INTRODUCTION

There is considerable epidemiological interest in the suggestion that exposures acting in early life have long-term consequences for health in adulthood. The early life factors include those acting during (or before) the period of fetal development, such as maternal diet, smoking, or alcohol use during pregnancy; those acting in infancy, such as breast or bottle feeding; and those acting in childhood, such as passive exposure to tobacco smoke. Nearly all domains of later health including cardiovascular disease (CVD), diabetes, various cancers, respiratory disease, mental health, and cognitive decline have been associated with early life exposures of one kind or another. In terms of public health policy, it is important to separate out causal associations, which offer the possibility of intervention and disease prevention, from noncausal associations.

In this chapter, we examine prenatal exposures only, and we pay particular attention to study designs that might shed light on whether or not the associations are causal, and if causal, what the likely underlying mechanisms might be. Many of the specific examples are related to CVD or its risk factors (including hypertension, diabetes, and obesity), though we do consider other health outcomes. The focus on CVD and its risk factors arises for a number of reasons.

First, CVD accounts for the majority of deaths in high-income countries and is an increasing cause of morbidity and mortality in low- and middle-income countries [1]. Second, much of the research on prenatal origins of disease has focused on CVD and its risk factors. Third, variation in normal pregnancy-related changes—such as increases in insulin resistance and blood pressure (BP)—are importantly related to CVD in later life in both mother and offspring. Lastly, the issues that arise in considering which prenatal risk factors might be importantly causally related to future CVD, or its risk factors, will equally apply to other disease/health outcomes.

We start by considering the relationship of birth weight to CVD and its risk factors, and then move on to the relationship of maternal pregnancy-related changes with future offspring health outcomes, before finally considering modifiable maternal behaviors during pregnancy that might be related to future offspring health. Our summary considers implications of current research findings for clinical and public health policy and also areas where further research should be directed.

BIRTH WEIGHT AND FUTURE CVD

Coronary heart disease (CHD) and stroke, the main manifestations of CVD, are rare until middle age, and over half of deaths due to these causes occur over the age of 70 years. Until recently, most of our knowledge concerning the etiology of CVD focused on adult risk factors focused on factors such as diet, smoking, physical activity, hypertension, and adult obesity [2]. There is indeed good evidence that these major adult risk factors explain most of the geographical and secular variations in CVD occurrence, and it has been

suggested that there is no need to seek further etiological risk factors [3,4]. Moreover, there are a range of drugs now available that are highly effective in secondary prevention (that work by reducing adult risk factors such as hypertension and total or low-density lipoprotein cholesterol), which, together with reductions in population levels of smoking, have contributed to the sharp decline in CVD in high-income countries in recent decades [5]. However, ultimately, primary prevention of the development of atherosclerosis and CVD risk factors in the first instance has to be better than treating risk factors in adults, and this is likely to require a better understanding of prenatal risk factors.

It has been known for decades that the pathophysiological process of atherosclerosis, which ultimately leads to CHD and ischemic strokes, begins in childhood and young adulthood [6–8]. Cardiovascular risk factors, such as high BP, obesity, dyslipidemia, and insulin resistance are present in childhood, associated with atherosclerosis and endothelial dysfunction, and track into adulthood [9–13]. Thus, understanding the determinants of variation in these risk factors from very early in life is likely to be important.

A large number of studies have demonstrated inverse (sometimes "J" shaped) associations of birth size (most commonly birth weight) with CVD endpoints [14] and risk factors, including BP [15], fasting glucose [16], insulin [16], total cholesterol and triglycerides [17,18], and positive associations with high-density lipoprotein cholesterol [17]. Conversely, birth weight is positively associated with body mass index (BMI) [19] and with both total fat mass and lean mass assessed by DXA scan [20]. The strength of associations of lower birth weight with adverse CVD events and risk factors is generally smaller, often considerably so, than those between risk factors measured in adult life and these outcomes. Furthermore, it is unclear what mechanisms underlie the associations of birth weight with later CVD outcomes.

Few investigators suggest that size at birth per se matters; rather this is a proxy marker for some other causal risk factor(s). The mechanisms that have been proposed for this association fall broadly into one of three areas:

- *Intrauterine programming.* The suggestion here is that factors affecting intrauterine nutrition/growth provide signals to the developing fetus about the environment in which they will grow up and develop and, as a result, "program" the developing fetus for an environment of thrift or plenty [21,22]. Poor intrauterine nutrition results in poor intrauterine growth, and hence low birth weight, and also programs the offspring for a life of thrift. If offspring subsequently experience a life of nutritional plenty, typified by high-fat energy-dense diets (common in many high-income countries and urban areas of low- and middle-income countries), they are at particular increased risk of future CVD. Epigenetic mechanisms are increasingly thought to mediate these processes [23].
- *Genetic mechanisms (the fetal insulin hypothesis).* The fetal insulin hypothesis suggests that associations are largely due to the effects of genetic variants that have pleiotropic effects influencing both fetal growth and later insulin resistance and hence CVD risk [24,25].
- *Confounding or bias.* It has been suggested that the associations of birth weight with CVD and its risk factors are largely due to confounding (e.g., by socioeconomic position or shared familial behaviors such as smoking, physical activity, and diet that could affect both perinatal outcomes and later disease risk in offspring), statistical artifact, and/or publication bias [26,27].

Family-based studies have been increasingly employed to try and distinguish between these possible different mechanisms, and these are summarized in the subsequent sections; a fuller discussion of these can be found elsewhere [28].

Twin Studies and the Association of Birth Weight with CVD

Twins, compared to singletons, experience intrauterine growth retardation and have on average birth weights that are 900 g lower than those of singletons. If the fetal growth impairment experienced by twins occurs through similar processes to that experienced by growth-impaired singletons, one would expect twins to be at greater risk of CVD. The salience of comparing twins with singletons (or the general population, which is largely made up of singletons) is reinforced by the fact that there is evidence that twins tend to exhibit upward growth centile crossing [29]. Thus, twins are, in general, naturally small for gestational age but rapidly regain weight to become similarly sized to age-matched singletons, the very pattern of intrauterine and postnatal growth that has been suggested in general populations to increase the risk of CVD. Despite this, large studies show that twins (whether monozygotic [MZ] or dizygotic [DZ]) are at no greater risk of CVD than are singletons or the general population [30,31], nor do they have higher levels of CVD risk factors [32,33].

An alternative use of data on twins is the more traditional twin comparison design. In this context, one can examine (1) whether variation in size at birth *within* MZ pairs (where there will be control for fetal and maternal genotype, intrauterine environment, and maternal size and behaviors during pregnancy and background family socioeconomic position) is associated with differences in adult CVD *within* these pairs, (2) whether variation in size at birth *within* DZ pairs (controlling for intrauterine environment, maternal genotype, size, and behaviors during pregnancy and background family socioeconomic position, but not for fetal genotype) is associated with differences in adult CVD *within* these pairs, and then (3) compare whether these within twin-pair associations differ from associations *between* unrelated pairs (representing

the general association without control for factors that are shared within twins) [34].

Twin studies comparing within and between pair associations have been used to explore the association of birth weight with BP [35], dyslipidemia [36], glucose intolerance [37], and CHD events [38,39]. There are more studies of BP (treated as a continuous variable) than of any other risk factors or of CVD events. A systematic review and meta-analysis of twin studies examining the association of birth weight with BP failed to provide conclusive evidence for a stronger role for either genetic or environmental factors [35]. This was attributed to small sample sizes and between-study variation in the way in which zygosity was defined and BP measured. In a subsequently published study using data from Sweden that included 594 DZ and 250 MZ pairs who were discordant for hypertension (a binary measure), within MZ pairs, a 500 g lower birth weight was associated with an odds ratio of hypertension of 1.74 (95%CI: 1.13, 2.70) and within DZ pairs of 1.34 (1.07, 1.69). The equivalent association in the whole cohort was 1.42 (1.25, 1.61). These results suggest that the inverse association of birth weight with hypertension is independent of genetic and environmental factors shared by twins, including maternal and fetal genotype (except mitochondrial DNA, which differs in MZ as well as DZ twins), maternal physiology and behaviors in pregnancy, and background familial socioeconomic position. However, in general, such twin studies have contributed relatively little to understanding the (causal) mechanisms linking birth size to CVD or its risk factors because few have adequate sample sizes and because an underlying assumption of these studies is that variation in birth size in twins represents similar pathophysiological processes as those that result in variation in birth size in the general population, the majority of whom are singleton; this assumption may not be correct.

Sibling Studies and the Association of Birth Weight with CVD

A natural extension of the within- and between-twins study is to examine associations within and between siblings. Factors that influence birth size can be broadly categorized into those that vary from one pregnancy to the next in the same mother (e.g., fetal genotype, placental implantation and function, maternal age, parity, and pregnancy complications) and factors that are shared by full siblings (e.g., family socioeconomic background, maternal genotype, maternal pelvic size, and maternal exposures across her life course up to the birth of her first child).

Sibling studies provide a useful method for distinguishing between the impact of shared maternal/family characteristics and those factors that vary between full siblings in explaining the associations between perinatal exposures and later outcomes. They have the advantage over twin studies that they are generalizable to the majority of the population, but the disadvantage that they cannot control for fetal genotype and hence cannot distinguish whether the fetal insulin hypothesis (genetic pleiotropy) or intrauterine mechanisms explain the association of birth weight with CVD and its risk factors.

To our knowledge, only three studies have employed a sibling design to explore the association of birth weight with CVD outcomes. The outcome examined in all three independent Swedish studies was BP [40–42], and their key findings were in broad agreement: in childhood and young adult life, there was an inverse association between birth weight and mean systolic BP within sibships having accounted for gestational length. In the largest of these studies, inverse associations of birth weight, and gestational age, with systolic BP were found both within and between sibships [41]. The authors concluded that the inverse associations of birth weight and gestational age with later BP were not explained by confounding due to family socioeconomic position, maternal skeletal size, or factors from across the earlier part of a mother's life course. Instead, the most likely alternative explanation for these associations involves differences between pregnancies (within the same mother) in maternal metabolic or vascular health during pregnancy and/or differences in placental implantation. Differences in maternal metabolic or vascular health during pregnancy might be related to her behaviors such as smoking, diet, and physical activity. However, in common with many of the general studies examining the association of birth size with CVD, these sibling studies did not have data to examine the role of these behaviors.

Intergenerational Studies of Offspring Birth Weight and Parental CVD Risk

Examining the association of offspring birth weight with CVD risk factors and events in their parents has been used as a means to determine whether genetic or intrauterine factors are the most likely explanation for the association of birth weight with CVD in individuals. If the birth weight–CVD association seen within individuals is due to a genetic mechanism from both maternal and paternal genes, then one would expect that offspring birth weight would be inversely associated with CVD in both mothers and fathers. Associations in fathers are of particular importance, since many factors that could influence maternal CVD risk (e.g., maternal diet and smoking) could also affect the intrauterine environment and thus the birth weight of her offspring. In contrast, paternal factors other than via fetal genotype cannot influence the intrauterine environment, so an association between offspring birth weight and father's CVD risk is more likely to be explained by genetic factors or shared familial lifestyles.

A meta-analysis of all published studies of the association of offspring birth weight with parental CVD endpoints found that among mothers, the pooled confounder adjusted hazard ratio of CVD mortality for a one standard deviation increase in offspring birth weight was 0.75 (95% CI: 0.67, 0.84), and among fathers, the equivalent association was 0.93 (95% CI: 0.91, 0.95), with statistical evidence of a difference between these two effects $p < 0.001$ [43].

The generally stronger associations of offspring birth weight with maternal CVD compared with paternal CVD can be explained by a number of different mechanisms, including paternal misclassification, fetal programming (possibly via epigenetic effects), and reverse causality with maternal predisposition to CVD resulting in intrauterine growth restriction, all of which could be operating simultaneously, and that have been discussed in detail elsewhere [28]. The implausibly high levels of non-paternity (30%) that would be required to explain the magnitude of the difference in maternal–paternal associations and the non-specificity of the association in fathers, with similar magnitudes of association for other outcomes that could be due to confounding, have lead to the suggestion that these intergenerational studies support a maternal specific (most likely intrauterine) explanation for the inverse association of birth weight with CVD risk seen in the general population [43].

This intergenerational design has also been used with the same rationale to explore the associations of size at birth with insulin resistance and type 2 diabetes [44–51]. These have reported contradictory results, with inverse [46,47,49], positive [45,50], and null [44] associations of offspring birth weight with insulin resistance/type 2 diabetes reported in mothers and inverse [45–47,50,51] or null [45,48] associations reported in fathers.

A key issue may explain these contradictions between using this design for CVD and using it for insulin resistance/type 2 diabetes. Gestational diabetes (and gestational hyperglycemia) is associated with increased risk of type 2 diabetes in the mother and with greater offspring birth weight and fat mass [52]. Thus, in mothers, a positive association of offspring birth weight and her risk of later type 2 diabetes and insulin resistance would be expected. Any effect of other mechanisms (intrauterine programming or genes with pleiotropic effects resulting in lower birth weight and insulin resistance) might be somewhat masked in these intergenerational studies. This line of reasoning in itself suggests that the intergenerational design may not be as helpful for studying insulin resistance/glucose intolerance/diabetes as it is for CVD itself [45].

MATERNAL PREGNANCY-RELATED CHANGES AND FUTURE OFFSPRING CVD

Normal physiological changes in pregnancy, including maternal increases in BP, fat deposition, and insulin resistance that are essential for normal growth and development of the fetus, may in extremis result in abnormal development that has long-term adverse health consequences in offspring. In the subsequent text, we consider evidence for the effect of prenatal exposure to hypertensive disorders of pregnancy (HDP), gestational diabetes/hyperglycemia, greater maternal adiposity, and greater maternal gestational weight gain (GWG) on future health outcomes. These exposures have largely been related to future risk of greater adiposity, CVD, and metabolic risk factors in offspring, and thus this section focuses on these outcomes.

Prenatal Exposure to Hypertensive Disorders of Pregnancy

Hypertensive disorders of pregnancy (HDP) (preeclampsia and gestational hypertension) are the most common complications of pregnancy and are associated with adverse health outcomes for both the mother and her offspring. Preeclampsia is defined as newly elevated BP and proteinuria after 20 weeks of gestation and occurs in about 2%–7% of otherwise healthy first pregnancies [53,54]. Gestational hypertension is defined as newly elevated BP after 20 weeks of gestation but without proteinuria and has been found to occur in 6%–17% of pregnancies [53,54].

Exposure prenatally to maternal preeclampsia and gestational hypertension is associated with higher BP in offspring [53,55–60]. The underlying mechanisms explaining the associations of HDP with offspring BP remain unclear and could include genetic, intrauterine mechanisms or shared familial risk factors [61]. Given the familial clustering of adiposity (either as a consequence of genetic predisposition or shared lifestyle) and the strong association of obesity with both HDP and elevated BP, in general (including in children; [11]), adiposity either as a consequence of genetic predisposition or shared lifestyle might be important in the mechanism linking maternal HDP to elevated offspring BP.

However, a recent analysis in the Avon Longitudinal Study of Parents and Children, a prospective U.K.-based pregnancy cohort, found that the associations of both preeclampsia and gestational hypertension with greater offspring diastolic and systolic BP assessed at mean age 9.9 years ($N = 6343$) were not explained by maternal/paternal BMI or offspring fat mass [53]. Results from that study did, however, suggest that the mechanisms linking preeclampsia to offspring BP may differ from those linking gestational hypertension to offspring BP. Preeclampsia was associated with lower birth weight and preterm birth (whereas gestational hypertension was not), and adjustment for these birth characteristics attenuated the preeclampsia–offspring BP associations to the null [53].

In a second study with smaller numbers but more detailed offspring vascular phenotype, preterm infants born of mothers with HDP ($N = 19$) had higher BP, thicker carotid intima, and lower flow-mediated dilatation in their mid-20s than a group who had been born preterm but whose mothers were normotensive throughout pregnancy ($N = 52$; [62]). By contrast, arterial stiffness was greater in those born preterm to normotensive mothers than those born preterm to hypertensive mothers. Since endothelial dysfunction is a defining feature of preeclampsia [63], the authors interpreted their findings as indicating that either genetic predisposition to endothelial dysfunction or the exposure in utero of the developing fetus to the same placenta-related factors (including inflammatory markers) that affect the mother may explain their findings.

Several studies have also examined the extent to which HDP are related to other CVD risk factors and other outcomes such as cognitive function in offspring but have generally reported null associations [57,59]. These null findings may reflect lack of statistical power in small studies.

Prenatal Exposure to Gestational Diabetes/Hyperglycemia

Gestational diabetes is associated with higher birth weight and greater fetal adiposity [52,64]. Among nondiabetic mothers, there is a linear association between fasting and post-challenge glucose and greater birth size [65]. Fuel-mediated teratogenesis, also known as developmental overnutrition, has been suggested as the most likely mechanism for these associations [66–68].

Developmental overnutrition, resulting from maternal hyperglycemia/diabetes, may also program offspring to lifelong increased adiposity and type 2 diabetes risk [69]. In studies of the Pima Indians of Arizona (a population with very high prevalences of obesity and type 2 diabetes), mean BMI, fasting glucose and insulin, and type 2 diabetes is greater in offspring (during childhood, adolescence, and early adulthood) born to mothers who had diabetes during their pregnancy compared with either the offspring of mothers who developed diabetes later in their lives or those who never developed diabetes [70–72]. In a sibling study (182 individuals from 52 families), also conducted in the Pimas, risk of obesity and type 2 diabetes was greater among offspring born after the mother had been diagnosed with diabetes than in their siblings born before their mother's diagnosis. Furthermore, within siblings, there was no association of paternal diabetes around the time of pregnancy with these offspring outcomes [73]. These findings suggest that, at least in a population at high risk for obesity and diabetes, intrauterine mechanisms make an important contribution to the link between gestational diabetes and offspring greater adiposity, insulin resistance, and type 2 diabetes [73].

More recently, the association of diabetes (type 1, type 2, or gestational) or hyperglycemia during pregnancy with offspring obesity and diabetes risk has been examined in European and North American populations, with the majority of such studies finding that offspring of mothers with gestational diabetes of hyperglycemia have greater BMI and fasting glucose and insulin [74–80]. These associations could be explained by genetic inheritance, shared familial lifestyles for risk factors increasing the risk of obesity and diabetes or intrauterine mechanisms.

