women was significantly reduced by 49% after 1 year and 41% after 3 years compared with placebo.

Modest changes in markers of bone turnover have been observed with strontium therapy, but the exact mechanism by which strontium ranelate exerts its effect is unknown. Drug-related adverse effects included venous thromboembolism and significant increases in nausea and diarrhea that resolved after 3 months [27].

Parathyroid Hormone 1–84

The full-length PTH, PTH 1–84, marketed in Europe and other countries as PreOs, is not yet approved in the United States. In a randomized controlled trial in 2532 women with postmenopausal osteoporosis, PTH 1–84 administered as a daily subcutaneous injection in a 100-kg dose increased BMD in the lumbar spine by 6.9% and in the total hip region by 2.1% compared with placebo [65]. Vertebral fracture risk was reduced by 58%. No effect was observed on nonspine fractures. Hypercalcemia and hypercalciuria occurred more commonly with PTH 1–84 compared with placebo [27].

Bazedoxifene

This Ea/EAg has prevented bone loss and decreased bone turnover without stimulating the endometrium in healthy postmenopausal women with normal or low BMD [66]. In a 3-year randomized controlled trial involving 6847 postmenopausal women with osteoporosis (average age 66 years), bazedoxifene 20 or 40 mg/day reduced the incidence of vertebral fracture by 42% and 37%, respectively, in the active control group [67]. Side effects included an increased incidence of vasomotor symptoms, venous thromboembolism, and leg cramps compared with placebo.

Lasofoxifene

Lasofoxifene is another selective estrogen receptor modulator that increased lumbar spine BMD and reduced bone markers modestly more than did raloxifene in young postmenopausal women without osteoporosis [68].

Nitroglycerine Ointment

In Toronto, Ontario, Canada, a single-center, double-blind, placebo-controlled randomized trial was conducted for 24 months. Postmenopausal women with lumbar spine *T*-score between 0 and −2.0 who used nitroglycerine ointment 15 mg/day showed a significant increase in BMD at the lumbar spine, total hip, and femoral neck; an increase in bone-specific alkaline phosphatase of 34.8%; and a decrease in urine *N*-telopeptide of 54.0%. It was concluded that among postmenopausal women, nitroglycerine ointment modestly increased BMD and decreased bone resorption [69].

MONITORING THE THERAPY OF OSTEOPOROSIS

In the present era, we have highly effective treatments for osteoporosis; however, studies have shown that more than 50% of patients who are prescribed osteoporosis therapy do not fill their prescriptions and of those who do, many discontinue treatment within the first year. Regular follow-up coupled with testing of biochemical markers of bone turnover may be useful interventions to improve adherence. Follow-up BMD should be performed at regular intervals every 2 years until stable on treatment to make sure that there is no further bone loss and to understand the concept of least significant change when monitoring therapy with BMD testing. This is a measure calibrated regularly for each individual DXA machine, change greater than which is clinically significant. Knowing the least significant change is important when interpreting the serial bone density scans. Annual rates of bone loss in untreated postmenopausal women vary between 0.6% and 1.7% but may be as high as 4%.

Biomarkers of bone formation (bone alkaline phosphatase, osteocalcin, procollagen type I propeptides) and resorption (hydroxyproline, urinary pyridinoline and deoxypyridinoline, N-telopeptide of collagen type I NTX and CTX in urine and serum) reflect the overall osteoblastic and osteoclastic activity in the skeleton and in some situations may serve as surrogates for histological examination of bone (Table 24.5). Their use in clinical practice, however, is limited by high in vivo and assay variability (resorption markers), poor predictive ability in individual patients, and lack of evidence-based thresholds for clinical decision making [27]. Nevertheless, biochemical markers of bone turnover may be useful in certain situations, including for assessment of fracture risk in elderly patients when the finding of elevated levels would influence the decision to begin pharmacotherapy, as an early indicator of therapeutic response to anabolic or antiresorptive therapy or in the laboratory evaluation of patients losing BMD despite antiresorptive therapy, and for assessment of medication compliance [27].

INDIVIDUALIZING THE TREATMENT OF OSTEOPOROSIS: CASE DISCUSSIONS

Case 1

A 51-year-old healthy Caucasian woman without other significant comorbidities. She had hysterectomy for fibroids/menorrhagia at age of 45 years and currently experiencing disruptive hot flashes and night sweats for the last 1.5 years. Her family history is significant of maternal hip fracture. BMD shows a *T*-score of −2.2 in the femoral neck. No secondary causes of low bone density are identified on a thorough history, physical examination, and appropriate laboratory workup.

She will get maximum benefit from ET along with calcium and vitamin D supplementation. She should be reevaluated annually to assess the dose adjustment or screen for any side effects.

Case 2

A 55-year-old African American woman whose last menstrual period was at age of 50 years denies vasomotor symptoms. Her mother had multiple vertebral fractures with dowager's hump. The patient's mammogram indicates high breast density, and she has a history of two breast biopsies in a 3-year period. BMD shows *T*-score at spine = −2.2, hip = −1.4. Ea/EAg therapy, for example, raloxifene will provide reduction in spine fracture and prevention of estrogen receptor–positive breast cancer.

Case 3

A 56-year-old Caucasian woman status postmenopause for 5 years with controlled hypertension on hydrochlorothiazide presents post wrist fracture after she slipped on the ice. BMD shows a *T*-score of −1.2 at the spine and −1.3 at the hip. Clinically, she has osteoporosis; however, she needs a secondary workup to identify any underlying disease contributing to it. She will require treatment in addition to calcium and vitamin D.

Case 4

A 72-year-old Caucasian woman with past medical history of hypertension, hyperlipidemia, and gastroesophageal reflux disease, stable on medications. No prior history of cancer or fractures. She presents with acute low back pain with midline tenderness; x-ray reveals a vertebral fracture at T7. Lumbar spine *T*-score = −3.4, *T*-score at femoral neck = −2.8. Secondary evaluation reveals only borderline low 25-OH vitamin D of 30 ng/mL.

She has severe osteoporosis and should be treated with anabolic agent, Teriparatide for 2 years, after her low vitamin D is treated. Two years after the completion of treatment, she should be reevaluated and possibly treated with bisphosphonates or preferably with denosumab.

Case 5

A 56-year-old postmenopausal Caucasian woman presented with persistent pain along the anterior aspect of her left lower leg. X-ray failed to identify fracture; a bone scan showed intense uptake over anterior part of tibia consistent with a stress fracture. Her BMD is consistent with total hip −2.5. Laboratory workup is significant for anemia, low vitamin D, and normal thyroid function. The patient denies any diarrhea or eating disorder and her BMI is stable at 24. She was further screened for hyperparathyroidism and celiac disease and turned out to have gluten-sensitive enteropathy.

She should be treated with gluten-free diet, calcium, iron, and vitamin D supplementation. Once her vitamin D level is within normal limits, she could be treated with IV or oral bisphosphonates.

PEARLS

1. Identify osteoporosis as a major public health problem
2. Initiate timely screening and treatment of osteopenia and osteoporosis to prevent morbidity and mortality associated with hip fractures
3. Interpretation of the DXA reports and screening the at-risk population for causes of secondary osteoporosis
4. Individualization of the various options of pharmacotherapy available
5. Institute awareness regarding the risks associated with osteoporosis and address the misconceptions, due to rare side effects reported with treatment
6. Incorporate the use of new FDA-approved medications for osteoporosis by educating ourselves and our patients

INTRODUCTION

To improve health and lower risk for certain chronic diseases, the U.S. Surgeon General, the American Heart Association, and the American College of Sports Medicine have long recommended that adults perform a minimum of 30 min of moderate-intensity aerobic physical activity on most days of the week or, alternatively, vigorous-intensity physical activity for at least 20 min on 3 days of the week.[1–3] In 2008, the U.S. Department of Health and Human Services issued a similar guideline—at least 150 min/week of moderate-intensity physical activity or 75 min/week of vigorous-intensity physical activity for "substantial health benefits" (basic guideline) and 300 min/week of moderate or 150 min/week of vigorous-intensity physical activity for "additional and more extensive health benefits" (advanced guideline).[4] However, only 28% of U.S. women and 31% of men exercise enough to meet the basic guideline, and 41% of women and 39% of men engage in no leisure-time physical activity at all.[5]

Aerobic exercise has been the focus of most epidemiologic investigations of physical activity to date, but there is growing evidence that resistance exercise also confers health benefits, including the preservation of bone density and musculoskeletal function,[6] which is particularly important for women, as they are more susceptible to osteoporotic fracture than are men. Yet only 17.5% of U.S. women engage in strength training at least twice per week,[7] as recommended by current guidelines.[4,6,8]

Aerobic exercise intensity is typically measured in kilocalories burned per minute of activity or in metabolic equivalents (METs), defined as the ratio of the metabolic rate during exercise to the metabolic rate at rest. Moderate-intensity activities, such as brisk walking (i.e., at a pace of ≥3 miles/h), are those that burn 3.5–7 kcal/min or, equivalently, those that expend 3–6 METs. Vigorous activities, such as running, are those that burn >7 kcal/min or expend >6 METs. Epidemiologic findings are often presented in

TABLE 25.1
Effects of Physical Activity on Health

All-cause mortality	↓	Cognitive decline	↓
		Depression and anxiety	↓
Cardiovascular disease	↓		
Coronary heart disease	↓	Pregnancy outcomes	
Stroke	↓	Gestational diabetes	↓
		Preeclampsia	↓
Type 2 diabetes	↓	Low birthweight	↑ (vigorous activity)
Cancer	↓	Risks of physical activity	
Colon cancer	↓	Musculoskeletal injury	↔ (at recommended levels)
Colon adenoma	↓	Acute cardiac events	↑ (especially vigorous activity)**
Breast cancer	↓	Menstrual dysfunction	↑ (female athletes)

** In terms of the balance of cardiovascular benefits and risks, regular physical activity of moderate or vigorous intensity is associated with an overall decrease in cardiovascular disease events that far outweighs the transient cardiac risks associated with physical exertion.

terms of MET-h (total volume) per week of physical activity, but because physical activity of long duration at low intensity and physical activity of short duration at high intensity can yield the same MET-h score, such analyses cannot disentangle the effects of duration and intensity of activity on health outcomes.

This chapter reviews epidemiologic evidence on the relation between physical activity and health outcomes in women (Table 25.1), with a focus on results that are presented in a manner that translates into easily understood public health recommendations for exercise for disease prevention, such as walking for a certain number of hours per week as opposed to achieving a certain number of MET-hours week. The emphasis is on studies that use self-reported physical activity, a behavior, rather than physical fitness, an attained physiologic state, as the exposure variable for this reason as well.

METHODOLOGICAL CONSIDERATIONS

Most investigations of physical activity in relation to disease endpoints have been observational studies rather than randomized clinical trials. When interpreting the inverse associations between physical activity and risk for disease reported in observational studies, one must consider various possibilities: that unmeasured or unknown factors may influence the selection and participation of study respondents (selection bias), that unmeasured or unknown third factors may account for the association (confounding), that imperfectly measured exposure or disease status could influence the results (misclassification), and—for case–control studies—that knowledge of disease status may affect recall of past exposures (recall bias). Surveillance bias should also be considered; for example, respondents with putative risk factors such as physical inactivity may be more likely to be screened by their physicians for occult diseases such as diabetes or cancer and be diagnosed with the condition earlier than other respondents, leading to an overestimate of the strength of the exercise–disease association. In addition, self-reported physical activity questionnaires—the most common method for assessing physical activity in epidemiologic studies—may more accurately capture actual activity levels in some groups than in others (e.g., women vs. men, or normal-weight vs. obese persons), causing spurious interaction effects. However, for outcomes such as CVD and diabetes, the consistency of the main effects results across studies—including studies that relied on exercise testing rather than physical activity questionnaires to assess exposure or, in the case of diabetes, on glucose tolerance

or fasting glucose tests rather than self-reported diagnoses to assess outcome—supports a causal association, as does the biologic plausibility due to the known salutary effects of increased physical activity on cardiometabolic risk factors, many of which have been demonstrated in small randomized trials. It should also be noted that, in an effort to control confounding, many studies statistically adjust for baseline conditions such as hypertension, dyslipidemia, and glucose tolerance. Because these represent biological intermediates in the causal pathway between physical activity and cardiometabolic disease outcomes, statistical overcontrol may result in an underestimate of the strength of the association.

ALL-CAUSE MORTALITY

Many prospective studies show an inverse association between physical activity and all-cause mortality. A systematic evidence review conducted to develop the 2008 federal physical activity guidelines found a 30% risk reduction in all-cause mortality comparing the most with the least active persons.[9] The dose–response gradient appears curvilinear in that larger risk decreases are seen at the lower end of the physical activity spectrum than at the upper end. Compared with <0.5 h/week, there was an approximate reduction of 20% in risk for all-cause mortality from 1.5 h/week of moderate to vigorous activity, and a further 20% reduction for an additional 5.5 h/week (i.e., a total of 7 h/week) of activity.

A 2011 meta-analysis of 22 large cohort studies with a total of 643,000 women and 335,000 men quantified the relation between moderate-intensity physical activity and all-cause mortality.[10] Compared with inactive individuals, those who performed 2.5 h/week of moderate activity (equivalent to 30 min/day on 5 days/week) experienced a 19% (95% confidence interval 15%–24%) reduction in mortality risk, and those who performed 7 h/week of light and moderate activity reduced their mortality risk by 24% (19%–29%). Five studies included in the meta-analysis specifically examined walking—the most common leisure activity among U.S. adults—and found a smaller effect. Compared with not walking, 2.5 h/week of brisk walking was associated with a relative risk (RR) of 0.89 (0.82–0.96). A 2008 meta-analysis of 10 prospective studies with a total of 106,000 women and 39,000 men found a stronger effect for walking; there was a 20% (9%–29%) reduction in mortality risk associated with an exposure approximately equivalent to walking 3 h/week at a normal pace (3 km/h [1.9 miles/h]), with the relation similar in women and men.[11]

Among 253,000 women and men aged 50–71 years who were followed for an average of 5 years in the National Institutes of Health (NIH)-AARP Diet and Health Study, engaging in physical activity of at least moderate intensity for >3 h/week predicted a 27% decreased risk for mortality compared with no physical activity, while engaging in vigorous exercise for 20 min for ≥3 times/week predicted a 32% reduction in risk.[12] Among those with little vigorous activity, women and men who engaged in recommended levels of moderate physical activity were 35% and 40% less likely to die, respectively, than their inactive counterparts. In this cohort, engaging in physical activity at less than recommended levels was also related to reduced mortality risk (RR = 0.81).

Data from a recent study of >416,000 Taiwanese women and men aged ≥20 years followed for 8 years also support the idea that even minimal levels of physical activity can favorably affect health.[13] Compared with their inactive peers, individuals who reported a low volume of leisure-time physical activity—i.e., those who exercised for an average of 92 min/week (~15 min/day)—had a 14% reduced risk for total mortality and a 3-year longer life expectancy. (RRs were 0.86 and 0.73 for those reporting moderate- and vigorous-intensity exercise, respectively.) Each additional 15 min of daily exercise beyond the minimum amount of 15 min/day (up to 100 min/day, after which additional exercise gave no benefit) further reduced total mortality by a statistically significant 4%. In other words, the dose–response gradient was curvilinear, with the largest health gains from the first 1–2 h/week of exercise. These benefits were observed in both sexes and across all age groups.

Recent studies have also implicated amount of time spent sitting as risk factor for mortality independent of amount of physical activity. Among 70,000 women and 53,000 men aged 50–74 years followed for 14 years in the American Cancer Society's Cancer Prevention Study II (CPS-II) Nutrition Cohort, physical activity level and time spent sitting were independently associated with total mortality in both sexes.[14] For women with total physical activity of <17.5 (bottom decile), 17.5 to <24.5, 24.5 to <31.5, 31.5 to <42, 42 to <52.5, 52.5 to <63, and ≥63 MET-h/week, RR were 1 (referent), 0.98, 0.81, 0.78, 0.76, 0.75, and 0.73 (p, trend <0.0001). Each categorical increase in the exposure is roughly equivalent to 3 h/week (25 min/day) of light-intensity activity, which suggests that an increase of 1 h/day of such activity reduces mortality risk in women by 19%. Daily sitting time was also predictive of total mortality in both sexes, with the relation stronger in women (for ≥6 vs. <3 h/day, RR = 1.37) than in men (RR = 1.18) (p, heterogeneity = 0.003). These associations remained "virtually unchanged" after adjustment for physical activity. The RR for the joint effects of sitting and physical inactivity (≥6 h/day sitting and <24.5 MET-h/week of physical activity) were 1.94 and 1.48 in women and men, respectively, compared with their counterparts who reported both sitting the least (<3 h/day) and being the most physically active (≥52.2 MET-h/week). Similarly, in a cohort of 17,000 Canadians aged 18–90 years followed for an average of 12 years, there was a dose–response relation between daily time spent sitting and total mortality, after adjustment for total physical activity.[15] For women who sat "almost none," "1/4," "1/2," "3/4," and "almost all of the time," RR were 1 (referent), 1.17, 1.37, 1.61, and 1.85, respectively (p, trend <0.0001); for men, there was a weaker though still significant trend.

CARDIOVASCULAR DISEASE

A 2011 meta-analysis of data from nine prospective studies that quantified the dose–response relation between leisure-time physical activity found that persons who met the federal government's basic guideline had a 14% (4%–23%) lower risk for coronary heart disease (CHD) than those who engaged in no activity, whereas those who met the advanced guideline had a 20% (12%–26%) lower risk.[16] There was a significant interaction by sex. Women who met the basic guideline were at 20% (8%–31%) lower risk than those who engaged in no leisure-time activity, whereas women who met the advanced guideline were at 28% (17%–37%) lower risk. For men who met the basic and advanced guidelines, respectively, the RR were 0.91 (0.79–1.04) and 0.82 (0.74–0.91).

A look at findings from specific studies strongly supports the prescription of either vigorous or moderate-intensity physical activity to prevent CVD in sedentary women.[17] Among 73,000 postmenopausal participants aged 50–79 years in the Women's Health Initiative Observational Study, walking briskly for ≥2.5 h/week (e.g., a half-hour 5 times/week) was associated with a 30% reduction in cardiovascular events over a 3-year follow-up.[18] After controlling for total exercise energy expenditure, brisk walking and more vigorous exercise were associated with similar risk reductions in CVD events, and the results did not vary substantially by race, age, or baseline body mass index (BMI; Figure 25.1). Prolonged sitting also predicted an increased risk for CVD, even after accounting for time spent in recreational exercise. Women who spent ≥16 h/day sitting were 68% more likely to develop CVD than those who spent <4 h/day sitting.

Cardiovascular benefits of walking have been observed in other studies of women. For example, in an 8-year follow-up of 72,000 healthy female nurses aged 40–65 years in the Nurses' Health Study, 3 h/week of brisk walking had the same protective effect as 1.5 h/week of vigorous exercise.[19] Women reporting either type of exercise were 30%–40% less likely to develop myocardial infarction than their sedentary peers. Among 39,000 healthy female health professionals aged ≥45 years followed for 7 years in the Women's Health Study, walking ≥1 h/week was associated with a 50% reduction in CHD risk among participants reporting no vigorous physical activity.[20] In the Study of Osteoporotic Fractures, which followed 9704 women aged ≥65 years for 10 years, participants whose weekly walking energy expenditures averaged ≥300 kcal (about ≥1 h/week of walking) were 34% less likely to die from a cardiovascular cause than were those with weekly walking energy expenditures <70 kcal.[21] Independent of physical activity, more time spent sitting has also been significantly associated with cardiovascular mortality in several cohorts.[14,15]

Cardiovascular benefits of moderate-intensity activities have been observed in males, although somewhat less strongly, perhaps because background activity levels in men are generally higher than those in women. For example, in the Health Professionals Follow-up Study, which followed 44,000 men aged 40–75 years for 12 years, brisk walking for ≥30 min/day was associated with an 18% reduction in CHD incidence.[22] Studies in men suggest that vigorous exercise is even more beneficial than moderate-intensity exercise for CVD risk reduction. For example, in the Health Professionals Follow-up Study, each 1-MET increase in exercise intensity was associated with a 4% reduction in CHD risk independent of total exercise energy expenditure.[22]

Resistance exercise may also lower risk for CHD, although existing data are equivocal and more research is needed.[6] Men in the Health Professionals Follow-up Study who trained with weights for ≥30 min/week were 23% less likely to develop CHD during an 8-year follow-up than men who did not train with weights.[22] Comparable studies in women are lacking.

Findings from prospective studies suggest that aerobic physical activity may reduce the risk for stroke, although data are less extensive and consistent than for CHD. A meta-analysis of 18 cohort studies with follow-up periods ranging from 5 to 26 years found that moderately active and highly active persons were 17% and 25% less likely to have a stroke or die from stroke-related causes than were persons with low activity.[23] On the basis of six ischemic and three hemorrhagic stroke studies in the meta-analysis, physical activity appears to protect against both types of stroke. However, variation in the measurement and classification of physical activity in the original studies precluded a precise definition of "high," "moderate," and "low" activity, and sex-specific estimates were not provided. In the Nurses' Health Study, there was a strong inverse gradient of risk with volume of physical activity that was primarily due to the relation with ischemic rather than hemorrhagic stroke, with the most active women experiencing only half the risk for ischemic stroke as the least active women.[24] More recently, a 12-year follow-up of the Women's Health Study cohort found an inverse relation between walking time or pace and risk for stroke.[24a] Compared with women who did not walk, women who walked ≥2 h/week had 30% lower risk for stroke, and women whose usual walking pace was brisk (>4.8 km/h) had a 37% lower risk; associations were found for both ischemic and hemorrhagic stroke, although they were significant only for the latter outcome. However, vigorous-intensity physical activity was unrelated to stroke risk in this cohort.

Research indicates that previously sedentary individuals who become physically active in mid- or late life derive cardiovascular benefits. For example, among initially sedentary participants in the Nurses' Health Study, 6-year changes in activity level were significantly associated in dose–response fashion with CHD incidence during the subsequent 8 years.[19] Compared with women who remained sedentary, women with increasing quintiles of total physical activity energy expenditure were 15%, 21%, 33%, and 29% less likely to have a coronary event. In the Study of Osteoporotic Fractures, which assessed changes in physical activity over 6 years among 7553 women aged 65 years at baseline, women who increased their physical activity were 36% less likely to die from cardiovascular causes during the subsequent 7 years than were women who remained sedentary.[21] However, exercise must

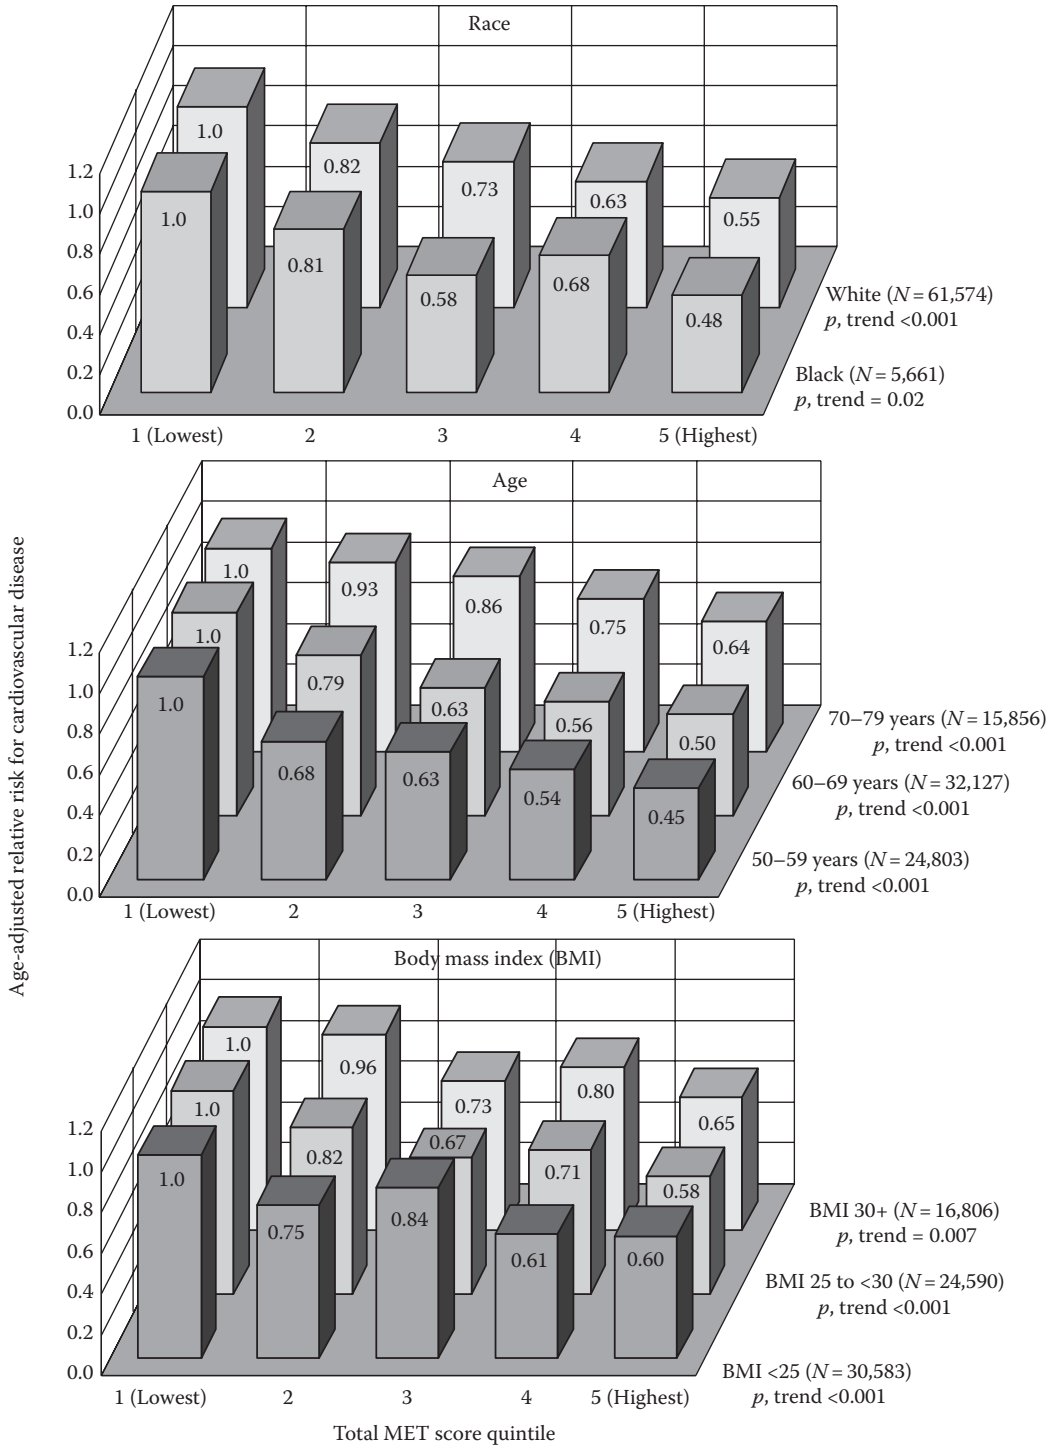

FIGURE 25.1 Age-adjusted relative risks for cardiovascular disease according to quintile of energy expenditure from recreational activities in subgroups defined by race, age, and body mass index, Women's Health Initiative. Quintile medians (ranges), in MET-h/week, are as follows: quintile 1, 0 (0–2.4); quintile 2, 4.2 (2.5–7.2); quintile 3, 10.0 (7.3–13.4); quintile 4, 17.5 (13.5–23.3); quintile 5, 32.8 (≥23.4). Quintile 1 is the reference category. (Adapted from Manson, J.E. et al., *N. Engl. J. Med.*, 347, 716, 2002.)

be current and habitual to confer cardiovascular protection; women who became inactive in later life had a similar risk of cardiovascular mortality as those who had remained inactive over the course of follow-up. From a public health perspective, knowing that "it's not too late" may motivate older individuals to become physically active.

Short bouts of activity (10–15 min) favorably affect the cardiovascular risk profile of otherwise sedentary persons.[25] One prospective study has examined the relation between brief bouts of exercise and clinical CVD. After controlling for total energy expenditure, exercise sessions lasting 15, 30, or 45 min offered equal protection against incident CVD

in a cohort of 7307 middle-aged and elderly male Harvard alumni followed for 5 years.[26] Although there are no studies of this issue in women, it is reasonable to speculate that similar results would be observed. Such findings may help motivate busy individuals to view exercise as a manageable part of their daily routine rather than as a time-consuming activity reserved for rare occasions.

Cardiorespiratory fitness as assessed by maximal treadmill exercise test is inversely correlated with cardiovascular mortality in persons without coronary symptoms at baseline. A 2009 meta-analysis of data from 24 prospective cohorts with a total of >84,000 initially healthy participants and nearly 4500 CVD endpoints (primarily cardiovascular mortality) found a significant 15% decline in cardiovascular risk for each 1 MET increase in exercise capacity.[27] The relation was similar in the 16 studies that included only men (risk reduction, 14%) and in the eight studies that included both sexes or only women (risk reduction, 16%).

Physical activity appears to slow the initiation and progression of CVD through beneficial effects on adiposity, insulin sensitivity, glycemic control, type 2 diabetes incidence (see the following section), blood pressure, lipids, endothelial function, hemostasis, and inflammatory defense systems.[17] In the Women's Health Study, these factors explained 59% of the observed inverse relation between physical activity and incident CVD over 11 years of follow-up.[28] Inflammatory/hemostatic risk factors (C-reactive protein, fibrinogen, and soluble intercellular adhesion molecule 1) made the largest contribution to lower risk (32.5%), followed by blood pressure (27.1%), traditional lipids (19.1%), the novel lipids lipoprotein(a) and apolipoproteins A1 and B100 (15.5%), BMI (10.1%), and hemoglobin A1c/diabetes (8.9%). Findings from observational studies and randomized trials indicate that regular moderate-intensity activity is as effective as more vigorous activity in reducing blood pressure and improving insulin sensitivity.[17] In contrast, strong dose–response associations between exercise intensity and blood lipids—specifically, triglycerides and high-density lipoprotein cholesterol—have been reported.[17] Resistance exercise has also been shown to reduce blood pressure.[29] A randomized trial in patients with type 2 diabetes found that a combination of aerobic and resistance exercise yielded greater improvement in glycemic control than did either type of exercise alone.[30] However, whether resistance exercise alone can favorably affect other cardiovascular risk markers in patients with type 2 diabetes remains unclear.[31]

TYPE 2 DIABETES

Cohort studies consistently show a marked reduction in the incidence of type 2 diabetes among physically active individuals as compared with their sedentary peers. A 2007 meta-analysis of 10 cohort studies involving 301,000 participants found that individuals who regularly engaged in moderate-intensity physical activity were 17% (10%–24%) less likely to develop type 2 diabetes than inactive individuals, after adjustment for BMI.[32] A look at findings from specific studies, some of which were included in the meta-analysis, provides empirical support for the prescription of 30 min/day of moderate-intensity activity in women. Among >70,000 participants in the Nurses' Health Study, walking briskly for at least 2.5 h/week—e.g., 30 min/day for 5 days/week—was associated with a 25% reduction in diabetes over 8 years of follow-up among those reporting no vigorous exercise, after adjustment for BMI and other risk factors for diabetes.[33] This is a conservative estimate that excludes the risk reduction attributable to lower body mass from physical activity. Given equivalent total exercise energy expenditures, brisk walking and more vigorous exercise were associated with similar magnitudes of risk reduction. In a 7-year follow-up of the Women's Health Study cohort, participants who reported walking 2–3 h/week were 34% less likely to develop diabetes than women who reported not walking.[34] In the Iowa Women's Health Study, which tracked >34,000 participants aged 55–69 years for 12 years, women engaging in moderate-intensity exercise 1, 2–4, and >4 times/week were 10%, 14%, and 27% less likely, respectively, to develop diabetes than women engaging in such exercise <1 time/week.[35] Among >86,000 women followed for an average of 5 years in the Women's Health Initiative Observational Study, walking was inversely related to diabetes risk, with RR for increasing quintiles of walking of 1.0 (referent), 0.77, 0.87, 0.74, and 0.82 (p, trend = 0.009). The relation was significant in white women but was less clear-cut in women of other races/ethnicities.[36] All estimates reflect adjustment for the effects of BMI and potential confounders.