A recent large sibling analyses of Swedish men (280,866 men from 248,293 families) found that the BMI of men whose mothers had diabetes during their pregnancy was on average 0.94 kg/m^2 greater (95% CI: 0.35, 1.52) than in their brothers born before their mother was diagnosed with diabetes [77]. This finding suggests that, as in the Pima Indians, intrauterine mechanisms contribute importantly to the link between maternal diabetes in pregnancy and later offspring adiposity.

Prenatal Exposure to Greater Maternal Adiposity and Weight Gain in Pregnancy

Since maternal obesity is a key risk factor for gestational diabetes and greater maternal fat deposition during pregnancy is related to greater levels of circulating glucose and free fatty acids, which freely cross the placenta resulting in increased fetal secretion of insulin and hence insulin-mediated growth, it has been suggested that greater maternal pre- or early-pregnancy adiposity and greater GWG will result in greater offspring obesity via intrauterine mechanisms. If this hypothesis is true, in particular, if greater maternal adiposity at the start of pregnancy programs offspring to greater adiposity later in their lives, the public health consequences would be extreme, as this could drive the obesity epidemic through subsequent generations irrespective of any improvements in key risk factors for obesity [81]. This is because women going into their pregnancy with greater adiposity would program their offspring to greater adiposity, and their daughters would go into their pregnancies with greater adiposity and so on.

Despite a number of studies demonstrating that maternal pre- or early-pregnancy BMI is positively associated with offspring BMI, there is little evidence that intrauterine mechanisms play a substantial role in these associations in general. In the larger epidemiological studies, the magnitudes of associations of maternal BMI with offspring adiposity are similar to those of paternal BMI with offspring adiposity [82–84], suggesting that these associations are driven by shared familial genetic or lifestyle characteristics. Where associations have been found to be stronger in mother–offspring compared with father–offspring associations, the differences are small and unlikely to be important drivers of the obesity epidemic [85]. Furthermore, when maternal genetic variation in *FTO*, conditional upon offspring *FTO,* was used as an instrumental variable for the causal effect of exposure to greater maternal adiposity in utero this did not support a strong effect [85].

The one exception to these general findings is with extreme maternal obesity in pregnancy. In an elegant sibling study, adiposity in the offspring of mothers with extreme obesity (BMI > 40) was lower in children born after their mother had undergone bariatric surgery and subsequent weight loss than those born before she had received this surgery [86]. Taken together with the findings relating to gestational diabetes, these studies suggest that developmental overnutrition resulting in long-term effects on offspring adiposity and associated metabolic disturbance via intrauterine mechanisms only occurs in the extremes of clinical obesity or where there exists metabolic disturbance such as diabetes in pregnancy. Variation at lower levels of maternal prepregnancy adiposity, and without diabetes, does not appear to have long-term effects of offspring risk.

On an average, healthy women gain 10–12 kg during pregnancy, with approximately 55% of this gain being maternal tissue related to fat deposition, blood volume expansion, and increases in breast and uterine tissue, a further 15%–20% is due to placenta and amniotic fluid and 25%–20% fetal tissue [87–89]. Rates of deposition of maternal fat parallel GWG with women gaining between 2–6 kg of fat during pregnancy [90]. Pregnancy is associated with maternal deposition of both subcutaneous and visceral fat, with most subcutaneous deposition being centrally located [90–94]. Maternal pregnancy-related fat accumulation is relatively constant from the start of pregnancy to the middle of the second trimester when

the rate of accumulation flattens [88,90]. Most maternal fat accumulation has occurred by the end of the second trimester [88,90]. In general, this fat accumulation is a normal physiological response to pregnancy and it together with women becoming temporarily more insulin resistant during pregnancy is important for providing the developing fetus with essential nutrients for normal growth and development.

Several studies have examined associations of GWG with offspring adiposity and have consistently (all but one) [95] reported positive associations with offspring mean BMI or obesity measured in childhood [96–99], adolescence [100], and adulthood [101]. Other studies have examined the association with offspring BP with conflicting results [96,98,101,102–104].

The three most recent and largest studies suggest positive associations of GWG with offspring BP in childhood [96,98] and adulthood [101] that may be mediated by the association of GWG with offspring adiposity [96,101]. In the Avon Longitudinal Study of Parents and Children, a U.K.-based prospective pregnancy cohort, GWG was also associated with other CVD risk factors in childhood, including adverse lipid and inflammatory profiles, with these associations largely mediated via associations with offspring adiposity [96]. It is difficult to determine whether these associations are causal and act via intrauterine mechanisms. The associations are independent of maternal pre- or early-pregnancy BMI, which suggests that they are unlikely to be solely driven by genetic and lifestyle characteristics related to greater adiposity in general.

A recent sibling comparison found that GWG within siblings was positively associated with birth weight, and the authors concluded that this suggested the association was unlikely to be confounded by background family socioeconomic position [105]. They also implied that these findings provided indirect evidence that the associations of GWG with later offspring adiposity was unlikely to be confounded by fixed family characteristics, such as background socioeconomic position, because of the positive association of birth weight with later adiposity. However, in general, studies examining the associations of GWG with later offspring adiposity have found that birth weight does not mediate this association [96,101]. Thus, sibling studies of the association of GWG with offspring adiposity measured in childhood or at older ages would be valuable.

MATERNAL BEHAVIORS DURING PREGNANCY AND FUTURE OFFSPRING HEALTH

Identifying modifiable prenatal exposures that importantly influence future disease is clearly important for public health. While potentially modifiable maternal behaviors during pregnancy such as maternal smoking, diet, and alcohol consumption have been related to a wide range of later offspring health outcomes, determining whether these are truly causal (which is essential for appropriate public health policy interventions) is difficult as randomized controlled trials of these behaviors in pregnancy are likely to be unethical or unfeasible [106]. In the subsequent sections, we consider four key potentially modifiable maternal pregnancy behaviors (smoking, alcohol, diet, and physical activity) and evidence for their association with later offspring health. As in previous sections, we pay particular attention to studies that might help with causal understanding, including parental comparisons, cross cohort comparisons, and Mendelian randomization studies.

Maternal Smoking in Pregnancy

Maternal smoking in pregnancy has been found to be associated with greater offspring obesity (and associated CVD and metabolic consequences), lower cognitive function, poor mental health, and reduced bone density in offspring. However, there are many confounding factors that could generate non-causal links between the smoking of mothers and the health of their children.

In the Avon Longitudinal Study of Parents and Children, maternal smoking during pregnancy is associated with lower offspring birth weight, whereas smoking by the father (at the time of their partner's pregnancy) is only weakly associated with birth weight (possibly because of confounding with maternal smoking, or through effects of environmental tobacco smoke), and when both maternal and paternal smoking during pregnancy are taken into account, the former shows a robust association that is little attenuated, whereas the latter association is essentially abolished [107]. These findings demonstrate the face validity of using such parental comparisons to determine whether maternal behaviors in pregnancy have a causal effect via intrauterine mechanisms on offspring outcomes since for birth weight, it is accepted that maternal smoking in pregnancy does indeed have this causal effect.

Maternal–paternal comparisons have suggested that the associations between maternal smoking in pregnancy and offspring greater adiposity [106], reduced bone density [108], lower child cognitive function [109], and higher BP [110] are all unlikely to be caused by specific intrauterine mechanisms, since similar associations are found for the association of maternal smoking with these offspring outcomes as for that of paternal smoking with the same outcomes. Thus, for these outcomes, shared familial socioeconomic position or genetic variations are more likely explanations for the association than are causal intrauterine mechanisms. However, stronger maternal associations are reported with respect to components of stature in childhood, particularly of leg length, suggesting that for offspring postnatal growth in stature there may be causal intrauterine effects of maternal smoking during pregnancy [111].

Another approach to addressing whether the association of smoking in pregnancy with offspring outcomes is via intrauterine mechanisms or confounded (particularly by socioeconomic position) is to use cross cohort comparisons [112]. If smoking in pregnancy is unrelated to (or less markedly related) confounding factors in one cohort compared

with another, this difference in confounding structures can be exploited to explore causality. This approach has been used to examine the relationship between maternal smoking in pregnancy and offspring behaviors. Associations were examined in the United Kingdom, Avon Longitudinal Study of Parents and Children and in the Brazilian, Pelotas 1993 pregnancy/birth cohorts [112]. Socioeconomic patterning of maternal prenatal smoking was stronger in the United Kingdom compared with the Brazilian cohort. Despite this difference in a key confounder, consistency in observed associations of maternal smoking with child psychological problems was found between these cohorts [112]. In both cohorts, after full adjustment for indicators of socioeconomic position, parental psychological factors, and paternal prenatal smoking, maternal smoking was associated with child externalizing/conduct problems in both cohorts. Furthermore, maternal smoking associations were much stronger than paternal smoking associations with externalizing/conduct problems in both cohorts [112]. Thus, for this adverse psychological outcome, there may be a causal intrauterine effect of exposure to maternal pregnancy smoking.

This is hypothesized to occur via adverse effects of exposure to smoking-related toxins in utero on early brain development: the fetal brain is particularly vulnerable to exogenous nicotine because it contains specific nicotine-sensitive receptors [113]. There is some concern, however, that in most studies, there are insufficient measures of parental psychological factors to adequately capture confounding by parental psychopathology and in parental antisocial behaviors (which were not available in the two cohorts from Brazil and the United Kingdom described earlier). Indeed, in two studies with more detailed measures of parental psychopathology [114] and measures of maternal and paternal antisocial behavior [115], associations of maternal smoking with offspring behavioral problems were essentially abolished when these parental characteristics were controlled for. These findings are consistent with those from a twin study and an assisted conception study, which suggest that shared genetic variation explains most of the association of maternal smoking with offspring antisocial behavior rather than this being due to intrauterine mechanisms [115,116].

In summary, the adverse effects of maternal smoking during pregnancy on prenatal and perinatal outcomes, such as increased risk of preterm birth and low birth weight, are now well established. However, the extent to which exposure to maternal smoking in utero translates into long-term effects on offspring health has been more difficult to determine. While, associations with many different offspring outcomes have been reported in the literature, it has since been found that the vast majority (including offspring adiposity, BP, cognitive function, and bone density) of these are not likely to be causal via intrauterine mechanisms. With child behavior problems, identifying whether or not associations with maternal smoking are causal remains a challenge, and studies using different methodological approaches are increasingly being explored in an attempt to resolve this. To date, these studies have yielded conflicting results, and thus, the extent to which associations of maternal smoking and child behavior are causal remains controversial.

Maternal Alcohol Consumption in Pregnancy

The fact that *heavy* alcohol use by pregnant women has adverse effects on health outcomes in their children, including effects on cognitive development, is well established [117,118]. Thankfully, few women drink heavily during pregnancy, so in most populations "fetal alcohol syndrome" is not a major public health issue. Many women, however, do drink some alcohol during pregnancy, generally at light or moderate levels, and there is conflicting evidence (and hence policy advice) regarding whether levels of light or moderate alcohol consumption are safe.

For example, two publications from the U.K. Millennium birth cohort suggest that light alcohol use during pregnancy (1–2 units/week maximum) is actually associated with *better* cognitive outcomes in children compared with abstention from alcohol in pregnancy [119,120]. These publications have led to suggestions in the media and by the eminent statistician Professor David Speigalhalter that advising women to abstain from alcohol use while pregnant is not "evidence based" (http://understandinguncertainty.org/node/890). However, the findings in this study might be due to residual confounding.

Women who drink small levels of alcohol during pregnancy tend, in most populations, to be relatively affluent compared with women who drink heavily and those who do not drink at all. The children of relatively affluent mothers are likely to have better cognitive outcomes, and thus socioeconomic position and maternal education may be important confounders in this association.

The metabolism of alcohol in the body is influenced by several genes, and the metabolic differences associated with particular genotypes are themselves associated with differences in alcohol consumption behavior between individuals carrying different genes [121]. These differences are generally small, but they are consistent, and importantly possession of the genes that underpin them is completely independent of the other factors that typically cluster with substance use [121]. For example, a particular rare variant of the alcohol dehydrogenase gene is consistently associated with abstinence from alcohol (compared with moderate use) with a particularly strong association with abstinence from alcohol use during pregnancy. But this genetic variant is not associated with mothers' education or other socioeconomic characteristics and nor is it associated with other lifestyle characteristics such as smoking.

This genetic instrument was used to investigate effects of maternal alcohol use on children's cognitive outcome in a large United Kingdom-based birth cohort study. In this study, in keeping with the results of the previous study, the children of mothers reporting light alcohol use during pregnancy had higher intelligence quotient (IQ) scores and did better in standard school tests than the children of mothers reporting abstinence from alcohol. Light alcohol-using

mothers, however, were also more affluent, more educated, less likely to smoke, more likely to take exercise, and to have a healthy diet, in other words, more likely to have a favorable profile with regard to a range of possible influences on their children's cognition. Adjusting for these factors in statistical models attenuated but did not abolish the apparently beneficial effects of alcohol on the cognitive outcomes studied. By contrast to these observational findings, children of women with the "abstinence gene" did better in school tests and had higher IQ scores than women with "light/moderate use" genes.

This is convincing evidence that maternal alcohol use actually exerts a damaging effect on children's cognitive development, an effect that only became apparent with use of a study design—Mendelian randomization [122,123]—able to adequately address the issue of residual confounding. A nice feature of this study is that the problem of residual confounding could not be addressed by an RCT as it would be unethical and very likely unfeasible to find a group of pregnant women who were happy to be randomized to either drink no alcohol or a light amount throughout their pregnancy.

Maternal Diet in Pregnancy

There are some extreme examples of how maternal diet during pregnancy can affect offspring development and long-term health such as inadequate periconceptual folate intake resulting in increased risk of neural tube defects in offspring [124] and exposure to famine in utero being associated with increased risk of CHD and glucose intolerance in adult offspring [125]. However, evidence of effects of less extreme variation in maternal diet during pregnancy, particularly in contemporary well-nourished populations, is less well established.

Although the influence of maternal diet on offspring size at birth has been investigated since the 1930s, the overall evidence for effects on birth weight remains inconclusive, with unresolved methodological challenges, inconsistent results among studies and only modest effects, where associations have been observed [126]. Beyond birth weight, several historical studies undertaken among women who were pregnant in the 1940s [127], 1950s [128], and 1960s [129] have reported that specific variations in dietary composition of pregnant women may alter long-term health in offspring; in particular, there is evidence that maternal diet in pregnancy may influence offspring BP.

High maternal animal protein intake [129] and both high and low maternal protein to carbohydrate ratios [127,128] have been associated with greater adult offspring BP at 30–50 years. While this might suggest that modifications to maternal protein or carbohydrate intake during pregnancy might influence long-term cardiovascular health of offspring, effects on offspring BP have not been observed in RCTs of protein or protein and energy supplementation for pregnant women in Guatemala [130], Gambia [131], and India [132] or in later observational studies of larger, more contemporary cohorts [133,134].

One of these RCTs—that of maternal protein and energy supplementation in India—while not finding an effect on offspring BP, did report beneficial effects of supplementation on other cardiovascular risk factors (lower insulin resistance and arterial stiffness) in adolescent offspring, however, as the intervention consisted of supplementation for both pregnant mothers and their offspring in infancy and childhood (up to 6 years of age) effects of prenatal and postnatal supplementation cannot be disentangled in that study [132]. Furthermore, a recent review found that there was no strong evidence of a wide variety of food groups, micronutrients, and macronutrients eaten by mothers during pregnancy being related to offspring BP [135]. The only exception was modest evidence that greater maternal calcium intake in pregnancy may be associated with lower offspring BP [135].

The impact of maternal prenatal diet on other components of offspring health has also been explored. For example, in contemporary, well-nourished women, greater maternal macronutrient intake in pregnancy was associated with greater intakes of the equivalent macronutrients in offspring at 10 years [136]. The stronger associations (with offspring intake) for maternal macronutrient intake prenatally, compared with both paternal macronutrient intake and maternal intake postnatally suggested that greater maternal macronutrient intake during pregnancy may have specific in utero effects on offspring macronutrient intake in later life. This could occur, for example, via programming effects on offspring appetite. However, this did not translate to effects of maternal prenatal macronutrient intake on offspring adiposity [136].

Finally, observational studies have reported that greater maternal intake of fish and seafood during pregnancy is associated with improved cognitive function in offspring [137,138]. It is believed that omega-3 fatty acids are responsible for these associations, and while several small trials of maternal omega-3 supplementation report some evidence of improved cognitive development in infants and children [139–142], there are concerns regarding these findings because of the small sample sizes and high attrition rates in these studies. Indeed, in a recently published large RCT maternal supplementation with omega-3 in pregnancy did not result in improved cognitive and language development in their offspring during early childhood [143].

In conclusion, based on the existing epidemiological evidence, there is little support for consistent effects of maternal diet in pregnancy on offspring health and development. As others have remarked [126], while this translates to limited options for nutritional intervention at present and few specific recommendations can be made, the prenatal period remains an ideal window of opportunity for clinical and health care practitioners to encourage overall healthy eating behavior in pregnant women.

Maternal Physical Activity in Pregnancy

Until several decades ago, physical activity during pregnancy was a cause for concern because of the perceived associated risk of maternal injury and of physiological changes

physical activity induces in blood flow, body temperature, and fetal oxygen delivery that could potentially have both short-term and lasting detrimental effects on the fetus [144]. More recently, several observational epidemiological studies have reported beneficial effects of greater levels of physical activity during pregnancy for the pregnant woman, such as a decreased risk of gestational diabetes [145] and preeclampsia [146,147]. Thus guidelines recommend that pregnant women maintain the same level of moderate physical activity as non-pregnant women [148].

However, current evidence is inconsistent on whether exercise during pregnancy is beneficial, harmful, or neutral for the health of the developing fetus [149]. These mixed findings are likely to reflect different methods of exposure and outcome assessment, different timing during the pregnancy for exposure and outcome assessments, differences in pre-pregnancy exercise habits between the study populations, and differences in the studies' abilities to control for potential confounding factors.

By far, the largest observational study to date, including over 90,000 participants in the Danish National Birth Cohort, found a strong and linear association between increasing levels of physical activity in early pregnancy and miscarriage before 18 weeks gestation [150]. As with other behaviors in pregnancy, RCTs in this area are difficult. However, a Cochrane systematic review of randomized controlled trials to promote aerobic exercise during pregnancy concluded that regular aerobic exercise during pregnancy (mostly swimming, static cycling, and floor exercises) appears to improve women's physical fitness, but that current evidence was insufficient to draw firm conclusions about its likely overall risks or benefits for the woman or baby [149]. The reviewers concluded that larger, better quality trials are needed before confident recommendations could be made about the benefits and risk of exercise during pregnancy.