Metabolic benefits of moderate-intensity exercise have also been observed in male populations. For example, among 38,000 men followed for 10 years in the Health Professionals Follow-up Study, each 10 MET-h increment in weekly walking energy expenditure was associated with a statistically significant 11% reduction in diabetes risk; an equivalent increase in weekly vigorous activity conferred a 12% reduction in diabetes risk.[37] Some data suggest that the inverse association between physical activity and risk for diabetes may be somewhat stronger for women than for men, perhaps due to generally lower baseline activity levels for former as compared with the latter, but this is not a consistent finding.[17]

Cardiorespiratory fitness as assessed by bicycle ergometer or treadmill test has been shown to correlate inversely with type 2 diabetes risk. Among 6249 women aged 20–79 years followed for 17 years in the Aerobics Center Longitudinal Study, the adjusted RR for incident diabetes across increasing tertiles of fitness were 1.0 (referent), 0.86 (0.59–1.25), and 0.61 (0.38–0.96).[38] In 834 women and 709 men (mean age, 37 years) followed for 15.5 years in the Canadian Physical Activity Longitudinal Study, the risk for incident diabetes was 70% lower for each standard deviation increase in cardiorespiratory fitness; sex-specific analyses were not reported.[39]

Randomized trials in high-risk populations provide strong evidence that regular physical activity can prevent or postpone the onset of type 2 diabetes. To date, four large (>500 participants) randomized studies of exercise and diet in the prevention of type 2 diabetes have been conducted.

In the Da Qing IGT and Diabetes Study, 577 middle-aged Chinese women and men with impaired glucose tolerance (IGT) were randomized to one of three treatment groups—diet only, exercise only, or diet plus exercise—or to a control group.[40] Participants assigned to exercise were encouraged to increase their daily physical activity by ≥1 units, with a unit defined as 30 min of mild-intensity activity (e.g., walking), 20 min of moderate-intensity activity (e.g., brisk walking or cycling), 10 min of strenuous activity (e.g., slow running or climbing stairs), or 5 min of very strenuous activity (e.g., jumping rope or swimming). Over the 6 years of the trial, the three interventions were associated with statistically significant reductions of 31%, 46%, and 42% in diabetes risk, respectively, with similar benefits for both lean and overweight individuals. The protective effect of the lifestyle intervention persisted for a lengthy period; there was a statistically significant 43% reduction in diabetes incidence among persons assigned to any of the treatment groups—and a statistically significant 49% reduction among those assigned to exercise alone—14 years after the trial's end.[41]

In the Finnish Diabetes Prevention Study, 522 middle-aged, overweight women and men with IGT were randomized to an intensive lifestyle intervention designed to promote healthy eating and exercise patterns or to a control group.[42] Members of the intervention group lost significantly more weight than did the control group (3.5 vs. 0.8 kg) and reduced their risk of developing diabetes by 58% over 3 years. There was a strong correlation between the number of lifestyle goals achieved during the first year of the trial—weight loss of >5%, reduction in fat intake to <30% of calories, reduction in saturated fat intake to <10% of calories, increase in fiber intake to ≥15 g/1000 kcal, and performing the equivalent of ≥150 min/week of moderate-intensity exercise—and diabetes incidence. Of note, exercise reduced diabetes risk even when participants did not attain the weight loss goal. Among intervention group members who did not lose >5% of their initial body weight, those who achieved the exercise goal were only one-fifth as likely to develop diabetes as compared with their counterparts who stayed sedentary; the association remained strong after adjustment for baseline BMI. The corresponding exercise-associated risk reduction in the control group was ~40%. Data from a subsample of participants who had a frequently sampled intravenous glucose tolerance test at baseline and at the end of the trial suggest that improved insulin sensitivity, rather than preserved insulin secretion, largely explained the reduction in diabetes risk.[43] Participants who had not developed diabetes by trial's end were observationally followed for a median of 3 additional years; during this time, a significant 36% reduction in diabetes incidence was noted in the intervention as compared with the control group.[44]

The U.S. Diabetes Prevention Program, which randomized 3234 adults aged 25–85 years with IGT and BMI ≥24 kg/m^2 to either a diet and exercise program, the drug metformin, or placebo, also found a 58% reduction in risk for diabetes associated with the lifestyle intervention (vs. placebo).[45] (Metformin was also effective; the drug vs. placebo comparison yielded a 31% risk reduction.) On average, participants assigned to lifestyle modification exercised at moderate intensity for 150 min/week and lost 5%–7% of their body weight during 3 years of follow-up. The lifestyle intervention reduced diabetes risk in both sexes and in all age, racial/ethnic, and BMI groups. A 10-year follow-up, in which all participants were offered lifestyle intervention and metformin was continued in the metformin group, found that, although incidence rates of diabetes were similar in the three groups during follow-up, the cumulative incidence remained lowest in the original lifestyle group.[46]

The Indian Diabetes Prevention Programme, a randomized trial among 531 middle-aged Asian Indian adults with IGT, reported a 28% reduction in diabetes risk associated with a diet and exercise intervention.[47]

A meta-analysis of 17 randomized trials involving 8084 participants followed for an average of 4 years—12 trials evaluated lifestyle interventions, mainly weight loss and exercise; 12 trials evaluated pharmacologic interventions, mainly metformin and acarbose; and several trials evaluated both—reported a pooled RR for developing diabetes of 0.51 (0.40–0.60) with lifestyle intervention and 0.70 (0.62–0.79) with oral diabetes drugs.[48] An ongoing large randomized trial, the Look AHEAD (Action For Health in Diabetes) trial, should provide valuable information about the long-term (≥10 years) effects of sustained weight loss through decreased caloric intake and exercise on the risk for CVD in obese individuals with diabetes; results are expected in 2012.[49]

CANCER

For cancer prevention, the American Cancer Society recommends at least 30 min of moderate to vigorous physical activity on 5 or more days of the week but notes that 45–60 min is preferable.[50] Similarly, the World Cancer Research Fund and the American Institute for Cancer Research recommend moderate physical activity for at least 30 min every day but state that, "as fitness improves, aim for 60 min or more of moderate, or for 30 min or more of vigorous, physical activity every day."[51]

Observational studies show an association between physical activity and a reduced risk for several types of cancer, particularly colon, breast, and endometrial cancer. (Some studies have found an inverse relation between physical and total cancer incidence or mortality,[12,13,52] but most studies have examined site-specific cancers only.) Data from observational studies and small randomized trials suggest that physical activity may protect against cancer by reducing risk for overweight/obesity and favorably affecting circulating levels of sex hormones, insulin, and inflammatory cytokines, as well as immune function and apoptosis.[53–55] Other biological mechanisms that may account in part for a chemoprotective effect of physical activity include decreases in insulin-like growth factors; favorable changes in prostaglandin profile; strengthened DNA repair systems; increased gut motility and reduced intestinal transit time for potential carcinogens (colon cancer); and improved pulmonary function

and shortened exposure time between lung tissue and carcinogens (lung cancer).[54] However, the evidence regarding mechanistic pathways is not definitive. Additional studies are needed to clarify which mechanisms, individually or in combination, account for the physical activity–cancer link.

Colon Cancer

Dozens of observational studies have found an inverse relation between physical activity and risk for colon cancer. A 2009 meta-analysis of 28 cohort and 24 case–control studies found an overall RR of 0.76 (0.72–0.81) comparing the most with the least active individuals.[56] The risk reduction was similar for women (RR = 0.79) and men (RR = 0.76). However, the risk reduction observed in the cohort studies (RR = 0.83) was smaller than that observed in the case–control studies (RR = 0.69), perhaps because of recall bias in the latter type of study. Moreover, the risk reduction in the cohort studies (although not the case–control studies) was smaller in women (RR = 0.89) than in men (RR = 0.81), perhaps because of sex differences in the absolute physical activity levels being compared. Women typically engage in less physical activity than men, and higher amounts may be needed to prevent colon cancer.

The studies included in the meta-analysis did not quantify physical activity uniformly, precluding the ability to determine the amount of physical activity necessary for the observed risk reduction. However, at least 30–60 min/day of moderate- to vigorous-intensity physical activity appears to be required to lower colon cancer risk significantly.[4,50] For example, among 79,000 Nurses' Health Study participants followed for up to 16 years, there was a 23% risk reduction comparing the most with the least active women (RR = 0.77 [0.58–1.01]).[57] The most active women expended >21.5 MET-h/week in leisure-time physical activity, whereas the least active expended <2 MET-h/week. These levels are equivalent to brisk walking for ~5 to 6 h/week in the most active and 0.5 h/week in the least active women. However, among women whose only reported activity was walking, there was a 31% risk reduction in those who walked 1–1.9 h/week (RR = 0.69 [0.47–1.03]) compared with those who did not walk, with little additional benefit for more time spent walking. A faster walking pace was also associated with reduced risk (very brisk vs. easy walking pace: RR = 0.43 [0.17–1.05]). Among women who participated in moderate or vigorous activity other than walking, those exercising >4 h/week had a 44% lower risk for colon cancer than those exercising <1 h/week, with a significant dose–response relation (p, trend = 0.01). On the other hand, in a 6-year follow-up of the CPS-II Nutrition Cohort, walking alone (without other recreational physical activity) was not significantly related to colon cancer risk,[58] although a protective association was observed for those who reported walking plus other recreational activity. For women, the RRs for <4, 4–6, and ≥7 h/week of activity vs. no activity were 0.99 (0.67–1.47), 0.72 (0.43–1.19), and 0.59 (0.36–0.98) (p, trend = 0.07).

Colon adenoma is the precursor lesion to colon cancer that is detected and removed during sigmoidoscopy or colonoscopy. A 2011 meta-analysis of 20 observational studies (cohort and case–control studies were not analyzed separately) of physical activity in relation to colon adenoma risk found an overall RR of 0.84 (0.77–0.92) when comparing the most with the least active persons.[59] The associations were similar for women (RR = 0.87 [0.74–1.02]) and men (RR = 0.81 [0.77–0.92]).

Breast Cancer

A 2011 systematic review of 33 cohort and 40 case–control studies found an average decrease of 25% in risk for breast cancer when comparing the most physically active with the least active women, with a stronger effect in the case–control studies (average risk reduction, 30%) than in the cohort studies (average risk reduction, 20%).[60] The majority of studies with significant results found a dose–response relation between increasing levels of physical activity and decreasing breast cancer risks. The risk reductions observed for recreational and household activities were generally greater than for walking or cycling alone or occupational activity. Some though not all studies suggest a stronger protective effect for physical activity among women who are postmenopausal, of normal weight (BMI < 25 kg/m^2), parous, and who have no family history of breast cancer.

Many studies suggest that at least 4–7 h/week of moderate to vigorous physical activity is necessary to yield a statistically significant reduction in breast cancer risk. For example, among 95,000 postmenopausal women followed for 20 years in the Nurses' Health Study, women who engaged in ≥27 MET-h/week of physical activity (equivalent to ~1 h/day of brisk walking) during follow-up were 15% less likely to develop breast cancer than those who engaged in <3 MET-h/week of physical activity. In analyses specifically of brisk walking, this activity was associated with lower risk (per 20 MET-h/week [5 h/week]: RR = 0.91). Compared with women who were least active at menopause and remained so through follow-up (<9 MET-h/week [walking at an average pace for ~30 min on most days of the week]), women who increased their activity were at reduced risk (<9 MET-h/week at menopause and ≥9 MET-h/week during follow-up: RR = 0.90).

Some studies suggest that a lower level of physical activity may also be beneficial for breast cancer prevention. For example, among 74,000 participants followed for 4.7 years in the Women's Health Initiative, women who engaged in 5.1–10 MET-h/week of physical activity (the equivalent of 1.25–2.5 h/week of brisk walking) at the start of the study had an 18% decreased risk for breast cancer compared with inactive women, while women who exercised >40 MET-h/week (the equivalent of >10 h/week of brisk walking) had only a slightly greater reduction in risk.[61] In this cohort, the beneficial effect of exercise was most pronounced in women in the lowest tertile of BMI (<24.1 kg/m^2) but was also apparent in women in the middle tertile (24.1–28.4). The protective effect did not vary by family history of breast cancer, parity, or menopausal hormone therapy use.

Endometrial Cancer

A 2010 meta-analysis of 11 prospective cohort studies found a significant inverse relation between physical activity and endometrial cancer risk.[62] In the nine studies that assessed recreational physical activity, a comparison of women who reported the most activity with those who reported the least yielded a pooled RR of 0.73 (0.58–0.93); adjustment for BMI—obesity is a strong risk factor for endometrial cancer—produced only a small attenuation (RR = 0.78 [0.63–0.95]). Eight of the nine studies reported significant or nonsignificant inverse associations. Seven of the nine studies included a statistical test for trend; of these, four found a significant dose–response relation. In the five studies that assessed occupational physical activity, a comparison of women reporting the most vs. the least activity yielded a summary RR of 0.79 (0.71–0.88).

Some reviewers have suggested that ~1 h/day of moderate-intensity physical activity appears to confer protection against endometrial cancer.[54] However, results of large prospective studies published recently (2008 or later) have been equivocal regarding the intensity required for risk reduction. Among >109,000 women aged 50–71 years followed for an average of 7 years in the NIH-AARP Diet and Health Study, vigorous physical activity was inversely associated with endometrial cancer risk after adjustment for BMI and other potential confounders (≥5 times/week for ≥20 min vs. never/rarely: RR = 0.77), but light/moderate, daily routine, and occupational physical activity were not predictive of risk.[63] Among >32,000 women followed for an average of 9 years in the Women's Health Study, women reporting any vigorous activity had lower risk than those reporting none (BMI-adjusted RR = 0.74, with no trend of declining risk with increasing energy expended in such activities), but walking was unrelated to risk.[64] In the CPS-II Nutrition Cohort, which followed >42,000 women for up to 10 years, recreational physical activity (primarily low to moderate intensity) was significantly associated with lower risk in analyses unadjusted for BMI (≥31.5 vs. <7 MET-h/week: RR = 0.67 [0.44–1.03]; *p*, trend = 0.007), but the association was attenuated after adjustment for this variable (RR = 0.79 [0.52–1.22]; *p*, trend = 0.18).[65]

Ovarian Cancer

Whether physical activity plays a role in the prevention of ovarian cancer remains uncertain, as results from epidemiologic studies have been inconsistent. A 2007 meta-analysis of seven case–control studies and six cohort studies of recreational physical activity in relation to ovarian cancer risk estimated a 20% reduced risk for the most vs. least active women.[66] For the case–control studies, the summary OR was 0.79 (0.70–0.85); for the cohort studies, the summary RR was 0.81 (0.57–1.17). However, results from several large prospective studies published since completion of the meta-analysis fail to provide support for a protective effect of physical activity against ovarian cancer.[67–70] Indeed, data from one such study, the NIH-AARP Diet and Health Study,[70] suggest that vigorous physical activity may be associated with an increase in ovarian cancer risk, a result also seen in two earlier studies, the Iowa Women's Health Study[71] and the Nurses' Health Study.[72] Such a relation could be explained by detection bias if more vigorously active women tend to exhibit cancer symptoms earlier than their less active counterparts. Additional research is needed to clarify the relation between physical activity and ovarian cancer.

Lung Cancer

A 2011 systematic review of 20 cohort and seven case–control studies of physical activity and lung cancer risk concluded that physical activity is associated with risk reductions of 20%–30% in women and 20%–50% in men, with evidence of a dose–response effect.[73] Because cigarette smoking is the major determinant of lung cancer, controlling for its effect is a critical methodological consideration in studies of this cancer site. Although most studies adjusted for smoking status or history, the potential for residual confounding remains high. Indeed, most studies that provide results stratified by smoking status have found either no effect or a much smaller protective effect of physical activity on lung cancer risk among nonsmokers than among current or former smokers.[74] Additional studies are needed to clarify whether there is an association between physical activity and lung cancer among never smokers.

Other Cancers

Cancers with insufficient data to determine whether physical activity plays a role in risk reduction include pancreatic, esophageal, kidney, bladder, cervical, and hematological cancers.[54] Results from epidemiologic studies have been inconsistent or null for these outcomes.

OSTEOPOROTIC FRACTURE, BONE MINERAL DENSITY, AND FALLS

Osteoporosis is a significant public health problem among older women in developed countries. It is characterized by rapid loss of bone density after menopause, which appears to be directly related to a decrease in estrogen levels and is associated with an increased risk for hip, spine, and wrist fracture. Physical activity may reduce the risk for osteoporotic fracture by increasing bone strength (weight-bearing aerobic and resistance exercise) and preventing falls (resistance, balance, and flexibility exercise).

Fracture

Observational investigations of physical activity in relation to fracture risk have largely focused on hip fracture, for two reasons. One, virtually all individuals with hip fracture seek medical attention, facilitating use of this endpoint in

epidemiologic studies. Second, because the proximal femur (part of the hip bone) undergoes loading during walking and all activities that involve ambulation, it is likely that any effect of physical activity on fracture risk would be most pronounced at this site. Indeed, a 2008 meta-analysis of 13 prospective studies found that moderate to vigorous physical activity was associated with a hip fracture risk reduction of 38% (31%–44%) in women and 45% (31%–56%) in men.[75] For example, among >61,000 postmenopausal women followed for 12 years in the Nurses' Health Study, each increase of 3 MET-h/week of physical activity (equivalent to 1 h/week of walking at an average pace) was associated with a statistically significant 6% reduction in risk for hip fracture.[76] Women performing ≥24 MET-h/week of physical activity had a 55% lower risk for hip fracture compared with women performing <3 MET-h/week. Among women who reported no other exercise, walking for ≥4 h/week was associated with a 41% lower risk for hip fracture compared with walking <1 h/week.

Fewer prospective studies have examined the association between physical activity and risk for vertebral fracture, and the results have been largely nonsignificant.[75] However, among 7239 women followed for 3.7 years in the Study of Osteoporotic Fractures, moderate to vigorous physical activity (>2 h/day) reduced the risk for radiographically assessed vertebral fracture by 33% as compared with no activity.[77] Limited data from prospective studies suggest that physical activity may *increase* the risk for wrist and other upper-limb fractures.[75]

Randomized clinical trials with fracture as a primary prespecified endpoint are lacking. A 2011 meta-analysis of 43 randomized trials (4320 participants) designed to test the effect of various exercise interventions on bone mineral density (BMD) in postmenopausal women reported a nonsignificant reduction in fracture risk (OR = 0.61 [0.23–1.64]), but most trials were not powered to detect this endpoint.[78]

Bone Mineral Density

Many randomized clinical trials have evaluated changes in BMD in response to exercise training in women. The aforementioned 2011 meta-analysis of 43 such trials in postmenopausal women reported that interventions that utilized a combination of exercise types slowed loss of BMD at the spine by a statistically significant 3.2% and that exercise interventions of any type slowed loss of BMD at the hip by a statistically significant 1.0%.[78] However, the magnitude of this effect is of questionable biological significance for reduction of fracture risk.[75] Also, most trials were ≤12 months in duration, so the extent to which age-related decreases in BMD can be attenuated through longer-term exercise training needs additional study.[9]

Falls

Prospective studies of the relation between usual physical activity and risk for falling suggest a U-shaped effect, with the most inactive and the most active persons at highest risk.[75] Several randomized trials have assessed the effect of exercise on fall prevention. In a meta-analysis of 12 such trials conducted in older community-dwelling persons, the pooled RR was 0.71 (0.61–0.82).[9] Of these trials, seven assessed strength and balance training; three assessed tai chi; one assessed endurance training and/or strength training; and one assessed computerized balance training and tai chi independently. An earlier meta-analysis of eight randomized trials showed a marginally significant 10% reduction in risk for falls associated with general exercise and a significant 17% reduction associated with balance training but no significant effect of aerobic, resistance, or flexibility training.[79]

NEUROPSYCHOLOGICAL OUTCOMES

Cognitive Decline

Many though not all prospective cohort studies show that physical activity is associated with better cognitive function in older populations.[9,80] For example, among >18,000 women aged 70–81 in the Nurses' Health Study, higher levels of long-term regular physical activity (average of biennial assessments occurring in 8–15 years prior to cognitive testing) were strongly predictive of better cognitive performance (a global score created by averaging scores on the Telephone Interview for Cognitive Status; a category fluency test; working memory and attention tests; and a verbal memory test).[81] The apparent benefit for women in the highest vs. lowest quintile of physical activity was similar in magnitude to that conferred by being ~3 years younger in age. A higher level of physical activity was also predictive of less cognitive decline over the subsequent 2 years. Notably, the protective effect of physical activity was not restricted to women engaging in vigorous activity; those who performed the equivalent of walking at an easy pace for ≥1.5 h/week had significantly better cognitive function than those who walked <40 min/week, with the magnitude of the difference equivalent to that observed for women ~1.5 years apart in age. Among 5925 women aged ≥65 years followed for 6–8 years in the Study of Osteoporotic Fractures, there was also a significant inverse relation between the number of blocks walked per week and cognitive decline as assessed by the Mini Mental State Examination.[82] Taken in aggregate, prospective cohort studies of physical activity in relation to incident dementia have also found an inverse relation. A 2009 meta-analysis of 16 prospective studies reported that, compared with individuals in the lowest activity category, those in the highest activity category experienced a 28% (14%–40%) reduction in risk for dementia and a 45% (16%–64%) reduction in risk for Alzheimer's disease.[83] Small, short-term randomized trials in nondemented older adults have demonstrated that exercise training, particularly a combination of aerobic, strength, and flexibility regimens, can improve certain cognitive processes, particularly executive function.[84] Moreover, imaging trials have shown beneficial changes in brain activity[85] and volume[86] in aerobically trained older adults. Animal studies

demonstrate that exercise has favorable effects on cognition (water maze performance), neurogenesis, neurotransmitter systems, and expression of brain-derived neurotrophic factor in young and aged rodents,[80] suggesting mechanisms by which physical activity may protect against cognitive decline. Physical activity also likely sustains the vascular health of the brain by lowering blood pressure, improving lipoprotein profiles, promoting endothelial nitric oxide production, ensuring adequate cerebral perfusion, and favorably affecting insulin and glucose parameters.[81]

Depression and Anxiety

In an analysis of data from 28 prospective cohort studies with a mean follow-up of 4 years, the average odds of experiencing elevated depressive symptomatology was 14%–25% lower among physically active compared with inactive individuals, after adjustment for potential confounders.[9] There was a protective benefit for people meeting the basic physical activity guideline (OR = 0.77 [0.72–0.82]) as well as for people who engaged in physical activity at less than recommended levels (OR = 0.84 [0.78–0.90]). Prospective observational data also suggest a protective effect for clinical depression. Prospective observational data on the relation between physical activity and anxiety are limited. However, short-term randomized trials indicate that physical activity can reduce depressive and anxiety symptoms in healthy adults,[9,87] medical patients without psychiatric disorders,[9,88] and depressed or anxious patients.[9,89]

WEIGHT CONTROL

Together with caloric intake, physical activity is a key determinant of energy balance and thus degree of adiposity. The Institute of Medicine first highlighted the issue of weight control in its 2002 recommendation espousing 60—rather than 30—min/day of moderate-intensity physical activity for weight maintenance and maximal health benefits.[90] In 2005, the Dietary Guidelines for Americans issued by the U.S. Department of Health and Human Services and U.S. Department of Agriculture included a physical activity guideline of 60 min/day to prevent weight gain and 60–90 min/day to sustain weight loss.[91] In 2009, the American College of Sports Medicine reviewed the empirical literature on physical activity in relation to weight control and concluded that, in the absence of caloric restriction, 150–250 min/week of moderate-intensity activity appears to be effective for preventing weight gain but not for producing clinically significant weight loss, while >250 min/week of such activity appears to be necessary for clinically significant weight loss as well as for the prevention of weight gain following weight loss.[92]

Recent large cohort studies in women provide perspective. Among 34,000 participants in the Women's Health Study, physical activity was associated with less weight gain among normal-weight women (BMI < 25 kg/m^2) but not among overweight (BMI 25 to <30) or obese women (BMI ≥ 30).[93] Women who were successful in maintaining a normal weight and gaining <2.3 kg over a 13-year follow-up period averaged ~60 min/day of moderate-intensity activity throughout the study. On the other hand, in an 8-year follow-up of >46,000 women aged 25–43 years in the Nurses' Health Study II, physical activity for ≥30 min/day was associated with a significantly lower likelihood of weight gain of >5%, with the strongest effect in those who were overweight. Compared with women who maintained <30 min/day of physical activity over 8 years, women were less likely to gain weight if they sustained ≥30 min/day (OR = 0.68) or increased to this level (OR = 0.64). However, there was a clear dose–response relation, such that even a small increase in physical activity in sedentary women (11–20 min/day) appeared beneficial. There was also no threshold above which physical activity and risk for weight gain were unrelated. Indeed, data from this study suggest that the amount of daily discretionary physical activity needed to eliminate, not just reduce, the risk for weight gain was 1.6 h for normal-weight women, 1.5 h for overweight women, and 45 min for obese women.[94] The Nurses' Health Study II investigators also examined physical activity as a predictor of weight maintenance after intentional weight loss among 4558 cohort members who had intentionally lost >5% of their body weight in the previous 2 years. Women were less likely to regain >30% of the lost weight over a 6-year period if they maintained ≥30 min/day of physical activity (OR = 0.69) or increased to this level (OR = 0.48), compared with those who remained inactive.[95]

Recent genetic epidemiologic research has shown that physical activity may counteract a genetic predisposition toward weight gain. In a 2011 meta-analysis of data from 45 studies with a total of 218,000 adults, the relation between the "fat mass and obesity associated" (FTO) gene—the strongest known susceptibility locus for obesity, albeit with low penetrance—with risk for obesity was attenuated by 27% in physically active compared with inactive persons.[96]

It should be noted that although weight control is an important goal, focusing on it as the main reason for engaging in physical activity gives an incomplete assessment of exercise's impact on disease risk. For example, with few exceptions, prospective observational studies find that inverse relations between physical activity and risk for cardiometabolic diseases persist even after factoring out the effects of BMI, suggesting that the benefits derived from physical activity are not solely attributable to weight regulation. As shown in Figure 25.2, data from the Nurses' Health Study indicate that physical inactivity and obesity independently contribute to the development of CHD and type 2 diabetes in initially healthy women.[97] Findings from other large cohorts are similar.

PREGNANCY OUTCOMES

The American College of Obstetricians and Gynecologists (ACOG) recommends that pregnant women participate in ≥30 min of moderate-intensity physical activity on most days of the week in the absence of medical or obstetrical contraindications.[98] ACOG neither endorses nor recommends against participation in vigorous activities, for which information on pregnancy outcomes is sparse. Similarly, the

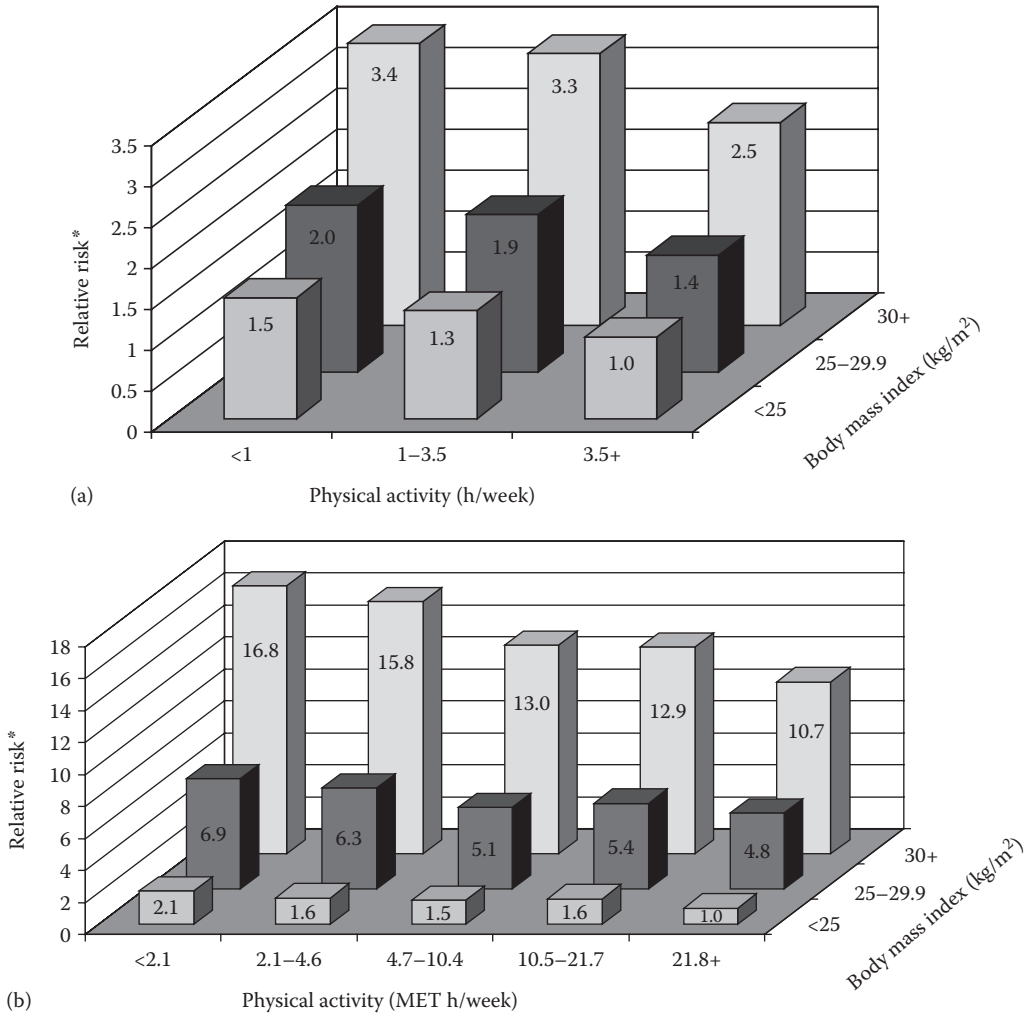

FIGURE 25.2 (a) Relative risk for coronary heart disease according to body mass index and physical activity level, Nurses' Health Study, 1980–2000. *Relative risks are adjusted for age, smoking status, alcohol consumption, menopausal status, postmenopausal hormone use, aspirin use, and parental history of CHD. (Data from Li, T.Y. et al., *Circulation*, 113, 499, 2006.) (b) Relative risk for type 2 diabetes according to body mass index and physical activity level, Nurses' Health Study, 1986–2002. *Relative risks are adjusted for age, smoking status, alcohol consumption, menopausal status, postmenopausal hormone use, and family history of diabetes. (Data from Rana, J.S. et al., *Diabetes Care*, 30, 53, 2007.)