The long-term effect of physical activity in pregnancy on offspring future health is even less well studied. Two small prospective studies assessed outcomes in offspring of women who exercised regularly throughout pregnancy compared with offspring of active women who did not exercise at 1 and 5 years of age. In the first study [151], which included 104 mother–offspring pairs, weight, length, and abdominal and head circumferences at mean age 1 year were similar in offspring of women who did or did not continue regular physical activity throughout pregnancy. In another study by the same group [152], which included just 40 mother–offspring pairs, at mean age 4 years, offspring of women who engaged in vigorous physical activity during pregnancy were lighter and had less subcutaneous fat but were of similar height as offspring of women who voluntarily stopped exercising in pregnancy. They also scored higher for oral language skills and general IQ (assessed by the Wechsler Preschool and Primary Scale Intelligence). Motor, integrative, and academic readiness skills were similar between groups. In both studies, women were matched for pre- and postnatal characteristics known to influence outcomes [151,152].

Thus, to date evidence suggests that maintaining moderate levels of physical activity during pregnancy may be beneficial to the health of the mothers, but it is unclear whether variation in levels of physical activity during pregnancy is causally (either beneficially or detrimentally) related to health outcomes in the developing fetus or longer term in offspring.

CONCLUSION AND IMPLICATIONS FOR HEALTH POLICY AND FUTURE RESEARCH

The inverse association of birth weight with CVD and risk factors is unlikely to be fully explained by residual confounding or genetic variants with pleiotropic effects on both fetal growth and later insulin resistance. However, birth weight per se is unlikely to be the key risk factor and it is relatively resistant to modification. Therefore, identifying modifiable prenatal risk factors that might have important impacts on future health is where future research should primarily focus. Current evidence supports a causal intrauterine effect of maternal diabetes and extreme obesity on increased risk of offspring obesity, but not of an important effect of variation in maternal early-pregnancy BMI across the distribution on offspring adiposity.

There is also evidence that physical activity both prenatally and during pregnancy reduces the risk of gestational diabetes [145]. Thus, interventions that promote healthy levels of physical activity in women of reproductive age and other means of preventing gestational diabetes are likely to be beneficial for both the mother and her future offspring.

Clinically, screening of women for gestational diabetes and treatment of this has been shown to be beneficial with respect to perinatal outcomes but effects on long-term maternal and offspring health are currently unknown. The mechanisms underlying the link between HDP and offspring elevated BP are unclear, but the reliability of these associations suggests that there may be some benefit in monitoring future BP of both mothers and offspring where the mother has experienced HDP.

There is increasing evidence that maternal consumption of alcohol during pregnancy, even at modest levels, results in lower cognitive function on offspring. This effect is modest, but nonetheless, women should be provided with this information so that they can make informed choices about drinking during pregnancy. For other modifiable behaviors such as smoking, diet, and physical activity, there are associations with a wide range of health outcomes in offspring but for most of these, currently it is unclear whether these are causal via intrauterine mechanisms or not.

Since RCTs in situations where timing of exposure/intervention (here, in mothers during pregnancy) is several years from assessment of outcome (here, in later childhood or adulthood), are expensive, and likely to be importantly affected by attrition and because RCTs of behavior change in pregnancy are difficult and in some cases unethical, it is likely that answers regarding causal effects of maternal behaviors during pregnancy on future offspring outcomes will largely rely on evidence from observational studies. Thus, investment in family-based studies such as sibling

comparisons and maternal–paternal offspring association comparisons, as well as cross cohort comparisons and Mendelian randomization studies (in which genetic variants that are robustly associated with the risk factor of interest, e.g., alcohol consumption), are important in this area. Such studies in general require large sample sizes and collaborative efforts.

There is a lot known generally about the adverse health effects of cigarette smoking, heavy alcohol consumption, consumption of a diet that is energy dense and low in fruit and vegetables, and low levels of physical activity, and therefore, women of reproductive age, as with the rest of the population should be encouraged to maintain healthy behaviors irrespective of any causal effects on their future offspring. However, there are a number of reasons why further research to determine whether different behaviors have causal effects via intrauterine mechanisms on offspring health is important.

First, pregnancy is perceived as a time when women are receptive to health advice, particularly, if it is likely to benefit their offspring, but such advice has to be correct and evidence based, otherwise there is the risk that all health-promoting advice will be discredited.

Second, if the mechanisms linking health behaviors to offspring health act via general family lifestyles then targeting pregnant women may achieve less benefit than interventions that are focused at all family members.

Third, for some behaviors during pregnancy, there may be both beneficial and detrimental effects. For example, increasing physical activity levels in pregnancy may have some benefit for mothers but may cause harm in terms of early fetal loss. It is key that a wide range of both maternal and fetal/offspring short- and long-term health outcomes are examined for these behaviors so that women are provided with clear information and relevant advice.

Part XVII

Family Practice

Charles B. Eaton, MD, MS

97 Introduction to Family Medicine Section

Charles B. Eaton MD, MS

This part is written for generalist physicians (family physicians, internists, pediatricians, and general practitioners), nurse practitioners, and other health care providers to address the needs of lifestyle counseling (physical activity, weight loss, smoking cessation) in the context of a busy, primary care office setting. When necessary, it reiterates topics explored in more depth in other parts of the book, not from the viewpoint of an exercise physiologist, clinical psychologist, nutritionist, or medical specialist but from the perspective of a generalist.

Since the last printing of this book, the impact of the lack of regular physical activity and healthy eating in the U.S. population with the resultant epidemic of obesity and diabetes has become apparent. There has also been an explosion of the use of the e-health (Internet, cell phone, integrated voice response, electronic health record) in care of patients with chronic diseases and in lifestyle counseling in the research setting, and these channels of communication are beginning to be utilized in clinical practice.

In the first chapter, I review the literature on office-based physical activity counseling as well as more recent interventions done via the Internet and in the community setting and discuss how the results of this research may be used in daily office practice.

Dr. Carol Garber addresses exercise counseling in patients with chronic disease within the office setting in the next chapter. Safety and screening considerations to exercise prescription are reviewed, and the volume of exercise and estimating the intensity of exercise are discussed. Tips regarding resistance exercises, flexibility exercises, and neuromotor training are also reviewed in this chapter.

Drs. Kim Gans, Kelli Drenner, and colleague Gemma Gorham discuss nutritional counseling in a busy office practice in the next chapter. They discuss the importance of nutritional counseling and the potential role of primary care physicians and review effective patient-focused counseling strategies including motivational interviewing techniques and the 5As construct. Brief dietary assessment tools, such as Rate your Plate, Rapid Eating, and Activity Assessment for Patients, are discussed, and multiple resources for providers and practices are highlighted in this chapter.

Dr. Sean David describes the state of the art of using pharmacogenomic data, to tailor smoking cessation counseling particularly focusing on pharmacologic therapy for smoking cessation. While not quite ready for clinical practice at this time, the exciting potential of this personalized medicine approach is discussed.

In the last chapter of this part, Dr. David Ahern and colleague Judy Phalen review the e-health resources presently available to support Lifestyle Medicine. They review the evidence of e-health interventions aimed at improving rates of smoking cessation, healthy eating and weight loss, physical activity, and decreasing the morbidity of mental health problems such as anxiety and depression, which make up the majority of health behaviors attributable to preventable deaths and disability. They discuss the challenges in this behavioral medicine research including problems with adoption and implementation of these e-health tools by both providers and patients. They also review some of the proposed solutions needed to advance this field forward including tailoring of the behavioral messages, user-centered designs, and incorporating cultural values as well as behavioral economics into the e-health tools.

98 Office-Based Physical Activity Counseling in Healthy Adults

Primary care providers in office-based practice have the potential to play an important role in reducing health risks related to their patients' physical inactivity. With the advent of the Patient-Centered Medical Home, electronic health records, patient portals, e-health tools, and practice redesign with group visits and care managers, primary care physicians now have the opportunity to go beyond time-consuming face-to-face encounters and provide more comprehensive lifestyle counseling using a team-based approach. This chapter will review the rationale for promoting physical activity counseling by primary care providers; results of studies on physical activity counseling in primary care and other relevant settings; and a recommended approach to patient-centered physical activity counseling in primary care settings both for the clinician and the health care team.

GUIDELINES FOR PHYSICAL ACTIVITY

Lack of physical activity has been identified as one of the leading preventable causes of death,[1] and regular physical activity demonstrates an inverse relationship exists between volume of physical activity and all-cause mortality.[2,3] In addition, regular physical activity decreases the risk of cardiovascular disease,[3] type 2 diabetes mellitus, osteoporosis, depression, obesity, breast cancer, colon cancer, and falls in older adults.[3] In addition, promoting physical activity has been shown to have large potential savings in cost-benefit analyses.[6,7]

Given the numerous health benefits of physical activity participation, various guidelines have been published on the recommended volume and intensity of physical activity for healthy adults over the past 35 years. In 2008, the Centers for Disease Control and Prevention (CDC) released the Physical Activity Guidelines for Americans, which are summarized in the subsequent sections.[8] For children and adolescents (aged 6–17 years), they recommended 1 h (60 min) or more of physical activity every day. Most of these should be either moderate- or vigorous-intensity aerobic physical activity. As part of their daily physical activity, children and adolescents should do vigorous-intensity activity on a minimum of 3 days per week. CDC also recommended muscle-strengthening and bone-strengthening activity on at least 3 days/week.

For adults (aged 18–64), recommend 2 h and 30 min a week of moderate-intensity, or 1 h and 15 min (75 min) a week of vigorous-intensity aerobic physical activity, or an equivalent combination of moderate- and vigorous-intensity aerobic physical activity. Aerobic activity should be performed in episodes of at least 10 min, preferably spread throughout the week. Additional health benefits are provided by increasing to 5 h (300 min) a week of moderate-intensity aerobic physical activity, or 2 h and 30 min a week of vigorous-intensity physical activity, or an equivalent combination of both. They also recommended that adults should do muscle-strengthening activities that involve all major muscle groups performed on ≥2 days/week.

For older adults (aged 65 and older), they recommended that older adults should follow the adult guidelines. If this is

not possible due to limiting chronic conditions, older adults should be as physically active as their abilities allow. Older adults should do exercises that maintain or improve balance if they are at risk of falling. For all individuals, some activity is better than none. Physical activity is safe for almost everyone, and the health benefits of physical activity far outweigh the risks. People without diagnosed chronic conditions (such as diabetes, heart disease, or osteoarthritis) and who do not have symptoms (e.g., chest pain or pressure, dizziness, or joint pain) do not need to consult with a health care provider about physical activity.

For adults with disabilities, it is recommended that they follow the adult guidelines. If this is not possible, these persons should be as physically active as their abilities allow. They should avoid inactivity. For children and adolescents with disabilities, they suggest, when possible, to meet the guidelines for children and adolescents—or as much activity as their condition allows. Children and adolescents should avoid being inactive.

For pregnant and postpartum women, regardless of trimester, it is suggested that healthy women who are not already doing vigorous-intensity physical activity should get at least 2 h and 30 min (150 min) of moderate-intensity aerobic activity a week. Preferably, this activity should be spread throughout the week. Women who regularly engage in vigorous-intensity aerobic activity or high amounts of activity can continue their activity provided that their condition remains unchanged and they talk to their health care provider about their activity level throughout their pregnancy.

Despite the numerous benefits of physical activity and the recent federal guidelines, only 48.8% of U.S. adults meet recommended levels of moderate to vigorous physical activity, 37.7% have suboptimal levels of activity, and 14.2% are inactive by self-report.[9] Accelerometer data suggest an overreporting bias with 42% of children aged 6–11 years meeting the current 60 min/day recommendation but only of 8% of adolescents meeting this goal and fewer than 5% of adults meeting the ≥30 min/day recommendation.[10]

PHYSICAL ACTIVITY COUNSELING: THE ROLE OF PRIMARY CARE PROVIDERS

Health care settings offer a potentially attractive vehicle for making changes in the levels of physical activity of inactive individuals because patients visit physicians and other health care providers frequently. Approximately 76% of the U.S. population visits a physician in the course of a year, with an average of 5.3 visits per year.[9] Moreover, patients look to physicians for advice regarding preventive behavior.

The U.S. Preventive Task Force (USPTF) previously in 1996 recommended physical activity counseling based upon the proven efficacy of regular physical activity in reducing the risk for coronary heart disease, diabetes, hypertension, and obesity, and the potential impact of physician counseling on patients' levels of physical activity.[11] However, the more recent USPTF recommendations concluded that evidence was insufficient to recommend for or against behavioral counseling in primary care settings to promote physical activity.[12] This conclusion was based upon the mixed results of physician-based counseling studies on sustained behavior change but fails to include more recent studies and the lessons learned from the research done from other settings such as workplaces, community, and Internet-based studies. In the next section, we review the research done over the past decade in relevant settings and recommend physical activity counseling in physician office based upon expanded primary care office setting using the Care Model proposed by Wagner et al.[13]

The Care Model proposes that improved patient outcomes such as regular physical activity will be fostered in a primary care office setting when an informed, activated patient and family interact with a prepared proactive team approach focusing on such a behavioral change. This requires the synergistic interaction of community resources (safe walking paths, YMCAs, schools, worksites, exercise facilities); self-management support (setting goals, tools for monitoring); delivery system design (previsit motivational assessment, physical activity vital sign, exercise prescriptions, referrals to exercise specialists where applicable, care managers, telephone follow-up); clinical information systems (reports detailing the percentage of patient who are sedentary, overweight, or obese); decision support (pop-ups reminding the provider that patient needs exercise prescription and is motivated to make change, metabolic equivalent (MET) levels of activity choices, injury prevention); the motivated patient, family, and social support (chat rooms, group activities); and the provider and office team (medical assistants, nurses, care managers, community health workers, pharmacists, exercise physiologists, health coaches) trained to perform a role in this system of care.

While not all elements of the care model may be feasible in a given practice, many aspects have been studied and shown to have promise and are discussed in the next section. Indeed, this idealized model of care is a far cry of present primary care practice. Podl et al. observed 4215 office visits in primary care in Ohio and found that only 23% of visits were documented exercise counseling being performed, and on average, this counseling lasted about 47 s.[14] A Canadian survey found that only 11.8% of family physicians routinely counseled about exercise. A total of 58% of the physicians felt less than 25% of their patients would respond to such counseling, less than half felt knowledgeable about exercise counseling, and two-thirds said they didn't have enough time to perform this counseling.[15] These barriers to face-to-face counseling by primary care physicians, namely, lack of physician education, lack of time, and lack of effectiveness of counseling, have been consistently found and suggest a new approach focusing on the team-based model as found in the care model (decision support tools, referral to community resources, exercise specialists, health coaches, and care managers) might overcome these barriers.

RESULTS OF STUDIES ON PHYSICAL ACTIVITY COUNSELING IN PRIMARY CARE SETTINGS

A review of the literature by the American Heart Association Council on nutrition, physical activity, and metabolism in 2006, found that interventions in primary care health care settings can increase physical activity, at least in short-term follow-up.[16] They concluded that some research has shown that even brief (3–10 min) interventions can increase physical activity, and although physicians typically delivered the advice, effective interventions often involved other members of the health care team, such as nurses and health educators. Written prescriptions, provided in addition to verbal advice, may enhance the effectiveness of interventions. Multiple-component interventions that include behavioral strategies such as goal setting, problem solving, self-monitoring, and feedback, as well as supervised exercise and provision of equipment, have generally been more effective than advice only, although these findings have not been entirely consistent across studies. Technological innovations such as using the Internet or making automated phone calls may reduce the effort and cost of interventions, although further research is needed to clarify this.[16]

Walking is the most prevalent and preferred method of physical activity for both work and leisure purposes, thus making it a prime target for physical activity promotion interventions. Williams et al. reviewed 14 randomized controlled trials, which tested interventions assessing walking behavior and found that intensive interventions can increase walking behavior relative to controls.[17] Brief telephone prompts seem to be as effective as more substantial telephone counseling. They found preliminary evidence that prescriptions to walk 5–7 days/week did better than those that recommended 3–5 days/week and that moderate-intensity pace did better than vigorous-intensity pace. They found no differences in benefit in the volume of physical activity, measured as total walking minutes, when single or multiple daily walking bouts were prescribed. Interventions delivering physical activity promotion through non face-to-face channels showed efficacy in promoting overall physical activity, especially when theory-based and individually tailored. Mass media campaigns targeting broader audiences did not increase walking behavior.

Since these reviews several more recent trials inform recommendations for physical activity counseling in primary care. The Activity Counseling Trial was a 24 month trial in 11 primary care practices that tested social-cognitive theory-based interventions to increase self-efficacy, social support, and environmental resources as a means to increase physical activity in primary care practice.[18] They compared 2–4 min of brief physician counseling including assessing present level of activity, providing advice to increase activity, and setting long-term goals of physical activity using a target of ≥5 days/week of ≥30 min of moderate activity or ≥3 days of 30 min of intense vigorous activity. In addition, the providers referred patients to an on-site health educator for further health education and counseling. A second group received a more intense intervention including the same brief counseling plus a 30–40-minute behavioral counseling session with the health educator, a motivational videotape, confirmation of physical activity goals, plus an individualized activity plan. Telephone calls were made 1 week after intervention for advice and support, and this second group also received monthly newsletters, weekly mail-back cards for reporting weekly physical activity, current goals, etc. This group was also given a step-counter. A third more intense intervention group received all aspects of the first two groups plus biweekly counseling calls and monthly calls after the first 6 weeks and during the second year, telephone calls were made on a mutually negotiated basis. In addition, participants received weekly classes at centers by the health educators on enhancing behavioral skills. The investigators found that all three groups increased physical activity (PA) at 6 months: in the brief advice group, 14.3% (from a baseline of 1.5%) were at the PA goal for women and 16.4% (from a baseline of 0.6%) were at the PA goal among men; in the second group, 9.9% (from a baseline of 0.8%) were at PA goal in women and 29.9% (from a baseline of 2.5%) were at the PA goal in men; and in the third group, 25.7% (from a baseline of 0.8%) were at the PA goal in women and 18.5% (from a baseline of 1.3%) were at the PA goal in men. *This study suggests that even a brief physician intervention of 2–4 min resulted in significant improvement in physical activity, with only modest increased benefit for more intensive interventions.*

Looking at psychosocial mediators of physical activity changes in the Activity Counseling Trial, Baruth et al. found that behavioral processes seemed more important than cognitive processes with some sexual dimorphism in this trend.[19]

Behavioral processes such as self-commitment, substituting alternatives, rewarding oneself for being physically active, and increased self-efficacy played the most important role in predicting increased in physical activity. *The authors suggested that physical activity interventions should incorporate strategies that specifically aim to increase participant's use of behavioral processes, such as encouraging participants to enlist social support, reward themselves for being active, or substitute alternatives for being active instead of sedentary.*

Petrella et al. compared exercise prescription alone vs. stage-based exercise counseling program in older sedentary adults in family practice in Canada.[20] Similar to the activity counseling trial (ACT), they found that the both groups increased physical activity and cardiovascular fitness, suggesting that a brief intervention may be quite effective, especially if it accounts for the patient's level of cardiovascular fitness.