2008 federal physical activity guidelines advise pregnant women that "it is reasonable … to follow the moderate-intensity physical activity recommendations set for adults unless specific medical concerns warrant a reduction in activity."[9] A 2011 meta-analysis of observational studies (five prospective cohort studies, two retrospective case–control studies, and two cross-sectional studies) found that physical activity before pregnancy (OR = 0.45 [0.28–0.75]) or in early pregnancy (OR = 0.76 [0.70–0.83]) was associated with a significantly lower risk for gestational diabetes.[99] The inverse association did not differ by study design, alleviating the concern for recall bias among the retrospective studies. Observational and very limited randomized trial data suggest that physical activity during pregnancy may also reduce risk for preeclampsia.[100–102] Moderate-intensity activity during pregnancy does not appear to increase risk for low birth weight, preterm delivery, or early pregnancy loss, although vigorous activity has been associated with small reductions (~200 to 400 g) in birth weight.[100,101] Sufficiently powered randomized trials of the effect of physical activity on pregnancy outcomes are needed.

RISKS OF PHYSICAL ACTIVITY

Along with its many benefits, physical activity has certain risks, including musculoskeletal injuries, cardiac events, and—particularly in athletes—menstrual dysfunction.

Musculoskeletal Injuries

Musculoskeletal injuries are the most common adverse events associated with physical activity. The risk for injury varies by activity type, with low-impact activities such as walking, gardening, cycling, and swimming associated with the fewest

risks.[9] Available data suggest that engaging in regular physical activity at currently recommended levels is associated with a low risk for musculoskeletal injury, although this risk has not been precisely quantified.[9] Research has also shown that when individuals increase their usual amount of physical activity, the risk for injury is related to the size of the increase.[9] Gradual, modest increases in physical activity allow for bodily adaptation and have been shown to reduce injury risk. Safely achieving a desired level of activity may require up to a year, especially for sedentary, elderly, or obese persons.[9]

With respect to sex differences in susceptibility to injury, available data suggest that, aside from stress fractures and injuries to the anterior cruciate ligament of the knee, which occur more frequently in females, women and men are equally likely to experience activity-related injuries, after adjustment for differences in activity and fitness levels.[9]

Acute Cardiac Events

Physical exertion can trigger acute cardiac events. A 2011 meta-analysis of case-crossover studies—a study design useful for examining a brief period of risk related to a brief exposure and in which cases serve as their own controls—found that episodic physical activity of ≥5–6 METs (moderate to vigorous intensity) was associated with an increased risk for myocardial infarction (10 studies; RR = 3.45 [2.33–5.13]) and sudden cardiac death (3 studies; RR = 4.98 [1.47–16.91]).[103] The associations appear to be similar for women and men, although more data are needed to determine this conclusively.[104] Importantly, the absolute increase in incidence of transient adverse cardiac events was low—i.e., 2–3 per 10,000 person-years for myocardial infarction and 1 per 10,000 person-years for sudden cardiac death. Also, habitual physical activity significantly attenuated the association between episodic physical activity and adverse cardiac events. For every additional time per week an individual habitually engaged in physical activity, the RR for myocardial infarction triggered by episodic physical activity dropped by 45% and that for sudden cardiac death dropped by 30%. The meta-analysis did not assess the transient cardiac risks associated with moderate-intensity physical activity only. However, limited data on this issue are consistent with the expectation that such risks are lower than those associated with vigorous activity. In terms of the balance of cardiovascular benefits and risks, it is critical to recognize that regular physical activity of moderate or vigorous intensity is associated with an overall decrease in CVD events that far outweighs the transient cardiac risks associated with physical exertion.[9]

Menstrual Dysfunction

Most of the research on the relation between physical activity and menstrual dysfunction has focused on competitive athletes rather than the general female population. Indeed, the American College of Sports Medicine coined the term "female athlete triad" nearly 20 years ago to describe a constellation of disordered eating, amenorrhea, and osteoporosis that occurs in these women.[105] Women engaged in sports that emphasize leanness, such as gymnastics, ballet, figure skating, and long-distance running, are particularly susceptible to the condition, suggesting that exercise alone is not the main culprit of reproductive abnormalities and that chronic-restricted caloric intake that does not balance energy expenditure also plays a role.[106]

CONCLUSION

Epidemiologic studies suggest that as little as 30 min/day of moderate-intensity physical activity can improve health and reduce risk for a variety of chronic diseases among sedentary women. A critical challenge for clinicians and policymakers is identifying and implementing approaches to facilitate sustained physical activity at this level.

Although more than two in three U.S. adults do not exercise enough to meet the basic federal guideline of 30 min/day, national survey data indicate that only one in three persons who saw a physician in the prior year reported receiving advice about physical activity at his or her last visit.[107] On the other hand, a survey of primary care physicians in Canada found that 70% reported routinely counseling patients about physical activity.[108] Although the prevalence of clinician counseling is uncertain, failure to counsel may result from a perceived lack of time, training, and appropriate patient materials. However, counseling need not be time intensive or intricate. Data from the multicenter Activity Counseling Trial suggest that clinicians can easily learn to incorporate 3–4 min of physical activity advice into routine office visits[109] and that counseling can increase activity in sedentary patients.[110]

A simple blueprint for physicians who wish to incorporate brief counseling about physical activity into their daily practices is available.[111] Lay publications to help sedentary individuals become more active can be retrieved online at no charge from various agencies.[112–114] Elements for an exercise "prescription" for patients are provided in Table 25.2. Data from randomized trials suggest that lifestyle activity interventions, which encourage the incorporation of short bouts of physical activity into daily routines (e.g., walking during lunch breaks, doing yard work or gardening, and taking the stairs rather than

TABLE 25.2
Possible Elements for a "Prescription" for Increased Physical Activity

- Take the stairs whenever possible
- Purchase a pedometer; aim for 10,000 steps/day
- Display "exercise prescription" in a visible place
- If you drive to work or stores, park in a space far away from the door and walk
- If you take public transportation, get off a stop early and walk
- Walk on your lunch break
- Try exercising with friends or a group
- Consider strength training for 20 min 2–3 times/week

the elevator), can be more effective than structured exercise programs in increasing physical activity and improving fitness and cardiometabolic risk profiles.[115] The use of self-monitoring strategies such as pedometers or exercise diaries also encourages regular activity. A meta-analysis of data from 26 studies (including eight randomized trials) in which 85% of the participants were women found that use of pedometers led to a significant 27% increase in physical activity as well as significant reductions in BMI and blood pressure.[116] Additional studies are needed to elucidate the features of individual- and community-based interventions and policies that successfully promote healthful levels of physical activity.[117]

In a sedentary society such as the United States, a widespread effort to help patients achieve even modest increases in regular physical activity should lead to measurable improvements in health. As observed by the eminent British epidemiologist Geoffrey Rose,[118] the reduction in disease burden in a given population is greater when a large segment of the population makes small improvements in health behaviors than when a small segment of the population makes large improvements.

INTRODUCTION

Interest in body composition can be traced back to the Greeks who believed that the human body was composed primarily of the cosmic elements: earth, water, fire, and air. More formal contemporary body composition investigation was launched in the 1850s as the chemical composition of body tissues began to be scrutinized. Throughout the twentieth century, scientists soon discovered novel methods for the measurement of body composition. The spectrum of discoveries included tetrapolar bioelectrical impedance analysis by J. Nyboer, A. Keys' densitometric technique, N. Lifson's use of the $D_2{}^{18}O$ dilution method for the measure of total body water and carbon dioxide production, and S. Heymsfield's application of dual-energy x-ray absorptiometry (DXA) in the measurement of appendicular skeletal muscle.[1] Air-displacement plethysmography (BodPod) soon replaced the older and less practical underwater weighing as both a research tool as well as a commercial offering by health clubs and sports medicine centers. More recently, the use of multislice axial computed tomography (CT) and magnetic resonance imaging (MRI) heralded a new era of both clinical and research applications.

Three historical events occurred bringing the importance of body composition front and center to the lives of women. The first was the emergence of the diet and weight loss industry which traditionally use one metric, overall body weight loss, as the hallmark of success. To achieve their numeric goal, women have often used any means possible, from cycles of self-induced starvation, to dieting and binging, often with little or no exercise component. In doing so, the maintenance and integrity of lean body mass (LBM) was typically neglected and sacrificed.

Second, the latter part of the twentieth century witnessed the growth of the fitness sector. Health clubs and gyms began to offer aerobic and strength training programs customized to women's needs. The emphasis shifted from a goal of weight loss to one of increased fitness, improved physical activity performance, and optimized body composition. The emergence of an athletic physique as a goal to strive for was supported by women's increasing participation in recreational and competitive sporting events. This new fitness focus has especially been integrated into the lives of the approximately 40 million women over the age of 50 years for whom beauty is less motivating than the need for strength and endurance to achieve and sustain physical independence.

The third historic milestone is the publication of data now linking suboptimal body composition to increased morbidity and mortality and decreased quality of life. In a 15-year study of 19,518 Finnish men and women aged 20–92 years, researchers found that obese, unfit participants had a significantly increased number of unhealthy life-years due to premature work disability, hospitalization for coronary heart disease, and need for long-term medication.[2] Comprehensive analyses of the relationship between fat distribution and health provide correlations between waist circumference (WC) and cardiovascular risk and mortality.[3]

This chapter begins with a description of the evolution of body composition through a woman's lifespan including the effect of genetics, age, ethnicity, and hormonal milestones. Next, a brief summary of the different modalities available for the measurement of body composition is presented as well as methodological challenges. This is followed by an epidemiologic review of the relationship between body fat and disease risk, including diabetes, heart disease, and

cancer. Finally, the impact of exercise as a lifestyle habit on body composition is examined with suggestions for ways to advise and guide women as they strive to achieve optimal body composition and well-being.

GENETICS

Clearly a host of factors influence body composition, including age, gender, genetics, and environment. To date, no major gene effect has been demonstrated for muscle or fat-free mass (FFM).[4] However, the investigation of the heritability of body fat content proved to be more forthcoming. The National Heart, Lung and Blood Institute Twin Study[5] suggested that genetic factors could explain between 57% and 86% of variability in BMI over a 10-year period. Other researchers began to document trends in heritability. In two clinical experiments, Bouchard et al. overfed pairs of monozygotic twins (MZT) by 1000 kcal/day for 22 days and then 100 days, noting that the amount of weight gained or fat stored was significantly influenced by the genotype of the subject.[6] In another set of MZT experiments, Poehlman et al. utilized an exercise-induced 1000 kcal energy deficit using the same time periods and found a significant intra-pair correlation with FFM changes in the short-term trial, while long-term weight loss resulted in significant resemblance for both body weight reduction as well as fat mass.[7] The results of these experiments suggest some genetic influence in the presence of alterations in energy balance.

Studies of familial inheritance patterns of fat distribution suggest the presence of genetic components. Analysis of data from the Canada Fitness Survey notes that genetics accounts for a 40% of the variance noted in fat topography.[8] The Heritage Family Study demonstrated significant familial aggregation for truncal and extremity fat, skinfold, and WC.[9] Interestingly, the significance of this correlation did not hold when these families were subjected to 20-week exercise training, where the variability in body fat changes increased.

Over the past decade, much attention has been focused on the role of excess intra-abdominal visceral adipose tissue (VAT) as it relates to increased disease risk. Men are more prone to upper body or android obesity throughout their lifespan. Typically, women deposit excess fat in the lower body hip, thigh, and buttock region, resulting in a gynoid pattern of overweight and obesity. However, at the time of peri- and postmenopause, women begin shape shifting, preferentially depositing excess fat in the VAT compartment and assuming a more android body habitus. Both men and women experience some increase in VAT with age regardless whether they are lean or obese.[10] Using CT to evaluate abdominal fat, the Quebec Family Study and the Heritage Family Study noted consistent heritabilities of 42%–70%.[11,12] It is implied from these studies that there are genetic characteristics influencing the propensity of individuals to store or draw from specific fat depots. This gene effect, when combined with a multifactorial constellation of environmental influences, helps explain an individual's typical phenotype and body fat distribution.

AGE, RACE, AND ETHNICITY

In describing the evolution of a woman's body composition over her lifetime, it is important to acknowledge her racial and ethnic background, as both significantly impact on any variability observed. Racial characteristics refer to the presence of a biologically distinct group with common genetic inheritance. Ethnicity relates to factors that involve culture, ancestry, language, beliefs, habits, and lifestyle behaviors. Because there is often considerable genetic and cultural overlap, the term racial–ethnic will be used to describe differences seen between demographic groupings.

From infancy to the age of 3 years, there are negligible differences in FFM between males and females.[13–15] From the age of 3 years until adolescence, males carry less water in their FFM, as well as more protein and bone mineral. This maintains until adolescence and young adulthood at which time males significantly increase muscle mass and bone mineral content. The average FFM of young adult females is approximately 70% of the mean value for adult males. Racial–ethnic comparisons from childhood through age 19 years indicate that differences in FFM between American white, black, and Mexican American females are small.[16]

Goulding measured regional fat distribution using DXA in a population of predominantly American white males and females from ages 5 through 29 years.[17] Sexual dimorphism in fat patterning was noted in prepubertal children, with girls exhibiting less waist fat and higher hip circumferences than boys. These differences were magnified as the children transition through adolescence and early adulthood, leading to an increase in waist fat especially in males.[18]

Sex differences in FM are negligible until the age of 6 years at which time females accrue more FM, reaching a plateau about the age of 13–15 years, just as males begin their dramatic increase in FFM and bone mineral. By the age of 19 years, females have about 1.5 times the FM of males.[19] On the other hand, from infancy through early childhood, females in general carry a higher BF percent than males. Although males do increase FM somewhat throughout childhood, FM then declines with adolescence, reaching its lowest point by age 17 years, and then gradually increases throughout adulthood.

Using DXA technology, Ellis found that throughout childhood and adolescence, American black females tended to have greater muscle mass as well as bone mineral content. Mexican American females trended toward higher FM and BF percentage. In comparison, American white females had slightly larger muscle mass and similar bone mineral content as Mexican Americans, but less FM and BF percentage.[20] Similar findings were noted by Chumlea et al. from their analysis of bioimpedance data.[21]

VAT and subcutaneous adipose tissue (SAT) regions were quantified with CT by Goran et al. who found negligible sex differences in VAT and SAT from infancy through adolescence, although SAT showed more variation than VAT.[22] The data that do exist suggest that VAT begins to accumulate later in adolescence and continues to increase throughout

adulthood, more so in males. SAT increases throughout adulthood until the age of 60 years when it declines in both sexes. There are no discernable racial–ethnic differences between American blacks and whites in VAT and SAT growth patterns.[23] Throughout the lifespan, adult males have more VAT than females. However, postmenopausal females tend to gain more VAT.[10] An analysis of VAT and SAT using multislice MRI comparing Japanese and American whites revealed that Asian American females have slightly less total adipose tissue and SAT, but more VAT than American white females.[24] Overall, general patterns of sex differences in body composition changes tended to be the same across racial–ethnic groups, with variances in the magnitude of such differences.

FEMALE SEX HORMONES

The relationship between hormones and body composition is powerful and complex. As observed throughout childhood, growth hormone (GH) stimulates the transformation of preadipocytes into fully differentiated adipocytes.[25,26] Once a girl reaches puberty, GH secretion is further stimulated by female sex hormones resulting in increased overall growth, enhanced FFM, and relative reduction in FM. The presence of higher levels of VAT obesity is associated with lower GH levels.[27] Interestingly, GH levels are restored after weight reduction, suggesting that the reduction in GH is secondary and not the cause of the obesity.[28] This phenomenon may also help explain why, as a woman passes through middle age and beyond, and her FM increases (especially VAT) and FFM decreases, her GH is also low.[28] Further, increased levels of cortisol caused by age-related dysregulation of the hypothalamic–pituitary–adrenal (HPA) axis, combined with the lower levels of GH and thus decreased lipolysis, contribute to the increase in VAT as well.

Female sex hormones influence body composition throughout a woman's lifetime. In premenopausal women, gluteal–femoral adipocyte enlargement is associated with an increase in the fat storage enzyme, lipoprotein lipase (LPL), as well as a low sensitivity to lipolysis.[29] In late pregnancy and during lactation, this pattern is reversed allowing release of lipids from this fat depot as energy to fuel the mother's increased caloric requirements during breastfeeding.

Women produce much less testosterone than men, and the effects of this androgen may be quite different than that noted in men. In males, testosterone deficiency is associated with an increase in VAT while administration of testosterone markedly decreases VAT mass. Male VAT is characterized by a higher density of androgen receptors (AR) than that found in SAT.[30] In women, elevated testosterone levels are associated with the polycystic ovarian syndrome which is characterized by an increase in VAT, associated with hypertension, type 2 diabetes, and hyperlipidemia. Estrogen, on the other hand, appears to function like male testosterone. Until menopause, estrogen appears to down regulate the AR density in adipose tissue apparently protecting against adipose deposition in truncal SAT as well as VAT.[31]

The BioCycle Study investigated the influence of adiposity on sex hormone patterns across the menstrual cycle in premenopausal normal-weight and obese women with regular menstrual cycles.[32]Adiposity was measured by DXA. Compared with normal weight women, obese women were noted to have lower levels of progesterone, luteinizing hormone (LH), follicle-stimulating hormone (FSH), and higher free E2 across the cycle. Women with central adiposity (increased amounts of VAT) averaged lower levels of total E2, FSH, with FSH and LH peaks occurring later in the menstrual cycle.

TABLE 26.1
Methodological Considerations in the Study of Hormonal Replacement Therapy and Body Composition

- Age at initiation of HRT
- Initial anthropometrics (weight, WC, BMI, FM, %BF, FFM, VAT, SAT)
- Type of HRT: single or combined (estrogen, progesterone, testosterone)
- Dosage of HRT
- Changes in type and/or dose
- Duration of HRT
- Compliance with HRT
- Preexisting medical conditions (metabolic syndrome)
- Presence of acute or chronic stress
- Medications (hypoglycemics, antidepressants)
- Weight management history (weight cycling, bariatric surgery)
- Quality of dietary intake and any changes during HRT
- Level of physical activity and any changes during HRT

WC, Waist circumference; BMI, body mass index; FM, fat mass; BF, body fat; FFM, fat-free mass; VAT, visceral adipose tissue; SAT, subcutaneous adipose tissue.

There are a variety of methodological considerations that significantly impact upon the study and interpretation of data involving the relationship between hormonal replacement therapy (HRT) and body composition. Table 26.1 provides a summary of key factors that must be addressed as investigations proceed. This list is further enhanced by emerging research shedding light upon new mechanisms of action of female sex hormones' effect on body weight, composition, and fat distribution. It is for these reasons that the current literature is inconclusive regarding the effect of HRT on a woman's body composition. This is evidenced by the following studies.

In early clinical experiments, postmenopausal women were administered estrogen replacement, and there appeared to be a shift from abdominal to premenopausal adipose gluteofemoral adipose deposition.[33] Estrogen replacement therapy decreased VAT accumulation somewhat.[34] However, when Blackman et al. conducted a randomized placebo-controlled study of estrogen replacement therapy with and without GH, and with GH alone, he found no effect of HRT alone on either FFM or FM.[35] In postmenopausal women, the reduction in estrogen levels and relative increase in androgens favors fat partitioning from the periphery to VAT. Gower conducted a longitudinal study of body fat distribution among postmenopausal women either on or off HRT.[36] CT and DXA were utilized to analyze VAT, SAT, and total adiposity. Sex hormones were assessed. Over 2 years, both cohorts experienced

a 10% increase in VAT. The HRT users were found to have an inverse relationship between estradiol levels and VAT.

In another experiment, Sites found that conjugated estrogens plus medroxyprogesterone acetate had no effect on body composition or body fat distribution but reduced insulin sensitivity. The decreased insulin sensitivity reversed after discontinuation of the HRT.[37] A *Cochrane Database of Systematic Reviews* analyzed 27 randomized, placebo, or no-treatment controlled trials describing the effect of HRT on body weight or fat distribution and found no evidence of an effect of unopposed estrogen or combined estrogen with progesterone on the menopause-related increase in body weight or BMI. There was insufficient evidence to enable examination of the effect of HRT on FM or skinfold thickness.[38] Onur evaluated the effects of a spectrum of HRT options including oral and transdermal forms of administration on postmenopausal women and found that all HRT types reduced WC most notably in women with a WC >35 in. Body weight and BMI did not change significantly suggesting a shift in fat distribution.[39]

More recently, Clegg and colleagues discovered that estrogens regulate body weight, energy expenditure, and fat distribution through estrogen receptor α (ERα) located on two distinct hypothalamic neurons: steroidogenic factor 1 and proopiomelanocortin.[40] These findings may lead to new targeted estrogen replacement therapies in which estrogen is delivered to the brain, obviating disease risks associated with whole-body estrogen delivery, including breast cancer and stroke.

GLUCOCORTICOIDS

Glucocorticoid receptors (GR) are found in human fat tissue with a higher density noted in VAT as compared to SAT.[41] When hypercortisolemia exists, there is a reduction in GR density in the various adipose tissue compartments that maintains this same rank order.[42] The hallmark of Cushing's syndrome is the presence of excess cortisol secretion and the associated insulin resistance which leads to a marked decrease in FFM and increase in VAT. The combination of cortisol and insulin is critical to increasing LPL activity and inhibiting lipolysis as well as GH secretion.[43] The interplay between these hormones leads to an increase in VAT as well as the presence of the metabolic syndrome, including type 2 diabetes, hyperlipidemia, and hypertension.

The relationship between chronic or episodic stress-induced elevations of cortisol and central obesity has been noted by numerous studies. In a study of prepubertal Hispanic girls, the presence of a high cortisol awakening response (CAR) as measured by salivary cortisol, a marker for psychological stress, was highly associated with the presence of both increased VAT and SAT, determined by multislice MRI.[44] In studying premenopausal women, Epel and colleagues found that those noting the highest levels of stress demonstrated overeating of dense calories, and accumulation of VAT leading to central obesity and higher BMI.[45]

This effect apparently increases in magnitude with the aging process, in which there is a decline in the resilience of the HPA resulting in longer exposure to higher levels of cortisol. This, combined with decreasing GH as well as estrogen, leads to a further tendency to increase VAT and thus central obesity.

ADIPOKINE INFLUENCES

Leptin is both a cytokine as well as a pleiotropic hormone with multiple effects including endocrine regulation, as well as reproduction and immune function. Adipocytes secrete the hormone leptin, which, through receptors located in the arcuate nucleus, regulate FM through alterations in energy expenditure as well as appetite. Decreases in FM result in lower leptin levels which then stimulate increased appetite and decreased energy expenditure restoring FM to normal levels.[46] Studies have shown that fasting and the use of very low calorie dieting reduces leptin levels. This makes adherence to such regimens difficult if not impossible. Although leptin administration in normal obese women does not produce weight reduction, it may instead have utility in restoring leptin to normal levels to support weight maintenance.

Beginning at puberty, women have higher levels of plasma leptin than men, while premenopausal women have higher levels than postmenopausal.[47] The etiology may be due in part to some measure of leptin resistance as well as the influence of female sex hormones. It has been postulated that obesity may occur in part to a leptin-resistant state. Leptin insufficiency is a rare syndrome leading to serious obesity beginning in childhood. It does respond to exogenous leptin administration reducing but not completely correcting obesity. As a woman ages, her leptin levels decline more rapidly than men accounting in part for a woman's increase in FM postmenopausally.

Levels of another adipokine, adiponectin, are inversely associated with adipose tissue mass and have a negative correlation with FM throughout the lifespan.[48–50] As well, adiponectin levels in women were found be higher than men, and, like men, to be inversely correlated with leptin levels.[51] Adiponectin levels increase with age in both men and women, when compared to younger people with similar anthropometrics. Since estrogen in women and testosterone in men lower adiponectin, it is presumed that the age-related phenomenon may be affected by sex hormone status. There may also be an ethnic influence. A study of Hispanic and African American men and women found that the inverse association of VAT with adiponectin was strongest in the latter, suggesting a possible racial–ethnic effect as it relates to central obesity.[52] Adiponectin exerts its metabolic effects on muscle tissue by increasing the combustion of free fatty acids while decreasing total triglyceride content.[53] In contrast to leptin, adiponectin levels rise after weight loss which is also associated with improvements in serum lipids and insulin sensitivity.[54]

BODY COMPOSITION AND DISEASE

The relationship between body composition and disease in women is confounded by significant methodological issues, including the use of indirect measures of body composition as well as biological, environmental, lifestyle habits, preexisting medical conditions, hormonal status, use or disuse of

HRT, and changes in an individual's anthropometrics over time. For purposes of this chapter, the discussion of disease risk as it relates to body composition will be limited to a group of disease states relevant to women's health.

In analysis of the relationship between body fat distribution and breast cancer incidence in premenopausal women participating in the Nurses' Health Study II, researchers found no correlation between body fat and the overall incidence of breast cancer in this cohort. However, WC, hip circumference, and waist-to-hip ratio were associated with an increased risk of ER-negative breast cancer.[55] For postmenopausal women, obesity appears to increase the risk of breast cancer.[56] It has been estimated that for every 10 kg increase in overall weight in postmenopausal women, there is a 6%–7% increase in the risk for breast cancer.[57] Further, it appears that the increased risk for breast cancer is more likely due to increases in weight over time.[58] The increased risk of breast cancer in postmenopausal women, especially noted in those with central obesity, may be related to the presence of insulin resistance, hyperinsulinemia, as well as high levels of estrogens and androgens.[59]

Ovarian cancer is the fourth most frequent cause of cancer death in women and the most lethal of the gynecological tumors in women from North America. The influence of body composition on risk of ovarian cancer has been inconsistent and inconclusive. Holman and colleagues examined the relationship between the risk of ovarian cancer, BMI, height, and weight in a cohort of Chinese women and found a significant correlation between high BMI and body weight 5 years prior to diagnosis but not at time of diagnosis.[60] Yet Møller et al. found no increased risk of ovarian cancer in a cohort of obese Danish women.[61] Higher BMI in young women may be associated with an increased risk of premenopausal ovarian cancer.[62]

Obesity increases the risk of colon cancer. Studies have noted that increased obesity-related hazard ratios for colon cancer were similar for men and women and also proved to be the same in multiracial–ethnic studies as well.[63,64] Weijenberg and colleagues examined the relationship between body size and the incidence of colorectal cancer among 120,852 men and women aged 55–69 years in the Netherlands Cohort Study. They found that in women, a large waist size coupled with a low physical activity level significantly increased the risk of distal and proximal tumors.[65] It is postulated that the higher levels of leptin associated with obesity may contribute to the growth of colon epithelial cells, as leptin receptors are typically found in colon cancer cell lines.[66]

Obesity is a well-established risk factor for type 2 diabetes, prompting some to refer to this pairing as "diabesity." The majority of women with type 2 diabetes are obese. Thirty-four percent of U.S. adults are obese and over 11% of men and women over the age of 20 years have type 2 diabetes.[67] Location of increased adiposity, primarily visceral fat, is more important than total adipose tissue mass. Increased VAT associated with an increased WC is associated with the metabolic syndrome, type 2 diabetes, and increased cardiovascular disease. Fox et al. assessed patterns of abdominal obesity in the Framingham cohort (N = 3348, 48% women, average age 52 years) using multidetector CT and found that 30% of both women and men had high SAT, while 44% of women had high VAT compared to 42% men. Further, the prevalence of the metabolic syndrome (elevated triglycerides, low HDL cholesterol, hypertension) was higher in women and men who had relatively more VAT than SAT.[68] An analysis of the relationship between body fat distribution and risk of type 2 diabetes in participants of the Nurses' Health Study demonstrated that BMI, WHR, and WC are powerful independent predictors of type 2 diabetes in U.S. women.[69]

Increased risk for coronary disease is associated with the metabolic syndrome which, as has been presented, is correlated with the presence of central obesity. Obesity was found to be a significant independent predictor of increased risk for coronary heart disease in a 20-year follow-up of over 88,393 women aged 34–59 years in the Nurses' Health Study.[70] In another prospective study of U.S. women aged 30–55 years, researchers found that even mild to moderate overweight significantly increased the risk for heart disease.[71] There is strong evidence that the presence of obesity and weight gain significantly increase the risk for coronary heart disease in women diagnosed with type 2 diabetes.[72]

MEASUREMENT OF BODY COMPOSITION

It is evident from current data that in order to optimize disease prevention and treatment, clinicians should monitor not only body weight but also body composition and body fat distribution. Although more emphasis has been placed on the relationship between adiposity and disease, it is also important to be aware that muscle is an integral component of body composition. Although not associated with metabolic disease per se, maintaining optimal endurance, strength, flexibility and balance is essential to avoid disabilities and frailty. The issue of muscular integrity will be addressed later in this chapter.

Table 26.2 outlines the basic body composition tools available to clinicians as well as fitness professionals and research scientists. What follows is a simple blueprint for

TABLE 26.2
Body Composition Measurement Clinical and Research Tools

Clinical use
Body weight scale

Computed tomography (CT)

understanding the benefits and limitations of using each measurement modality.

One of the first attempts to diagnose obesity was done by associating body weight with height. This event occurred with the creation of actuarial tables from the Metropolitan Life Insurance Company.[73] The standardized body weights were based upon data derived from young healthy white males who could afford life insurance. Extrapolations were made for female body weight. Moreover, the tables were based upon the subjective observation of an individual's frame. Despite the limitations, these tables were utilized as the accepted template for many years until it became clear that total body weight was but one part of a larger body composition equation.

A commonly used anthropometric measure to detect total body adiposity is the body mass index (BMI) defined as body weight in kilograms divided by height in meters squared. A host of epidemiological studies have demonstrated the strong association between BMI >30 kg/m^2 and increased morbidity and mortality.[74] There are limitations to the application of BMI, especially in individuals whose BMI is ≤30 kg/m^2 because total weight does not distinguish between FM and FFM. This works two ways. People who carry higher than average amounts of muscle mass and/or have increased bone density but normal to low FM may be erroneously diagnosed as overweight or obese. Conversely, individuals who are of normal weight and BMI but have lower than average muscle mass and higher than average FM, a condition referred to as sarcopenic overweight or obesity, would be counted as normal. BMI, therefore, has low sensitivity for the diagnosis of obesity. Sex and racial–ethnic differences exist, further complicating the precise detection and diagnosis of obesity.[75] Shah and Braverman have shown that these limitations lead to a significant under estimation of obesity prevalence, especially in older women.[76] Despite these limitations, it is recommended that clinicians add this measurement as one more element in their body composition equation as it does have a high specificity in detecting obesity.