Van Sluijs et al., in a Dutch general practice cohort, compared brief physician advice with a trans-theoretical model of physical activity intervention using the PACE protocol.[21,22] After 1 year, both groups increased physical activity to greater than 300 min of leisure time physical activity at least moderate-intensity. *This study again suggests that tying a patient's medical condition to the need to increase regular*

physical activity and performing brief exercise counseling appear to be helpful.

Morey et al.,[23] using a multicomponent physical activity counseling protocol involving clinical endorsement of the need for more physical activity, frequent telephone counseling, and quarterly tailored mailing in elderly veterans in primary care in North Carolina, found a significant increase in physical activity from 57 to 127 min of weekly physical activity in the intervention group but no change in the usual care group. *This study demonstrates that even in elderly patients with multiple comorbidities, unsupervised physical activity is safe and an intensive physical activity counseling protocol was effective in a primary care setting.*

Use of the Internet to increase physical activity has been tested in several clinical trials with mixed results. Marcus et al. compared tailored Internet, to tailored print to standard Internet from overweight, sedentary community participants. All three groups had less than 10 min of moderate to vigorous PA per week, and by 6 months, the tailored groups did slightly better than the standard Internet, but this finding was not statistically significant (120, 112, 90 min, $p = 0.15$, respectively). By 12 months, all three groups sustained their increased physical activity (90, 90, 80 min; $p = 0.74$, respectively) but with no superiority of the tailored interventions. The most commonly used standard Internet site was the American Heart Association website, http://www.startwalkingnow.org/.[24]

APPROACH TO PATIENT-CENTERED PHYSICAL ACTIVITY COUNSELING IN PRIMARY CARE

Based on the barriers to physical activity counseling including the lack of education and confidence in exercise counseling by primary care physicians, the lack of time during a 12–15 min office visit in primary care and the lack of perceived efficacy of the interventions available to primary care physicians, and the body of evidence from clinical trials regarding physical activity interventions, the following approach is recommended.

Assess Present Level of Physical Activity

Most primary care physicians assess physical activity in selected patients using no standardized approach such as during new patient visits, during health maintenance exams, and during assessment of patient visits regarding obesity, diabetes, hypertension, dyslipidemic, osteoarthritis, and other musculoskeletal problems. However, many primary care physicians do not document these assessments at all and few perform them routinely unless they have a systems-based approach. One relatively successful technique is to incorporate physical activity into the vital sign assessment.[25] With the increasing use of electronic medical records, the physical activity vital sign assessment can be easily added to body mass index assessments. Two relatively simple questions, one assessing sedentary behavior, i.e., how many hours of sitting, including commuting time, TV watching, and computer use, and the second, asking about moderate to vigorous physical activity. The questions used by the Behavioral Risk Factor Survey are appropriate, i.e.,—During the past month, other than your regular job, did you participate in any physical activities or exercises such as running, calisthenics, golf, gardening, or walking for exercise? If yes, how many hours per week. Alternatively, the following question has been used in successful clinical trials.[26]

> As a rule, do you do at least half an hour or moderate or vigorous exercise (such as walking or a sport) on five or more days of the week?

After reviewing a patient's level of physical activity in more depth to determine if the screening question truly defines patients who are in need of exercise counseling, link the patient's physical inactivity to an important medical problem that the patient has or to a future health concern.

That is, as you are probably aware, your lack of exercise is associated with you _____ (being overweight, having high cholesterol, having diabetes, having high blood pressure, being at risk for having thin bones and breaking a hip, etc). This risk can be helped with a change in your physical activity levels.

Assess Patients Willingness to Change Behavior

How willing are you to increase your physical activity over the next 2 weeks? If the patient is willing, then proceed with exercise prescription. If they are not willing, ask them why not?

Assess Patient Safety to Exercise

Physical activity, while known to increase longevity, reduce cardiovascular risk, promote weight loss, cease smoking, improve mood, lower blood pressure, and increase bone density over the long term, may also be associated with increased risk of injury, accidents, and sudden cardiac death during exercise bouts. Exercise stress testing and supervised exercise programs are rarely needed even for elderly patients with multiple comorbidities. Other chapters in this textbook review the indications for exercise testing and medical evaluations of at risk patients. However, multiple studies have shown that gradual exercise at a mild to moderate pace for patients is safe without the need for formal exercise testing even in deconditioned, high-risk patients such as those postmyocardial infarction.[27] Reviewing any history of prior injuries with exercise and suggesting corrective action is appropriate. Most injuries occur due to overuse injuries from a rapid escalation of physical activity or improper equipment such as shoe wear without appropriate insoles, heel counters. A rule of thumb is to not increase activity by more than 10% per week in terms of total minutes.

Write Exercise Prescription

Multiple studies have shown writing a written exercise prescription is more effective than simply giving advice. Each prescription should specify four components of the physical activity plan: Frequency, Intensity, Type, and Time (or duration). These four components can be easily remembered by both providers and patients when the mnemonic FITT is used.[27]

Determining the appropriate level of intensity of physical activity is usually the first step in completing the prescription. Physical activity has been defined as "any bodily movement produced by skeletal muscles that results in energy expenditure,"[27] while moderate physical activity refers to any activity performed at an intensity of 3–6 METS (work metabolic rate/resting metabolic rate) or 4–7 kcal/min.[26] This level of physical activity can be achieved by most healthy adults by walking briskly (3 mph), cycling for pleasure (<10 mph), swimming with moderate *effort,* pulling a golf cart, mowing the lawn with a power mower, painting, or performing general cleaning at home.[26] Moderate activities have also been defined as activity at 50%–70% of maximum heart rate (220 – age) (Table 98.1).[28]

In contrast, vigorous activity has been defined as more than 6.0 METS, more than 7 kcal/min, or more than 70% maximum heart rate. For most sedentary patients, a moderate level of physical activity is an appropriate initial goal, especially if they have not engaged in vigorous physical activity in the recent past or if they have a medical condition that would preclude their participation in vigorous activity or require formal exercise testing.[27] For individuals already engaged in moderate activity, advancement to vigorous activity may be an appropriate goal, while those individuals who have been totally sedentary might be best off starting out with a goal of activity that falls below the level of moderate intensity (e.g., walking slowly, light stationary cycling, or light stretching).

Patients can be taught to monitor the level of intensity of physical activity in several ways, including determining their desired heart rate zone and instructing them to take their pulse rate while exercising using a perceived exertion scale, such as the Borg Perceived Exertion Scale.[28] (Figure 98.1).

If patients are able to talk comfortably but get a little sweaty while exercising, this usually indicates that they are within 50%–75% of their maximum heart rate.

Once the level of intensity of physical activity is decided upon, the other elements of the FITT exercise prescription can be completed. To meet the national physical activity recommendations, the goal for moderate-intensity activity should be ≥5 days a week, and the duration of activity each day should be 30 min; for vigorous levels of activity, the goals are three sessions of ≥20 min.[27,29] However, as noted previously, for patients who are not willing to meet the goal for moderate-intensity activity, an appropriate initial goal might be to engage in very short bouts (e.g., 5–10 min) of activity a few times per week. Such patients might be encouraged to gradually increase the time spent during each session of activity so that they eventually accumulate at least 30 min/day. Patients who choose to engage in activities meeting criteria for moderate or vigorous intensity should also be encouraged to spend a few minutes to warm up with stretching exercises or light activity, especially if they are older adults or have been very sedentary. Finally, the type of activity chosen for the exercise prescription should be based on several criteria: something the patient enjoys, an activity that was previously engaged in on a regular basis, an activity that can be easily integrated into daily routine

TABLE 98.1

(e.g., walking during lunch break, housework, yard work), an activity that meets social or recreational needs or goals (e.g., sports, dancing), and an activity that can be performed safely or under supervision (e.g., walking clubs, use of a fitness facility). The prescription plan may also specify a variety of activities that can be combined to meet the overall goal for frequency and duration.

The use of an exercise or physical activity prescription facilitates the behavior change process in a number of ways. First, it sets a specific physical activity goal for the patient. Second, like other prescriptions written by the health provider, it conveys the importance of physical activity to the patient and builds on the influence and authority of the health care provided. Third, it gives the health care provider something concrete and tangible to do to address the problem of sedentary behavior. Fourth, the process of completing the prescription facilitates the development of a mutually agreed-upon plan for addressing physical activity. The prescription, if also signed by the patient, serves as a written contract between patient and provider that may enhance the patient's adherence to the plan. Finally, if a copy of the prescription is saved in the chart, it can be used during subsequent visits to review the patient's progress.

Encourage Behavioral Processes

Behavioral medicine research has shown that patients that track their behavior are more likely to accomplish a behavioral change compared with those who do not. Asking patients to fill out a physical activity log is a helpful way to accomplish this. Social support such as exercising with a buddy or support person, joining a walking club or gym, and training for an event can lead to increased physical activity.

While regular walking is the most common form of exercise by most Americans, finding safe, walking paths can be an issue. Recently, there has been much work by communities, states, the CDC, and the American Heart Association to develop access to safe walking paths. Primary Care Practices should investigate or be aware of walking paths in their patient's neighborhoods.

While multiple websites are available, the American Heart Association's website, http://www.startwalkingnow.org/, provides tips about starting a walking program, nutrition and physical activity logs, walking paths near patients who have a job and a social networking site to find other community members starting a walking program, and providing emotional support via a monitored chat room.

Another helpful web-based resource is a wellness programs supported by the patients health plan or employer. Shape UP the Nation, http://www.shapeupthenation.com/, provides programs for physical activity as well as programs related to weight loss, healthy eating, and smoking cessation. Additional websites and e-health tools are described in Chapter 101.

Arrange Follow-Up

The last step of exercise counseling is to arrange follow-up. This can be either by a face-to-face office visit with either the provider or other member of the care team, i.e., team nurse, health coach, care manager, or by remote contact such as by telephone, e-visit, or some combination of office visit and remote contact. Most studies suggest that follow-up contact should be within several weeks of the initial exercise counseling session.

SUMMARY

Physical inactivity and sedentary behavior are reversible risk factors for multiple chronic diseases. Primary care physicians, particularly in the setting of a Patient-Centered Medical Home, have the opportunity to use the "teachable moments" within patient's visits to provide exercise counseling in the context of a comprehensive system of care and thus are able to mimic clinical trials that have shown to be effective in improving physical activity. This office system of care in conjunction with public health and policy initiatives in changing the physical activity environment (safe walking and cycling paths, take the stairs campaigns) and social media campaigns provide new opportunities for incorporating exercise counseling in primary care.

INTRODUCTION

The purpose of this chapter is to provide advice for physicians prescribing exercise for their patients during an office visit. A goal of increasing intentional exercise, while concurrently reducing sedentary time by interspersing short periods of physical activity and standing between periods of sedentary activity throughout the day is a goal for most adults, including persons with chronic disease or disability [1–5]. Because of the complexities of exercise training in individuals with chronic diseases and the considerable benefits of an individualized exercise program, referral to a certified advanced fitness professional with training experience working with people with chronic diseases is recommended [1].

SAFETY CONSIDERATIONS AND SCREENING

For most people, the risks of exercise are greatly exceeded by the benefits of exercise [1,5]. A very low risk of musculoskeletal and cardiovascular disease (CVD) complications is associated with walking and moderate-intensity physical activities, and these activities are recommended for most adults to achieve improved health [1]. The risks of adverse CVD and musculoskeletal sequelae increase when an inactive individual engages in *unaccustomed* vigorous exercise [1,6], so it is important to gradually progress to vigorous exercise in those insufficiently active or sedentary.

Nonetheless, there are individuals in whom exercise may be hazardous, and the reader is referred to current clinical guidelines for exercise for contraindications to exercise [1,5,7–9]. Preexercise screening is helpful for those beginning exercise for the first time or after a long hiatus, regular exercisers who plan to substantially increase or change their exercise program, and anyone with a change in health status or new onset signs or symptoms. It is important *not* to assume that people who regularly exercise do not need regular evaluation for signs and symptoms of CVD, as these are often overlooked by both the individual and the health care provider [1,10]. Diagnostic exercise testing may be useful in persons who have suspected or known coronary heart disease (CHD) [1,8,11–13]. The evidence is less clear in asymptomatic persons with diabetes or with multiple CVD risk factors, but there may be value of diagnostic testing particularly in individuals at moderate or high risk [12]. Diagnostic exercise testing is of questionable value as a routine screening in asymptomatic low risk adults [1].

Prescreening for exercise should generally include

- Physical examination and review of the current and past medical history to identify contraindications to exercise
- Screening for and educating about prodromal signs and symptoms of CVD
- Diagnostic exercise testing as indicated according to clinical practice guidelines

RECOMMENDATIONS FOR EXERCISE PRESCRIPTION

A program of regular exercise *beyond physical* activities of daily living is *essential* for most adults to improve and maintain physical fitness and health [1–5]. Optimally, an individual exercise program will include several types of exercise: cardiorespiratory, resistance, flexibility, and neuromotor exercise training [1–3,5]. It is important to individualize the exercise prescription according to an individual's habitual

TABLE 99.1
Recommendations for the Individualized Exercise Prescription

Cardiorespiratory ("Aerobic") Exercise	Recommendation
Frequency	• ≥5 days · week^{-1} of moderate exercise
	• Or ≥3 days · week^{-1} of vigorous exercise
	• Or a combination of moderate and vigorous exercise on ≥3–5 days · week^{-1}
Intensity	• Moderate and/or vigorous intensity
	• Less intense exercise may be beneficial in deconditioned persons.
Time	• 30–60 min · day^{-1} of purposeful moderate exercise
	• Or 20–60 min · day^{-1} of vigorous exercise
	• Or a combination of moderate and vigorous exercise per day
Type	• Regular, purposeful exercise that involves major muscle groups and is continuous and rhythmic in nature
Volume	• A target volume of ≥500–1000 MET · min · week^{-1}
	• Or >1000–1500 kcal · week^{-1}
	• Or increasing pedometer step counts by ≥ 2000 steps · day^{-1} to reach a daily step count ≥7000 steps · day^{-1}
Pattern	• One (continuous) session per day
	• Or multiple sessions of ≥10 min
Progression	• A gradual progression of exercise volume by adjusting exercise duration, frequency, and/or intensity as tolerated
Resistance Exercise	
Frequency	• 2–3 days · week^{-1}
Intensity	• Moderate to hard intensity for novice to intermediate exercisers
	• Very light to light intensity for older or sedentary persons
Time	• Duration to complete exercises
Type	• Resistance exercises using each major muscle group
Repetitions	• 8–15 repetitions
Sets	• 1–4 sets
Pattern	• 2–3 min rest between each set of repetitions
	• A rest of ≥48 h between sessions
Progression	• A gradual progression of greater resistance, and/or more repetitions per set, and/or increasing frequency as tolerated
Flexibility Exercise	
Frequency	• ≥2–3 days · week^{-1}
Intensity	• Stretch to the point of feeling tightness or slight discomfort
Time	• Hold for 10–30 s
Type	• Exercises for each of the major muscle-tendon units
Volume	• 60 s of total stretching time for each flexibility exercise
Pattern	• Repeat of each exercise 2–4 times
Progression	• Gradual progression as tolerated
Neuromotor Exercise Training	
Frequency	• ≥2–3 days · week^{-1}
Time	• ≥20–30 min · day^{-1}
Type	• Exercises involving motor skills such as balance, agility, coordination, and gait, and multifaceted activities such as tai chi and yoga
Volume	• ≥60–150 min per week
Pattern	• Single or multiple shorter sessions per day
Progression	• Gradual progression as tolerated

Source: Adapted from Haskell, W.L. et al., *Med. Sci. Sports Exerc*., 39, 1423, 2007; Garber, C.E. et al., *Med. Sci. Sports Exerc*., 43, 1334, 2011, 2010, 2008a; Nelson, M.E. et al. *Med. Sci. Sports Exerc*, 39, 1435, 2007.

physical activity, physical function, health status, individual exercise responses, and stated goals [1]. Warming up, cooling down, employing a gradual progression of exercise volume and intensity, attention to proper training technique, and avoiding exercise under extreme heat or cold may be effective in reducing the risks of exercise [1,10].

Current recommendations for exercise are presented in Table 99.1. These volumes of exercise should be considered as targets for optimal exercise behavior, exercise less than these amounts is beneficial due to the dose response nature of exercise [1,5]. Therefore, an effective approach is to develop an exercise program that is feasible and enjoyable according to the individual patient's physical capabilities, personal goals and preferences, and limitations imposed by factors such as time and the physical and social environment [1]. The goal is to progress the exercise program gradually over time as tolerated to attain levels of exercise at or above the recommended targets and to enhance health benefits [1].

THE EXERCISE TRAINING SESSION

The exercise training session optimally includes several phases [1,7]:

- Warm-up: ≥5–10 min of low- to moderate-intensity cardiovascular and muscular endurance activities
- Conditioning: ≥20–60 min of aerobic, resistance, neuromotor, and/or sports activities
- Cooldown: ≥5–10 min of low to moderate-intensity cardiovascular and muscular endurance activities
- Stretching: At least 10 min of stretching exercises performed after the warm-up or cooldown phase

CARDIORESPIRATORY (AEROBIC) EXERCISE

Cardiorespiratory or aerobic exercise is sustained endurance exercise such as walking, cycling, aerobic group exercise classes, and "cardio" equipment found in gyms (e.g., elliptical trainer, treadmill, and stair stepper). These exercises do not require much skill to perform and so can be recommended for most adults [7]. Adequate levels of physical fitness and some skill are needed to engage in other cardiorespiratory exercises such as jogging, running swimming, rowing, kayaking, cross country skiing, sports, and some group exercise classes, so these can be part of the exercise program for more advanced exercisers [7]. Table 99.1 shows the recommended quantity and quality of aerobic exercise.