Bioelectric impedance (BIA) technology is now accessible for clinicians as well as consumers. Impedance is measured through the use of a small, alternating, single-frequency current passing between points of contact measuring body tissues based upon their water and dissolved electrolyte content, noting that fat and bone are generally nonconductive. Total FFM is calculated based upon the estimate of total body water.[76] Using BIA, consumers as well as clinicians can monitor body weight as well as FM, body fat percentage, and FFM. The simplest consumer BIA scale measures body weight and body fat percentage. More expensive models include FFM as well as total body water and the regional distribution of FM and FFM. Clinicians can purchase these commercial BIA devices, which yield higher levels of accuracy and sensitivity. Level of hydration is important as dehydration results in an overestimate of body fat. BIA provides a measurement of total body fat and does not account for location of body fat.

Body fat norms for women based upon the *American College of Sports Medicine's Health-Related Physical Fitness Assessment Manual* are presented in Table 26.3.[77]

Combining BMI with a measurement of total body weight and body fat as well as appropriate girth measurements provides the clinician with a more complete picture of an individual's body composition. WC is a simple yet powerful way to assess central obesity, as it correlates well with intra-abdominal imaging and is highly associated with coronary vascular disease risk, morbidity, and mortality.[78,79] The only equipment needed is a cloth or flexible metal tape measure. The girth or abdominal circumference is the critical measurement as it is directly related to disease risk. Measure the narrowest part of the waist. This is often difficult to determine due to the presence of excess abdominal adiposity. If this occurs, take the measurement at the midpoint between the lowest rib and the top of the iliac crest. Other options include taking consistent measurements at the level of the umbilicus. In women, the goal is to achieve a girth of between 28.5 and 35 in. as the risk for disease and the metabolic syndrome increases with increasing girth size.[80]

Fitness professionals use BIA devices as well as skinfold measurements in assessing body composition. Skinfold testing should always be performed by a certified fitness professional using a calibrated skinfold caliper and ideally done by the same person each time. Body fat is estimated by skinfold thickness using between 3 and 12 anatomic sites. The mean of

two measurements is typically taken. Skinfold measurements do not measure body fat percentage, but offer an estimate of FM. Limitations to the use of this modality include morbid obesity, significant weight loss resulting in substantial excess subcutaneous skin, and the elderly who typically present with age-related muscular atrophy, loss of fat mass, and excess skinfolds.[81]

Recognized as the "gold standard" for the measurement of the two-compartment (FM and FFM) model, underwater or hydrostatic weighing requires a specialized stainless steel tank (or pool) usually located at a university research setting. When done correctly, body density is measured and body fat percentage can be calculated. Limitations include an underestimation of body fat in individuals with increased bone density and increased musculature, an overestimation of body fat in osteoporotic persons and the inability to measure young children, frail elderly and those with cardiovascular or pulmonary disease, including the obese.[82]

DXA has classically been used to study bone demineralization and to monitor osteoporosis. This technology can provide a comprehensive breakdown of FFM, fat tissue mass, and bone mineral content. The individual is scanned with photons generated by two low-dose x-rays at different energy levels. The body tissues' absorption of the photons at each level is measured. DXA scanning not only can provide a quantifiable assessment of the three body composition compartments but can also distinguish each by anatomical region. DXA cannot distinguish between VAT and SAT. Although DXA-derived abdominal fat assessments may underestimate CT-generated measurements, the DXA data still correlate well with that of CT.[83] Generally, DXA technology is accurate and reliable. It is still inaccessible for most consumers as insurance does not cover this service.

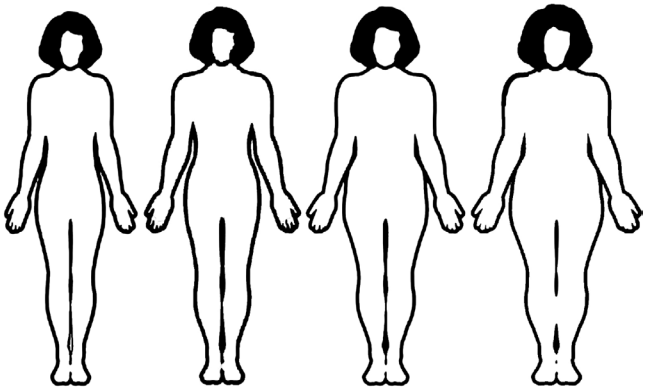
Although whole-body air-displacement plethysmography has been in use for many years, only recently has a practical, commercial device, the BodPod, been made available. This tool is expensive and is used primarily by research institutions, although the BodPod measurements have been made available to consumers on a fee-for-service basis. The BodPod measurement is as accurate as hydrostatic weighing, using air instead of water, and is more accessible to individuals for whom underwater weighing is not possible.[84]

MRI uses a powerful magnetic field, radio frequency pulses, and a computer to stimulate water and fat molecules in the body, producing detailed pictures of organs, soft tissues, bone, and virtually all other internal body structures. MRI does not use oxidizing radiation and is safer than CT scans and x-rays. CT scanning produces cross-sectional images of the body that can then be processed into 3D images. Specialized CT scans highlight fat depots and can provide a ratio of VAT to SAT. Both MRI and CT imaging provide the most reliable data on VAT depots.[85]

WOMEN'S BODY COMPOSITION AND EXERCISE

Optimizing body composition throughout a woman's lifespan yields multiple rewards. First, muscular strength enhances physical independence and the ability to perform activities of daily living as well as enjoy recreational pursuits. It also helps to prevent the frailty and sarcopenia associated with the aging process. Frailty in particular is linked to early mortality and increases exponentially with age throughout the adult lifespan. A 12 year study of 14,713 people, 54% of whom were women, found that at all ages, people who were relatively fit had a lower mortality and used fewer medical care services.[86] Sarcopenic changes are associated with age-related changes in body composition, inflammation, and alterations in hormonal balance.[87]

Second, maintaining an active lifestyle preserves bone health and can reduce the risk of osteoporosis and osteoporosis-related fractures. Children and adolescents who exercise show a higher bone accrual compared to sedentary peers.[88] In a *Cochrane Database of Systematic Reviews* of exercise interventions in the prevention of bone loss and fractures in postmenopausal women, an important effect of exercise on bone density was noted.[89]



Third, by incorporating more activity into daily life, successful long-term weight management is possible as well as disease prevention. Sedentary behavior is a critical factor in the accrual of excess body fat from childhood throughout adulthood.[90] This increased adiposity, especially VAT, is associated with a spectrum of chronic diseases including type 2 diabetes, dyslipidemia, coronary vascular disease, and hypertension as well as increased mortality.[91,92]

Historically, women approached weight reduction by manipulating dietary intake with little or no regard to altering energy expenditure as well. Over time, this strategy has failed. In 1996, the Surgeon General issued a report summarizing relationships between physical activity and health.[93] In it, regular physical activity was shown to be an effective method to reduce and control excess body fat, especially in combination with a healthy diet. Given that there is no optimal diet for everyone, the report also recommended the people seek out a registered dietitian who can provide individualized dietary guidance.

A host of studies have shown that the most effective strategy for promoting weight loss is a combination of diet modification as well as regular physical activity.[94] Changes in the quality and quantity of food intake are responsible for initial weight loss, but regular physical activity helps by both supporting weight maintenance as well as preventing weight regain.[95,96] This two-pronged approach has been applied to chronic diseases such as type 2 diabetes in which weight management through lifestyle modification (e.g., healthy nutrition and regular physical activity) is now recognized as the "gold standard" for effective and sustainable weight reduction.[97]

More recently, researchers are focusing on alterations in body composition as well as markers of health and fitness during weight loss trials. Kreider et al. at Texas A&M University compared the efficacy of a structured diet and exercise (SDE) program vs. a meal replacement–based (MPB) diet in which obese female participants were only given verbal encouragement to increase activity.[98] Both groups underwent a 10 week weight loss phase followed by a 24 week maintenance period.

TABLE 26.4
Body Composition Variance with Identical Body Weight and BMI

	40 Year Old 5'4" 140 lb Female BMI 24			
	Figure 1 Athlete	Figure 2 Recently Weight Reduced, Regular Exercise, Healthy Nutrition	Figure 3 Recently Weight Reduced, Sporadic Exercise, Poor Nutrition	Figure 4 Chronic, Yo-Yo Dieter, No Exercise
				
Dress size	6	8	10	12
Waist circumference	↓	↓	↑	↑
Body fat%	↓	↓	↑	↑
Fat mass	↓	↓	↑	↑
Lean body mass	↑	↑	↓	↓

Results showed that daily energy intake was relatively the same, but while the MPB group did minimal activity, the SDE women engaged in moderate to vigorous activities. As compared to the MPB group, the SDE women lost more body weight, reduced FM as documented by BIA, decreased WC, and saw improvement in maximal aerobic capacity and strength.

Table 26.4 provides a simple model to illustrate Kreider's findings and to emphasize the importance of monitoring body composition during weight loss. This model is by no means inclusive of all factors related to alterations in body composition, but presents a basic template with which to understand the need to incorporate body composition assessments in clinical practice.

Despite identical age, height, and weight, the four women depicted have different body compositions and thus dissimilar sizes and WC. Clearly the amount of LBM and FM noted in athletes is dependent upon their sport, but for purposes of this model, it is assumed that the Figure 1 athlete might be one with greater muscularity such as a triathlete, and thus represents the woman with the least body fat, smallest WC, and maximal muscle mass.

At the other end of the spectrum is Figure 4, a woman representing a more typical scenario of weight cycling through periods of chronic caloric restriction with no exercise followed by compensatory overeating and weight regain. This pattern of "yo-yo" dieting without exercise has been found to have variable effects on body composition but no significant effect on mortality.[99] Factors affecting outcome on body composition in women who weight cycle include the motivation for initiation of the cycle (intentional vs. unintentional weight reduction), type of dietary intervention used (level of caloric restriction), duration of program, quantity of weight lost and regained, and frequency of cycling. In this model, it is assumed that the sedentary chronic dieter is not building muscle mass and is, as she ages, losing muscle.[100] Adults who do not engage in regular strength training lose on average 4–6 lb of muscle tissue per decade, further thwarting efforts to shed excess weight.[101] In addition, as previously noted, increasing WC is associated with increased disease risk. Thus, her already widened girth increases her future disease risk. As a result, the inactive yo-yo dieter carries the highest load of fat and, compared to the other women, average to below normal LBM.

The ideal body composition goal is represented by Figure 2, the woman noted to have recently undergone a weight reduction program utilizing regular exercise and a healthy diet. This strategy is supported by data provided by the National Weight Control Registry, a cohort of over 6000 people, primarily women, who have successfully lost weight and maintained that weight for an average of 5.5 years.[102–104] And finally, Figure 3 represents a woman who has also recently reduced weight, but is inconsistent with a healthy diet and exercise, another common pattern. Her anthropometric and body composition indices fall between the ideal scenario and the inactive dieter.

Important to note is that all of the women have the same normal BMI, yet their sizes, girth, and body composition are quite dissimilar, once again repeating the limitations presented by monitoring only body weight and BMI. It is important that clinicians and the women they guide understand that dieting alone is a failed strategy. Further, a healthy diet and exercise are *both* critical to achieve effective and sustainable weight loss and maintenance and that monitoring body composition is key to optimizing fat loss and muscle optimization.

The exercise prescription to achieve and maintain a woman's optimal body composition involves three components:

1. *Regular aerobic or cardio exercise*: Consistent with the recommendations of the Physical Activity Guidelines for Americans and the ACSM, women should strive to achieve 5 days or more per week of 30–60 min of moderate-intensity physical activity, or 3 days or more per week of 20–30 min of vigorous activity, or ideally a combination of both.[91,105] Studies now support the inclusion of high-intensity interval training for optimal weight reduction and maintenance in women.[106,107] Of note, participants of the National Weight Control Registry engage in high levels of physical activity, with more than one half of the members expending 2000 kcal/week (200 min/week of moderate-intensity exercise, the most common of which is walking). Exercise can be broken up throughout the day and ideally these sessions include higher levels of effort similar to short-burst training.[108]
2. *Strength training*: The age-related reduction in muscle mass previously noted is a major reason for the 2%–3% per decade reduction in resting metabolic rate observed in adults.[109,110] Current ACSM Strength Training Guidelines call for 2 or 3 nonconsecutive training days per week, 2–4 sets of each exercise with 8–10 repetitions, or 1 set with 12–15 repetitions, with 8–10 exercises for the major muscles.[91] The benefits of strength training include increased FFM, decreased FM, increased resting metabolism, improved cardiovascular fitness and metabolic profile, increased glucose uptake, increased bone mineral density, and increased muscular strength and functional performance.[111] Ideally, a woman is guided by a certified fitness professional when she begins her strength training.
3. *Activities of daily living*: Becoming active throughout the day is an integral component of healthy lifestyle. This includes time spent at work as well as in home and leisure.[112] Aggressive efforts are needed to enlighten both clinicians and consumers about the hazards of sedentary lifestyle habits.[113] Increased activities of daily living in combination with structured aerobic and strength training sessions is the ideal prescription to maintain optimal body composition.

CONCLUSION

The case has been made that one critical component of health and well-being is the need to optimize body composition throughout a woman's life. Increasing physical activity, in concert with a healthy dietary intake, is crucial to achieving this goal. It is imperative that clinicians actively engage in a meaningful dialogue with women and be prepared to offer effective suggestions as well as connections with the appropriate certified fitness experts, nutrition professionals, and community resources.

In the clinical setting, practitioners have not traditionally prescribed exercise nor have they placed significant emphasis on the need to change lifestyle habits to prevent and treat disease. Happily, a new trend is emerging. According to 2010 data from the CDC's National Health Interview Survey, one in three adults who had consulted a physician within 12 months were advised to engage in physical activity as part of their health management strategy.[114] This represents a 10% increase in physician-derived exercise promotion between 2000 and 2010. This advice doubled for consumers aged 85 years and above. Physicians were most likely to discuss physical activity with those who were overweight and obese. As well, the presence of a medical condition such as hypertension, diabetes, or heart disease prompted more physicians to suggest incorporating physical activity into daily life habits.

New resources are now available to assist clinicians in their efforts to convey the importance of physical activity in daily life. In 2007, ACSM launched what has transformed into a global multiorganizational supported campaign called Exercise is Medicine. Their vision statement notes:

> To make physical activity and exercise a standard part of a global disease prevention and treatment medical paradigm. For physical activity to be considered by all health care providers as a vital sign in every patient visit, and that patients are effectively counseled and referred as to their physical activity and health needs, thus leading to overall improvement in the public's health and long-term reduction in health care cost.[115]

The website www.exerciseismedicine.org provides clinicians and consumers alike with practical tools to help understand the invaluable role of physical activity in disease prevention, treatment, and the enhancement of quality of life.

Women seeking guidance as they strive to build a strong body, maintain a healthy weight, and mentally embrace the joy and challenge of their life journey look to form a powerful and productive partnership with health and wellness professionals. Lifestyle medicine is predicated on the belief that lifestyle habits and choices are central to disease prevention, treatment, and quality of life. Optimizing body composition provides an excellent opportunity for the practitioner–consumer partnership to transform this belief into a life-saving reality.

INTRODUCTION

Health care providers know that a healthy lifestyle is essential to optimal health, but they do not know how to enable patients to adopt new healthy habits and abandon old harmful ones. Medicine was beautifully designed to manage acute medical emergencies and conditions, but it is not as well suited to helping patients manage a lifelong journey to sustain health-promoting behaviors. In many cases, patients need to master new life skills—how to develop a personal formula for health and vitality and how to become confident in their ability to implement, sustain, and adjust that formula over a lifetime. Most patients do not believe that they are capable of mastering these life skills.[1] Many patients have never even considered these life skills as important, and some patients probably have never even contemplated them at all. In fact, the patients facing bariatric surgery face the greatest doubts in this arena.[2]

Professional health and wellness coaches are emerging as an expert competency designed to help people become personally responsible, self-motivated, confident, and fully engaged in leading a healthy lifestyle.

EPIDEMIOLOGY

It's Getting Harder to Develop and Sustain Healthful Behaviors

Over the past 10 years, American adults have been consistent with their lifestyle behaviors, and that does not bode well for their health status. According to the CDC's Behavior Risk Factor Surveillance System, the numbers are holding steady for the statistics from 2001 to 2009 surveys of Americans consuming five fruits and vegetables a day and the number of Americans who engage in moderate-intensity exercise for 30 min or engage in vigorous-intensity exercise for 20 min a day or 5 or more days in the week.[3] Less than one quarter of American adults get the phytonutrients and healthy ingredients of five or more fruits and vegetables per day, and only half of Americans engage in the recommended level of physical activity known to produce optimal health benefits. Thus, it is not surprising that well below half of Americans fall in the normal weight category by body mass index (BMI), only 35% in 2010 decreasing from 42% in 2000.

Interestingly, the overweight category was ~36% in 2000 and 2010, but the obese category gained in girth with 20.1% of Americans obese in 2000 and 27% obese in 2010. In terms of diabetes, in 2010 the survey shows that 8.7% of American adults had been told by a physician that they had diabetes compared to 6% of Americans in 2000. It looks as if things are getting worse, not better.

What are we doing to get us into this predicament? According to a report by the United States Department of Agriculture, Center for Nutrition Policy and Promotion, about two-thirds of all adults reported that on average they had watched 2 h of TV or videos per day or more in the past 30 days. Not only that but about a quarter of Americans supplement this sedentary activity with two or more hours of computer time outside of work. Close to three quarters of Americans reported that, over the past 30 days, they had not walked or bicycled as a form of commuting to work or school or running errands.[4]

What accounts for the current trend of lifestyles full of sedentary behavior as well as fat-filled, sugary snacks and over scheduling of everyone from age 1 to 70 years? With the spread of fast food and supersized portions, Americans received a double blow of reduced quality of food and increased quantity of food. Other factors stacked up against a healthy lifestyle include the following:

1. The trend away from cooking at home
2. The wide availability of processed white carbohydrates which hijack our brain's reward centers
3. The invasion of technology into personal lives—stealing away opportunities to unplug, recharge, and rest
4. The common long commute, mixed with long hours of work, serious responsibilities of raising families, and the intense pressure to advance career for social status and/or financial reward
5. The confusion that patients feel as a result of being bombarded by the latest fad diet, diet supplement, exercise regimen, or the newest exercise equipment for strong abdominal muscles

In addition to all these factors, a recent survey from the nonprofit International Food Information Council (IFIC) found that concerns about weight and weight loss are at an all-time low. With the U.S. economy in trouble, a high unemployment rate, and global unrest, people are worried about money and security. Oddly, at a time when there is an increased emphasis on health and wellness, more and more concrete evidence in favor of fruits and vegetables as well as physical activity, plus more and more obesity and diabetes, Americans are not following the guidelines of a healthy lifestyle. David Katz, MD MPH, founding Director of the Yale University Prevention Research Center in New Haven, CT, surmised, "I think there is a certain element of burnout." He also emphasized a critical point, "We have not yet done a nearly good enough job empowering people to make them feel like they really can get to the prize—the prize being sustainable weight loss, their weight controlled without being hungry and miserable for the rest of your life."[5]

Now is the time to heed the words of wisdom from Ralph Waldo Emerson, "The first wealth is health," and put stock into our health by addressing the things we can control like how physically active we are, what we put into our mouths, and what we schedule or not schedule into our daily lives.

GENETICS

Healthful Behaviors Can Change Our Genes

What is responsible for our health and our lifestyle choices? Nature or nurture? Or both? More and more evidence is mounting in support of a combination of both nature and

nurture as the answer. As we have come to accept that certain people carry a specific gene that puts them at risk for breast cancer, ovarian cancer, or colon cancer, we have also realized that the environment can play a key role in whether these genes are activated. For example, if people smoke, they are putting themselves at risk for lung cancer as cigarette smoke is a known carcinogen. Similarly, drinking alcohol to excess will put someone at greater risk for liver cancer. On the other hand, if people with a family history of heart disease engage in healthful behaviors such as a diet of healthful fats and no *trans*-fats, low in sugar, low in salt, yet high in fruits and vegetables, nuts, and lean protein; exercise regularly at least for a half an hour 5 days of the week; don't smoke; and drink only one glass of red wine a day, then they mitigate their increased risk of a heart attack by their behaviors.

Epigenetics is the study of the impact of environmental factors on our genes' behavior. How our lifestyles affect the expression of our genes has long been of interest to scientists and researchers, but it was not until about 10 years ago that this new field emerged and has grown exponentially along with the research—there are epigenetic studies on prostate cancer, lymphoma, autoimmunity, diabetes, atherosclerosis, fetal alcohol syndrome, rheumatic diseases, schizophrenia, nephritic syndrome, and Alzheimer's disease, to name a few.

Benjamin Tycko and John Ashkenas in the *Journal of Clinical Investigations* wrote an interesting overview of epigenetics in 2000.

> The adjective "epigenetic" has been used to describe many types of biological processes, but with the evolution of epigenetics into a sub-discipline of molecular biology, its meaning has become quite focused. Although the term is sometimes used more broadly, epigenetic effects are usually taken to encompass changes in the genetic material—the genomic DNA and chromatin—that alter gene expression in a manner that is heritable during somatic cell divisions (and sometimes even in germline transmission), but that is nonmutational and therefore fundamentally reversible.[6]

Looking at epigenetics at the microscopic and macroscopic level will help put it in focus. Microscopically, there are chemical "marks" on the DNA that are not part of the actual DNA coding sequence of A (adenosine), T (thiamine), G (guanine), C (cytosine). These marks are methylations on the tips of the DNA or acetylations/deacetylations of histones (proteins that the DNA winds around to make chromatin). Some of these marks suppress DNA expression and some of the marks enhance its expression. In other words, these marks are like switches that can turn the DNA on or off. Thus, they can help control the expression of our genes or the behavior of our genes, not our genes themselves. That is why it is epi (above) genetics.

Lifestyle choices can influence our genes. Studies of identical twin studies help demonstrate this point. In these studies, one identical twin has developed cancer or heart disease and the other has not. Two individuals can share the exact same DNA code, but they do not have the same DNA expression. An interesting study in mice helps demonstrate this further. Mice and humans have a gene called agouti. The sequence of the gene is the same in all mice. However, its genetic expression differs. For example, if the agouti gene is unmethylated, then the mouse is fat and yellow. If that gene is methylated, then the mouse is brown and thin. Amazingly, if researchers fed a yellow, fat female mouse a diet rich in methionine, then most of its pups were born brown and skinny, and they remained that way throughout their life span. Nutrients known to affect the human epigenome include methionine, folic acid, vitamin B12, and vitamin B6. Dietary sources of methionine include sesame seeds, Brazil nuts, fish, peppers, and spinach. Sources of folic acid include leafy vegetables, sunflower seeds, baker's yeast, and liver. Vitamin B12 is found in meat, liver, shellfish, and milk. Meats, whole grain products, vegetables, and nuts are good sources of vitamin B6.[7]

There is also evidence that exercise plays a role in epigenetics. In a study of rats, it was demonstrated that regular exercise affects the demethylation of DNA and the acetylation of histones. Also, exercise affects the transcription of an important protein in the regulation of brain-derived neurotrophic factor (BDNF) that is heavily involved in the learning process for rats.[8]

The study of epigenetics is fascinating and especially pertinent to lifestyle change efforts as it strengthens the case for a healthy diet and exercise to help people reach their optimal wellness. Randy Jirtle studies epigenetics at Duke University Medical Center and he has said, "The thing I love about epigenetics is that you have the potential to alter your destiny."[9]

Each Patient Is Unique

In addition to unique genetics and epigenetics, each person is unique with respect to dietary history and preferences, diet trials and tribulations, and exercising habits or lack of exercising. More and more information on dietary allergies emphasizes the unique differences in our systems. Dr. Mark Hyman's book, Ultrametabolism, encourages people to evaluate how their bodies function when fueled by certain foods and nutrients. He recommends an elimination diet, eliminating common allergens such as dairy, gluten, caffeine, and sugar. By eliminating all of the allergens, you can start with a clean slate and then add them back on one by one to see how you feel. Some people are gluten sensitive and others are not. Some are lactose intolerant and cannot eat dairy. This approach backs up the theory that there needs to be an individualized approach to nutrition counseling in order for it to be effective.

People also have their own exercise preferences. Some people love to jog and have been doing so since they were teenagers. Those same people are not necessarily swimmers. Other people love cycling or spinning. Disability or pain, such as knee pain from osteoarthritis, might limit the exercise options for some clients. Team sports like basketball or soccer might be the best recommendation for an exercise routine. Zumba (a form of exercise dance which started in Latin America) has taken off among women as a fun, musical

experience that doesn't feel like exercise. Preferences depend on the person, their past experience with sports, and their current interests.

When it comes to providing information, just as children have different learning styles, some adults are visual learners who can benefit from graphs and pictures while others are auditory learners who rely on lectures and conversations to consolidate information. Knowing your patient and his or her learning style helps to adapt your approach so that your efforts will be effective and efficient.

When working with patients on behavior change, as well as on the delivery of expert knowledge and guidelines, it is important to approach each patient as a unique individual, supporting his/her journey to find the formula which best fits his/her genetics, history, capacity, and way of life.

RISK FACTORS

What Makes Lifestyle Change Even More Difficult?

There are various mental health barriers to sustainable behavior change that people need to overcome in order to reap the benefits of good health. Certain conditions such as attention deficit disorder (ADD), depression, and addiction make it even harder to adopt healthy lifestyles. Other high hurdles include physical disability and chronic pain. Although these health conditions add complexity to adopting and following a healthy lifestyle, they can be overcome when addressed specifically and strategies are built in specifically for each condition. For many, the first priority in these cases is managing the condition to put stability and balance in place before tackling healthy lifestyles. For some, the enhanced energy and confidence gained from a new, healthy behavior can improve the motivation for tackling the medical condition.

Another risk factor for an unhealthy lifestyle is socioeconomic status. Patients with low income cannot afford to shop at farmer's markets, upscale grocery stores such as Whole Foods, most of which do not accept food stamps. On $40 budget a week for food, it is often difficult and overwhelming to plan for fresh produce at every meal. Along with low socioeconomic status, a low education level adds to the difficulty because if a person does not know the dangers of sugar and partially hydrogenated fats, then they are not likely to avoid them. In addition, fitness apparel, sneakers, gym equipment, and gym memberships are additional expenses. These are important barriers, but there are solutions on an individual and societal level. For individuals, frozen fruits and vegetables are often cheaper, readily available at all grocery stores, and a good alternative to fresh produce. At the societal level, educating people about the importance of donating healthful foods to the food pantries is a great place to start. There are nonprofit organizations that work to educate people in the low socioeconomic classes about healthful food choices and the importance of physical activity. You do not have to be a member of a gym, sporting fashionable athletic wear, to enjoy physical activity. Walking is an accessible and effective form of exercise and 15 min a day can have a significant impact on your health and longevity. In a large study of over 400,000 people in Taiwan, it was demonstrated that those subjects who exercised 15 min a day had a 14% reduced risk of all-cause mortality and a life expectancy 3 years longer than subjects who were not active.[10]

Also, the library is a wonderful resource for all. Computers are free. Books are free. DVDs are free. All of which can be useful to people whose finances are limited.

Weak family system support is another risk factor for unhealthy lifestyles. When family members are unhealthy, whether they are overweight, smokers, junk food junkies, or sedentary, it is often a challenge to spread your wings and take the path less traveled. Aligning with friends who share the same priorities for health can help. If there is no one immediately available, free online support group sites can fill this gap. Social support for change is a key ingredient. What else is important?

PSYCHOLOGY OF POSITIVE LIFESTYLE CHANGE

Now that we have recapped the large-scale health care crisis of unhealthy lifestyles and described the need for people to take action to improve their genes and the additional challenges faced by those who struggle most, the good news is that the scientific study of how humans change behavior, and the important ingredients which enable sustainable change, is evolving rapidly in the fields of psychology and neuroscience.

Social and behavioral psychologists pioneered the field over the past few decades, joined by positive psychologists in the late 1990s, focusing on (1) what enables the adoption of behaviors shown to improve physical and mental health, such as exercise, healthful nutrition, weight and stress management, and mindfulness practices; (2) what behaviors lead to positive mental health or flourishing; and (3) whether and how mental flourishing improves physical health.

Psychologists are now joined by neuroscientists who are exploring the biological processes of neuroplasticity, which some call self-directed neuroplasticity, the generation of new neural connections and integrated brain-wide networks which undergird the formation of new habits, and the cognitive and emotional mind-sets needed to sustain them.

Coaching is a human relationship designed to facilitate positive and sustainable change. Prior to more fully exploring how coaching competencies can be used by physicians and health care providers, including the evidence for coaching outcomes to date, this section presents and integrates a set of robust, evidence-based theories that make up the foundation of core coaching competencies. The presentation uses a conversational style to assist the reader to more readily put the concepts into practice in discussions with patients and addresses the development of five domains, which are the basis of 12 coaching competencies, summarized in Appendix A:

1. Mindful attention
2. Self-acceptance
3. Autonomous motivation
4. Self-efficacy
5. Process of change of mind-set and behavior

Mindful Attention

Change begins with a mindful focus on a need and/or desire for a positive change. Focused attention may be triggered and supported by a wide variety of inputs—for example, a physician's diagnosis, prodding by a spouse or friend, observing a respected role model, new information reported in the media, a state of low vitality or energy, an annual trigger (get fit for summer, back to school, or new year, new you), or a health crisis—perhaps personal or someone close.

While many triggers can be a catalyst to start, they do not necessarily lead to the full focus needed for lasting change. Given finite brain resources to attend to change and challenge, including stress and adverse events, expanding self-awareness of personal health competes with other life foci which can appear more urgent or pressing. Psychologist Jon Kabat Zinn and physician David Ludwig conclude in their paper on Mindfulness in Medicine in *JAMA* in 2008:

> The current age has been referred to as one of "continuous partial attention." E-mail, cell phones, and other technology invade nearly every moment of waking life. Economic pressures demand ever-increasing productivity, even as time to enjoy the fruits of labor declines. These factors adversely affect the health care system overall and diminish the patient-physician relationship. In this context, mindfulness may hold promise as a potential way to help prevent and treat disease, increase ability to cope with pain and chronic illness, reduce stress in patients and practitioners, foster compassion, improve quality of care and reduce medical errors. High-quality, mechanism-oriented studies and randomized controlled trials of mindfulness in medicine are needed.[11]

A calm coaching conversation can provide mindful, focused attention to personal health and enhance self-awareness by quieting a client's emotional frenzy for a short time, tuning out distractions, and enabling a curious and insight-generating inquiry into "what's really going on here?"[12]

In the *Handbook of Primary Care Psychology*, Carson and Langer describe the cognitive flexibility of mindfulness, vital in self-managing a process of changing behavior: (1) the ability to view both objects and situations from multiple perspectives and (2) the ability to shift perspectives depending upon context.[13]

Not only is it helpful to patients but physicians who completed an intensive mindfulness training experienced sustained improvements in well-being, burnout, and attitudes toward care of patients.[14]

Coaching competency: Facilitate a calm, mindful focus of attention on a patient's state of health and well-being which expands self-awareness of deficits and awakens the desire for possible benefits of positive change.