Estimating Exercise Intensity

Cardiorespiratory exercise intensity can be measured in absolute or relative terms. The metabolic equivalent (MET) is an index that represents the rate energy expenditure, so that 1 MET is the rate of energy expenditure at rest and 10 METs represents an energy expenditure 10 times greater than resting energy expenditure [1,13]. Tables of the METs for a wide range of physical activities and exercise are available [14,15]. Absolute measures of energy expenditure can result in misclassification of exercise intensity (e.g., moderate, vigorous), so *relative* measures of exercise intensity (energy expenditure of an activity relative to the individual's maximal capacity) are preferred for exercise prescription [1,3]. The most practical methods for clinical use is percent of the estimated or measured maximum heart rate ($\%HR_{max}$) or heart rate reserve ([Maximal heart rate – resting heart rate] + resting heart rate) or the maximal oxygen uptake ($\%VO_{2max}$) [7]. Direct measurements of heart rate and oxygen uptake as gained by exercise testing are recommended for greater accuracy, but when not feasible, estimation of exercise intensity is acceptable [1]. Table 99.2 shows the approximate absolute and exercise intensity ranges for various levels of exercise intensity. Self-rating scales that measure perceived effort and the pleasantness of exercise can be used to monitor or refine the prescribed exercise intensity of exercise in conjunction with the absolute or relative measures described earlier.

Estimating Exercise Volume

It is helpful to estimate exercise volume as part of the exercise prescription because of the important role of exercise volume in the attainment of beneficial health and fitness outcomes, particularly weight management [1]. Pedometers are effective for promoting physical activity, and they can provide an approximation of exercise volume [16]. The $MET \cdot min \cdot week^{-1}$ and $kcal \cdot min \cdot week^{-1}$ can be used to more precisely estimate exercise volume for individuals. The $MET \cdot min^{-1}$ and $kcal \cdot min^{-1}$ for many of physical activities can be estimated using published tables [14,15].

RESISTANCE EXERCISE

There is increasing evidence for the health benefits resulting from participation in resistance exercise and with improvements in muscular fitness [1–3,5]. Resistance training each major muscle group (i.e., the muscle groups of the chest, shoulders, upper and lower back, abdomen, hips, and legs) using weight machines, free weights, stretchy resistance bands, or other resistance equipment is recommended. A program that includes multijoint exercises (more than one muscle group) and single joint exercise can be recommended. This might include multijoint exercises such as the chest press, shoulder press, pull-down, dips, lower-back extension, abdominal crunch/curl-up, leg press, and squats, and single joint exercises such as biceps curls, triceps extensions, quadriceps extensions, leg curls, and calf raises target single muscle groups.

Resistance training should be performed with at least 48 h separating the exercise training sessions for the same muscle group [1,17]. To improve muscular strength, a resistance level that allows a person to complete about 8–15 repetitions (up to 20 repetitions) per set should be selected. Each set should be performed to the point of muscle fatigue but not failure.

TABLE 99.2
Relative and Absolute Exercise Intensity for Cardiorespiratory Endurance and Resistance Exercise

	Relative Intensity				Absolute Intensity (MET) by Age		
Intensity	%HRR or %VO_2R	%HR_{max}	%VO_{2max}	Perceived Exertion (Rating on 6–20 RPE Scale)	Young (20–39 Years)	Middle Aged (40–64 Years)	Older (≥65 Years)
Very light	≤30	≤57	≤37	≤ Very light (RPE ≤ 9)	≤2.4	≤2.0	≤1.6
Light	30–40	57–64	37–45	Very light–fairly light (RPE 9–11)	<4.8	<4.0	<3.2
Moderate	40–59	64–76	46–63	Fairly light to somewhat hard (RPE 12–13)	4.8–7.1	4.0–5.9	3.2–4.7
Vigorous	60–89	77–95	64–90	Somewhat hard to very hard (RPE 14–17)	7.2–10.1	6.0–8.4	4.8–6.7
Near maximal to maximal	≥90	≥96	≥91	≥Very hard (RPE ≥ 18)	≥10.2	≥8.5	≥6.8

Source: Adapted from Garber, C.E. et al., *Med. Sci. Sports Exerc*., 43, 1334, 2011, 2008a; Swain, D.P., *Sports Med*., 30, 17, 2000; Nelson, M.E. et al., *Med. Sci. Sports Exerc*, 39, 1435, 2007.

VO_{2max}, maximal oxygen uptake; HR_{max}, maximal heart rate; VO_2R, oxygen uptake reserve; HRR, heart rate reserve; (% HR_{max}, percent of maximal heart rate; %VO_{2max}, percent of maximal oxygen uptake; RPE, ratings of perceived exertion; MET, metabolic equivalent.

FLEXIBILITY EXERCISE

Joint range of motion can be improved by flexibility exercises, and these may also enhance postural stability and balance—more so when combined with resistance exercise [1]. Flexibility exercises are most effective when preceded by a warm-up with light-to-moderate cardiorespiratory or muscular endurance exercise. The stretch position is best held for 10–30 s at the point of tightness or slight discomfort. Attaining 60 s of total stretching time is the goal for each exercise [1]. Many types of stretching exercises can be effective, but for most adults, the most appropriate types are as follows:

- Active static stretching entails holding a position using the strength of the agonist muscle, typical of many forms of yoga.
- Passive static stretching in which a body position is held by another part of the body, or employing a device such as elastic bands or a barre.
- Dynamic slow movement stretching encompasses a gradual transition from one body position to another.

NEUROMOTOR EXERCISE TRAINING

Neuromotor exercise, or functional fitness training, focuses on motor skills such as balance, coordination, and agility. Neuromotor exercise training improves balance, agility, and muscle strength and reduces the fear of falling and the risk of falls in older people [1,3]. Tai chi, qigong, and yoga are multifaceted activities that involve varying combinations of neuromotor, flexibility, or resistance exercise, and so can be particularly helpful when included in a program of exercise for adults.

NUTRITION AND HEALTH

Consuming a healthy diet is associated with lower risks for chronic disease morbidity and mortality.[1] It has been estimated that 400,000 to more than 500,000 deaths/year are attributable to poor diet and physical inactivity.[2] If the increasing trend of overweight is not reversed, poor diet and physical inactivity will likely overtake tobacco as the leading preventable cause of mortality in the near future.[2] The most recent data indicate that 72% of men and 64% of women are overweight or obese, with about one-third of adults being obese.[3] Even in the absence of overweight, poor diet is associated with major causes of morbidity and mortality. These include coronary heart disease, stroke, hypertension, type 2 diabetes, osteoporosis, and some types of cancer.[1,4,5]

DIETARY GUIDELINES

Nutritional problems are prevalent in the United States. Adults and children eat inadequate quantities and varieties of fruits, vegetables, and whole grains and consume insufficient amounts of calcium and iron, too much saturated fat and sodium, and too many calories from solid fats, added sugars, and refined grains.[1,6] The U.S. Department of Agriculture recently released the 2010 Dietary Guidelines for Americans.[1] By law, these guidelines are reviewed and updated every 5 years by a committee of scientific experts. The 2010 Dietary Guidelines recommendations encompass two overarching concepts:

- Maintain calorie balance over time to achieve and sustain a healthy weight by balancing calories consumed through food and calories expended through physical activity.
- Focus on consuming nutrient-dense foods and beverages. Limit intake of sodium, solid fats, added sugars, and refined grains and emphasize nutrient-dense foods and beverages (vegetables, fruits, whole grains, fat-free or low-fat milk and milk products, seafood, lean meats and poultry, eggs, beans and peas, and nuts and seeds).

Specific dietary guidelines are shown in Table 100.1. To meet these guidelines, many would need to make significant changes in their eating habits and lifestyles. To facilitate these changes, individuals will need support from all sectors of society, including health professionals, educators, other individuals and families, communities, organizations, businesses, and policymakers.[6]

NUTRITION COUNSELING: THE ROLE OF PRIMARY CARE PHYSICIANS

Nutrition counseling is effective in changing dietary habits and has been shown to reduce medication costs.[7–12] National guidelines stress the importance of physician involvement

TABLE 100.1
Specific Dietary Guidelines, 2010

- Reduce daily sodium intake to less than 2300 mg (1500 mg among persons 51+ and those of any age who are African American or have hypertension, diabetes, or chronic kidney disease)
- Consume less than 10% of calories from saturated fatty acids by replacing with monounsaturated and polyunsaturated fatty acids
- Consume less than 300 mg/day of dietary cholesterol
- Keep trans fatty acid consumption as low as possible
- Reduce intake of calories from solid fats and added sugars
- Limit consumption of foods that contain refined grains, especially refined grain foods that contain solid fats, added sugars, and sodium
- If alcohol is consumed, consume in moderation—up to one drink per day for women and two drinks per day for men
- Increase vegetable and fruit intake
- Eat a variety of vegetables, especially dark-green and red and orange vegetables and beans and peas
- Consume at least half of all grains as whole grains. Replacing refined grains with whole grains
- Increase intake of fat-free or low-fat milk and milk products
- Choose a variety of protein foods, which include seafood, lean meat and poultry, eggs, beans and peas, soy products, and unsalted nuts and seeds
- Increase the amount and variety of seafood consumed by choosing seafood in place of some meat and poultry
- Replace protein foods that are higher in solid fats with choices that are lower in solid fats and calories and/or are sources of oils
- Use oils to replace solid fats where possible
- Choose foods that provide more potassium, dietary fiber, calcium, and vitamin D. These foods include vegetables, fruits, whole grains, and milk and milk products

Dietary guidelines for Americans, 2010,* U.S. Department of Health and Human Services, U.S. Department of Agriculture, Washington, DC, 2010, http://www.cnpp.usda.gov/DGAs2010-PolicyDocument.htm, accessed April 26, 2011.

in nutrition counseling.[5,6,13] Healthy People 2020 includes objectives to (1) increase the proportion of physician office visits made by patients with a diagnosis of cardiovascular disease, diabetes, or hyperlipidemia that include counseling or education related to diet and nutrition (target: 22.9%); (2) increase the proportion of physician office visits made by adult patients who are obese that include counseling or education related to weight reduction, nutrition, or physical activity (target: 31.8%); and (3) increase the proportion of physician visits made by all child or adult patients that include counseling about nutrition or diet (target: 15.2%).[6] Specific clinical guidelines regarding hypertension, hypercholesterolemia, and diabetes mellitus also contain specific nutrition counseling recommendations.[14–17] In addition, the need for primary care physicians to provide counseling on nutrition and physical activity has been highlighted by both the 2010 *Surgeon General's Vision for a Healthy and Fit Nation*[18] and First Lady Obama's "Let's Move Campaign."[19]

Most Americans have a primary care physician whom they see at least once in every 2 years.[20] Experts suggest that there is a nutrition-related reason for more than 25% of all visits to primary care physicians[21] and patients want their physicians to provide nutrition counseling.[22–25] Despite this, however, most primary care physicians do not adequately deliver nutrition counseling to their patients.[5,21,26–39] For example, a study that directly observed physicians' counseling on dietary habits in private medical practices found that physicians counseled adult patients on dietary habits in only 25% of visits.[28] Healthy People 2020 reports even lower rates for adults and children combined: 12.2% of physician office visits of all child or adult patients included counseling about nutrition or diet in 2007 (Healthy People 2020 report). Furthermore, when dietary counseling does occur, the time spent is usually less than 5 min per patient, with the average time being 1 min.[27] Other studies have shown varying rates, but all are low.[25,40]

Barriers to nutrition counseling in the physician's office include time limitations; inadequate reimbursement; lack of financial incentives; inadequate nutrition training in medical schools and residencies; lack of confidence in counseling skills; uncertainty of the effectiveness of nutrition counseling; working in an acute care environment; lack of a systematic, organized approach within the practice structure; and lack of resources, tools, and support systems to facilitate nutritional counseling.[21,39,41–44] Primary care physicians do think nutrition counseling is important[21,38] and when they provide nutrition counseling to patients, they can be effective.[45–47] However, the current, time-pressured care process makes it difficult to accommodate this type of intensive lifestyle counseling into usual practice.[21]

Thus, nutrition counseling in the primary care office setting needs to be performed more frequently; but it is unlikely that this will happen unless it can be accomplished in a short period of time with little additional training. Evidence is growing that brief counseling strategies by the physician can be effective.[5,48–55] Results from less intensive, minimal-contact interventions to supplement brief primary care physician advice/counseling appear similar to results achieved through medium-intensity, routine face-to-face counseling from nutritionists, dietitians, or specially trained primary care physicians.[5] However, translation to practice of brief physician interventions is less than optimal, and more effectiveness and translational research is needed.[5,21] In the meantime, what is a primary care physician to do? Something is better than nothing. Providing 5 min or less of nutrition counseling during a patient visit is feasible and can be effective as discussed earlier, and if physicians do not discuss nutrition, patients may take this as a sign that they don't need to make any dietary changes.[56]

HOW TO DO IT?

The following principles of patient-focused behavioral counseling can help physicians improve the effectiveness of their communications with patients regarding lifestyle changes,

including dietary changes: (1) accept the patient as he or she is, (2) acknowledge that the patient has some answers, (3) build the patient's confidence, (4) set realistic expectations for self and patient, and (5) share responsibility.[56] Effective interventions combine nutrition education with behaviorally oriented counseling to help patients gain the motivation, skills, and support needed to change their eating patterns and food preparation practices.[5] In general, these interventions can be described by the 5A behavioral counseling framework.[5,57] In addition to the 5As model, patient-centeredness is an important quality of the physician–patient interaction. Patient-centeredness can be defined as being responsive to a patient's needs, beliefs, values, and preferences.[58,59] An effective technique for ensuring that the patient–provider interaction is patient-centered is motivational interviewing (MI), which can be woven into the 5As.

The primary "spirit" of MI is that it takes a *collaborative* approach to motivating an individual toward behavior change by eliciting the individual's own internal resources for change in an *evocative* manner and supporting the *autonomy* to make his/her own decision about change.[60] MI focuses on behavior change as identified by the patient rather than the physician. In this collaboration, the physician takes on a guiding role as a resource for patient-guided change.[60] Physician advice can be incorporated into these encounters but only after eliciting the patient's permission.[60,61] MI helps patients identify behaviors that they may be willing or ready to consider changing, and therefore, the counseling is less likely to be frustrating for both physician and patient. The goal of MI is to elicit "Change Talk" (desire, ability, reasons, or need for change [DARN]), which, in turn, leads to commitment language from the patient. MI is especially useful for individuals who are less ready to change,[60–62] making it especially useful in the primary care setting where physicians may be raising previously unaddressed health issues or sensitive issues like overweight and obesity. MI has been used effectively in a brief format for many health and lifestyle issues including diet, exercise, and weight.[60,61,63–65]

The 5As construct (ask, assess, advise, assist, and arrange) has been promoted as an approach to brief health behavior counseling, including nutrition and weight management.[57] Following the 5As protocol has been associated with greater patient motivation to lose weight and intentions to change behavior.[58] The 5As construct has been reinterpreted in several ways[56,58,66] but is often organized as shown in the following text for nutrition counseling and weight management. The interpretation in the following text integrates MI communication techniques into the 5As construct to increase patient motivation for dietary change:

1. *Assess* dietary practices in the context of health risks.
2. *Advise* to change dietary practices with clear, specific, and personalized advice for behavior change.
3. *Agree* on focus of counseling and treatment based on the patient's interest and willingness to change.
4. *Assist* the patient in setting and achieving goals to change dietary practices. Address motivational barriers by using counseling and self-help techniques. Determine whether the patient needs additional information or help; refer to dietitian or other resources as needed.
5. *Arrange* regular follow-up and support.

Each of these 5A steps will now be discussed in more detail with an inclusion of MI concepts. In Table 100.2, see an example of a brief counseling encounter using these principles that can be accomplished by a physician in 5 min.

Assess Dietary Practices in the Context of Health Risks

The first step in nutrition counseling is to assess patients' current dietary behaviors. Most physicians who do not have formal training in nutrition need user-friendly tools that can rapidly and accurately assess diet and monitor change among adult patients in primary care settings. There are a variety of such tools available. They can be self-administered, are easily scored, and take 10 min or less to complete. Some of these tools focus on specific health problems (like high cholesterol or heart disease),[67–70] while others focus on the total diet.[71,72] In addition, some of the tools not only assess patients dietary behaviors but also provide information to aid physicians in discussing patients' answers and counseling them appropriately. Two such tools are highlighted in the subsequent sections. These were chosen because they are brief and user-friendly and enable physicians not only to rapidly and accurately assess patients' diets but also to immediately facilitate discussion and goal-setting. Both of these tools can be self-administered by the patient at home, in the waiting room, or in examining room prior to meeting with the physician. The physician then can quickly review the completed questionnaire and use it to advise the patient.

Rate Your Plate

This semi-quantitative questionnaire directs a patient to record his or her eating patterns and provides an assessment of the nutritional quality of the food choices.[69] This tool has been validated and shown to be an effective part of a program to lower patient's cholesterol in primary care practice, worksites, and other community settings.[73] Questions are focused on food choices and preparation methods with responses separated into three columns (A, B, C) with column C having the most healthful response choices. Several different versions (a heart disease prevention version and a total diet version) are available by contacting Dr. Gans. The Rate Your Plate tool can be easily self-scored or scored by the physician. Physicians can quickly interpret the patient's score and responses, praise the patient for positive eating habits (Column C), help the patient determine which nutrition issues are most problematic (Column A), and determine whether the patient would like to change these eating habits. There is also an area for goal-setting, which can be self-administered or done jointly with the physician.