Self-Acceptance

One of the benefits of mindfulness is that it helps people get out of a rigid mind-set, expand their perspectives on themselves, and come to accept themselves as well as take control and responsibility for changing their future course.[13] For patients who realize that their past and present lifestyles are damaging their health, over-ruminating on negative self-judgments ("what a loser I am") is a potent source of negativity. Negative emotions have been shown to narrow the brain's focus and attention, decrease open-mindedness, and impair creativity, problem solving, as well as strategic thinking. Feeling badly about past behaviors restricts the brain's resources for problem solving and change even before first steps are taken.[15]

Empathy is also a potent tool in fostering self-acceptance. Physician empathy has been shown to improve patient outcomes.[16] A mindful, nonjudgmental, and empathetic coaching dynamic helps patients to appreciate how self-judgment is holding them back, to choose to let go of the weight of self-judgment, and to affirm the lessons of the past, so they are more positive about proceeding to make change. A coach's empathy and nonjudgment fosters a client's self-empathy and self-acceptance.

Coaching competency: Empathize with a patient's circumstances, show acceptance, and foster a nonjudgmental and affirmative perspective ("let's appreciate and learn from the past and move forward to build a better future").

Autonomous Motivation

Once the groundwork of a mindful focus and self-acceptance have been laid, we can turn our attention to helping patients find the motivation and drive to succeed in the process of change. The most respected theory of human motivation is self-determination theory (SDT), developed by psychologists Edward Deci and Richard Ryan at the University of Rochester over 40 years of study. Deci and Ryan have identified three primary human drives honed by our evolutionary biology: autonomy, competence, and human connection. They have explored various types of external and autonomous motivation, and identified the type of motivation which leads to sustainable change.[17] As they summarize in 2008 in *European Health Psychologist*, SDT argues that

> developing a sense of autonomy and competence are critical to the processes of internalization and integration (of motivation), through which a person comes to self-regulate and sustain behaviors conducive to health and well being …. When patients have their psychological needs for autonomy, competence, and relatedness supported in the process of their health care, they experience more volitional engagement in treatment and maintain outcomes better over time. This pattern of findings appears to hold for broad lifestyle changes such as smoking cessation or dietary regulation, as well as discrete behaviors such as the adherent use of medications.[18]

Autonomy is the first of the three core human drives; we are wired to want to march to our own drummers and dislike being told what to do. Not just toddlers and teenagers, even adults resist being told what to do, including their physician's recommendations. They resist and rebel even when resistance is not in their best interest. People (all ages) perform best when they are free to make an autonomous choice.

This is good news because people also assume personal responsibility for their health when they act autonomously.

To support autonomy, it is important to "get out of sails and get into fishing" by open questions, undistracted listening, and reflecting to clarify and demonstrate listening, with an open, mindful, and curious mind-set, rather than preaching and prescribing which shuts down autonomy and can elicit resistance. Imagine your patients and clients sitting in the driver's seat, holding the steering wheel. Resist the urge to grab the steering wheel. This is a simple metaphor for an autonomy-supporting relationship. We explore the contrast of the expert approach and coach approach further in the next section on physicians applying coaching skills.

Coaching competency: Encourage autonomy, putting patients in the driver's seat and yourself in the passenger seat, by undistracted listening, open-minded inquiry, refraining from mindless advice giving, and helping patients to make choices by brainstorming a few options to select from.

Deci and Ryan have identified two types of motivation—external motivation ("I exercise because my doctor told me to") and autonomous motivation ("I choose to exercise because I want to"). External motivation comes in two forms—an external source such as a boss, spouse, or authority figure or "internalized" external motivation when one has swallowed the external rules (e.g., eat less and exercise more) whole, without digestion and connection to a positive desire for what's good for oneself. This internalized external force turns into an inner critic who might say something along the lines of "I should exercise. I'm a failure because I don't exercise."

There are also two types of autonomous motivation—intrinsic motivation, related to present engagement ("I go to yoga classes because I have fun and enjoy the challenge; I do it for its own sake") and internal regulation, related to one's identify and future self ("I choose to exercise because I am convinced that it's good for me, helping me live the life I value now and in the future"). Future-focused internal regulation is the form of motivation that enables sustained behavior change.

Psychologist Barbara Fredrickson has shown that people are more likely to persist in developing new habits if they start noticing benefits that they value early, within a short period such as 2 weeks, which likely enhances internal motivation. Hence it's important to help clients identify new habits which may yield a benefit quickly, or motivation may drop off.[15]

Coaching competency: Help patients find health behaviors that are intrinsically motivating (enjoyed for their own sake) and/or find internal motivation (articulating and valuing future personal benefit) for a health behavior, for example., it will allow them to make a difference in the world or do more of things they treasure most, now and in the future. Help patients select behaviors which have the potential to enhance autonomous motivation quickly.

Self-Efficacy

> Whether you think you can, or think you can't, you are right.
>
> **Henry Ford**

Self-efficacy, one's belief in one's ability to be successful, is a codependent companion of motivation: both are essential for successful change. Ryan et al. assert that the desire for "competence" is the core human drive behind self-efficacy.[18] A robust source of motivation fades quickly if confidence in succeeding is inadequate. Fortunately, there are many roads to building self-efficacy, beyond cultivating autonomous motivation, which include the following.

Identify and Deploy Strengths and Talents, Especially Those Used in Other Life Domains Such as Work

Only one-third of adults can describe their strengths (Linley et al. 2010) and are more focused on their weaknesses and how to overcome them. In addition to an informal survey of friends, colleagues, and family members, there are a variety of validated strengths assessments, including www.viacharacter.org, www.strengthsfinder.com, and www.strengths2020.com, which identify top character strengths and talents. Applying top character strengths in novel ways in support of health goals can be an unexploited opportunity.[20]

Coaching competency: Help clients identify personal strengths and talents and brainstorm ways to deploy strengths in the pursuit of lifestyle change and better health.

Develop Positive Emotions That Enhance Resilience, Reframing Setbacks as Opportunities

Barbara Fredrickson has shown that a main mediator of resilience is the level of positive emotions summoned in a time of stress or adversity. The level of negative emotions is not a determining factor; people with high levels of negativity are resilient if they have high levels of positivity. Hence, higher levels of positive emotions predict higher levels of resilience.[21]

Marcial Losada and Barbara Fredrickson determined a positivity "tipping point" of 3:1 positive to negative emotions, above which people are on an upward spiral—resilient, adapting well to adversity, and having the capacity to change, and below which people are stuck and languish. Positive emotions have an immediate positive impact on brain function, increasing openness, creativity, and strategic thinking. In addition to psychological resilience, they also deliver other cumulative effects over time, improving memory, reducing pain, and improving relationships and health.[22]

Losada identified the 3:1 tipping point by developing a nonlinear mathematical model of team dynamics. Fredrickson validated the tipping point for individuals, which also correlated with Gottman's research on marriages (5:1 ratio needed for successful marriages). Fredrickson's research suggests that 80% of American adults are below the 3:1 tipping point, making lifestyle change a significant challenge, and positivity an important domain for personal development.

Domains for cultivating positive emotions are plentiful. Time orientation is one useful way to think about ways to improve positivity. Positive emotions related to the past that can be developed include forgiveness, appreciation and gratitude, and finding silver linings as well as lessons in negative

experiences. Present-oriented sources of positivity include mindfulness (improves focus, reduces negativity, and fosters positivity), savoring of small pleasures including caring relationships, and engaging one's strengths in meaningful activities. Future-oriented positive emotions emerge from cultivating an inspiring vision, as well as improving hope, and optimism.

Coaching competency: Cultivate positive emotions by starting sessions with positive topics—experiences, lessons, successes, strengths, which improves brain function for more challenging topics. Unpack and harvest positive topics at the close of sessions.

Adopt the Mind-Set of a Scientist, Experimenting with a Variety of Approaches

The field of hope psychology has shown that success increases with higher levels of hope, and has focused on what builds hope, which includes setting goals and identifying multiple pathways to reach them.[23] There are a multitude of ways to engage in exercise, eating healthful foods, developing mindfulness and positivity, and managing weight and stress. It's important to adopt a "scientist" mind-set and test or experiment with several options in order to find and settle on a good fit, and even better a personal formula of —three to four behaviors that work together synergistically to deliver desired results.

Coaching competency: Help clients brainstorm on various paths to reach goals so that they appreciate that if one path doesn't work, one or more other paths are possible, which increases hope and confidence.

Design Behavioral Goals to Be Engaging and Realistic

While goal-setting researchers have taught us that ambitious goals are more engaging and lead to higher performance than more modest goals,[24] a moderating factor is their impact on confidence. Too challenging goals can lead to stress and anxiety, damage confidence, and arrest interest in continuation. It's important to find the right balance of "stretch" which is engaging and doesn't jeopardize confidence. For example, at the beginning of a change process, people often commit to too ambitious goals (common for New Year's resolutions), setting them up for failure. Thus it is important to negotiate more realistic goals at the outset and reserve the ambition for a motivational vision statement that has an indefinite end point. There is great power in succeeding at small goals because it builds self-efficacy and keeps motivation high.

Rating confidence on a scale of 1–10 (10 is the maximum score) and defining how to increase confidence can also improve results. Designing one's environment to be supportive (e.g., removing processed foods from kitchen shelves or keeping running shoes under an office desk) and soliciting social support from family, friends, and colleagues (requesting encouragement, reminders, or help) are strategies to improve confidence.

Coaching competency: Help clients select goals and develop strategies, including environmental and social support, which enhance confidence.

Process of Changing Mind-Set and Behavior

Now that we have cultivated mindfulness, self-acceptance, and developed autonomous motivation and self-efficacy, we have the foundation needed for a successful change process. Lasting change depends upon both a lasting change of mind-set (I love being fit and don't want to go back to my old sedentary ways) as well as lasting behavior change (I consistently do four 30 min workouts weekly).[25]

While we do not have brain images of developing neuronal networks that support sustainable habits, one can imagine an extensive network supporting new habits which emerges when a mind-set of greater mindfulness, self-awareness, heartfelt motivation, positivity, confidence, and resilience develops over a period of weeks and months. Following are the important features, identified by psychologists, of a successful change process.

Develop and Implement Plan for Change—Vision and Goals

We addressed in the section on autonomous motivation the use of a vision statement as a means to summarize the basis for a client's internal motivation (I want to be fit and healthy in order to have the vitality I need to be my best at home and work).

Setting goals and implementing action lists are a process by which clients can move toward their motivational visions. If lifestyle change is the desired outcome, it is wise to help clients set specific behavioral goals—such as "I will be consistently walking for 30 min four times per week by 3 months from now" rather than vague goals of outcomes "I will improve fitness by walking regularly."

Confirmation of small details (what, when, where, how) and backup plans leads to more success. Creating SMART goals is one of the keys to success with behavior change. SMART goals are specific, measurable, action oriented, realistic, and time sensitive.[26]

Coaching competency: Help clients define motivational vision statements and specific behavioral goals to provide structure for pursuing lifestyle change.

Coaching Conversations That Elicit New Perspectives and Insights Lead to New Actions

Coaching sessions or brief discussions at their best generate or catalyze small shifts in mind-set as clients adopt new perspectives, question their assumptions, and find new meanings for their experiences. A surprise question or observation can open a client's mind and lead to a new insight that likely initiates new neuronal connections, the beginnings of the neuroplasticity needed to support lasting change. Nonjudgmental harvests of lessons from recent goal performance, particularly setbacks and challenges, are rich ground for new insights. There are no "failures" in this process, only opportunities to grow and learn.

Coaching competency: Alternate open questions and reflections to generate new insights and perspectives that support new behaviors. Acknowledge and unpack new insights and perspectives to help them stick.

Accountability

New habits are formed by much practice and repetition until they are well supported by new neuronal pathways and networks and become more automatic. It takes weeks and months of experimenting, practicing, developing skills, gaining knowledge and insights, bouncing back from setbacks, and recharging motivation as well as confidence, for lasting change. The limiting factor may be the pace at which the brain can lay down a robust, lasting network.

In the early stages of change, accountability between a client and physician and/or coach, as well as with other social supporters, is a key success factor. Goal-setting theorists, Latham and Locke, note that people perform better when they commit to others that they will succeed.[25] A commitment to a coach or physician provides valuable accountability in the early stages of change.[27]

We see examples of people seeking "extreme" accountability when they choose to go on reality TV shows and share their journeys with a large audience. There are many methods of scheduling and follow-up to choose from—reminders, written progress reports, coaching sessions, phone/e-mail check-ins, and behavioral "apps."

Coaching competency: Help clients select and build in methods for commitment and accountability, decide on level of goal ambition (bold or baby steps) and behavioral goal time frames which will work best (3 months, 1 year, beyond).

Referrals

During the change process, clients will need to learn, acquiring both knowledge and skills, to become confident and competent. A physician and coach can facilitate referrals "just-in-time," just at the moment needed to avoid distraction or overwhelm, to sound informational sources (e.g., Mayo Clinic website) and other professionals for particular skills, including how to exercise, how to cook and shop for food, how to develop mindfulness and positivity, and how to manage sleep, stress, and weight. If clients have mental health conditions such as depression or anxiety, referrals to therapists may be critical before or alongside a change process.[26]

Coaching competency: Help clients find resources to support gaining of knowledge and learning of skills just-in-time to enhance motivation, confidence, self-awareness, and new insights, and support their goal attainment.

PREVENTION AND TREATMENT—COACHING INTERVENTIONS

Physician Using Coaching Skills

Gap in Medical Education and Training

Our current medical education system falls short—counseling on healthful lifestyle behaviors such as physical activity, nutrition, and weight management is not routinely taught in medical school core curricula and clinical training, which focuses on the knowledge and tools for diagnosing and treating disease. In fact, the literature reveals that since 1975 physicians have been wondering, "Will physicians of the future be able to prescribe exercise?."[28] Thirty years later, medical school deans where polled about exercise prescription competence of medical students. The Deans reported that only 10% or their graduates were able to prescribe exercise.[29] Internal Medicine residents reported a lack of confidence in exercise prescription counseling, and only one-third of the residents were able to list three ways to integrate physical activity into the patient's daily life, to identify the personal exercise stages of change, and to calculate their own target heart rate.[30]

Helping patients uncover their motivation to change behavior is a key part of counseling patients and there is little time spent on this topic in medical schools. It has also been noted that personal trainers and group exercise instructors rely on motivation, but they receive little specific education in this area.[31]

Training medical students and health care professionals how to effectively counsel patients on lifestyle issues such as exercise and diet has never been more critical. In 2011, the U.S. Preventive Services Task Force (USPSTF) reviewed the medical literature in this area and reported:

> Thus, the current literature, while much improved over the past, may still be insufficient to unequivocally define for the clinician what does and does not work across all primary care behavioral counseling interventions. However, given the prevalence and health impact of unhealthy behaviors, clinicians may still use the time and resources readily available to them to reinforce the importance of healthy behaviors with their patients.

Walk the Walk

The first thing that physicians can do to help themselves and their patients is to "walk the walk." In a study by Abramson et al., it was demonstrated that physicians who perform aerobic exercise counsel patients on aerobic exercise and physicians who perform strength training counsel patients on strength training.[32] If providers are comfortable with the activity and familiar with it on a personal level, then they are more likely to discuss it with their patients. Physician Erika Frank and colleagues looked specifically at women physicians and their counseling and personal exercise habits. Her study demonstrated that 96% of women physicians reported engaging in exercise but that only 49% of them reached the levels of activity recommended by the American College of Sports Medicine (ACSM). In addition, this study showed that women physicians who met the ACSM guidelines were more likely to counsel on exercise, to counsel with confidence, and to be trained in counseling.[33] Given the obesity epidemic in our country, it is time for all health care providers to take the lead and model healthy lifestyles.

By "walking the walk," health care providers can then do something that takes minimal time (30 s) in the office with the patient, and the effects are motivating and inspiring. That something is called self-disclosure. Frank et al. conducted a study at Emory University and discovered that physicians who spent an additional half a minute disclosing information

about their own personal dietary and exercise practices during an office visit and also had an apple and a bike helmet on their desks were more motivating and more believable regarding exercise and diet than physicians who did not disclose their personal practices or have an apple and helmet on their desks.[34] To be motivating and believable, the health care provider does not have to be in "perfect shape." They just need to be working on sustaining a healthy lifestyle with regular exercise and a balanced diet. Striving for health is not something a physician does for his patients only but he must do it for himself also.

Evidence for Use of Coaching Skills by Physicians

There is encouraging evidence in the current literature that counseling on lifestyle behaviors works. Grandes et al. demonstrated that when family physicians provide advice and an exercise prescription to patients, those patients increased their minutes of moderate and vigorous activity per week at a 6-month follow-up significantly more than those patients in a control group who received standard care.[35]

Teasing out what approach works well in counseling was the subject of another study by Hillsdon et al.[36] In this study, two approaches of counseling patients on physical activity were compared to a control. Each approach took 30 min. One approach involved negotiating and collaborating with the patient on the subject of exercise and the other approach involved advising, warning, and educating the patient on exercise benefits, dangers of sedentary behavior, and physical activity guidelines. When comparing the results of their efforts by examining the minutes of walking accumulated per week, the patients who received the negotiation and collaboration counseling walked significantly more minutes than a no-intervention control at follow-up. Patients who received the advising and warning counseling had no significant difference in minutes accumulated walking per week at follow-up when compared to patients in the control.

Thus, if a physician is going to spend time counseling a patient on physical activity, the best use of this time would be to put on a collaborative hat, ask patients questions about their physical activity habits, likes, and desires, engage them in a brief discussion, and then cocreate a plan for increasing physical activity.

Motivational interviewing has been demonstrated to have beneficial effects on patient health. For example, in a randomized controlled study by Watkins et al., stroke patients were placed in two groups; one that received usual care in a stroke unit and the other group received usual care plus four individual, weekly sessions of motivational interviewing. Twelve months after the intervention, the stroke patients in the intervention group had improved mood and reduced mortality.[37]

Additional support for the use of motivational interviewing by primary care physicians comes from an observational study published in the *American Journal of Preventive Medicine*. In this study by Pollak et al., 41 primary care physicians and 461 of their overweight or obese patients were the subjects. Physicians were observed during their office visits with these patients. Physicians were rated on their use of motivational interviewing techniques and specifically reflective statements. The results showed that patients who saw physicians who had the highest scores on the global Motivational Interviewing-Spirit score had greater weight loss (1.6 kg greater) than those patients who were seen by physicians with lower scores on this motivational interviewing assessment.[38]

A study by Hojat et al. demonstrated that physicians' empathy is also associated with positive clinical outcomes for diabetic patients.[16] In the study, 891 diabetic patients and 29 family physicians were studied. The hemoglobin A1C and LDL-C were obtained for each patient, and a Jefferson Scale of Empathy score was calculated for each physician. Patients of physicians with high empathy scores were significantly more likely to have good control of hemoglobin A1C and LDL-C than patients of physicians with low empathy scores. This study serves to underline the importance of empathy in the physician–patient relationship.

Expert and Coach Approaches

Most health professionals are trained in what is known as the "expert approach," which works well with acute situations, medical emergencies, and sick visits. However, when dealing with "chronic" behavior change, the "coach approach," using collaboration and negotiation, can yield better results as various studies have reported. There are several key differences in the two approaches. In the expert approach, the health care provider shares his or her knowledge and gives "mini lectures" to educate patients. In the coach approach, the provider checks in with the patient to discover what the patient knows and understands and then asks permission to share information that is directly pertinent to the patient's problem. In the expert approach, the provider listens, but is often doing more than one thing, such as writing down the history while continuing to ask closed ended questions provided by checklists in medical care systems.

In the coach approach, the provider listens and concentrates solely on what the patient is saying and the emotions he or she is conveying at that moment, not thinking about the next sentence he is going to say or the next question he is going to ask. More often than not, in the expert approach, a problem requires quick response and an immediate solution from the provider. In contrast, in the coach approach, a problem is an opportunity to learn more about a patient, his desires, needs, and barriers. A roadblock on a behavior change journey requires creative brainstorming and collaboration in order to cocreate a viable approach for getting around the roadblock.

When providers are in the expert mode, they shoulder responsibility for the patient, the diagnosis, the treatment, and the cure. When providers are in the coach mode, they realize that the patient is ultimately responsible for their daily actions, steps, and strategies. It is up to the patient to change. The provider cannot "make" a patient abandon one behavior and adopt another, but he can help and guide a patient by collaborating, negotiating, motivating, brainstorming, and

empowering. This takes time. The expert is often looking to solve a problem in a 15 min visit whereas the coach realizes that behavior change takes time—weeks to months, and a year or two to demonstrate sustainability. The coach prepares for the marathon, not the sprint.

Moving from the expert approach to the coach approach can be a challenge, especially in the area of sharing our knowledge and asking permission. Sometimes it seems as if it is more time efficient simply to blurt out our recommendations and insist on compliance after warning patients of the dangers of their current behaviors. However, this approach often elicits resistance because it steps on a patient's autonomy and does not help the patient to move forward. Spending time, 5 or 10 min, asking open-ended questions, and cocreating the next steps forward to optimal health is a more efficient use of time.

Coaching skills for physicians: Utilizing a five-step cycle will help the expert transition into the coach approach. Be empathetic—Align motivation—Build confidence—Set SMART goals—Set Accountability plan—Be empathetic.

This is a simple cycle to focus on when you are dealing with behavior change.[39]

Step 1: Empathy involves truly connecting with and understanding a patient's emotions and calls for a mindful approach to patient care. In the medical literature, there are several studies that demonstrate the positive effects of empathy on the patient encounter from increased patient satisfaction, better adherence to recommendations, improved collection of clinical data, and a more therapeutic physician–patient relationship (Coulehan et al.). In order to feel and express empathy, a physician needs to listen attentively and patiently. Thinking about the review of systems or the pertinent lab value is not part of listening mindfully or being fully present for the patient. Mindfully listening means sitting and looking into the patient's eyes, face to face, not working at the computer, not taking notes, not examining the patient as he or she tells her or his story. Reflecting back what was said and restating it is a powerful way of letting the patient know that you were paying careful attention and you understood the situation. These reflections are ways to express empathy.

Step 2: Motivation plays a crucial role in behavior change. Motivators are similar to the corner pieces of a puzzle; they hold everything else together. Tapping into a patient's internal motivating forces is the only way to make these motivators work. Telling a patient that they have diabetes and they have to lose weight, in essence making their diagnosis of diabetes his or her motivator might not work because the patient might not understand the disease process or the sequelae. People are more motivated by ideas that they themselves think of rather than ideas given to them. It is hard to know what motivates people without asking. Thus, asking patients questions about what they value most in life can help patients put things in perspective and align their motivation for behavior change.

Step 3: Building confidence is key. This is one of the most important pieces of the behavior change puzzle. In order to help patients gain confidence, you need to focus on what is working well right now and what has worked well in the past. Inquiring about previous successes with behavior change will help the patient identify strengths that might be utilized with this current effort to adopt healthy lifestyles. Also, drawing on character strengths, celebrating them, and figuring out how they will help the patient achieve their goals will serve to increase confidence.

Step 4: Setting SMART goals that are specific, measurable, action oriented, realistic, and time sensitive is another critical part of the behavior change plan. Stating I will exercise more this week is good goal, but a SMART goal involves stating more details such as next week, I will walk for 30 min on Monday, Wednesday, and Friday at 7 a.m., before work. On Saturday and Sunday, I will take an hour walk mid morning with my husband. If it rains on any of those days, I will go to the local mall to walk. Working with patients to cocreate SMART goals is important and success with these goals will help empower patients. Success breeds success.

Step 5: Holding patients accountable for their goals is the only way to ensure that the goals are prioritized and that they get done or that they are at least attempted or experimented with. If a patient creates goals but no one ever checks up on them, then the patient might be more likely to avoid them or even forget about them as time goes by. A physician can have an office assistant to call the patient in a week to check-in. Check-ins can be e-mail check-ins as well. In fact, sending a postcard reminding them about their goals and asking them to contact the office is another way to keep accountability high. This is another area where physician and patient need to collaborate and find the system that works best for both of them.

Health and Wellness Coaches

Since 2000, a handful of commercial and academic coach training organizations for health professionals have trained more than 5000 health and wellness coaches who work in diverse settings—corporate wellness, health club, medical fitness facility, hospital, clinic, health plan, spa, and private practice in the United States and other countries. Health and wellness coaches typically become coaches as a second career, coming from diverse health backgrounds including medicine, nursing, exercise, nutrition, mental health, and complementary medicine.

In 2009, an Institute of Coaching was launched at McLean Hospital, an affiliate of Harvard Medical School, to fund and support coaching research and the translate and bridge the most robust theories and research into best coaching practices. Teams of health and wellness coaches are piloting coaching interventions for a variety of patient populations at several academic medical centers, including Duke, Vanderbilt, and University of Minnesota. Clinical applications include diabetes, cancer survivors, heart disease and cardiac rehabilitation, cardiovascular risk reduction, obesity, smoking cessation, chronic pain, and comorbid mental and physical conditions.

The groundwork for the professional health and wellness coach was developed and cultivated through the efforts of many leaders focused on changing the direction of patient care from disease-focused to one of patient empowerment, disease prevention, and wellness. The 2005 guidelines for the practice of health care in all settings, as mandated by both the Joint Commission on Accreditation of Health Care Organizations (JCAHO) and the Institute of Medicine (IOM) include[40]:

- Placing patients at the center of their health care
- Treating the patient as a whole person
- Shared decision making

In November 2011, Centers for Medicare and Medicaid announced that

> The evidence is adequate to conclude that intensive behavioral therapy for obesity, defined as a body mass index (BMI) ≥30 kg/m^2, is reasonable and necessary for the prevention or early detection of illness or disability and is appropriate for individuals entitled to benefits under Part A or enrolled under Part B and is recommended with a grade of A or B by the U.S. Preventive Services Task Force (USPSTF).[41]

Intensive behavioral therapy for obesity consists of the following:

1. Screening for obesity in adults using measurement of BMI calculated by dividing weight in kilograms by the square of height in meters (expressed in kg/m^2)
2. Dietary (nutritional) assessment
3. Intensive behavioral counseling and behavioral therapy to promote sustained weight loss through high-intensity interventions on diet and exercise

Government reimbursement of personal counseling sessions for obesity is a promising step forward and paves the way for coaching interventions based upon science-based coaching competencies.

While the research literature on coaching interventions in health care is limited, several randomized controlled studies support the use of coaching interventions to help treat and prevent disease. Clinical outcomes examining lab values as well as well-being and activity levels have demonstrated that coaching interventions can improve health and reduce depression scores.

Johns Hopkins University[42] investigated the effectiveness of two weight loss coaching interventions, one delivered remotely through telephone sessions, a study-specific website, and e-mails and another delivered through in-person coaching sessions, in 415 obese patients with at least one cardiovascular risk factor. Weight loss at 2 years was significantly greater in both intervention groups compared with the control group (self-directed weight loss). Weight loss of 5% or more occurred in 18.8%, 38.2%, and 41.4% of controls and those receiving remote and in-person support, respectively.

Lowering hemoglobin A1C levels among diabetics,[43] increasing diabetic patients' satisfaction with care,[44] reducing diabetes-related distress,[44] lowering cholesterol in cardiac patients,[45] increasing number of days per week or exercise,[46] increasing weight loss,[46] increasing consumption of fruits and vegetables in teenage girls,[47] lowering rehospitalization rates in pediatric asthmatic patients,[48] decreasing pain severity in cancer patients,[49] and increasing activity levels in the elderly[50] are among the outcomes demonstrated in these randomized controlled clinical trials (Table 27.1).

While coach training, coach backgrounds, and coaching protocols vary widely in these studies, shared features include multiple coaching sessions over 3 months or longer, in-person or by phone, collaborative goal setting and problem solving, and ongoing accountability. The alliance of the coach and patient shows potential in supporting sustainable lifestyle change, which needs to be confirmed in additional randomized studies.

To expand coaching research, it is critical to define standards for coaching competency, training, and education. To meet this need, a National Consortium for Credentialing of Health & Wellness Coaches[51] formed in 2010 and has grown to 75 organizations. The Consortium is committed to developing coaching competency and training and education standards for health and wellness coaches to support a collaborative coaching research endeavor. A further mission is to support the integration of coaching competencies into health professions, including the work of physicians as discussed earlier. The consortium's work is focused on job definition and tasks, scope of practice (including appropriate recommendations of other health professionals), and prior degrees, credentials, and coach training and education necessary to deliver a minimal standard level of competency demonstrated through a national certification process.

At a 2 day Summit of the National Consortium held in September 2010, a collective vision of the role of health and wellness coaches emerged:

1. Being a vehicle to create a paradigm shift to the "whole person"
2. Being a catalyst for change of the delivery of health care from dependency to empowerment
3. Empowering, inspiring, and transforming both clients and providers
4. Spanning the continuum of health: from the very sick to those pursuing increased health (primary prevention)
5. Becoming a routine and integrated part of the health care system and consumer wellness

While it will take many years for health and wellness coaches to be well established in health care and consumer wellness, good foundation blocks are in place and there is no reason to delay the dissemination of coaching skills wide and far.

Now let's explore coaching in action.

TABLE 27.1
Randomized Controlled Trials of Health and Wellness Coaching

Authors	Design	Subjects	Intervention	Results
Wolever et al.[43]	RCT comparing integrative health coaching with usual care (control)	56 patients with type 2 diabetes	Fourteen 30 min coaching sessions by telephone over 4 months	Significant reduction A1c levels among participants with to baseline values > or equal to 7% ($p = 0.03$)
Whittemore et al.[44]	Pilot RCT; nurse coach as usual care intervention group received a nurse coach intervention	53 women with type 2 diabetes	Six coaching sessions were delivered over 6 months	Intervention subjects had better diet self-management ($p = 0.002$), less diabetes-related distress ($p < 0.01$), better integration ($p < 0.031$), greater satisfaction with care ($p = 0.01$), and trends toward better exercise self-management ($p = 0.13$) and lower BMI ($p = 0.15$)
Vale et al.[45]	RCT; coach as usual care	792 patients with CVD	Five telephone coaching sessions were delivered for 6 months	Intervention subjects demonstrated greater decrease in total cholesterol ($p < 0.0001$), more weight loss ($p < 0.0001$), greater reduction in the intake ($p = 0.041$), and more walking activity ($p < 0.0001$)
Vale et al.[46]	RCT; COACH model as usual care	245 CHD patients	Six telephone coaching sessions were delivered for 6 months	Intervention subjects had significantly lower fasting total cholesterol ($p < 0.0001$) and LDL-C levels ($p < 0.0004$)
Edelman et al.[47]	RCT; personalized health plan and a health coach with a medical provider as usual care plus health report	154 patients with one or more CV risk factor	28 two-hour in-person group training sessions with biweekly 20–30 min individual telephone sessions for 10 months	Intervention subjects had significantly greater decrease in CHD risk ($p = 0.05$), greater increase in number of days of exercise per week ($p = 0.002$) and greater weight loss ($p = 0.54$)
Debar et al.[48]	RCT; group meetings and coaching as usual care	228 teenage girls	Annual visits, fitness center membership, biweekly team meetings, quarterly telephone sessions, and team meetings with parents, all of which are supported by a study website	Intervention on subjects had higher BMD in the spine ($p = 0.007$) and trochanter ($p = 0.03$) regions and greater consumption on of calcium ($p < 0.001$ and fruits and vegetables) ($p = 0.01$) for 2 years
Fisher et al.[49]	RCT; child and parent received coaching as usual care	191 children ages 2–8 years with diagnosis of asthma	Telephone and in-person visit with parent then biweekly telephone calls for 3 months, after which calls were monthly for the duration of the 2 year intervention	Intervention subjects had significantly lower rehospitalization rates ($p = 0.002$)
Oliver et al.[50]	RCT; individualized education and coaching as usual care group with additional education	87 cancer patients with moderate pain	20 min visit before visit with doctor	Intervention group experienced lower pain severity ($p = 0.014$)
Holland et al.[51]	RCT; nurse coaching as usual care	51 subjects with chronic health condition	Group classes on health topics and three 1 h exercise training sessions with 11 contact hours with the nurse health coach by telephone and e-mail for 12 months	Intervention subjects demonstrated increased minutes of weekly aerobic activity ($p = 0.001$) and increased minutes of weekly stretching ($p = 0.0008$)

COACHING SCENARIOS

To bring to life the work of health and wellness coaches, and the use of coaching competencies by physicians, we present four coaching scenarios, and explore how the principles of coaching change can be applied.