TABLE 100.2
5 Min Nutrition Counseling for Dietary Change

Steps (5As)	Action[a]
ASSESS: Eating habits	Have patient complete a dietary assessment tool such as REAP, Rate Your Plate, or web-based resources at home or in the waiting room. Review their responses
ADVISE: Give clear, specific, and personalized behavior change advice	You might say: "May I give you some advice that I give other patients with your health concerns?" Examples of what to say: "As we discussed, your blood cholesterol is too high. An important way to lower cholesterol is to reduce the saturated fat that you eat" For patients taking medication for high cholesterol: "What you eat is important even if you are taking medication because eating better helps the medicine work better. By changing your eating habits, you may be able to save money by cutting down on the amount of medicine you take"
AGREE: Collaborate with patient to select treatment focus	Offer a menu of options for discussion instead of just one idea. Patients are less likely to be resistant if they have choices "Based on what I see from your Rate Your Plate, it looks like there are some food choices that could be changed to lower the saturated fat you eat. These include eating more chicken and fish instead of red meat, eating fewer fried foods, or using different fats for cooking" "Which of these ideas would you like to discuss?"
Readiness to change negotiated behavior	"Picture a scale from 0 to 10 with 0 meaning *not at all* and 10 meaning *very*. How *ready are you* to make this change?" Why are you a _____ (insert number) and not a 0?" Reflect patient statements that indicate DARN (desire, ability, reason, and need) For patients NOT ready to change behavior, add: "I'd like to help you when you are ready to make changes in your diet." "Is it okay if I ask you again at our next visit?"
Confidence to change behavior	"How *confident* are you that you can make this change? If the patient says "5," then ask: "What would it take for you to go from a 5 to a 6 or 7?" This gives the patient the opportunity to reflect on why dietary change is important and how they might overcome barriers to change
ASSIST: Assist patient in setting goals, addressing barriers, and securing support	Problem-solve barriers to change. Ask "What might you do to overcome these barriers?"
Note: Can be done by physician, support staff or external resources	Focus more on how the patient can change than on the barriers that get in the way. Reflect DARN and offer suggestions if they ask
Set goal	"What do you think you will do now?" Help patient set a reasonable goal for change "You are going to substitute more chicken and fish for red meat. How many times a week will you make this substitution?" "You are going to use a different fat for cooking. What will you use instead of (butter, shortening, stick margarine)?" "How many fewer fried foods will you eat each week?" "What will you eat instead?" Ask "How can I help you achieve your goal?" • Provide handouts and web resources according to patient interest and need • Provide lists and recommendations for community resources (nutrition classes). • Refer to registered dietitian if there is a need and patient is interested.
Ask: "What other changes might you want to make to your eating habits?	Repeat the confidence exercise, problem-solving barriers, and goal-setting
ARRANGE: Schedule follow-up	For those who set goals: "Would you be willing to come back in about a month weeks to discuss your progress?" or "At your next visit, would you be willing to talk about your progress?" For those who did not set goals: "Would you be willing to come back in about a month and talk about this again?" or "At your next visit, can we talk about this again?"

[a] These steps can also be used by providers treating children. For younger children, these steps would address the parents. Older children could be addressed directly involving both the child and parent.

Rapid Eating and Activity Assessment for Patients

Rapid Eating and Activity Assessment for Patients (REAP) was developed to help physicians evaluate and counsel for healthy eating.[71,72] REAP has been designed to assess diet related to the Food Guide Pyramid and the U.S. Dietary Guidelines. REAP includes questions to assess intake of whole grains, calcium-rich foods, fruits and vegetables, fat, saturated fat and cholesterol, sugary beverages and foods, sodium, and alcoholic beverages and physical activity. REAP also includes questions regarding whether the patient shops and prepares his or her own food, ever has trouble being able to shop or cook, follows a special diet, eats or limits certain foods for health or other reasons, and how willing he or she is to make changes to eat healthier. REAP has an accompanying provider key, which provides guidelines for counseling advice to give for specific patient's dietary issues.

Another option is to use an online tool, such as the My Pyramid Tracker, which allows patients to enter their food intake and receive a printout with recommendations (http://www.cnpp.usda.gov/or http://www.mypyramidtracker.gov) that could be discussed with the provider.

Advise: Give Clear, Specific, and Personalized Behavior Change Advice

The purpose of this step is for the physician to establish dietary behavior as an important part of health care and enhance the patient's motivation to change. Such advice is most powerful when it is personalized by linking dietary behavior change to the patient's specific health concerns, past experiences, or family or social situation.[57] For example, this could be tied to medical conditions such as diabetes or high cholesterol, to developing a disease linked to the patient's family history or even to a spouse's health. Asking permission first and using advice messages with wording such as "As your physician, I feel I should tell you" rather than "You should" are a powerful, yet respectful way to avoid undermining patient autonomy.[57] "As your doctor, I need you to know that reducing the amount of saturated fat you eat is important for your health because it will help you lower your blood cholesterol." Strong, clear, and personalized advice is best. Personalizing the message plays to the strengths of the physician who knows the patient and his/her medical history well. [56] Most patients in adult practice will have a specific health-related reason for changing their diet. Advice messages can be compactly constructed and brief (30–60 s).[5]

Agree: Collaborate with Patient to Select Treatment Focus

Here the patient and physician "come to common ground" on whether dietary change is to be undertaken and which area(s) should be the focus.[57] To prevent resistance, physicians should actively engage the patient's agreement before proceeding with further counseling.[57] When both patient and physician agree that change is warranted, they then collaborate to define dietary change targets. For example, "Based on what I see from your Rate Your Plate, it looks like there are some food choices that could be changed to decrease the amount of saturated fat you eat. Which of these approaches (substitute chicken and fish for meat, eating fewer fried foods, or using different fats in cooking) would you like to discuss?" If the patient is ready to make specific dietary changes, the physician and patient together should identify acceptable goals. For patients with multiple areas of necessary dietary change, the physician and patient should come to agreement regarding which change(s) to address first.[57] After considering a variety of options and based on patient preference, the physician and patient together set specific goals for dietary change.

Physicians can assess readiness and motivation to make dietary changes by using a method developed by Rollnick et al.[60] To determine readiness, ask: "On a scale of 0–10, how ready are you to make this change (i.e., using different fats in cooking)?" If the patient says 5 or less, he or she is probably not yet ready to make a change. Ask: "Why are you a XX (i.e., 4) and not a 0?" to get a sense of what might be motivators of change for the patient. Listen for motivators of change (DARN) and reflect these back to the patient. Reflecting this Change Talk is empathy in action.

A warm, empathetic, and nonjudgmental style by the physician elicits greater cooperation and less resistance from patients, particularly those not yet interested in changing their dietary behaviors.[57] If the patient is not ready to change, the physician provides a motivational intervention to boost readiness and confidence and to address patient-specific barriers to change.[57] In this case, the physician would express empathy, e.g., "It is understandable that you might not want to take steps to change right now" or "Changing your diet can be difficult." Empathy for the difficulty of behavior change is an important component of successful behavior counseling. One of the most powerful predictors of patient compliance is the feeling that "my doctor cares about me as a person."[56] The physician should also emphasize his/her confidence in the patient's ability to change the behavior (building self-efficacy) and reassure the patient that there are multiple ways to approach successful dietary change.[57]

Self-efficacy (confidence) is another important factor in behavior change. To determine confidence, ask the patient: "How confident are you that you can make this change?" If the patient says "5," one could then ask: "What would it take for you to go from a 5 to a 6 or 7?" The patient's answers will give an idea of what his or her barriers and facilitators might be. These issues can be addressed later in the counseling session and be reassessed in later visits to help move a patient along the continuum of readiness to change.

Assist Patient in Setting Goals, Addressing Barriers, and Securing Support

In this step, the primary care physician (or other office staff) offers additional assistance to the patient in addressing barriers to change, setting goals, and/or securing needed supports and provides motivational interventions to increase motivation and/or skills. Those not ready to set a goal or commit to making a specific behavior change can benefit from MI strategies that explore ambivalence and enhance motivation.[57] Problem solving is a critical aspect of behavior change. First, identify the patient's barriers to making dietary changes. There are typically two types of barriers: (1) attitudes that maintain the problem behavior (e.g., "I don't like vegetables") and (2) triggers—situations or feelings that lead to the problem behavior (e.g., "When I go out to dinner, I always eat too much"). To assess barriers, physicians can ask a question like: "What might make it difficult for you to eat less meat?" After identifying the specific barriers, the physician would then discuss possible ways in which the patient could overcome them. Again a focus on overcoming the barriers gives the physician the opportunity to elicit DARN. Physicians need not have all the answers—the patient has many of them. In this capacity, the physician serves as a "facilitator" rather than a "lecturer." The patient argues for behavior change rather than the physician.

The next step is to mutually set goals for dietary behavior change. Specific, measurable goals are best. For example, goals such as "I will eat fruit at breakfast and as an afternoon snack every day" is better than "I will eat more fruits and vegetables" and "I will only eat red meat two times each week" or "I will use only olive oil or canola oil for cooking" are specific. Write the goals down in the patient's chart and on paper for the patient to take home. Then the physician and patient should discuss the options available to help the patient achieve the dietary change goals including self-help materials, nutrition programs to join, and/or more intensive counseling by a dietitian or nutritionist.[57] Additional assistance is likely to produce better outcomes than minimal-contact, advice-only treatment[57] and does not need to be provided directly or solely by the primary care physician.

Effective assistance techniques could include problem-solving skills training, guidance in obtaining social support from friends and family, modeling and behavioral rehearsal, written contracts, stimulus control (removing environmental or social cues that trigger unhealthy eating and adding cues that trigger healthy eating), the use of self-monitoring and self-rewards, and the provision of self-help materials including print, video, or computerized or web-based resources.[57] Some patient education resources are included in the resources described in the subsequent sections.

Physicians can also provide assistance through referral to other health care staff within the clinic or health care system or to community dietitians/nutritionists or nutrition education programs in the community. Physicians should ask patients if they are interested in referrals; for example, "A nutritionist can help you make the changes in your eating habits that we discussed. Do you think you would be interested in seeing a nutritionist?" Internal Revenue Service tax laws allow patients to include in medical expenses the cost of a weight-loss or dietary counseling program undertaken at a physician's direction to treat an existing disease. These costs can also be reimbursed using medical flex accounts at many worksites.

Arrange Schedule Follow-Up

Routine follow-up assessment and support through repeat visits, telephone calls, or other contact is important. If the patient has agreed to make dietary changes and set a goal, scheduling a return visit will encourage the patient to follow through. Even if the patient isn't quite ready to make changes, setting the stage for future discussions is critical to maintaining a therapeutic doctor–patient relationship.[56] Keep the door open for further dialogue. Repeated "doses" of counseling are often necessary over months or years. Simply notifying patients that follow-up will occur is a powerful motivator, communicating that dietary change is important and that follow-up assistance will be available if needed.[57] Follow-up should be scheduled within a relatively short time period (e.g., a month)[57] and should refer back to the goals set at the previous visit. "When I last saw you, you agreed to work on substituting chicken and fish for meat 5 times a week and switching to canola oil and olive oil for cooking. How did that go?" Clinical staff can arrange patient follow-up assessment and support through repeat clinical visits, telephone calls, e-mail, or other methods of contact.[57] This step can also include referrals as discussed earlier.

In summary, the 5A's combined with MI techniques have promise for helping health care physicians talk with patients about dietary behaviors. These approaches have been incorporated into primary care practice successfully; however, it has been observed that the last two steps of Assist and Arrange are rarely completed by physicians.[21,29] These steps can be achieved better by involving other office staff, using quality patient education materials, and referring to community programs or dietitians in the community. Office-level systems supports (prompts, reminders, and counseling algorithms) have also been found to significantly improve the delivery of appropriate dietary counseling by primary care physicians.[57]

RESOURCES TO HELP PHYSICIANS DO NUTRITION COUNSELING

- *The Roadmaps for Clinical Practice Series: Assessment and Management of Adult Obesity Primer.* In 2003, the American Medical Association and the U.S. Department of Health and Human Services released this primer,[13] which offers practical recommendations for addressing adult obesity in the primary care setting. It includes 10 booklets plus clinical tools and patient handouts and offers

practical advice on evaluating patients for current and potential health risks related to weight, beginning with a measure of the body mass index (BMI); understanding medication and surgical options; improving communication and counseling; and making office environments more accommodating to obese patients.

- American Academy of Family Physicians (AAFP) *Americans In Motion-Healthy Interventions* (AIM-HI)[74]: AIM-HI resources are downloadable and available on the AAFP website. They include AIM-HI PracticeManual[75] for physicians to learn to use the AIM-HI tools to integrate fitness strategies in their practices; AIM-to-Change toolkit, which contains an array of patient educational materials and office resources to help physicians create a fitness culture and encourage patients to live healthy lives; *AIM-HI Fitness Inventory* for patients to complete prior to their visit to gauge their current level of fitness and their readiness to change; *AIM-HI Food & Activity Journal* for patients to use to record their behavior patterns related to physical activity, nutrition, and emotional well-being; *AIM-HI Prescription Pads* to use with patients to set goals and create a plan; *AIM-HI Children's Books* to share easy-to-understand health messages with young patients and their families; *Make a Change for Family Fitness DVDs* that promote a non-diet approach to healthy living and encourage families to be physically active, eat healthy foods, and strengthen their emotional well-being (English and Spanish in one DVD); *AIM-HI Tips for Healthy Children and Families*, a packet of free posters and patient education handouts that offers tips on small changes to improve health; and *AIM-HI Group Visits Guide*, a step-by-step guide to conducting and getting paid for group visits for patients with chronic conditions affected by overweight and obesity.

  AIM-HI also offers a series of free online continuing medical education (CME) program podcasts (webinars and audio seminars) to train physicians in nutrition counseling and treatment. Podcasts include the following: Putting Nutrition Science to Work in Family Medicine, a series of three webinars presenting evidence-based guidelines and practical approaches to integrating nutrition into family medicine offices; Healthy Steps to Treating Childhood Obesity, discussing recent data on childhood obesity, early intervention, and optimal ways to overcome barriers; Foods That Foster Healthy Hearts, a webinar that describes small dietary changes patients can make to significantly reduce the risk of coronary heart disease; Patient-Centered Approaches to Better Fitness, a 20 min audio podcast offers new strategies for effectively talking to patients about nutrition, physical activity, and emotional well-being; and Motivating Healthy Behaviors, a 10 min audio podcast provides tips for motivating patients to make and sustain lifestyle changes.
- *AMA Healthier Life Steps*™ provides information and resources for physicians and patients on four key health behaviors including poor diet and physical inactivity. These resources include the *Physicians' Guide*,[76] which includes patient screening, intervention, and motivation tools and techniques, and the AMA Healthier Life Steps Physician's Guide to Personal Health toolkit, which is designed to help physicians support their personal efforts to live a healthier lifestyle and serve as role models to their patients.[77,78]
- *Bright Futures Nutrition and Pocket Guide (2011, 3rd Edition)*[79–81] is the most thorough and current health care physician reference regarding nutrition assessment, counseling, and referral for children. Each chapter provides an overview of the developmental period, interview questions, screening and assessment tools, counseling topics and approaches, desired health and nutrition outcomes, and frequently asked questions and suggested responses. It also includes the latest thinking on prevention, early identification, and ongoing monitoring of nutrition-related health issues in children.
- *The Childhood Obesity Action Network Implementation Guide* was created to accelerate improvement in the prevention and treatment of childhood obesity. The guide defines three key steps to the implementation of the 2007 Expert Committee Recommendations Regarding the Prevention, Assessment and Treatment of Child and Adolescent Overweight and Obesity: Summary Report.[82] The guide includes the following: Step 1, Obesity Prevention at Well Care Visits (Assessment & Prevention); Step 2, Prevention Plus Visits (Treatment); and Step 3, Going Beyond Your Practice (Prevention & Treatment) and provides detailed guidelines for health care providers regarding assessment, prevention, counseling, and treatment.[83]
- *North Carolina Eat Smart, Move* developed and disseminated their own toolkit, which includes a physician reference guide, color-coded BMI charts, blood pressure charts, and prescription pads promoting the "5-4-3-2-1–Almost None" prevention message (five or more servings of fruits and vegetables daily, three structured meals daily—eat breakfast, less fast food, and more meals prepared at home, 2 h or less of TV or video games daily, 1 h or more of moderate to vigorous physical activity daily, limit sugar-sweetened drinks to "almost none").[21]
- *Let's Move in the Clinic*: In 2010, First Lady Michelle Obama launched "Let's Move in the Clinic," an initiative to encourage health care providers to make a clinical commitment to measuring

BMI and counseling patients about optimal nutrition and physical activity. The five-step program includes (1) a Health Care Provider Pledge to measure BMI and counsel patients about optimal nutrition and physical activity, (2) a tool to assess quality of services provided in their practice, (3) a commitment to make BMI screening a part of quality care, (4) the use of the Rx for Healthier Living prescription pad (which uses the 5, 2, 1, 0 rubric—eat at least five fruits and vegetables every day, limit screen time to 2 h or less per day, get 1 h or more of physical activity every day, and drink fewer sugar-sweetened drinks),[84] and (5) the provider's commitment to be a leader in the community. *Let's Move* provider tools are available on letsmove.gov or the aap.org website.

- *The American Academy of Pediatrics obesity prevention and counseling tools and toolkits*. These materials include the following: Connecting With a Provider: How to find a PCP or RD in your area for coordination of care; Suggested Pediatric Weight Management Protocols; visual reference charts for pediatricians and RDs to coordinate the process and scheduling of pediatric weight management care office visits[85]; Pediatric Weight Management–Medical Summary: A form for primary care providers to guide the assessment component of the child's first office visit; Pediatric Weight Management–Ongoing Care Coordination and Information Sharing: A form for PCPs and registered dieticians to summarize and document key information from each office visit[86]; *Healthy Active Living Prescriptions*, developed in concert with the "Let's Move" initiative to provide health care practitioners with tools to use in counseling families about healthy nutrition and physical activity; The Pediatric Obesity Clinical Decision Support Chart to provide child health care professionals practical support and guidance to help improve care and outcomes for overweight youth and is consistent with the 2007 Expert Panel Recommendations [82].
- Many state and local health departments and obesity prevention programs have also developed their own health care provider toolkits for nutrition and/or weight control. These include Iowa,[87] Minnesota,[88] Missouri,[89,90] Washington,[91] California,[92,93] Maryland,[94] Texas,[95] and Ohio.[96] These resources include various tools including prescription pads, posters, patient education materials, reimbursement information, and more.

In summary, primary care physicians can provide effective nutrition counseling in a busy office environment. Physician advice primarily gives the cue to action and acts as a catalyst for patient dietary change, while other health professionals or take-home resources provide the details.[57] Providers should look for and take advantage of opportunities to receive further training in nutrition counseling and weight management and download resources to help create office systems and counseling protocols that support nutrition counseling.