Diane, a 30 Year Old Woman Who Is Overweight, Prepregnancy

Diane is a 30-year-old woman who has a busy law practice and is eagerly working to become a partner. She has never been a big exerciser and did not participate in team sports growing up. Diane has had a serious "sweet tooth" her whole life, especially for chocolate cake and cookies. Although she was never excessively heavy growing up, she always considered herself a large framed girl. Since her mother's fight with cancer that ended in a long drawn-out death, Diane has been noticing her pants getting tighter and has had to buy new suits for work. Disgusted with herself, she has tried several different diet plans without success.

Coaching Tips for Physicians: Applying the Five-Step Cycle

Empathy: When Diane is talking about her problems, listen intently and don't think about what you are going to say next. Show empathy with Diane's lack of exercise experience growing up and with her difficult time during her mother's battle with cancer. At this point, you could use self-disclosure and share with the patient that you, too, have a sweet tooth so you are familiar with the challenges or that you were not an avid exercisers growing up but now you take walks in the evening or whatever is true for you.

Motivation: Explore and validate Diane's heartfelt reasons to embark on changing her lifestyle. Ask her what has been motivating her to try different diets.

Confidence: Ask her about her confidence level for embarking on lifestyle change and brainstorm possible supports to improve her likelihood of success. Discuss her strengths noting that as a lawyer, she must be dedicated, clever, and good at handling detail. You can mention that she must have perseverance as she made it through law school, and creativity in order to build strong legal cases, and both of those traits will be useful when adopting healthy lifestyle changes.

SMART goals: Given that Diane reports feeling, "disgusted with herself" she might be ready to set a goal for herself. In fact, she might have been thinking about possible steps forward, toward adopting a healthy lifestyle. Ask if she is ready to set a goal and what she would want to tackle first. Don't assume that she wants to cut out sweets even though she mentioned that. Make sure that Diane sets a specific, measurable, action-oriented, and time-sensitive goal. If she is not ready to set a goal, then ask her to think about this and contact the office when she settles on one.

Accountability: Negotiate and cocreate a system of accountability that works for both of you. If Diane is having a follow-up visit soon, then you can use this time to check in on the goals. Depending on your office setup, you could have an assistant call the patient or e-mail the patient to check in after a week. It is important to set up the plan with the patient at the visit and document it. If you have pen and paper in your office, the patient can write down the plan and you can document it in the chart.

Coach's Process—Deploying the Five Forces of Sustainable Change

Mindful attention—Diane begins to appreciate how she puts the needs of her work and family ahead of her own and that it is worth exploring whether investing more in self-care would payoff with more energy and zest at work and in close relationships.

Self-acceptance—Diane starts to notice how her inner critic eats away at her confidence and energy and learns that she is far more focused on her deficiencies than her strengths. She experiments with "changing the channel" from beating herself up about her weight loss failures to savoring and harvesting her successes and accomplishments and enjoying her strengths in action.

Autonomous motivation—Diane discovers that vanity about her appearance isn't the motivator that she thought it would be. Instead she wants her clients and loved ones to see her "sparkling" eyes, warm smile, and confidence that shine through when she is good to herself.

Self-efficacy—Diane has noticed how organized and persistent she is in getting things done at work and starts to intentionally bring those talents to her exercise and meal planning. She finds two friends to provide mutual accountability and support and they swap stories on how they use their strengths in their self-care weekly.

Process of change of mind-set and behavior—Diane has posted her vision for herself, with bright eyes and smile, on her fridge and smartphone, and her coach has set up a text reminder of her vision statement to arrive Sunday evening when she wants a boost to start the next week. She starts to imagine herself as energetic and full of life, instead of letting herself get down about her weight. Funny, her cravings for sweets have dropped enormously and sticking to "no carbs after 5 p.m." has been a simple change which has allowed her to lose 2 lb/month without feeling deprived. This Diane can sustain!

Shirley, a 40-Year-Old with Type 2 Diabetes

Shirley is a 40-year-old woman with type 2 diabetes who is the mother of three children. With her busy schedule at home, she finds it hard to fit in any regular exercise, despite the fact that she was a college volleyball player and enjoys sports. Her children are 10, 8, and 6 years and are picky eaters, refusing to eat anything except pizza and mac and cheese. Eating their leftovers has become habit now. Shirley is trying to eat less but finds it difficult. Having type 2 diabetes is something that scares Shirley and she wants to lose weight but can't find the time to commit to healthy eating habits or regular exercise.

Coaching Tips for Physicians: Applying the Five-Step Cycle

Empathy: After listening intently to Shirley, you could nod and use a reflection such as, "It sounds like you are really busy with your three children and finding time to exercise is a real challenge right now."

Motivation: It appears that Shirley is scared about her diagnosis of diabetes. You could check in with her about this and find out if it is a motivator for her interest in exercise by saying, "I heard you say that your diagnosis of type 2 diabetes worries you. What would it take to help mitigate that fear?" Or, "I heard you say that you are trying to fit exercise into your life right now and you are trying to eat less. How would your life be different if you were able to accomplish both of these goals?"

Confidence: You can help build up Shirley's confidence by pointing out some strengths that you identified while she was telling you her history. For example, you might say,

> From what I heard today, you sound like a dedicated mother who is prioritizing her children. Being a dedicated mother takes great patience. I also learned that you were a competitive volleyball player, which takes long hours of practice as well as skill. These combined strengths of dedication, perseverance, and the ability to train for a competitive sport will all come in handy to help you achieve success in adopting healthy lifestyles.

SMART goals: Ask Shirley if she is currently working toward a specific goal in terms of eating less, which she mentioned was an overall goal. Depending on her answer, you can work to help her create a specific, measurable, action-oriented, realistic, and time-sensitive goal. If Shirley is not interested in creating a SMART goal around eating less, then check in with Shirley and see what is most important to her right now. Let her tell you what she would like to tackle first. Then, help her create a SMART goal for that.

Accountability: Negotiate and cocreate an accountability plan as with the first case.

Coach's Process—Deploying the Five Forces of Sustainable Change

Mindful attention—Shirley has learned how mindless, "asleep at the switch," she is around food and exercise, on automatic pilot, and not intentional or thoughtful about her decisions and choices. She has swallowed her kid's leftovers without a moment to stop and reconsider what would be best for her, and her days fly by without a thought of scheduling exercise and resetting her priorities.

Self-acceptance—Shirley awakens to notice how bothered she is that she doesn't have the athletic body and fitness she once had. Exercising makes her feel bad about what she has lost and so she dreads it. She begins to think about how her body has borne three healthy children and what a great accomplishment that is. She begins to be more at peace with herself. She notices how her frenzy spills over to her children and when she is more relaxed and less controlling her kids are less picky about what they eat.

Autonomous motivation—Shirley is concerned that her kids will develop a lifetime of bad eating habits and get diabetes like she does. She really wants to be a role model of great health and physical fitness and decides that setting an example is a better strategy then nagging.

Self-efficacy—To handle her constant state of frenzy, she begins to make a schedule for the next day before she goes to bed, and then she does 10 min of deep breathing meditation before breakfast and her kids get up to clear her mind of static. She also completes a character strength assessment (www.viacharacter.org) to find that love of learning and curiosity are strengths. She finds new DVD exercise programs to experiment with.

Process of change of mind-set and behavior—Shirley has set a goal to do four 30 min workouts/week and she tells her kids when and what and asks them at bedtime to remind her before they go to school, which they love to do. They remember on their own to ask her when they get home whether she did her workout. She also set a goal to eat two veggies and one fruit at dinner and finds new recipes to prepare them in interesting ways. Her kids are starting to ask about the veggies and fruit and even ask for some to try. Shirley is now starting to see herself and her kids as a family team and is starting to ask them to share what family wellness means to them, which has led to some cool new ideas for weekend outings.

Audrey, a 55-Year-Old with Breast Cancer

Audrey is a 55-year-old breast cancer survivor who is anxious to do everything in her power to remain healthy. She is currently overweight but is trying to change that by exercising 3–5 days a week. Since her diagnosis of breast cancer, she has tried to be careful with her diet, avoiding processed red meat and eating more fruits and vegetables. However, she loves ice cream and finds herself indulging in this guilty pleasure late at night.

Coaching Tips for Physicians: Applying the Five-Step Cycle

Empathy: Start by acknowledging how hard it is to lose weight. Then, you can reflect back that you heard Audrey say she is exercising 3–5 days a week and that she is adding more fruits and vegetables into her diet. After that, you can say that you sensed some disappointment and guilt when Audrey spoke about eating ice cream late at night. At that point, you can say something like it is sometimes hard to quit a habit, especially if it gives you pleasure.

Motivation: Tapping into Audrey's motivation to "do everything in her power to remain healthy" after her breast cancer treatment is a good place to start. By saying, "It sounds like you are already moving in a positive direction with your desire to remain healthy after your battle with breast cancer." What do you think will keep you focused and on track with this desire in the long run?

Confidence: By spending a moment congratulating Audrey on her exercise routine that she started, you can help empower Audrey to continue to tackle lifestyle behavior challenges in the future. You can ask her how she mustered up the energy and commitment to get that done. Then, you can move to her diet and congratulate her on the changes that she already made and ask her a similar question. How did she make that change happen? By having Audrey relay her successes in the area of exercise and diet, you can set her up for feeling confident to tackle more obstacles, like the ice cream that she mentioned.

SMART goals: Ask Audrey what goals she would like to commit to for the upcoming weeks. Again, do not assume or even suggest that she simply "stop eating the ice cream." See what she comes up with. Audrey brought up the ice cream and she knows it is a problem. If she wants to tackle this as her first goal, that is fine. If she chooses something else, follow her lead, as she may need another week or two before she tackles this "guilty pleasure." Make sure to help Audrey create specific, measurable, action-oriented, realistic, time-sensitive goals.

Accountability: Negotiate and cocreate an accountability plan as with previous cases.

Coach's Process—Deploying the Five Forces of Sustainable Change

Mindful attention—Audrey has started to notice how sad and low she feels at the end of the day and how she uses ice cream as medicine to make her feel better. She decides to save ice cream for celebrations and special occasions and enjoy it as a fun treat, not to anesthetize her sadness.

Self-acceptance—Audrey is starting to cultivate pride in how she handled her cancer treatment and healing process, keeping herself active in her relationships and volunteer work, instead of focusing on her extra weight, which is a common side effect of cancer treatment. She starts to see her extra weight as an opportunity to get healthier, rather than a burden.

Autonomous motivation—Audrey has learned how precious her life is, and how her days are not limitless, and she wants to live every day to its fullest, enjoying small pleasures and helping others in small and large ways. Even if being in good health does not extend her life, she wants to look back and say "I lived many of my best days after cancer."

Self-efficacy—Audrey comes up with three strategies to get her through the evenings when she finds her mood sliding downward and her motivation slipping—to relive past memories by talking to old friends, or pulling out old photo albums and reminiscing, to plan a fun outing or adventure, or going for a walk with a friend to get some fresh air. She taps into her character strength of kindness by making sure she does something nice for someone everyday and then reflects on the pleasure that gave before going to bed.

Process of change of mind-set and behavior—Audrey has begun to notice that she has some control over her mood, that if she acknowledges that she feels sad, and then shifts from sad thoughts to good ones about helping others, doing something fun in the future, or appreciating her past rich life, she notices her energy lift and her desire for ice cream to fade—much faster than she thought possible. She wakes up more energized and now briskly walks for 30 min when it's not raining hard immediately after breakfast. She is thinking that it might be a good idea to get a used treadmill for rainy days because the walks make the rest of her day go so much better and why miss out on rainy days.

Rachel, a 65-Year-Old with Heart Disease

Rachel is a 65-year-old woman with heart disease. She recently suffered a heart attack. Currently, she is in the obese category by BMI. Although her cardiologist insists that she stop eating red meat, ice cream, and butter, Rachel is not convinced that she wants to give up the foods that she loves and relies upon for sustenance and comfort. Since Rachel has been sedentary for over 30 years, she is not only hesitant to start an exercise program now but also scared that her physical activity will bring on another heart attack. Rachel feels that it is too late to change and does not think that losing a little weight will do much for her anyway.

Coaching Tips for Physicians: Applying the Five-Step Cycle

Empathy: First reflect what you heard, "It sounds like you have been through a lot with your recent heart attack, your cardiologist insisting that you stop eating some of the foods that you most enjoy, and your fear that exercising will bring on another heart attack." You can also reflect back her powerful statement, "I heard you say that you feel it is too late to change and you feel that losing a little weight will not do much anyway." By repeating Rachel's words, you are letting her know you were listening and that you care. She is more than likely expecting you to side with her cardiologist and give her another lecture on diet and exercise, and your response will surprise her.

Motivation: Rachel did talk about being afraid of another heart attack, and you can use this as a starting point. "You mentioned that you are afraid of another heart attack. What do you want to do to help reduce your risk of another heart attack?" Another tactic would be to ask, "How would your life be different if you felt confident and comfortable exercising, instead of fearful?"

Confidence: It sounds like Audrey has been beaten down. You can ask her, "What would it take for you to feel confident about your future health?" By emphasizing that Rachel is a survivor, you can help increase her confidence. "Rachel you are a survivor. You survived a heart attack. I bet you have been successful at many things in your life. Tell me about one of them."

SMART goals: See if Rachel is ready to set any goals during this visit. If she is not, you can ask her to think about a goal she would love to achieve by 3 months. Do not jump in and start setting weight loss goals, exercise goals, and diet goals, even if that is what you are first compelled to do. In Rachel's

case, a goal might be to investigate how to avoid another heart attack or research exercise and heart attacks. You could not set these goals for her, but if she says she has no idea what goals to strive for, you could ask permission to brainstorm together. These might be some ideas that you toss out to her and see if any of them catch her interest. Remember it is her agenda. You must honor her autonomy.

Accountability: Negotiate and cocreate an accountability plan as with previous cases.

Coach's Process—Deploying the Five Forces of Sustainable Change

Mindful attention—Rachel begins to notice how angry she is about having a heart attack and that the anger clouds her thinking and takes over her brain leading her to conclude that she can't possibly summon the resources to do healthy things. She's also angry at doctors who don't understand how hard it is for her to give up the things she loves. She decides that a few therapy sessions to explore, heal, and release her anger would be valuable.

Self-acceptance—Rachel begins to feel grateful that her heart attack has "cracked" open her shell and that she is more aware of how her emotions affect her physical stress and energy. She decides that she wants to transform the energy of her anger into something healthy and positive rather than keep it bottled up.

Autonomous motivation—Rachel decides that what she wants most is to feel calm and at peace and that will allow her to heal and create a new beginning.

Self-efficacy—Once Rachel sees how much power she has in her bottled up emotions, which she had turned inside, she decides to channel that energy outward into exercise. Amazingly not only is she making her heart stronger, but she is putting her emotions through a spin cycle and she feels calm at the end of her workout. Rachel prides herself on thinking out of the box and looks forward to the next challenge.

Process of change of mind-set and behavior—Rachel is setting small goals, 1 week at a time, and accomplishing more than she planned for—longer and more intense workouts than she committed to herself to do. She learns that if she focuses on a small goal each day and week, she is successful, feels proud of her success, and now is starting to reach out to others in her rehab class to see how she can help them learn what she has learned. She can't believe that she has become a devoted exerciser.

It is a privilege for physicians and coaches to be catalysts for people whose health is calling them to move toward a health-giving lifestyle. Each of them has their own story and journey; how satisfying it is to watch them outgrow their old selves and turn their health crises into an opportunity to learn, change, and thrive.

> Change is the handmaiden Nature requires to do her miracles with.
>
> **Mark Twain**

APPENDIX A: 12 COACHING COMPETENCIES

1. Facilitate a calm, mindful focus of attention on a patient's state of health and well-being which expands self-awareness of deficits and awakens the desire for possible benefits of positive change.
2. Empathize with a patient's circumstances, show acceptance, and foster a nonjudgmental and affirmative perspective ("let's appreciate and learn from the past and move forward to build a better future").
3. Encourage autonomy, put patients in the driver's seat and yourself in the passenger seat, by undistracted listening, open-minded inquiry, refraining from mindless advice giving, and helping patients to make choices by brainstorming a few options to select from.
4. Help patients find health behaviors that are intrinsically motivating (enjoyed for their own sake) and/or find internal motivation (articulating and valuing future personal benefit) for a health behavior, for example, it will allow them to make a difference in the world or do more of things they treasure most, now and in the future. Help patients select behaviors which have the potential to enhance autonomous motivation quickly.
5. Help clients identify personal strengths and talents, and brainstorm ways to deploy strengths in the pursuit of lifestyle change and better health.
6. Cultivate positive emotions by starting sessions with positive topics—experiences, lessons, successes, strengths, which improves brain function for more challenging topics. Unpack and harvest positive topics at the close of sessions.
7. Help clients brainstorm on various paths to reach goals so that they appreciate that if one path doesn't work, one or more other paths are possible, which increases hope and confidence.
8. Help clients select goals and develop strategies, including environmental and social support, which enhance confidence.
9. Help clients define motivational vision statements and specific behavioral goals to provide structure for pursuing lifestyle change.
10. Alternate open questions and reflections to generate new insights and perspectives that support new behaviors. Acknowledge and unpack new insights and perspectives to help them stick.
11. Help clients select and build in methods for commitment and accountability, decide on level of goal ambition (bold or baby steps) and behavioral goal time frames which will work best (3 months, 1 year, beyond).
12. Help clients find resources to support gaining of knowledge and learning of skills just-in-time to enhance motivation, confidence, self-awareness, and new insights, and support their goal attainment.

The 2001 Institute of Medicine (IOM) report *Exploring the Biological Contributions to Human Health: Does Sex Matter?* notes that from the cellular to the societal level, gender matters in regards to health. According to the Centers for Disease Control and Prevention (CDC), men are at greater risk of death in every age group compared to women, with 1.6 times more mortality for all causes, 1.8 times for diseases of the heart, 1.4 times for cancers, and 2.4 times of for accidents.[1] While biological factors play a role in this gender gap, these are relatively small compared to the role of behavior.[2–4] Some of these behaviors—tobacco use, poor diet, physical inactivity, and alcohol consumption—represent the leading *actual* causes of death between 1990 and 2000 and are considered modifiable and preventable.[5] Yet men's participation in the health care system is noticeably lower than women's,[6] perhaps due to knowledge and help-seeking behaviors, gender beliefs, finances, or lack of unique health system attention.[2,7–16] Men from ages 18 to 44 years were 70% less likely to visit a physician in 2007 and 80% less likely to have a usual source of health care, as compared to women.[18] While the past decades have seen a necessary focus on understanding women's health and the creation of the Office of Women's Health (OWH) in the U.S. Department of Health and Human Services, no similar organization has been tasked with improving the health of men. Nevertheless, research on men's health has been increasing as the disparity in life expectancy has grown and as researchers, policy makers, and clinicians have realized the important contributions men make in the workplace, their families, and society.

Though male-specific cancers and sexual health receive much of the attention, conceptualization of men's health has expanded beyond this simple view. There has been increased attention to the reexamination of men's various roles throughout their life span and how this may affect opportunities to engage men with the health care system. Additionally, there has been a growing focus on the unique characteristics of men and their risk, protective, and help-seeking behaviors with attention paid to ways to engage men in maintaining their health and interacting with the health care system. In this chapter, we introduce a conceptualization of men's health that spans the life course and offers insights into when men's health interventions might prove most beneficial across the life span. Then we describe key preventive health steps for men to take along the life span in general and in adolescence in particular. Then we discuss a particular condition for men, namely fatherhood, and its impact on men's health and health behaviors. Finally, we provide suggested areas of future work that have the potential to fully optimize men's health.

LIFE COURSE HEALTH DEVELOPMENT AND MEN'S HEALTH

Research on health and behaviors over the life span has highlighted gateways and barriers to optimal health. The Life Course Health Development (LCHD) framework explains how health trajectories develop over a person's life, acknowledging the contributions of biopsychosocial and contextual determinants to health.[18] Halfon and Hochstein use this framework to suggest that a focus on early risk factors and protective factors leads to more effective preventive strategies and interventions to maximize health over time.[18] Lu and Halfon compliment the LCHD framework by further showing the importance of properly timed interventions on improving health outcomes along a developmental continuum.[19] The LCHD suggests that effective interventions or events that either lower risk or encourage protective behaviors provide the highest likelihood that an individual (or population) achieves his optimal trajectory over time (Figure 28.1).[20] This framework highlights the potential openings during a man's life to engage or reengage him with the health care system.

Some risk reduction strategies as related to men's health include avoiding smoking initiation and promoting cessation programs for those who have begun smoking, safe alcohol use, avoidance of illegal substance use, safe driving initiatives, and safe sex practices. Health-promoting strategies can include proper immunizations from childhood onward, appropriate health care encounters across the life span, weight surveillance and appropriate behaviors to maintain a healthy weight, and age appropriate health screenings such as for blood pressure, mental health disorders, and cancers

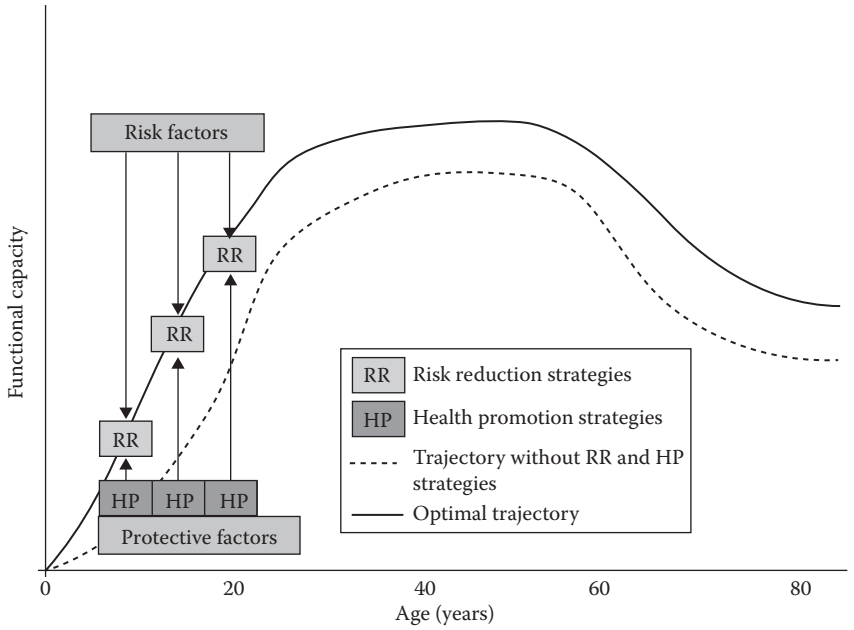

FIGURE 28.1 Maximizing functional capacity by risk reduction and health promotion over the life course.

(prostate, colon, etc.). Each of these behaviors can in turn shift the health trajectory curve toward optimization; the earlier the risk reduction occurs, the greater effect it has on the ultimate trajectory.

PREVENTIVE HEALTH FOR MEN ACROSS THE LIFE COURSE

The U.S. Preventive Services Task Force (USPSTF) recommendations for health care for men address many of the precursors or actual causes of death and comorbidities for men. These preventive measures are easily conducted by primary care providers and include (1) blood pressure measurement; (2) height, weight, and body mass index (BMI); (3) fasting lipid profile, (4) fasting glucose; (5) depression screening; (6) tobacco, alcohol, and other substance abuse and counseling; (7) injury prevention screening; and (8) provision of appropriate immunizations (Table 28.1).[21] While discussion of the specific attributes of the various screening tests in Table 28.1 is beyond the scope of this chapter, all the suggestions are recommended by the USPSTF review. The following suggestions are for screenings across the life span beginning at age 18 when young males leave pediatric care and enter young adulthood.

ADOLESCENT MALE HEALTH

Males going through adolescence have a unique set of developmental and health issues to consider. According to a 2008 IOM report,[22] most adolescents are considered healthy in terms of morbidity and mortality. However, adolescence is a time of transition when patterns of health behaviors, risk behaviors, identity issues, and relationship issues emerge as adolescents strive for independence and engage in experimentation. Adolescents need a safe, confidential, and accessible place to explore these issues and obtain reliable and confidential information. The IOM report outlines key requirements for quality adolescent health services, including (1) coordinating primary care; (2) focusing on disease prevention, health promotion, and behavioral health; (3) engaging the community; (4) maintaining confidentiality; and (5) preparing providers for the needs of young adults.

The adolescent stage in the life span is noted for several public health concerns that disproportionately affect young men, including homicides, suicide, motor vehicle crashes, substance use and abuse, smoking, and sexually transmitted illnesses. Accordingly, adolescent health is now one of the new objectives in the Healthy People 2020 framework. Table 28.2 lists a selection of these new objectives, their baseline incidence, the target goal for 2020, and the magnitude of the change expected.

Finally, there is promising research on interventions for adolescents that focus on positive youth development. The concept of resiliency, the ability of an individual to rise above obstacles, risks, and adversity in his environment and continuity to thrive and succeed, is receiving greater attention. Typical examples of resilient factors are supportive relationships with peers and others, social connectedness, and positive experiential opportunities.[23] Continued identification of those aspects of resiliency that pertain most to adolescent males and designing interventions to strengthen these factors hold great potential for improving adolescent male health.

FATHERHOOD AND MEN'S HEALTH

Becoming a father is a major transition for men with implications for motivations for change, altered life trajectories, psychological well-being, and roles in the family.[24–29] These changes may be "redefining," "jolting," or may result in "settling down."[24,26,30] Capitalizing on this developmental

TABLE 28.1
Suggested Screening Tests for Men Beginning at Age 18

Screening Test	Age 18–39	Age 40–49	Age 50–64	Age 65 and Above
Abdominal aortic aneurysm screening				Screen patients age 65–75 who have even smoked.
Blood pressure screening	Screen at least every 2 years if normal blood pressure is lower than 120/80.	Screen at least every 2 years if normal blood pressure is lower than 120/80.	Screen at least every 2 years if normal blood pressure is lower than 120/80.	Screen at least every 2 years if normal blood pressure is lower than 120/80.
	Screen once a year if blood pressure is between 120/80 and 139/89.	Screen once a year if blood pressure is between 120/80 and 139/89.	Screen once a year if blood pressure is between 120/80 and 139/89.	Screen once a year if blood pressure is between 120/80 and 139/89.
	Discuss treatment options with patients with blood pressure 140/90 or higher.	Discuss treatment options with patients with blood pressure 140/90 or higher.	Discuss treatment options with patients with blood pressure 140/90 or higher.	Discuss treatment options with patients with blood pressure 140/90 or higher.
Cholesterol screening	Starting at age 20 until age 35, obtain screening cholesterol test if patient is at increased risk for heart disease.	Check cholesterol regularly.	Check cholesterol regularly.	Check cholesterol regularly.
	Starting at age 35 and older, check cholesterol test regularly.			
Colorectal cancer screening (using fecal occult blood testing, sigmoidoscopy, or colonoscopy)			Beginning at age 50, screen for colorectal cancer.	Continue screening for colorectal cancer through age 75.
Diabetes screening	Screen for diabetes if blood pressure is higher than 135/80 or if on hypertension medication.	Screen for diabetes if blood pressure is higher than 135/80 or if on hypertension medication.	Screen for diabetes if blood pressure is higher than 135/80 or if on hypertension medication.	Screen for diabetes if blood pressure is higher than 135/80 or if on hypertension medication.
HIV test	Discuss risk with patient and test for HIV if patient at risk for HIV.	Discuss risk with patient and test for HIV if patient at risk for HIV.	Discuss risk with patient and test for HIV if patient at risk for HIV.	Discuss risk with patient and test for HIV if patient at risk for HIV.
Syphilis screening	Discuss risk with patients and test for syphilis if patient is at increased risk.	Discuss risk with patients and test for syphilis if patient is at increased risk.	Discuss risk with patients and test for syphilis if patient is at increased risk.	Discuss risk with patients and test for syphilis if patient is at increased risk.

TABLE 28.2
Selected Baseline and Target Adolescent Health Objectives in Healthy People 2020

Objective	Current Baseline	Target Goal by 2020	% Change
Adolescent wellness checkup	68.7%	75.6%	10% increase
After-school activities	82.5%	90.8%	10% increase
Adolescent–adult connection to discuss serious problems	75.7%	83.3%	10% increase
Graduate high school after 4 years	74.9%	82.4%	10% increase
School absenteeism due to illness or injury	14.6%	13.1%	10% decrease
Exposure to illegal drugs on school property	22.7%	20.4%	10% increase
Student safety at school as perceived by parents	86.4%	95%	10% increase
Serious violent incidents in public schools	17.2%	15.5%	10% decrease
Youth perpetration of, and victimization by, crime	444.0/100,000 adolescents	399.6/100,000 adolescents	10% improvement

event as men reconsider their responsibilities to their family and child may be beneficial for engaging men with the health care system and their own health promotion.

The health benefits of becoming a father are debatable and complicated by the fact that they have primarily been studied vis-à-vis the health benefits of being married. Men who are fathers and married have more proactive health beliefs related to health behaviors and outcomes compared to single men,[31] may gain health benefits from increased monitoring of health behaviors,[32,33] and derive psychological benefits through social support.[34,35] In the Panel Study of Income Dynamics, researchers found lower mortality risk in husbands with more children over a 20-year period compared to married men with fewer or no children.[36] Evidence from a sibling and twin model found among mostly married men that becoming a father after very young adulthood is associated with fewer chronic illnesses.[37] Alternatively, becoming a father could potentially be detrimental to male health. Approximately 5%–7% of new fathers screen positive for depression around the time of their partner's pregnancy.[38–40] Qualitative research describes the father-to-be as often unprepared, anxious, and experiencing role strain.[41] Another study of men during the first year of the transition to fatherhood found no significant changes in mental health but did find a significant decrease in general health,[42] while others report neither benefits nor risks.[43,44]

Hormone alterations also occur in expectant and new fathers and may have health implications for men.[45] Paternal cortisol increases in late pregnancy and during the labor process and then decreases postnatally, perhaps in relation to baby stimuli and cues. Prolactin increases in fathers prior to birth and is associated with greater responsiveness to baby cries and "pregnancy symptoms" in fathers.[45] The noted drop in men's testosterone during the postnatal period associated with greater paternal responsiveness may benefit men's overall health by decreasing high testosterone atherosclerotic and insulin sensitivity activity.[46,47] Finally, anticipation of a child appears to have both biological and behavior implications for men. In two observational studies, men and their pregnant partners were found to reduce smoking and drinking during the pregnancy with recent findings supporting the postnatal hospital stay as a successful venue for introducing a smoking cessation intervention.[48]

Changes in the mental health of men around the time of the birth of their children is another area of discovery in regards to men's health and fatherhood. Similar to the growing awareness and acknowledgement of the mental health of mothers in the peripartum, paternal perinatal depression is receiving attention for its effects on the father, his partner, and their children. Estimates of paternal depression within the first year of a child's life range from 7% to 10%.[49,50] An IOM report estimates that 4.3% of men with a child under 18 years had a major depressive disorder within the last 12 months.[51] This mental disorder has major ramifications for children, as it has been associated with decreased paternal warmth in parenting; increased parental conflict, hostility, and rejection; and lower psychosocial functioning in children.[52–54] Most of the current research focuses on the effect of paternal depression on the child; future work needs to examine the effect and natural history of paternal depression on the father's health and well-being.

While research in the area of fathering and its effect on men's physical and mental health expands, the current state of research suggests that becoming a father is a key period along the life course holds promise for interventions, supports, and further conceptualization of how this life altering event can be used to improve risk reduction, support positive health behaviors, and ultimately shift men's health trajectory.

FUTURE DIRECTIONS

There remains much to be learned in understanding and improving men's health. Future improvements will come from a variety of sources. First, improvements at the local level may have a particularly enduring effect on men's health. Ultimately, it is the relationship that men have with their health care provider that has the potential to prevent disease and improve their health. Men need to feel welcome, confident, and trusting of their health care provider. There are a number of successful ways to create a male-friendly health care practice. The creation of male-friendly healt hcare services helps men to identify a medical home, initiate, and continue to receive care. Developing health care programs or facilities especially designed for men that make use of gender-sensitive clinical practices is a growing trend within the health care industry.[2,15,16] Some of the approaches used to create a male-friendly practice include creating a welcoming office environment for men, striving to promote the use of health services via presentations and education, and encouraging clinicians to effectively engage men during the health care encounter (see Table 28.3).[55]

The second source for improvements is in the area of research. Researchers who focus on men's health must continue to expand and improve our conceptualization of men's health. This includes incorporating and accounting for protective and risk factors that contribute to men's health, as well as applying a life course perspective. Future research also must focus on the health of men in particular subgroups, such as immigrants, African American, Hispanic, Native American, Asian, and gay men. While there are many overlapping similarities in these groups, each possess unique challenges and opportunities that have an impact on men's health. Measures taken to include these subgroups in research and outcomes will improve our understanding of men's health.

Finally, men's health would benefit from greater involvement from public policy makers. Debate already exists around the creation of a center synonymous to the OWH called the Office of Men's Health (OMH). This government entity would be tasked with championing men's health across research, policy, and clinical care domains. With men generally poor participants in the health care system and with a dwindling life expectancy compared to women, an OMH could be a useful proponent of men's health during the ongoing health care reform discussions.

TABLE 28.3
Recommendations for Creating Male-Friendly Practices

General Topics	Suggested Clinical Practices
Welcoming health care setting	• Use administrative procedures that provide more anonymity (e.g., writing down reasons for visits) • Have men's interest magazines available • Make Internet access available • Provide health education materials targeting men's health issues • Gather feedback from male patients about the waiting room and how to improve it
Promoting service utilization	• Conduct outreach presentations where men routinely gather • Extend operating hours in the evening and on weekends due to men's work schedules • Use marketing strategies that appeal to men's characteristics • Collaborate with other agencies, key community figures, and women to get men into the health care system • Use direct mailings to promote knowledge of certain health risks and available services for male patients
Clinician–patient interactions	• Spend more time with men to inquire about health concerns • Affirm men for seeking help • Encourage health-promoting behaviors as ways to maintain independent, successful functioning • Provide education about relevant health issues (e.g., self-examinations, changing risky health behaviors) • Promote active involvement during health care visits

Taken together or separately, at the local practitioner level or the population level of researcher and policy makers, increased focus and attention to men's health has the potential to improve our understanding of men's health needs and to ultimately improve men's health outcomes across the life span.

In the early 1990s a new subfield emerged in psychology, which was termed the psychology of men and masculinity. The emergence of this subfield was perplexing to some in the psychology field because so much of psychological research, theory, and practice had historically been focused on men. However, the psychology of men and masculinity was new because it recognized an important limitation in the psychological history of men; namely, men were never considered gendered individuals. The new psychology of men and masculinity pays a debt of gratitude to the feminist movement of the 1960s and 1970s in the United States and to the psychology of women for bringing much needed attention to the gendered identity of people [1]. A recent search of the term of "masculinity" in Psych Info (the predominant research database among psychologists) further illustrates that masculinity was understudied although men were often the focus of previous research. A search from 1860 to 1990 revealed 485 results while a search from 1990 to 2011 revealed 1163 results, which indicated a substantial increase in research focused on the gender norms and identity of men. A similar search of PubMed resulted in 351 hits for "masculinity" between 1800 and 1990 and 504 hits between 1990 and 2011. The study of masculinity is a multidisciplinary effort involving a wide range of disciplines, such as history and sociology to economics and medicine [2–5].

The new psychology of men sought to examine masculinity identities, how men responded to the changing roles of women (e.g., more women in the workforce and in education), and how men's identities and roles related to their health and well-being. A key assertion among the founding scholars of the new psychology of men and masculinity is that gender is recognized to have a biological basis, but the expressions of masculinity and femininity are not innate, biological traits but rather social constructions that are taught, learned, reinforced, and performed by individuals [6]. Both males and females are socialized to fit certain molds that can be both beneficial and detrimental to their health and well-being. Boys and men have been socialized to adhere to such masculine norms as being tough, aggressive, competitive, dominant, independent, stoic, and self-reliant, which is typically referred to as traditional masculinity [7,8]. The gender role socialization process is multilayered, longitudinal, and occurring across systems [9]. For example, a young boy may be taught to be tough and aggressive by his father (family system), which is then positively reinforced by a football coach when the boy becomes an adolescent (social system), but may become detrimental when the boy becomes an adult and cannot express emotions and vulnerability in romantic relationships (relationship system). Although not exhaustive, the example highlights the potential rewards of gender socialization (e.g., parental approval, athletic achievement) as well as the potential drawbacks (e.g., relationship difficulties).

Although there are many definitions of masculinity, this chapter espouses the definition of masculinity as a set of socially constructed characteristics and behaviors that men adopt in order to remain congruent with societal, cultural, and contextual expectations [10]. Terms and concepts used in this chapter are included and summarized in Table 29.1. The expression of masculinity can vary from man to man, from groups of men to groups of men, across cultures, ethnicities,

TABLE 29.1
Terms and Definitions

Common Terms	Definitions
Psychology of men and masculinity	A subcategory in the field of psychology emerging in the early 1990s. Refers to a psychology that considers male identities, how men respond to changing roles of women, and how male roles and identities relate to their health and well-being.
Masculinity	Social constructions about what a man should be that are taught and reinforced.
Masculine norm	The way men are expected to behave, think, and act according to social and cultural views of men.
Traditional masculinity (norms, roles)	Posits that men should be tough, self-reliant, stoic, independent, and take care of their business.
Gender role socialization	The way males and females are taught to be and to act. This can be rigid and limiting and have a negative effect on the lives of males and females.
Gender role strain	Posits that gender role norms are constantly being violated because they lack consistency and are contradictory. Violators of gender role norms are condemned especially if they are males.
Gender role stress	Subjective feelings of intense demands to uphold gender role norms and expectations, causing cognitive distress and emotional conflict.
Gender role conflict	A conflict between how an individual is socialized according to the individual's gender and how that individual wishes to live.
Toxic masculinity	Constellation of socially regressive male traits that serve to foster domination, the devaluation of women, homophobia, and wanton violence [34].
Positive masculinity	Positive qualities of traditional masculinity that can be used to promote the well-being of men.
Possible masculinity	A type of masculinity that encourages men to create goals and aspire to the ideal self. Possible masculinity places an emphasis on individuality of each male and the ability of men to use strengths they already have to reach their goals.
Gender competence	An ongoing process in which personal awareness and biases regarding gender are examined and challenged and more knowledge is sought about gender and gender roles.

geographies, income statuses, and sexual orientations. It is beyond the scope of this chapter to describe all the different expressions of masculinity. This chapter focuses primarily on the expression of masculinity in the United States among adult, heterosexual men. Readers are directed to additional readings for a more nuanced understanding of masculinity across different subgroups and cultures (International populations of men [11]; gay men [12]; African American men [13]; Asian men [14]; Mexican American men [15]).

GENDER THEORIES AND MENTAL HEALTH OUTCOMES

Early scholarship in the 1980s [10] was able to identify and explain the struggle that many men were experiencing during that time and continue to experience in modernity. Many men struggle with a feeling of dissatisfaction from trying to live up to the traditional masculinity ideals that they were taught. When they attempt to deviate from traditional masculinity norms, they often feel pulled back "into the box" by societal pressure (e.g., bullying). In other words, many men do not want to adhere to traditional norms of masculinity, which they consider inflexible, but they adopt some or most of those norms because of external pressure or reinforcement. This struggle is defined as gender role strain [16]. For example, an adolescent male may internally desire to be a high-school cheerleader. However, he recognizes that all of the cheerleaders at his school and on television are females. Further, he clearly learned from his parents and friends that boys are positively reinforced for playing certain sports, but that cheerleading is not one. If the boy tries out for the cheerleading team, an expected outcome might be bullying by his peers. The boy, then, may suppresses his desire to be a cheerleader. As a result of gender role strain, some men may experience dissatisfaction, guilt, anger, and other psychological distress.

In addition to feeling strained, some men experience gender role stress, which is defined as men's subjective feelings of pressure to uphold gender norms and expectations that result in cognitive distress and emotional conflict [17–19]. The negative effects of stress and the importance of using stress management skills on an individual's lifestyle and health behaviors are likely well known to readers of this chapter [20,21]. Specifically related to men, gender role stress has been associated with aggressive behavior, intimate partner violence, feelings of anger, and severity of posttraumatic stress disorder symptoms [18,19,22,23].

Gender role conflict theory, another prominent theory in the new psychology of men and masculinity, sheds additional light on men's adherence to traditional masculinity roles [24]. According to O'Neil [25], gender role conflict "is defined as a psychological state in which socialized gender roles have negative consequences for the person or others." Gender role conflict occurs when a man rigidly adheres to gender roles that restrict their potential to be the man of their choosing [24]. As men experience their socialization and become afraid of exhibiting femininity, gender role conflict can take the form of six predominant patterns: (1) restrictive emotionality, (2) health care problems, (3) obsession with achievement and success, (4) restrictive sexual and affectionate behavior, (5) socialized control, power, and competition issues, and (6) homophobia in men's interpersonal, career, family, and

health lives [25]. Men's gender role conflict has been found to correlate with depression, anxiety, stress, feelings of shame, an inability to put words to feelings (i.e., alexithymia), use of unhealthy coping strategies, alcohol and substance abuse, and low self-esteem [25,26].

Indeed, a consistent finding in research over the years has found a strong association between rigid and restrictive adherence to traditional masculinity and negative health outcomes among men, such as a decreased ability to express emotions and to seek help [27–29]. Additional theoretical and empirical support has been found for the connection between many mental health issues (e.g., depression, anxiety, substance abuse, relationship conflicts, stress) and a man's conformity or nonconformity to masculine norms [30,31]. In a landmark study in 2000, Courtenay [32] connected 30 negative health behaviors (e.g., sunscreen use, wearing seat belts, and substance abuse) to behavioral factors, such as gender socialization, among men. The result of this research has been preliminary conclusions that there are "toxic" aspects of or a "dark side" to traditional masculinity [33]. Taken to the extreme, "toxic masculinity" refers to an exaggerated set of male traits that promote violence, devalue women and individuals of sexual minority orientations [34]. Based on the culmination of this body of research, it is easy to take an essentialist perspective and conclude that traditional masculinity is always negative. Therefore, it is important to recognize that traditional masculinity per se is not associated with negative mental health outcomes, but the rigid, restrictive, sexist enactment of stereotypical male roles [35].

In a contrarian response to the empirical findings linking traditional masculinity to negative outcomes, some scholars have begun to examine the positive aspects of traditional masculinity [36]. The term "positive masculinity" has been coined in order to refer to qualities of traditional masculine roles that are positive and can be used to better the lives of men. Research on positive masculinity is scarce and primarily theoretical. The primary theoretical assertion behind positive masculinity is that traditional masculinity norms such as self-reliance, risk-taking behaviors, and a male relational style can be more positive than previously thought [36]. These behaviors can be used to promote an understanding of men that is not based on a comparison using the standards by which females are measured. Rather, Kiselica and Englar-Carlson [37] assert that traditionally oriented men possess a list of strengths that should be recognized and valued as a starting point to interventions: male relational style, male ways of caring, self-reliance, generative fathering, fraternal organizations of service, worker–provider tradition, male courage, daring and risk taking, humor, and heroism.

More currently, scholars and health practitioners are beginning to merge the different threads in the scholarship by recognizing the negative outcomes associated with the toxic aspects of masculinity and acknowledging the positive aspects of traditional masculinity. The next step has been to encourage men to be flexible with their roles and take a more balanced perspective to masculine norm adoption. For example, men are choosing to be "stay-at-home dads" at an increasing rate and finding satisfaction with this nontraditional role in their families [38]. The assumption is that many men may improve their health and the health of their families and communities if they adhere less rigidly to traditional masculinity norms and feel free to assume nontraditional roles and identities.

"Possible masculinity" is a recently developed construct that, like positive masculinity, tries to shed a more positive light on men's attitudes, norms, and behaviors [39]. However, possible masculinity does not universally endorse the positive aspects of traditional masculinity and tries to align men's behaviors to what society currently needs from men to promote healthy communities (e.g., nonviolent conflict resolution, appropriate emotional expression, fostering of egalitarian relationships). To start, possible masculinity asks men to identify their aspirational goals and encourages men to aspire to the ideal self that they establish. In other words, possible masculinity, in theory, is different for each individual man and reflects his self-defined characteristics of a man that contribute to the well-being of himself and others. Further, possible masculinity has room for both traditional and nontraditional aspects of masculinity in a man's aspirational self. By having future goals in mind, men have been shown to be better prepared to identify obstacles to their goals and what is necessary to overcome these obstacles [39]. This in turn can be applied to men's psychological health because men are encouraged to take responsibility for their actions and aspire to a more positive ideal self. Research on possible masculinity is nascent as the concept arose from counseling men, but the construct has potential to help men lead healthier lives.

SHIFTING CLINICAL ORIENTATIONS AND PRACTICES

A troubling outcome of men's socialization is that many men do not seek help from health professionals for their concerns. Many men are less likely to seek psychological help for fear of appearing emotionally unstable, vulnerable, and weak when they were taught to be strong and handle their problems independently. In a study focused on men and depression, researchers found many reasons why men do not seek help for depression such as the need to look good "at all costs" and to maintain the appearance of being in control [40]. However, men's socialization only tells half of the story. The other half of men's lack of help seeking stems from a lack of training, responsiveness, and cultural sensitivity from health practitioners despite literature that details the study of men and masculinity as an important multicultural competency [41,42]. As a result, health practitioners can approach men in an awkward, ineffective manner, which may help explain why men have been found to spend less time with their physicians; receive less overall information, explanations, and advice about health care issues; and receive less instruction on how to conduct self-examinations [43].

The proceeding research that will be outlined in this section has been conducted with mental health professionals in mind; however, the findings and recommendations have practical implications for all health professionals who provide clinical services to men. One of the first characteristics health practitioners notice about their patients is gender, which comes with underlying assumptions and expectations [44]. Robertson and Fitzgerald [45] found that mental health therapists viewed their patients as more pathological if they did not conform to traditional and stereotyped gender norms. Counselor's initial assessment with a group of female and male patients revealed that women were more likely to be described as "vulnerable," and male patients were often portrayed as "stuck" and "difficult," which perhaps illustrates gender stereotyping in therapeutic interactions [44].

Although not always the case, the practitioner's gender may factor into biases and assumptions that arise in the treatment of male patients. Some research has found that female counselors are more likely to emphasize the emotional expression of male patients, compared to male counselors [44]. The emphasis on emotions may be incongruent with many men, especially men who have been socialized to be stoic and would typically avoid mental health interventions because of the perception that counseling is all about talking about feelings. Holly Sweet [46], a female psychologist in private practice, has written that female counselors must be mindful of the values of therapy, such as connecting with another and being emotionally open and expressive because these values and expectations put males at a disadvantage when entering therapy. Sweet continued by making two important recommendations for female practitioners that work with male patients. First, female counselors should become aware of male gender role socialization and the challenges men face, which would reduce negative interactions with male patients in health interventions [46]. Second, female practitioners should increase their self-awareness of how their personal gender norms may minimize their ability to be sympathetic and understanding of male issues.

Male health practitioners have also been found to have biases in their interventions with male patients. For example, male counselors have been found to be more likely to have empathy for male patients who express emotions that are typical of male roles (e.g., anger) while reporting negative attitudes toward male patients that expressed non-stereotypical emotions (e.g., sadness) [47]. In addition, Cottone et al. [48] found that male patients paired with male therapists were less likely to continue treatment after the initial intake, suggesting that there was some aspect of the help-seeking experience and/or gender dyad that influenced treatment duration. Male practitioners are susceptible to the same socialization of their male patients, which may result in avoiding appropriate emotional exploration or reinforcing dissatisfying, straining, or stressful masculine roles [49].

Overall, the gender of the health practitioner is not as important as the health practitioner's self-awareness of their gender socialization, awareness of how their gender socialization may affect their interventions with male patients, and commitment to offer services that are congruent with the diversity of male patients. In the counseling psychology literature, treatment outcomes for male patients (i.e., psychological well-being) have been shown to be contingent upon the gender competence of the practitioner [50]. It is helpful for both male and female practitioners to think about ways in which gender roles have impacted their lives in order to gain a greater appreciation for the dynamic ways in which gender may play a role in a male patient's presenting concerns [41,46]. Awareness of male gender norms and expectations allows for a less biased interpretation of the patient and decreases the likelihood of the health practitioner reenacting negative interpersonal experiences the male patient has experienced previously.

Researchers have begun to identify ways to engage men in help seeking. In a study focused on men and depression, researchers found that the best way to help men who are depressed but unwilling to seek help is through redefining help seeking in male-oriented language [51]. Brochures about mental health distributed to men used terms such as "mental health consultant" instead of counselor and "strategy for attacking," rather than therapy. They also reframed counseling as a team effort and cost-effective and help seeking as a sign of strength rather than weakness. The results of this study found that men had improved attitudes about help seeking [51]. Efforts such as these highlight the need to shift the orientation of clinical practice. Clinical efforts should be congruent with men's attitudes, beliefs, and behaviors of masculinity and a health setting should be a welcoming place for men to have their health concerns addressed in a careful, male-friendly manner. In a recent literature review of masculinity and men's health, Garfield et al. [52] posit a set of male-friendly recommendations for health practitioners: (1) provide a welcoming health setting such as having men's interest magazines and Internet in the waiting room, (2) promote service use by having extended evening hours and conducting outreach workshops at male gathering places, and (3) enhance clinician–patient interactions by encouraging help seeking, educating about self-examinations, and being conscientious about spending an appropriate amount of time with male patients.

Implementation of male-friendly practices can enhance a practitioner's clinical effectiveness with male patients. In particular, clinical efforts with men would benefit from beginning with and focusing on strengths instead deficits [37]. An ideal model to approaching men's health is integrative and accounts for positive masculinity as well as possible masculinity and all other self-defined strengths of men. It is necessary to shift away from a deficit model of clinical intervention and toward a strength-based approach. A strength-based approach is more encouraging to men seeking help for mental health concerns and allows health practitioners to convey a sense of respect, welcome, and congruence with their male patients. In order to enhance health practitioners'

competence and effectiveness in their interventions with men, an outline of a strength-based approach in conjunction with an overview of male socialization is provided.

STRENGTH-BASED APPROACHES: A BRIEF REVIEW OF THE LITERATURE

A strength-based approach to mental health interventions began to emerge in the 1990s and overlaps with positive psychology [53]. Strength-based approaches and positive psychology interventions are a shift from a sole focus on problems and weaknesses to treatment methods and intentional activities that aim to enhance strengths, positive feelings, behaviors, and cognitions [54,55]. Using a strength-based approach involves considering and examining strengths, resources, and other positives of the patient throughout the treatment process, although this does not exclude problems from being discussed as well [56,57]. Rather, strengths and problems should be understood in an integrated manner that provides a holistic conceptualization of the patient [57]. In fact, strength-based approaches are considered easy to integrate with many other treatment approaches and practitioner worldviews [54,57,58].

The major differentiation between a strength-based approach and other approaches is that in a strength-based approach, strengths are seen as what allows the patient to make positive changes [58]. Remedial interventions often require patients to do something new while a strength-based approach aims to capitalize on things that patients are already doing well that can contribute to improvements and well-being [56]. The exploration and enhancement of strengths, resources, and assets foster resiliency, which may allow for the prevention of future problems rather than remediation and management of existing problems [59]. Yet, health practitioners working from different approaches with patients may already rely upon patient strengths to facilitate recovery even if they do not discuss or emphasize strengths [58]. Viewing a patient from a strength-based focus creates an optimistic conceptualization among health practitioners, which may facilitate a better patient–practitioner relationship and enhance patient motivation to change [56,58,59]. In a recent meta-analysis, Sin and Lymbomirsky [55] found strong empirical support for a wide range of positive psychology interventions that enhance well-being and decrease depressive symptoms. Examples of interventions included setting positive goals, personal strengths activities, and goal training to name just a few [55].

STRENGTH-BASED APPROACHES AND LIFESTYLE MEDICINE

Health practitioners aligning with a lifestyle medicine approach to interventions may find a strength-based approach to be a good fit with their clinical practice and professional identity. Unlike traditional medicine that works from a remedial medical model and heavily relies on medications for treatment, lifestyle medicine aims to prevent the problem from happening by emphasizing changing the behavior of the individual. This is done through the use of lifestyle changes such as exercising, quitting smoking, and changing the diet of the patient. Behavioral changes such as eating healthy, exercising, and watching intake of sodium can lower blood pressure and in turn prevent medical problems [60].

The focus on prevention is what links lifestyle medicine and strength-based approaches to men's health. Both lifestyle medicine and strength-based approaches first assess what the problem is and then use the individual's strengths and resources to tackle the problem [60]. Similar to strength-based approaches, lifestyle medicine uses the individual's strength of being able to change and adapt as a preventative measure against the development of medical problems [61]. By using the individual's strengths, both practices use something that is already available and inexpensive. However, due to the fact that both lifestyle medicine and the strength-based approach are reliant on the individual and not medication, they may take time to become effective. Lowering blood pressure without medication through dietary changes and exercise may take months, but in the long run it costs the individual less in medication and has more global beneficial impact on the individual's health [62]. By focusing on changing behavior to better the health of an individual, lifestyle medicine poses the risk of fewer negative side effects than many medications [63]. Both lifestyle medicine and strength-based approaches value educating and empowering the patient through transparent clinical care. An informed patient is better equipped to deal with medical, psychological, physical, and mental health problems that may arise.

MEN AND MASCULINITY STRENGTH-BASED APPROACH

The following section provides a case description of a fictional male patient. The steps of the strength-based approach and its application to the case example is provided in order to detail a concrete example for health practitioners on how to use the approach in their clinical practice with men. Though this case describes a mental health encounter, the steps and advice contained within are equally applicable for general medical issues. However, the men and masculinity strength-based approach (MMSBA) should not be considered as the first line of treatment for patients with more severe psychopathology such as bipolar disorder, posttraumatic stress disorder, or schizophrenia, which require more specialized services. However, the MMSBA can be integrated with treatments that address severe psychopathology.

CASE DESCRIPTION

Mike is a 32-year-old man who presents for treatment on his own accord because he is concerned that he has been having outbursts of anger lately. He feels out of control of these outbursts and this is unsettling to him. Mike reports that these

outbursts started about 5 weeks ago when he was passed over for a promotion at his job where he works at a factory. Mike reports dissatisfaction with his job and the desire for a better paying job so that he can support his family. Mike is married and has two children. Mike's daughter is 2 years old and his son is 6 years old. Currently, his wife is a paralegal and makes more money than Mike.

Mike was raised in a family with a stay-at-home mother and a father who was a factory worker. In Mike's lower middle-class neighborhood, higher education was viewed suspiciously and the general sentiment was that people went on to higher education to avoid doing "real work." Mike appears to have retained some of this sentiment, and he never pursued education beyond high school. Mike does express the desire to have a "better job," but he does not have a clear idea of what this job would be. Mike expresses that he is "fine with my wife working because it is important to her to have a career, but I'd rather the family not be financially dependent upon her working."

Mike coaches a soccer team in the same league that his son plays in, but not his son's team. Mike explains that this is because he wants to be involved with his son's activities without the risk of pressuring his son or pushing him too hard. Mike plays friendly games of soccer in the backyard with his son but refrains from trying to coach him during these games. Mike enjoys taking his daughter for walks and "making music" with her on toy instruments. Currently, Mike's son is in kindergarten and Mike's daughter attends an early preschool program 2 days a week and stays at her maternal grandparent's house during the other times when Mike and his wife are working.

Mike describes his relationship with his wife as good except for the recent outbursts of anger. Mike and his wife communicate well about their children and relationship, though Mike says that he has some difficulty talking to his wife about frustrations at work. Mike and his wife share household tasks according to their preference for doing certain tasks and what they have decided are fair arrangements. For example, Mike's wife enjoys cooking and Mike does not, so Mike's wife makes meals and Mike does kitchen chores such as washing dishes. Mike takes on the responsibility of bath time for the children, and Mike's wife takes the kids to school and grandparents' house and picks them up in the afternoon. In addition to activities with his family, Mike reports that he enjoys listening to music and attending concerts, hiking, and traveling.

OVERVIEW AND APPLICATION OF MMSBA

There are 10 steps to our strength-based approach with men separated into three phases. It is important to note that the steps do not need to be followed in the exact order set forth in this chapter; rather, there are times to "retrace" to previous steps or to implement overlapping steps at one intervention point. The steps are likely to be implemented over approximately—two to four sessions. A brief listing and overview of the steps are included in Table 29.2.

TABLE 29.2
Overview of the Men and Masculinity Strength-Based Approach

Phase 1: Steps 1–3
Focuses on establishment of a rapport and a healthy clinical relationship with the patient
- Step 1—Establish rapport with the patient.
- Step 2—Give the patient the opportunity to discuss what has brought him to therapy.
- Step 3—Discuss the strengths and resources the patient has.

Phase 2: Steps 4–6
Focuses on identification of patient's strengths and integration of new psychology of men and masculinity
- Step 4—Help the patient identify his strengths.
- Step 5—Assess the patient's level of gender role adherence while providing the patient with necessary information.
- Step 6—Introduce possible masculinity into therapy.

Phase 3: Steps 7–10
Focuses on helping the patient engage in new behaviors and move toward concrete behavioral change
- Step 7—Work with the patient to create an action plan.
- Step 8—Discuss potential barriers to implementation of the action plan.
- Step 9—Discuss strengths and resources the patient has that can help overcome barriers to the action plan.
- Step 10—Schedule a follow-up meeting with the patient to discuss patient's progress with the action plan.

Phase 1: Establishing Patient–Practitioner Relationship

Phase 1 is the initial phase. The goals of phase 1 are to establish a healthy clinical relationship, identify the patient's presenting concerns, and to identify the patient's strengths and resources. Step 1 is establishing rapport and a healthy, clinical relationship with the patient. A clinical relationship is built on trust and safety while serving as the foundation for the following intervention steps. Utilization of basic helping skills in this step such as active listening, summarizing, clarifying, paraphrasing the patient's disclosures, and ensuring that the patient feels heard and understood are useful. It is also important that the practitioner maintains a nonjudgmental attitude toward the patient and exhibits genuineness [64].

With Mike, it may also be helpful to draw from research that suggests that men respond more to cognitive-oriented interventions in the initial stages of treatment instead of emotion-based interventions [65]. It is important to validate Mike's help seeking and reframe help seeking as a strength instead of a sign of weakness. Specifically, a practitioner can say, "I'm glad you came to consult with me today Mike. It's a real sign of strength that you noticed something is off with you and you want to fix it." Asking Mike about soccer, perhaps if he is a fan of a local Major League Soccer team or a World Cup team, could also help build rapport based on his interests in soccer.

Step 2 entails giving the patient an opportunity to discuss his presenting problems. The goal of step 2 is to discuss the patient's presenting problems while addressing resistance or defensiveness to talking about strengths [66]. People typically

expect that mental health interventions involve discussing problems and may be resistant to talking about strengths without first expressing their problems and concerns. The approach assumes that talking about strengths first would be confusing to patients and may lead to resistance and/or defensiveness from patients. When meeting with Mike, engage in an open discussion about his anger. Acknowledge that outbursts of anger are troubling, which validates his concerns. As a practitioner, you can also explore the anger outbursts in more detail by asking some open-ended questions such as "what triggers the outbursts of anger?" "Have you had difficulty with anger in the past?" "What do you do when you're angry (e.g., yell, punch a wall, berate yourself)?" These questions help to assess history with the problem, current coping mechanisms, and common patterns and antecedents to the problem. In addition to gathering pertinent information about the problem, the questions foster insight and reflection from the patient.

Mike reported that his anger is mostly triggered by "issues at work," primarily that he was passed over for a promotion that he felt he earned. Mike rarely expresses anger at work, but on a few rare occasions, he has snapped at coworkers, which has resulted in complaints to management and social avoidance from coworkers. In general, Mike described "sucking things up, finishing the day" and then "blowing up at home, later in the day." Mike described himself as normally quiet, having a good sense of humor, outgoing and never really angry, not like he is now. Mike admitted that he does not cope well with this new anger, which is why he is seeking help. He has punched his bedroom wall, making —two to three holes. He reports yelling at his wife as well. Mike has insight that this is not healthy for himself or his relationship with his wife.

Step 3 is the important process of shifting the orientation away from the patient's presenting concerns (i.e., their deficits, problems) to strengths. The goal of step 3 is to educate the patient about the process of the strength-based approach and answer any questions from patients. A critical part of the successful implementation of this step is being very transparent. It is important to tell the patient that you are going to tell them about how you work with patients and that your approach involves focusing on the strengths of patients. Practitioners should tell patients why focusing on strengths is important and integral to your approach. For example, a practitioner can say, "I work with all kinds of people, with all kinds of problems. I find that a common link between people and solutions to their problems is their strengths. Therefore, I spend a lot of time with patients identifying strengths and figuring out how patients can use their strengths in ways that lead to health and well-being." Practitioners should invite questions from patients about the strength-based approach and also be prepared to clarify any patient confusion.