INTRODUCTION

In 2009, health care spending in the United States amounted to nearly $2.5 trillion, making up 17.6% of the country's gross domestic product [1]. Some of the most costly, but often preventable, chronic medical conditions among Medicare beneficiaries include hypertension, heart disease, pulmonary conditions, diabetes, and mental disorders, with overall Medicare expenditures projected to reach $879 billion annually by 2018 [2]. Total U.S. health care costs attributed to smoking and obesity were calculated at $193 billion [3] and $147 billion [4], respectively. Concomitantly, physicians and other health care professionals are under increasing pressure to focus on prevention and health outcomes as Patient-Centered Medical Home (PCMH) efforts [5], payment reform [6], meaningful use [7], and consumers [8,9] press for improved patient care and better health outcomes over the current status quo in the United States of incenting health care professionals primarily for acute and chronic illness care.

One promising strategy for improving health outcomes involves engaging patients and consumers to become active participants in their own lifestyle management jointly with their health care providers. Several studies have noted the substantial role that prevention can play in reducing morbidity and mortality. Fine et al. [10] found that four risk factors (cigarette smoking, risky drinking of alcoholic beverages, limited physical activity, and being overweight) were attributable to 39% of the total deaths in the United States. Other research estimated that 50% of the preventable deaths in this country were associated with behavioral risk factors such as alcohol, tobacco, and illicit drug use; sexual behaviors; and diet and physical activity [11]. Mokdad et al. [12] found that 38.2% of the actual causes of death in the United States in 2000 were attributable to tobacco use (18.1%), physical inactivity/poor diet (16.6%), and alcohol consumption (3.5%), with sexual behaviors and illicit drug use accounting for another 1.5%. The National Cancer Institute estimated that 50%–75% of cancer deaths may be attributable to tobacco use, poor nutrition, and physical inactivity [13]. Finally, the link to mental health issues such as depression cannot be ignored as potential contributing factors to deaths from smoking, substance abuse, firearms, and the like.

In addition to their singular impact on a host of health conditions, unhealthy lifestyle choices often occur in combination with one another and are concentrated among nonrandom segments of the population. For example, traditionally underserved communities are most likely to have multiple behavioral risk factors but often have limited or no access to high-quality care on a regular basis [14]. However, the synergistic effects of multiple risk behaviors may be mitigated by small changes in one behavior which may, in turn, positively

influence other healthier actions (i.e., an increase in exercise patterns may motivate a change in eating behaviors) [15]. Others have also noted promising research efforts that target simultaneous multiple lifestyle behavior changes [16,17], though [18] suggest that further investigation into this approach is needed.

Despite all this, patient lifestyle management and monitoring are time-consuming and difficult for health care providers to do consistently. Given the estimate that primary care physicians have only 1 min for prevention within a clinical encounter [19], even when the desire exists to engage in face-to-face, ongoing health promotion endeavors with patients on a large scale, the capacity to do so within the confines of a practitioner's schedule may not. Indeed, the U.S. Preventive Services Task Force lists 45 preventative interventions that it believes should be conducted as part of the Patient Protection and Affordable Care Act [20]. In addition, truly integrated care coordination still eludes most clinicians [21]. Clearly, alternative models of patient-centered lifestyle management must be investigated [22].

Over the last decade, a wide range of consumer-facing e-Health tools, platforms, and programs (hereafter referred to as e-Health resources) have been developed for health behavior change and lifestyle management to prevent the onset of disease and improve overall health. Evidence-based e-Health resources can be scalable, cost-effective, tailored to reach traditionally underserved populations, and potentially act to both engage consumers and reduce the burden on health care providers in achieving optimal care coordination and patient health outcomes [23–26].

The purpose of this chapter is to provide a high-level, though not exhaustive, overview of existing e-Health resources and their current and potential use for supporting patient-centered adult lifestyle management (including within PCMH); how e-Health resources may enable and enhance clinical care and health outcomes via patient engagement, activation, and adherence to treatment recommendations; and the capacity for e-Health resources to bridge the digital divide and improve health equity for all groups. While numerous evidence-based e-Health resources have been created for chronic disease management, we will not focus on those platforms here.

e-HEALTH TOOLS, PLATFORMS, AND PROGRAMS

e-Health, as we define it, is the use of emerging interactive technologies (e.g., Internet, social media, mobile platforms and computing, CD- and DVD-ROMs, interactive television and voice response systems, computer kiosks, web portals, computerized tailored interventions) to enable health improvement and health care services [27]. A Cochrane Review on interactive health information communications found that these applications improved health behaviors and clinical outcomes [28]. Mounting research also indicates that consumers and patients (as well as their doctors) are increasingly interested in and expecting to use e-Health resources to connect with their practitioners, gather health information for themselves or a family member, and use these tools to improve their own health [9,29–32].

THE EVIDENCE

As they evolve, e-Health resources are being tested for efficacy, including both process (how the application is used) and outcome (what effect the program had on users' knowledge, attitudes, behaviors or clinical states) measures. Health care providers, purchasers (i.e., health care organizations interested in investing in population management tools), and increasingly, consumers are looking to the results of these evaluations for assurance of their quality and effectiveness.

Here, we provide a brief synopsis highlighting the evidence base for the use of consumer-facing e-Health resources to engage patients in their own lifestyle management. We focus on those behaviors with the greatest potential to improve patient health outcomes and reduce the burden (poor health, financial costs) of chronic disease management related to unhealthy lifestyle choices.

Tobacco Use

As the leading preventable cause of death in the United States [12], tobacco use (more specifically smoking) is an ideal target for lifestyle management. A host of recent research studies have indicated positive smoking/tobacco cessation results via the use of e-Health resources, including e-mail, the Internet, integrated phone/Internet, interactive voice response, and text messaging [33–36]. Norman et al. [37] also wrote about the importance of using e-Health resources on a global level to improve population health as it relates to smoking. Rabius et al. [38] noted higher quit rates with interactive, tailored Internet sites, though results were stronger for participants who did not report an indicator of depression. Two other studies found that components of an online site—interactive quitting tools/one-on-one messaging [39] and higher-depth tailoring [40]—were associated with higher cessation rates. Other topics raised included short- versus long-term cessation and the need to support long-term participant engagement [41], as well as the use of social support tools [33]. One literature review of available online sites highlighted the "underutilization of the interactive capabilities of the Internet to personalize treatment, to connect users with a virtual support system and to provide follow-up treatment contacts" [42], while another's review of randomized controlled trials (RCTs) for smoking cessation found mixed results, especially for younger adults, though pointed to the methodological and other learnings that will improve future efforts [43].

Mobile health ("mHealth"), perhaps the most nascent frontier in e-Health resources, has shown little success with regard to tobacco cessation efforts to date [44,45], despite the platform's feasibility and participant interest in multiple components [46]. This may be a result of the newness of this tool for lifestyle management, targeting a younger audience not yet ready to quit smoking, or the fact that some tools

are poorly designed with no underlying theoretical basis or actual resource provision [47].

Diet, Nutrition, Physical Activity, and Weight Management

Numerous e-Health resources have been developed for diet, nutrition, physical activity, and/or weight management, either as individual targets for lifestyle management or via multiple lifestyle behavior change programs.

With regard to diet and nutrition, the use of tailored and personalized e-Health resources influenced fruit/vegetable and/or fat intake [48–50] and other nutrition patterns [51], including among low-income families [52]. E-mail prompts supported more sustained use of a website along with a positive increase in fruit/vegetable intake, though changes were short-lived [53]. Webber and Lee found that an Internet-based program both improved the diet quality and reduced the caloric intake of women in an online weight loss program [54].

Recent studies for weight reduction and/or increased physical activity (with or without diet and nutrition components) have met with mixed results. Blanson Henkemans et al. [55] observed that the use of an online lifestyle diary supported increased motivation for self-management and lowered reported body mass index. A pilot study that explored the impact of an Internet-based exercise versus exercise and dietary advice weight loss program noted that the combined group (exercise plus dietary info) reduced its caloric intake, but there was no significant increase in weight loss in either the group [56]. Two tailored interventions for physical activity, both among ethnically diverse populations, observed conflicting results: one which used computerized tailored reports that were printed and mailed to participants found no significant differences between experimental subjects and controls [57]; the other determined that an Internet-based program, which also included e-mail support, had a positive effect on walking and moderate-to-vigorous activity [58]. A 2010 review of second-generation tailored health communications also uncovered stronger links to nutrition efforts than those for increasing physical activity [51]. As with smoking cessation efforts, the capacity to access social support to achieve behavior change for nutrition, physical activity, or weight management seems paramount [59–60].

Mental Health

Evidence-based e-Health resources for patient lifestyle management have also been created for improving mental health and psychological well-being. Given the strained availability of behavioral and mental health clinicians, the financial costs borne by consumers to receive this care, as well as the stigma felt by some patients regarding accessing these resources in-person [61,62], e-Health resources may bring care to those unwilling or unable to seek it out via other outlets [63,64]. Here, we focus on depression and insomnia.

Two depression studies that augmented usual treatment with online programs, the first with various informational components/questionnaires and e-consultations [65] and the second, which included multiple psychotherapeutic approaches [66], reduced depression severity/improved patient–clinician relationships and decreased symptoms of depression, respectively. Warmerdam et al. [61] showed that both an online cognitive behavioral therapy (CBT) intervention and an online problem-solving therapy program were successful in lowering depressive symptoms. A pilot study using web- and mobile phone-based interventions noted the feasibility of increasing depression medication adherence in the participants, as well as greater patient engagement in care, both of which hold the potential for decreasing depression severity [67]. Self-help websites for depression have also shown a reduction in depression severity among those using the programs [68,69]. Finally, a multilingual informational website for immigrants not only increased depression awareness and comprehension but also decreased the stigma felt by participants toward those with mental illness [70].

Roughly, one-third of U.S. adults experience secondary (or temporary) insomnia at some point with another 10% reporting this as a chronic condition [71]. This lack of sleep impacts overall health and well-being and can lead to more chronic health problems. Most e-Health-related insomnia treatments utilize components of CBT (which is the "usual care" standard), for which there is evidence of its effectiveness and capacity for tailoring [72,73]. An early online CBT intervention study noted improvements in total sleep time and sleep efficiency with similar improvements in the control group [74]. More recent web- and CBT-based RCTs for insomnia have shown improvements in sleep quality, with decreases in insomnia severity and daytime fatigue [75], as well as increases in sleep efficiency and decreases in both waking after sleep onset and scores on the Insomnia Severity Index [76,77]. Another RCT, which used an online self-help model targeting workers in Japan, increased sleep quality and other sleep-related behaviors while reducing sleep-onset latency [78].

CHALLENGES OF e-HEALTH RESOURCE IMPLEMENTATION

Many of the e-Health resources created to date show promise of being efficacious, whether it be for improved nutrition, smoking cessation, or increased physical activity. The functionality of the applications themselves and how they are actually used in the "real world" are understood to be paramount to achieving successful behavioral change. However, significant barriers and challenges continue to exist in realizing the full potential of these tools, platforms, and programs for coordinated patient–provider lifestyle management efforts.

Generalizability

The importance of developing an evidence-base for e-Health resources cannot be understated. However, what works in

a controlled research study may be difficult to replicate in an actual physician practice. Enwald and others remarked on the challenges of methodology (study design, selection bias, control groups, retention, self-reports, etc.) as barriers to truly assessing the efficacy of these platforms for physical activity (and, by extension, other behavior change efforts) [51,79]. Differences between study participants and providers' patients—gender, ethnicity, age, race, sexual orientation, socioeconomic status, primary spoken/read language, patients' health/technological literacy, and/or access to the Internet or mobile platforms—can all influence the capacity to reproduce encouraging results in real time or to reach those in greatest need of these programs [80,81].

Adoption, Integration, and Sustained Use

Often, e-Health solutions have been created as "stand alone" interventions or designed specifically for a particular research study. For example, evidence-based interventions that exist online may provide benefit to patients, but often run parallel to, and are not easily accessible by, that patient's provider. Those researchers who have received grants to develop and evaluate the efficacy of an e-Health resource often see the program stagnate once the grant funding ends.

Additionally, while many clinicians would appreciate the capacity to refer their patients to effective e-Health Resources for lifestyle management, their ability to vet and stay abreast of the "best of breed" in this arena is virtually nonexistent. Most e-Health tools, platforms, and programs are not designed or easily integrated into a physician's workflow [82] or/and electronic health record (EHR) system (when one exists) nor a consumer's activities of daily living.

There are also barriers to adoption with regard to patients and consumers. Beyond the issues of access and health/technological literacy (addressed in Section 4.4), many of the studies cited earlier in which lifestyle changes were realized also found that they were short-lived (often due to a decline in patient use of the e-Health resource over time) and pointed to the need for more ongoing lifestyle management support. As with health care providers, the use of many e-Health resources is not easily integrated into a patient's activities of daily living; rather, it is a separate endeavor that is not routinized into their lifestyle.

Quality

While not the focus of this chapter, a significant amount has been written about the quality (or lack thereof) of online information and e-Health tools, platforms, and programs for various health topics and disease states [83,84]. The key relevance for lifestyle management is the need for a trusted and timely vetting process for use by providers (and patients), which would allow for integrated, "just-in-time" referrals to appropriate and evidence-based e-Health resources. Currently, this capability is sorely lacking, with the exception of a few large, integrated delivery systems (e.g., Kaiser Permanente, Group Health Cooperative).

Traditionally Underserved Populations

Given the current lack of equity in health care access and outcomes for traditionally underserved populations [105], legitimate concerns have been raised about the "digital divide" in that e-Health resources may exacerbate disparities which already exist. Demographics such as gender, ethnicity, age, race, sexual orientation, socioeconomic status, primary spoken/read language, and health/technological literacy have been well documented in numerous scholarly writings (more than addressed here) as often having a negative impact on a patient's access to and utilization of computers, the Internet, and/or mobile platforms [85–89]. These issues add one more challenge for certain populations to effectively utilize e-Health tools, platforms, and programs.

OVERCOMING OBSTACLES TO THE USE OF e-HEALTH RESOURCES

Despite the challenges described earlier, e-Health resources are being used more and more to engage patients in their own care. While the current state of the art is imperfect, research and creative designers are producing new knowledge that will help to "build a better mouse trap."

Tailoring, User-Centered Design, and Cultural Relevance

Technology-based tools have the capacity to integrate large amounts of personal and demographic information quickly and over prolonged periods of time to provide patients and consumers with specific feedback regarding deeply relevant lifestyle management actions they can take. Indeed, many of the e-Health resources mentioned earlier showed greater efficacy through the use of tailoring or personalization. Kreps and Neuhauser [90] site this capacity as an opportunity to develop more engaging, accessible, and easily used e-Health resources for diverse populations. Kreuter et al. [91] outline how "cultural tailoring" can expand the ability of lifestyle management platforms to reach broader cultural groups.

Finally, the concept of user-centered design (UCD) must be central to the development of e-Health resources. UCD's basic principles are that the patients' and consumers' wants, desires, and limitations are the focus of and highly important to the entire design process. UCD "tries to optimize the product around how users can, want or need to use the product, rather than forcing the users to change their behavior to accommodate the product" Wikipedia 2011—quite the converse to, "If you build it, they will come."

Research Methods

In a special section of *Evaluation and Program Planning* on the methodological challenges in e-Health research, [92], as well as the other authors, highlighted areas of specific

concern to e-Health researchers. These include, for example, privacy/security, electronic informed consent, appropriate control groups/conditions, and other more generic issues that many grapple with across all behavioral health research (e.g., recruitment, retention, incentives, theory-based design).

Fortunately, efforts abound seeking novel approaches and models to create stronger and more generalizable e-Health tools, platforms, and programs. Ritterband and Tate [93] underscore the need for further development of methodological paradigms to guide the expansion of Internet research science. Ritterband et al. [76,77] go on to propose a scientific-based behavior change model for web-based interventions, the hope of which is to firmly strengthen the creation and use of Internet-based platforms.

There are also efforts to apply non-technology-based research frameworks to bolster e-Health research methodology. For example, the Reach, Efficacy, Adoption, Implementation and Maintenance model [94] may have applicable lessons for the evaluation of e-Health resources [95]. In addition, it has been noted that the Consolidated Standards of Reporting Trials recommendations hold great potential to better the quality of e-Health research [96].

DISCUSSION

In this chapter, we have reviewed targeted e-Health resources and the promise and potential for them to enable and support lifestyle medicine and management [97]. Overall, the available evidence indicates that many of these e-Health resources are effective and can be used by providers to activate and support collaborative self-care. Indeed, these e-Health tools, platforms, and programs are consistent with health care transformation to a more patient-centered, equitable, and efficient system as recommended by the Institute of Medicine [98]. As health care transformation proceeds, e-Health resources will become increasingly necessary to engage patients, including traditionally underserved populations [99], in lifestyle management.

e-Health resources for lifestyle management integrated with primary care will improve health outcomes through enhanced patient–provider communication, patient activation, reduced clinical inertia, and improved adherence to medication regimens. To meet this ambitious goal will require a UCD approach to development and implementation, working in collaboration with primary care and patients together [100–103]. There are a myriad ways that patients use e-Health resources currently; however, they are often disconnected from provider referral and documentation systems (e.g., EHRs), which makes them difficult to recommend and track.

Patient experience is emerging as an important measure of quality, as indicated by the requirement for measurement of patient experience in the context of Accountable Care Organizations (ACOs). e-Health resources that support patients' wants and needs are likely to enhance patient experience, (i.e., a strong desire for secure messaging with providers and use of social media/networks).

Future research is needed to evolve and extend these e-Health resources to further enhance impact and integration into clinical care. The future e-Health-enabled PCMH and ACO will likely incorporate a wide range of e-Health resources to fulfill the vision of a truly patient-centered health care system [104].

INTRODUCTION

The National Institutes of Health (NIH) Director, Francis Collins, defined personalized medicine as the use of "an individual's genetic profile and individual information about environmental exposures to guide decisions made in regard to the prevention, diagnosis, and treatment of disease" [1]. While there are many emerging applications of personalized medicine in lifestyle medicine, none have any greater potential impact on public health than smoking cessation. Tobacco use is responsible for approximately 5 million deaths annually, and current projections indicate that tobacco-related mortality will top 10 million deaths per year by the 2030s and 1 billion deaths throughout the twenty-first century [2,3]. Yet quitting smoking well into middle age eliminates most of the risk of dying prematurely from cancer or vascular disease [4].