Phase 2: Shifting the Clinical Focus to Strengths and Men's Issues

Phase 2 is the second phase of the steps of the strength-based approach. The goals of phase 2 are to shift the focus onto patient's strengths and resources and to integrate concepts from the new psychology of men into the process. Phases 1 and 2 could be completed in —one to two sessions depending on the pace and clinical judgment of the health practitioner. Additional time may be needed if formal assessments are utilized, which would require administering, scoring, and discussing the results with the patient. Discussing formal assessments should not be rushed.

Step 4 is strength identification. The goal of this step is to have the patient identify their own strengths. However, patients may not be comfortable talking about their strengths, or may be clouded by their mental health concern (e.g., a depressed patient may be less inclined to discuss their strengths because of their depression). In these instances, a practitioner can start the process by taking a more active role in identifying patient strengths. The identification of patient strengths can be a very informal or formal process. For example, a practitioner can simply ask the patient, "What are your strengths?" or "Tell me all the things that you do really well." Strength identification can also utilize formal measures and tests. For example, Dr. Martin Seligman from the University of Pennsylvania, the founder of the current positive psychology movement, operates a free website [67]. The website hosts several measures. A specific assessment, the Brief Strengths Test, measures 24 character strengths of an individual. The Brief Strengths Test is self-administered and takes approximately 5–15 min to complete. The output of the Brief Strengths Test provides the test taker with a ranking of their strengths.

When asked about his strengths in an informal manner, Mike answered that he is a hard worker, family man, cares about his children, athletic and fit, knows his way around a factory, and is a loving husband. The practitioner can identify additional strengths, such as that Mike does not push his son too hard in athletics but maintains involvement through coaching and practicing with his son. In addition to individual strengths, a practitioner should ask Mike about community and cultural strengths. Mike discussed having supportive parents and that he belongs to a group of "soccer dads" who all coach youth soccer, play a weekly pickup game together, and meet after the game at a local coffee shop to talk about life, family, children, work, and sports. Mike brightened up when he discussed the "soccer dads" and described them all as "good guys, good men." When asked more about this group, Mike described that the group can play soccer together and "bust each other's chops" but also discuss "really important things." It appeared that Mike was implying that this group of men could be vulnerable with each other and that this was refreshing and supportive. When this interpretation was presented to Mike, he agreed and added, "At the factory, it's all business, it is actually work and my mentality. Have to kind of keep a poker face all day. With the soccer guys, I can let my guard down, relax more."

After Mike discusses both his individual and community strengths, the practitioner validates those strengths and emphasizes the importance of Mike recognizing his strengths. This may also be a good time to note any discrepancies

between Mike's strengths and presenting problems (i.e., anger outbursts). Noting discrepancies is a clinical judgment based on the practitioner's assessment of the therapeutic relationship and appropriate timing of such an intervention. For example, a practitioner could say, "Ok Mike, I heard you say at the beginning of our time together that you get angry and you take out your anger on your wife by yelling at her even though she doesn't necessarily deserve it. Yet, I also heard you describe yourself as a family man and good husband. There seems to be a discrepancy here." Noting a discrepancy may lead to further exploration of the problems and strengths as well as helping Mike see how he can use his strengths of being a good husband and family man to change his presenting problems of angry outbursts. In other words, Mike should be aware that a good husband does not yell at his wife. The strength that is present in Mike but needs to be enhanced is being a good husband.

Step 5 entails assessing the patient's level of gender role adherence while providing the patient with necessary information. An additional goal of step 5 is to educate the patient about positive masculinity. This step is significant because many health professionals are not trained in the new psychology of men and masculinity, but assessing a man's gender role conflict and masculine identity is a cultural competency that will nourish the treatment process. Conceptualizing men's mental health through gender role socialization, gender norms, and masculinity contributes to a greater understanding of the etiology of mental health concerns. Similar to strength identification in step 4, assessment of masculine identity and gender role conflict can be done in an informal or formal manner.

Informally, a practitioner can ask Mike, "Some men don't like to ask for directions and are kind of stoic. Other men aren't like that, they don't mind wearing pink shirts and are less macho. How would you describe yourself as a man?" In response to this question, Mike reported that he was raised in a traditional home and that his father taught him to be tough, work hard, and to look other men in the eye and give them a firm handshake. Yet, he makes a point to show affection toward his children, stating that "they know that I love them." However, Mike also reported that he is not "too much of a touchy, feeling guy" but that his meetings with his soccer dads often end in a "group hug kind of thing." Asked to clarify, Mike described that all of the soccer dads wrap up their time at the coffee shop by going around and giving "man hugs" to each other. Mike further explained, "I guess it's situational for me. At work, in the factory, I'm gruff, stoic, and tough. That's how I have to be there. I guess that's traditional masculinity, more macho, but everyone acts like that there. But at home, with my kids, I hug and kiss them, tell them that I love them. I get lost all of the time, I have to ask for directions or I wouldn't get anywhere. And with my soccer friends, we are more emotional with each other, we give each other hugs. My dad would never do with his friends, but I feel comfortable doing that."

Overall, Mike was articulate in describing his masculinity identity and the complexity involved in describing his identity. However, more formal assessments may aid men who are less articulate or do not have a high level of insight. A useful assessment text for masculinity is the Conformity to Masculine Norms Inventory (CMNI) [31], which is a 94-item measure with 11 subscales that represent distinct masculine norms that are predominant in the United States. The 11 subscales are Winning, Emotional Control, Risk Taking, Violence, Dominance, Play Boy, Self-Reliance, Primacy of Work, Power Over Women, Disdain for Homosexuals, and Pursuit of Status. The scale is estimated to take about 10–15 min to complete. The items are answered on a 4-point scale (0 = strongly disagree; 3 = strongly disagree), with a calculated total score and scores for each subscale. The transformed total score (mean = 50; SD = 10) produces four categorical ranges of extreme conformity (above 60), moderate conformity (50–60), moderate nonconformity (40–49), and extreme nonconformity (39 and below). The total score can be used as an overall assessment and the subscales can be mined for detailed exploration. A clinical benefit of the CMNI is that it measures masculinity norms, which can then be explored with the patient to determine if conforming to the endorsed norms is healthy and positive for the patient or harmful and negative to the patient. Potential stress from not conforming to masculine norms can be explored as well [31].

The CMNI taps into masculinity roles and norms. Therefore, step 5 may also be a good place for psychoeducation about male socialization in relation to Mike's presenting concerns. For example, Mike is expressing anger, which is considered one of the few acceptable emotions for men to express. Mike may be feeling depressed, anxious, or shame because of work issues, but men are socialized to hide those emotions. Mike identified the antecedent of his anger outbursts at work as the lack of a promotion that he felt he deserved. Men are socialized to compete and succeed, especially in the business/career domain of life. Thus, Mike may perceive a lack of promotion as failing to succeed in an area that he is expected to succeed in. Taken deeper, Mike may feel that he is failing as a man if he is not able to achieve at work. Mike learned from his parents that the father works and is the "breadwinner" and the mother stays at home and cares for children. Mike and his wife appear more coparental and are in a dual career family structure, but Mike may be feeling ashamed or devalued that his wife makes more money than him and that his identity as a breadwinner is diminished in his family.

Male socialization does not necessarily lead to pathology. Introducing the concept of positive masculinity may allow him to view traditional masculinity as a source of strength. A practitioner could say, "Some men have difficulty being macho all the time. There can be positives and strengths found in traditional masculinity. What aspects of traditional masculinity are of value to you?" With Mike, it is clear that he exhibits generative fathering (e.g., actively involved in children's lives), males relational styles (e.g., soccer with other dads), and worker/provider tradition [37]. The practitioner should validate these positive aspects of traditional

masculinity and perhaps ask how those strengths can help to fix the angry outbursts that Mike has reported.

The goal of step 6 is to help the patient engage in possible masculinity by identifying goals, aspirations, and addressing any incongruence between the patient's adherence to male roles and aspirational self. In this step, there is a shift toward being aware of their possible masculinity as many men feel restricted by their gender role socialization. It is important to note that possible masculinity can be explored with men who fall along the masculine ideology continuum.

Possible masculinity is a broader concept that also tries to help men identify strengths in masculinity. A practitioner works from this broad stance, asking a man, "What kind of man do you want to be in the future? What aspirations and ideals are you striving to achieve as a man?" The key assumption with possible masculinity is that there is incongruence between how men are acting in the present versus how men want to be in the future. The typical pattern of incongruence, especially in clinical settings, is that men are dissatisfied with their current actions and have more admirable and positive future goals for themselves. One of the goals of possible masculinity is to facilitate men taking responsibility for the incongruence.

Mike has been able to identify his strengths as well as other positive aspects of traditional masculinity and the socialization that he is familiar with from his parents. Yet, Mike also recognizes that the angry outbursts "are not me, not who I want to be." When asked what kind of man that he wants to be, Mike explained, "I want to be a true leader, I want to handle my emotions and anger in a direct manner. I want to be an employee at work that can be counted on not just to do my job but to train others, manage others, lead a team. I also want to be a guy that can express my emotions in an appropriate manner and to not take them out on my wife." The next possible masculinity question is to ask Mike what is keeping him from achieving those ideals and goals. The intent of the question is to have Mike look inward, take responsibility, and express an internal locus of control and change.

Phase 3: Implementing an Action Plan

Phase 3 is the third and final phase of the MMSBA. The goal of phase 3 is to help the patient engage in new behaviors and move toward behavioral change. Steps 7–9 of phase 3 are likely to require one session. Phase 3 and the corresponding steps (7–10) are aligned with a behavioral approach to interventions, with a debt owed to scholarship written on the behavioral activation technique [68]. A key theoretical underpinning of behavioral activation is that a negative mood is related to disengagement from positive reinforcement [69]. Therefore, increasing positive moods and emotions entails re-engaging behaviors that increase positive reinforcement for the patient [70].

Step 7 is action planning. The action plan should focus on having the patient identify concrete behaviors to engage in that will enhance their current strengths, be a source of positive reinforcement, and help them meet their future-oriented goals identified in step 6. It is important for the practitioner to allow the patient to arrive at their own action items while also monitoring to ensure that the action items are indeed behaviors.

In order to introduce this important step to Mike, the practitioner is advised to discuss the importance of transforming thoughts, feelings, and goals into a plan that can be implemented. For example, a practitioner can say, "Mike, you have done a great job of seeking help, articulating your concerns, engaging in self-reflection on your strengths and the type of man you want to become. The next step is to help you to take some concrete behaviors that will help you to reach your goals. It is important to engage in new behaviors, not just talk about engaging in new behaviors." The health practitioner can then ask Mike what behaviors would he like to exhibit in the next week or two that will help him become more congruent with the type of man he wants to be. It is important to set an actual date for the completion of the behaviors and to have Mike schedule the behaviors.

Mike stated that he has two behaviors that he wants to implement in the next week. First, Mike reported that he wants to schedule a meeting with his boss at work in order to discuss his future at the company and how he can be better positioned in the future when promotions are available. The second behavior that Mike wants to engage in is to apologize to his wife for his angry outbursts and to communicate to her that his outbursts, although directed at her, are not caused by her but by his inability to manage his anger related to work issues and stress. Mike reported that he can talk to his boss after the mid-week department meeting and that he can talk to his wife tonight after the children go to bed. Both times and days were recorded on the action plan: Wednesday, 11:00 a.m. and Monday, 9:00 p.m., respectively. Mike's behavioral plan appears to be appropriate; therefore, the health practitioner should ask Mike what strengths that he can draw upon to help him exhibit these behaviors. Mike reported that his strengths of being a hard worker and loving husband (as identified in step 4) will help him talk to his boss and wife. As a practitioner, it is helpful to validate these strengths while also identifying other strengths such as using his ability to be emotionally open with his soccer dads group to be emotionally vulnerable with his wife. Second, the health practitioner can explore with Mike what new strengths may be developed as the result of him implementing his new plan. Mike explained that he may develop assertiveness skills as he talks to his boss and the strengths of open, honest communication as he talks with his wife.

The goal of step 8 is to identify potential barriers to the execution of the action plan. Therefore, the health practitioner and patient brainstorm potential barriers. Many barriers often prevent patients from taking the needed, yet difficult step of implementing their plan. Exploring potential barriers is a proactive step that helps patients gain awareness of the change process. Specifically related to men, gender socialization often entails pressure, punishment, and reinforcement

that maintain unhealthy and destructive behavior. Therefore, health practitioners are encouraged to ask their male patients about any perceived social and cultural barriers related to being a man that would impede the action plan. A health practitioner could ask a male patient, "I know men face a great deal of pressure to conform to a certain idea of manhood. What messages about masculinity and manhood have you noticed that may keep you from following through on your action plan?"

In addition to social and cultural barriers, men often have self-imposed barriers to positive change. Previous experience with exploring possible masculinity with male patients resulted in patients regularly taking responsibility for not reaching their aspirational goals of manhood. This represents a significant shift as many men often become defensive or deflect responsibility when prompted to identify their negative behavior and consider making changes in their lives. A health practitioner should view a man taking responsibility for the role they play in holding themselves back as a positive moment in the intervention.

Mike was asked about potential barriers and he quickly responded that he is a very stubborn person. As a result, admitting a mistake to his wife will be difficult. Mike also acknowledged that he is fearful and anxious about approaching his boss at work. Mike feared that he could get fired or will "say the wrong things." Mike's fears are valid and the health practitioner should review the pros and cons to Mike talking to his boss in order for him to make an informed decision of sound judgment.

In response to the question concerning masculinity barriers, Mike reported that talking to his boss about his future with the company will be a big departure from other men at the factory and what his father taught him. Mike explained that men should let the quality of their work do the talking, yet he was also raised to speak up for himself and to not get walked over. Therefore, Mike expressed conflicting messages about masculinity: should he stay quiet and hope that his boss recognizes his work or should he assert himself and alert his boss to the merits of his work? Mike should ultimately arrive at the answer to this question with the health practitioner facilitating exploration rather than offering direct advice.

Step 9 provides a complement to step 8 by asking the patient to brainstorm potential supports and any additional strengths that will help to overcome the identified barriers in step 8. The goal of step 9 includes identifying supports as well as an explicit conversation about how to access those supports. Given men's lack of help seeking, step 9 is a good opportunity to reinforce the idea that help seeking is a sign of strength, not weakness, and that it is okay for men to seek additional support. A simple question to ask a male patient while implementing step 9 is "What or who will help you overcome those barriers?"

When these questions were asked of Mike, Mike reported that he can talk to his wife more openly and comfortably when they are engaged in an activity together, such as walking. Mike described that he will arrange for a babysitter and ask his wife to go for a walk tonight after the children go to bed. He believes that doing something active helps him to open up more rather than just sitting and talking face to face. In terms of talking with his boss, Mike reported that he needs to develop a script on what he wants to communicate to his boss instead of speaking off the cuff. In particular, Mike wants to clearly communicate his contributions to the company and his desire to assume more of a leadership position. Mike also wanted to obtain feedback from his boss on his current performance and what he needs to do in order to earn a promotion. Mike reported that he will feel more confident if he practices the script before the meeting. Mike also stated that he has a good friend from the soccer dads group who is in the business field and would be a great sounding board for Mike to practice the script with and receive some feedback. Mike affirmed that he would seek the help of this friend. The health practitioner can validate and encourage Mike's use of the identified supports.

Step 10 is the final step and involves scheduling and having a follow-up meeting with the patient, with the goal of assessing how the patient progressed or is progressing through the action plan. To recap, steps 1–6 are expected to take about 1–2 sessions while steps 7–9 are expected to take about 1 session. Yet, some patients may work quickly, thus only needing 1 session to get through steps 1–9. Therefore, 1–3 sessions have occurred before the follow-up meeting. The follow-up meeting is intended to check-in with the patients about their progress implementing the action plan. A simple way to start this meeting is to ask the patients if they were able to do the behaviors that they listed on their action plan. A patient could answer with an array of answers, ranging from "yes, I completed the action plan" to "no, I avoided doing all of the behaviors on the action plan." Based on the patient's progress, the follow-up meeting can serve additional purposes. For patients you completed the plan, the follow-up meeting can be used to offer praise and positive reinforcement as well as to assess how the implementation of the plan went for the patient. For example, a health practitioner can say, "wow, that is great that you completed the plan. How did everything go?" For patients who avoided some or all of the plan, assessing what prevented them from doing so is appropriate. It is important not to shame patients or make them feel like they failed. Rather, it is valuable information for future interventions if the patient does not complete the action plan. The follow-up meeting can serve as a point of reevaluation, further exploration, and a recommitment to action and progress. The health practitioner can help patients discuss how the steps in this model can be used in the future to manage problems.

Mike returned for the follow-up meeting. When asked about his progress, Mike reported that he had a mixed bag of results. First, Mike explained that he could not find a babysitter and therefore could not go for a walk with his wife to apologize on the scheduled day. Instead, Mike waited until the weekend when the children were with his in-laws for the afternoon. Mike reported that he was very nervous and talked

about everything else (e.g., the weather, soccer) before finally getting around to apologizing to his wife. Mike expressed relief that he finally was able to apologize and that his wife accepted his apology. At this point, a health practitioner can offer praise and positive reinforcement with Mike, such as "great job Mike, I am glad you took this big risk and things worked out!"

Mike's face shifted to a look of embarrassment when asked if he talked with his boss. Mike reported that he did not talk to his boss as his anxiety increased and his fears of losing his job acted as barriers. The health practitioner should empathize with the difficulty of the task, "I understand that it is a very difficult thing to do, talking with your boss. It is a big risk." The health practitioner and Mike can try several new directions in the intervention. For example, Mike can set a new, intermediate goal to lead up to the previous bigger goal of talking to his boss. Breaking the big goal into smaller tasks may help Mike gradually build his confidence and decrease his anxiety and fears. Starting with drafting the script may be a good intermediate goal to focus on first. Mike and the health practitioner can also reexamine the pros and cons of the original task. Perhaps, Mike has concluded that the cons and the risks of possibly losing his job are too high and he wants to drop the task from the action plan. On the other hand, Mike may recognize that the pros of asserting himself and dealing with the work problem that is at the root of the anger outbursts outweigh the cons. At this point in the intervention, the health practitioner can remind Mike of the connection between the goal and his presenting concerns of anger by asking, "You seemed to have a lot of anger related to work, your boss, and being passed over for a promotion. Does not talking to your boss increase or decrease your anger?" The clinical assumption is that Mike's anger is increased by not talking to his boss and that talking to his boss, despite the risks, will help him manage his anger more positively. Finally, the follow-up meeting can re-explore how Mike's strengths can help him in this process or what are some new strengths that he needs to develop to help facilitate meeting his goals. Mike may need to schedule additional appointments or require a referral to a more appropriate health provider.

CONCLUSIONS

With the new surge in research focusing on masculinity, health practitioners are called upon to utilize this scholarship to better understand the positive and negative effects of male gender socialization, norms, and roles to men's health and well-being. Accounting for gender role socialization, gender norms, and masculinity contributes to a more thorough conceptualization of men's mental health concerns and more efficacious interventions. Masculinity is a changing construct dependent upon the current social and cultural norms, expectations, attitudes, and behaviors. Although the dominant (i.e., hegemonic) masculinity expression in the United States has historically been to value strength, toughness, competitiveness, success, stoicism and men as breadwinners, shifts seem to be occurring. Some men are emphasizing equal participation in household tasks and many fathers are striving to be more involved and coparental in childcare [71,72]. Ultimately, health practitioners are encouraged to challenge those norms that detract from positive help seeking and health behaviors among men.

Each particular male patient likely expresses their masculinity differently, with varying effects on their health and well-being [73]. Therefore, starting interventions from a strength-based perspective may allow health practitioners to build a stronger clinical relationship as male patients' unique strengths are recognized and used in the intervention process. Health practitioners need to be comfortable affirming or challenging aspects of predominant and marginal masculinity norms depending on the patient's presenting concerns and treatment goals. Often, health practitioner comfort with the continuum of masculinity expression is enhanced through self-reflection and awareness of one's own assumptions, biases, and beliefs about men, masculinity, and gender roles [39].

Focusing on the culture in which one's masculinity was created and reinforced helps health practitioners to understand the individual differences among many subgroups of men, who may present with additional cultural beliefs about masculinity and gender roles. A strength-based approach is also culturally sensitive as strengths are culturally dependent and defined. Clinicians are encouraged to always question their assumptions of what is considered a strength or weakness, considering what is seen as a strength in one culture may be considered a weakness in another [58,59]. Cultural competency has the potential to frame treatment and conceptualization in terms of deficits such as oppression, victimization, and discrimination [73]. Focusing on strengths is a positive way to integrate culture into interventions without focusing on the aspects of a patient's culture that impact the patient negatively [59]. Rather, patients can discuss culturally specific strengths that have helped them develop a positive identity, buffer against stress, and rise above challenges [59,74].

The MMSBA is a new, integrative model of intervention. The MMSBA takes into account male socialization and puts the focus of intervention on men's strengths rather than deficits. As such, the MMSBA is an exciting and promising approach to mental health interventions with men. Although research is beginning to support the use of strength-based approaches, the MMSBA lacks empirical support. Therefore, using the MMSBA in conjunction with, rather than as a complete replacement for, other empirically supported and evidence-based treatments (e.g., cognitive behavior therapy) is a useful approach. The MMSBA is considered to be most suitable for male patients with such mental health concerns as adjustment issues, adjustment disorders, and moderate psychopathology such as depression and anxiety.

Although the MMSBA was designed with mental health in mind, it is a broad enough approach to apply to other health concerns and lifestyle medical situations. For example, presenting concerns such as initiating an exercise program and eating a healthier diet have been situated within a

gendered context [52]. As a result, health practitioners could easily draw upon the 10 steps of the MMSBA to facilitate the adoption of healthier lifestyle decisions with male patients.

Men's health promotion is important since men are, generally, less interested in self-care and healthy living. A focus on diet is especially important since mens' food choices are traditionally more restricted and less healthy than their female counterparts. In this chapter, we will explore why men are typically disinclined to pursue healthy lifestyles and, in particular, why healthy eating poses such challenges for many men. The role of masculinity will be discussed, since many researchers suggest that gender identity is crucial in understanding mens' (and womens') health practices. We will then proceed to explore some recommendations for enhancing mens' engagement with healthy eating.

MASCULINITY AND MEN'S HEALTH

Men on average die 4 years younger than women, outnumber women in mortality statistics for most major illnesses, and generally lead unhealthier lives (e.g., drink more alcohol, eat less fruit and vegetables, exercise less) in the United Kingdom, United States, and Europe [1–3]. This "crisis" in men's health has attracted a lot of media attention in recent years, with various calls to explain the problem(s) and offer solutions. In the midst of debates about cause and effects, most attention has been directed at "masculinity." As early as 1978, for example, Harrison directly implicated masculinity in his influential paper entitled "Warning, the male sex role may be dangerous to your health," while a later review paper by the leading men's health researcher [4] and activist Will Courtenay in 2000 developed this argument, suggesting that disinterest in healthy living was bound up with masculine identity performance [5]. So, for example, men may be more concerned with appearing tough, independent, and unemotional than considering health advice, with help seeking viewed as weak and emasculating. But what exactly is this thing called masculinity, and how does it affect nutritional behaviors?

Over the years, social scientists have attempted to define and measure masculinity (and femininity). Originally, theorists tied biological sex to gender attributes such that "masculinity" was deemed exclusive to men and femininity tied to women—deviations from this pattern were judged problematic, if not pathological [6]. Later sex role theories, however, disrupted the connection between biological sex and gender such that men and women could display both masculine and feminine attributes. For example, on the Bem Sex Role Inventory (1974), one could score highly on both masculine and feminine dimensions ("androgynous"), low on both ("undifferentiated"), or high on one and low on the other ("sex-typed male/female")—regardless of biological sex [7]. In the past 20 or so years, however, theories of gender have moved on, and we now have a wide-ranging and developing literature on men and masculinity on which we can draw to help us understand men's (un)healthy behaviors.

The most influential and debated theoretical work on masculinity has been generated by Connell and colleagues [8,9], responsible for the term "hegemonic masculinity." Briefly, the concept refers to dominant constructions of masculinity which influence men's identities and practices, including health practices. For example, in most Western cultures men are assumed to be emotionally and physically strong, independent, and prone to risk taking [10]. Such attributes have been associated with unhealthy practices: men are less likely to admit to pain or seek medical advice compared to women, which leads to delays in receiving treatment and often serious health consequences such as advanced cancer or heart disease [11]. Men are also more likely to eat restricted meat-based diets and large portions [12]. While only few men such as celebrated sportsmen or musicians can ever (if at all) attain hegemonic status, all men are "complicit" in supporting hegemonic ideals through their practices, whether it be weight training, promiscuity, or eating unhealthy foods. Connell's analysis also explains that hegemonic masculinity is maintained via practices which oppress women (e.g., domestic violence) and other, "subordinated" and "marginalized" men (e.g., homophobic abuse). Such practices clearly have impact on the health of men, and women.

As a consequence of Connell and colleagues work, most researchers in gender studies now refer to *masculinities* in the plural to suggest many facets, that is, there is no one single masculinity factor which can stand for masculinity once and for all. A quick free association to the term masculinity will undoubtedly throw up many different characteristics, preferences, and roles, such as "strong," "rational," "active," "independent," "achievement oriented," interested

in sport, breadwinner, and leader. But these associated ideals and practices are not simply a matter of individual choice, since masculinities are validated in relation to other people and wider social contexts. For example, it is not enough to believe yourself to be a brave man—this is something that must be demonstrated to others in meaningful situations. In other words, masculinities can be thought as "socially constructed," that is, presented and negotiated during social interaction and subject to prevailing social influences and constraints. For example, a man's capacity to become a modern involved father will in part be limited by work patterns, financial pressures, and community norms about fatherhood. Similarly, a man's inclination toward eating healthier, "feminized" foods such as salad, vegetables, and fruit will be shaped to some extent by gendered expectations emanating from peers, family, and work colleagues.

In addition to being conceptualized as multifaceted and socially embedded, masculinity is conventionally considered to be defined in opposition to femininity. So, if femininity is defined as emotional, masculinity is unemotional or rational; if femininity is defined as weak, masculinity is strong; if femininity is defined as relational/dependent, masculinity is defined as autonomous/self-reliant; and so on. In an early study with male university students on modern masculinity, for example, participants preferred to talk about themselves indirectly, in terms of what they are not, which amounted to a critique of women as neurotic, demanding, and inferior—and a implicit construction of men as rational, relaxed, and superior [13]. However, for men today it is increasingly difficult to ignore changing gender relations and societal forces which, for example, place expectations on men to become healthier, more interested in their appearance, and more emotionally articulate. And so in the realm of health, men are being asked—by media, health services, significant others—to consider what they eat, how much/little exercise they do, their weekly level of alcohol consumption, and so on. It is no longer viable to disregard health concerns since modern societies are so "healthist" [14] that those who refuse to engage in healthy living risk being stigmatized as irrational, immoral, and unfit—we can highlight the critical attitudes to smokers, those deemed clinically obese, and binge drinkers (see also Ref. [15]). Old fashioned definitions of masculinity which rely on an irresponsible, cavalier approach to health are increasingly difficult to sustain, so men are now called upon to reconcile being masculine with being healthy. What research with men has demonstrated here is that men will draw upon a discourse of balance or moderation, a rational position where both health and gender concerns can be accommodated:

> It's like the smoking, I told you about that. I gave up when the second one [baby] was born … I thought I have got to be serious about this and I stopped … eventually. I still like to go on the lash [drinking alcohol] on a Saturday night. You've got to really, I mean you have got to have a good time some time, but not all the time. In moderation, if you know what I mean (Robertson and Williams [16], p. 364).

Robertson [17] articulates this challenge with reference to a dilemma between control and release, a "don't care/should care" dichotomy. This health-aware climate means, of course, that men are now encouraged to reflect on what they eat with a view to making their diets more nutritious—a project which only women (predominantly) have been concerned with until recently.

MEN, FOOD, AND HEALTH

In most Western societies, women have traditionally been socialized into roles and activities revolving around food—shopping, preparation, and distribution to loved ones—which have been linked to conventionally powerful feminized identities such as mother and wife [20,21]. Men, on the other hand, have been designated as consumers of food, ignorant of the cost or nutritious value of food [22,23], and removed from the kitchen environment [24]. As well, women have typically been positioned as knowledgeable about food and interested in healthy diets (albeit informed with feminized ideals of thinness), whereas men have largely been defined in terms of narrow food preferences usually involving red meat and large portions [25]. Indeed, it is only relatively recently that the area of men, food, and health has attracted the attention of academic researchers; traditionally, research on food has centered on women, with a particular focus on body image issues [16].

There are some statistics comparing the sexes on nutrition matters. We know, for example, that men generally consume less fruit, vegetables, and fish than women and eat more high calorie items than women [26]. Other research has found that men are not terribly interested in the health aspects of food and categorize healthy food (e.g., "salad") as insubstantial and tasteless [12]. Whereas women emphasize the notion of dieting and its role in weight loss and body image, men tend to regard food as a means to enhance fitness and strength [25]. Popular mens' magazines such as Men's Health reinforce this image, focusing on meat-based diets for the development of muscular physiques and decrying feminized practices such as vegetarianism and domestic cooking [24]. Indeed, when men have partaken in domestic cooking they are widely perceived as incompetent within this feminized space [27]—although in special circumstances "masculine" cooking is constructed as efficient, sophisticated, and distinctive rather than the messy, mundane, and uninspiring attributions tied to women's cooking [28]. In health promotion contexts though, media features directed at men emphasize the constricted and unhealthy male diet while at the same time ridiculing mens' engagement with healthier diets [29]. Recent work in the United States also suggests that meat eating for men has become more important as a way of affirming masculinity in the midst of "softer" contemporary masculinities which depart from traditional ideals of strength [30]. Taken together, such findings suggest that men's diets are nutrition-poor and place them at risk from serious diet-related diseases [31].

Only relatively recently researchers have begun to investigate men's eating habits, and the picture is more complex than gender stereotypes would suggest. For example, Roos et al. [32] interviewed men from different professional and social class backgrounds and found that while carpenters largely regarded food as fuel and favored meat-centered diets, engineers were interested in aesthetic, taste, and pleasurable aspects of eating and enjoyed a more varied diet. This example underlines the intersection of gender (masculinities) with other social dimensions such as class, and other social categories can be important here, including race, ethnicity, and age. For example, in a survey study by Courtenay et al. [33], it was found that most groups of men had poorer diets than women—it was only Hispanic men who compared well with their female counterparts. Other work suggests that older men are more reluctant to engage in healthy eating compared to younger men [34], while younger men may see cooking as a means of displaying masculinized values such as autonomy and control [35]. And work by Galdas and Cheater [36] points to the role of cultural traditions and rituals in inhibiting healthier eating practices in older men of South Asian origin. Another important influence on (heterosexual) men's health and dietary practices is relationship status, since female partners often play a significant role in supporting men toward healthier living and better nutrition [37]. There is also evidence that when men are ill or frail, they may be less responsive to healthy eating interventions, preferring to leave responsibility for food to women [38]. On the other hand, gendered expectations may well mean that wives and partners consolidate their male partner's unhealthy food preferences [39], while for some urbanized middle-class professional men who live alone healthy eating is embraced [35].