Even for the most efficacious pharmacological and behavioral therapies, the majority of smokers are unsuccessful in sustaining abstinence for any given quit attempt [5,6]. Twin studies established that nicotine metabolism, smoking initiation, smoking persistence, and smoking cessation are heritable and under the influences of genetic and environmental factors [7,8]. Thus, the "one-size-fits-all" approach to treatment has substantial room for improvement, and identification of specific genetic factors affecting nicotine neurobiology has the potential to advance the state of the science and improve clinical smoking cessation outcomes.

NEUROBIOLOGY OF NICOTINE DEPENDENCE

The neurobiology of nicotine dependence is complex and involves multiple neurotransmitters and metabolic enzymes. Once tobacco smoke is inhaled, nicotine is readily absorbed in alveolar capillaries and crosses the blood–brain barrier within seconds. Nicotine binds to its nicotinic acetylcholine receptors in the midbrain and elsewhere [9], which stimulates increased release of dopamine in the brain's reward centers and a complex interplay of multiple neurotransmitters responsible for the reinforcing properties of nicotine and conditioned smoking behavior [10–14].

Therefore, multiple investigations have explored associations among genes encoding neurotransmitter receptors and transporters within pathways implicated in nicotine dependence (e.g., dopamine, serotonin, norepinephrine, acetylcholine, gamma-aminobutynic acid (GABA), opioid, beta-endorphin) [15], the hepatic enzymes that metabolize nicotine (e.g., cytochrome p450 2A6/*CYP2A6*) [16], and smoking cessation drugs such as bupropion (*CYP2B6*) [17]. The goals of these investigations are to identify subgroups of patients most likely to be efficacious for smoking cessation, screen for individuals likely to develop side effects that limit treatment adherence, choose drug doses that are appropriate for each patient based on hypothesis-testing studies of pharmacologically selected "candidate genes" (pharmacogenetics), and to identify novel molecular targets for smoking cessation treatment based on hypothesis-generating genome-wide association studies (pharmacogenomics).

PHARMACOGENETIC AND PHARMACOGENOMIC INVESTIGATIONS OF SMOKING CESSATION

Most pharmacogenetic investigations of smoking cessation have evaluated associations between candidate genes in nicotine-associated pharmacodynamic and pharmacokinetic pathways using genotyping of samples from smoking cessation clinical trials post hoc—rather than prior to treatment to prospectively tailor therapy—in studies of nicotine replacement therapy (NRT) [18–33] and sustained-release bupropion [26,34–42]. In addition to NRT and bupropion, befloxatone, fenfluramine, and venlafaxine [43–46] as well as patient choice between NRT or bupropion [47] have been evaluated.

To date, there have been very few examples of replication of associations between candidate genes and drug response. Some candidate genotypes have shown opposite effects in different trials, such as the mu-opioid receptor 1 (*OPRM1*) rs1799971 A allele [25,30]; others have been associated with opposite effects in bupropion and NRT such as the *DRD2* rs1799732 Ins allele [26,48]; some are associated with treatment response to one drug but not another such as the *DRD4* L allele [21,27]; and others simply have not been replicated, such as the Beta 2 subunit gene for nicotinic acetylcholine receptors (*CHRNB2*) [35]. However, there are some examples of replication. For example, a gene that affects dopamine D2 receptor expression in brain reward regions (Ankyrin and Kinase Domain Containing 1 [*ANKK1* rs1800497 A2 allele]) [49] has been associated with improved smoking cessation outcomes with bupropion in three clinical trials [37,38,41], and the gene for Catechol-*O*-methyl Transferase (*COMT* rs4680 A allele) has been associated with improved response to NRT patches in two clinical trials [22,24,31]. There are also a growing number of studies showing associations between emerging *CYP2A6* genotypes, associated with rate of nicotine metabolism, and dose of NRT nasal spray used [28] and efficacy of NRT for smoking cessation [48,50,51].

Genome-wide association investigations have been published using samples from two clinical trials of bupropion [52] and three trials of NRT [52,53]. These studies have identified several hundred novel genotype associations predictive of the efficacy of these medications, which include some candidate genes with known associations with nicotine dependence and many newly identified candidate genes, such as cell adhesion molecules and solute transporters.

FUTURE DIRECTIONS AND CLINICAL APPLICATIONS

There are several important research questions and practical challenges that must be overcome for smoking cessation to be ready for widespread clinical use.

Research

More replication of associations between specific candidate genes and drug response are needed to establish the predictive value of genetic testing. Moreover, additional research is needed in different ethnic groups, as most published studies have examined only European-ancestry populations and in the interactions between genes and gender because there is limited evidence suggesting ethnic and sex subgroups are likely to moderate pharmacogenetic outcomes [33,39,50]. Prospective studies examining the use and impact of genetic tests to tailor treatment are needed to confirm that their use in real-world settings improves smoking cessation outcomes without unintended psychological or behavioral consequences. At the time of this writing, only one such trial has been published with promising results, but more prospective studies are in the pipeline [54]. Even if genetic testing improves clinical outcomes, its cost-effectiveness needs to be better demonstrated in order to convince health care organizations to offer genetic testing for smoking cessation; to persuade payers, policy makers, and opinion leaders that funding specific genetic testing for nicotine dependence treatment is a high priority public investment; and to compel industry to develop novel genetically tailored therapies. Cost-effectiveness studies of several pharmacogenetic smoking cessation investigations suggest that depending on the specific drug or combination of drugs, genetic testing is likely to be cost-effective, but data from prospective studies are needed [55,56].

Practical Issues and Best Practices

Evidence-based treatment guidelines—based on the analytic and clinical standards of validity—have been published for treatments other than tobacco dependence—and are likely to provide clinical annotations in the future [57]. Clinical information systems and protocols that support clinician decision making and processes of care for personalized medicine are needed [58]. The clinician workforce needs to be trained in both communication skills and medical indications for genetic testing in the treatment of nicotine dependence, and personalized smoking cessation treatment must be patient-centered, culturally sensitive, and utilize a shared decision-making model [59] to maximize the potential for positive health outcomes and minimize the risk of harm. Furthermore, patients and physicians should be aware of federal protections against genetic discrimination, such as the Genetic Information Nondiscrimination Act of 2008 [60]. Patients' genetic literacy should be assessed and appropriate education provided such that true informed consent in genetic tailoring of treatment is possible [61].

SUMMARY

Table 102.1 summarizes the important clinical take-home messages from this chapter. Research, to date, has provided encouraging evidence suggesting that genetic testing has the potential to transform the way we presently

TABLE 102.1
Personalized Medicine for Smoking Cessation—Clinical Take-Home Messages

Nicotine dependence and smoking cessation are under the influence of genetic and environmental factors and current "one-size-fits-all" pharmacotherapies have room for improvement
Some polymorphisms in genes affecting dopamine neurotransmission and nicotine metabolism have been associated with drug response for sustained-release bupropion and nicotine replacement therapy in multiple studies, but there are many examples of other candidate genes in the dopamine, serotonin, and other pathways lacking either not associated with smoking cessation or lacking replication. Pharmacogenetic studies of varenicline have not as yet been published
Hundreds of genetic variants spanning multiple pharmacological pathways have been associated with drug response for smoking cessation, but these associations have yet to be replicated
Cost-effectiveness studies have been inconclusive but suggest that based on some scenarios of cost of genetic testing and treatment selection, genetically tailored treatment may be cost-effective
Results from prospective, genetically tailored smoking cessation treatments have not as yet been published
Multiple research and practical implementation milestones need to be reached before personalized medicine will be ready for widespread clinical implementation
Tobacco treatments guidelines are available at http://www.surgeongeneral.gov/tobacco/ and clinical annotations for genetic testing to guide smoking cessation and other treatments will be available at http://www.pharmgkb.org/

care for treatment-seeking smokers. However, until multiple research and practical translational milestones have been reached, physicians and other practitioners of lifestyle medicine should combine the individualized, patient-centered smoking cessation care they are well trained to offer, informed by the *Agency for Health Research and Quality* Tobacco Dependence Treatment Guidelines (available at: http://www.surgeongeneral.gov/tobacco/). Interested readers are referred to the *Pharmacogenomics Knowledge Base* (PharmGKB; http://www.pharmgkb.org/), where clinical annotations for genetic tests guiding smoking cessation and other treatments are being released and updated regularly.

103 Lifestyle Medicine and the Older Population

Introductory Framework

Charlotte A. Tate, PhD

CONTENT

References 1245

On a population basis, people are living longer with increased average life expectancies becoming a global phenomenon. Not only are people living longer but they are also living healthier. In recent decades, on average, older people live with fewer disabilities and less loss of functioning than in generations past. Many live with more chronic diseases and postponement of disability [1,2]. As Crimmins [1, p. 94] notes, "The key to continued improvement in health is to delay the onset of risk factors, disease, and disability in older-aged individuals."

My purpose in this brief introduction is to provide a context for encouraging the agenda for the continued enrichment of the health of people living in the latter decades of their lives. Despite the nuances in interpretation, I use the less offensive (hopefully) generic expression, "older people," as an identity phrase for people living in their sixth decade and beyond. Moreover, the enrichment of health is often called healthy living, healthy lifestyle, healthy aging, and successful aging. Our preference is to use successful aging, which often is associated with the older population when in reality it is a descriptor for the entire human life course [3]. The conceptual framework of successful aging encompasses the depth and breadth of the human experience, as discussed by Rose [4] in the next chapter of this section. Following Rose, Chodzko-Zajko and Schwingel [5] discuss a major criterion for successful aging, that is, physical activity. They present a unique approach to actualize a regular program of increased physical activity in older persons. Then, I briefly discuss the impact of the stereotypes of old age and end with what I believe to be at the crux of lifestyle medicine: assisting people to live lives of meaning.

Because the older population is a heterogeneous group, dividing the later decades of the life span into apparently discrete, but continuous, chronological age ranges has facilitated investigating and developing the ways and means for improving the health of older adults. In 1974, Neugarten [6] coined the phrases, young-old and old-old, to distinguish those people between the ages of 55–75 years from those over the age of 75 years, respectively. Since then, her idea has been expanded to include other age ranges—from the young-old, the old-old, to the oldest-old. Although each respective "age group" is demarked by an age range that may differ among investigators or reporting agencies, each has a number of average distinguishing health-related descriptors, characteristics, and demographics (e.g., see entries in [7]). These age ranges are useful for comparisons on a population basis; however, individually, people may (or may not) transition to the next phase at any chronological age. Thus, the use of chronological age is arbitrary at best.

For our purposes here, Baltes and Smith [8], in capitalizing on the earlier work of Neugarten and their own extensive research findings, provide a framework for us to consider the importance of successful aging. They describe suitable descriptors for what they call the Third Age (or young-old) and the Fourth Age (or oldest-old), as shown in Table 103.1. They distinguish the two ages, not by chronological age, but by the major characteristics, from successful aging of the young-old to the tribulations of the oldest-old. In their view, optimization of the life course is possible in the Third Age but difficult in the Fourth Age. It, therefore, behooves older individuals to remain in the Third Age as long as possible by adopting or maintaining strategies and activities that delay the transition into the Fourth Age. As one example, Freedman et al. [9] looked at three possible candidates for intervening in the transition toward frailty, a Fourth Age descriptor: increasing physical activity, treating depression, and preventing falls. Of the three, they concluded that, while the other two were certainly effective, the prevention of falls might be the most efficacious in delaying the progression to the frailty associated with the Fourth Age.

We recognize that the growing knowledge base from life course research models increasingly supports the notion that aging-related diseases and functioning in adults have their origins in early life experiences and perhaps even fetal life [10]. Among a multitude of factors including heritability, epigenetic mechanisms linking the genotypes to the various environments produces a phenotypic matrix of characteristics and behaviors of health and disease. While some

TABLE 103.1
Later Years of the Human Life Course: The Good and the Bad News

Good news: The Third Age or the young-old
- Increase in life expectancy: more older people live longer
- Substantial latent potential for better fitness (physical and mental) in old age
- Successive cohorts (generations) show gains in physical and mental fitness
- Evidence of cognitive-emotional reserves of the aging mind
- More and more people who age successfully
- High levels of emotional and personal well-being (self-plasticity)
- Effective strategies to master the gains and losses of late life

Bad news: The Fourth Age or the oldest-old
- Sizeable losses in cognitive potential and ability to learn
- Increase in chronic stress syndrome
- Sizeable prevalence of dementia (about 50% in 90-year-olds)
- High levels of frailty, dysfunctionality, and multimorbidity
- Dying at older ages: with human dignity?

Source: Modified from Baltes, P.B. and Smith, J., *Gerontology*, 49, 125, 2003.

behaviors and characteristics resist modification, many lifestyle behaviors can indeed be modified by older persons resulting in a shift toward healthy aging or staying in the Third Age. Although earlier life experiences may point toward taking an unhealthy pathway, older persons can enter (or reenter) the pathway toward successful aging, *albeit* with requisite persistence.

To address that question, Rose [4] proposes entry points into the pathway of successful aging through changes in lifestyle. First, she explores the development of Successful Aging as a construct and its determinants, as we understand them today. As she rightfully points out, as we advance in age, many environmental and lifestyle factors mitigate or enhance the negative or positive impacts that our early life experiences and genetic makeup may have on our functioning as adults. She then points to a number of lifestyle modifications that can enhance the health, sense of wellbeing, and function of older people. She emphasizes the importance of a regular program of physical activity, a major determinant for the prevention or delay of lifestyle diseases. She then gives a few hints to health professionals to assist them in developing interventions that have lasting impact.

Indeed, a regular program of physical activity is vital to staying in the Third Age for as long as possible. Chodzko-Zajko and Schwingel [5] focus on the benefits of physical activity, or exercise, and some of the models used to assist older persons in adopting and maintaining a physically active lifestyle. They present, in a novel way, the answers to questions an older person might have about physical activity and its benefits. They then discuss a few strategies for helping older people adopt and stay on the active aging pathway. Importantly, they emphasize that frail older persons can reap the rewards of physical activity as well.

Encouraging previously sedentary older people to be physically active is a daunting task, but not impossible to achieve, in older people whose generation did not grow up in a society that supported and encouraged physical activity. In particular, older women who grew up in the United States before Title IX experienced the negative influences of gender stereotypes that supported sedentary behavior. Like all stereotypes, old-age stereotypes profoundly impact people as they advance through the life course.

Influenced by culture, ethnicity, socioeconomic status, and gender, the spectrum of the old-age stereotypes is multidimensional, crossing numerous domains of society. At its heart, the stereotype of old age is ageism, a social construct that embodies societal views and attitudes that have evolved over the decades [11].

Like many stereotypes, the internalization of the old-age stereotype is subconscious, probably begins at an early age, and may subsequently lead to changes in perception and projection, thereby impacting cognitive and physical performance, view of self, and so on [12]. Based on her own body of work and others, Levy [13] proposes that the stereotype embodiment through assimilation results in self-definitions that influence function and health in the latter decades of the human life span. She identifies three pathways of stereotype embodiment that exert their influence: psychological through expectations, behavioral through healthy practices, and physiological through the autonomic nervous system.

These internalized stereotypes can and do influence the outcomes of interventions aimed at assisting individuals in adopting lifestyle behaviors that keep them on the pathway of healthy living, or healthy aging in this case [14]. Perhaps, it is safe to say that most people, at the very least in North America and Europe, know that regular physical activity and a nutritious diet are important. Acting, though, requires overcoming lifelong patterns of living and reformulating many of the internalized stereotypes developed over the life course. As Tumosa [15, p. 540] states, "Knowing what needs to be done [adopting healthy eating habits] is one thing, but deciding to act, regardless of the barriers, is quite another." Moreover, extrinsic factors have profound influences. O'Brien Cousins [16, p. 361] notes "…it was not simply a lack of social support that explained older people's sedentary living patterns… but rather strong, negative, and discouraging remarks and behaviors by an individual's immediate family and network of friends."

Hope springs eternal for a gradual shift in the society's view toward people living in the late decades of life. Naturally, the old-age stereotype is not necessarily negative but may be quite positive depending on the culture, ethnicity, gender, and economic circumstances. A full exposition of the topic, however, is beyond our scope and purpose. We encourage health professionals to be sensitive to the negative and positive influences of old-age stereotypes and the impact that their own behaviors and attitudes have on the health and well-being of the older people they serve.

In conclusion, as we grow older, we wish to remain healthy and robust and lead independent lives of meaning. Indeed,

the Harvard geriatrician Gillick [17] states, "The ultimate determinant of a good old age is the ability to derive meaning from life, with all the other factors (health, emotional well-being, housing, and so on) serving to facilitate a sense of purpose, belonging, and continuity." Thus, our challenge, as individuals and as a society, is to create, develop, and live in an environment, however defined, that promotes and supports a healthy lifestyle regardless of a person's age.

According to the Centers for Disease Control and Prevention,[1] the United States is on the "brink of a longevity revolution." This prediction is supported by statistics showing that by 2030, one in every five Americans will be 65 years or older. Mortality rates and longevity are also expected to improve with global life expectancy at birth projected to increase by at least 10 years, reaching approximately 76 years by 2050. As a consequence of this disproportionate growth in the older adult segment of the population, health care spending is also projected to increase by as much as 25% unless the health of the older adult population can be preserved or improved substantially.[2] Indeed, current estimates of the number of older adults (65 years and older) in the United States who are considered to be aging "successfully" are alarmingly low.[3] Based on data derived from a national sample of older adults enrolled in the Health and Retirement Study, only 11.9% of older adults were categorized as aging "successfully" in any one year according to a similar set of criteria first established by Rowe and Kahn.[4,5] Moreover, the odds of successful aging (SA) declined by as much as 25% over the 6 year measurement period (1998–2004) with the adjusted odds of SA being lower for adults 75 years and older, males, and those at a lower socioeconomic level.[3]

In this chapter, I will briefly explore the construct of SA, the many definitions and methods used to test various SA models, some of the predictors of SA as currently supported by research across multiple disciplines, and the results of intervention research focused on building pathways to SA. Finally, the role of the health care professional in promoting SA will be discussed and recommendations for implementing intervention strategies that have been shown to be effective in primary and secondary health care settings will be provided in the final section of this chapter.

DEFINING SUCCESSFUL AGING

Both the concept of SA and the term itself is not universally accepted as noted in a review article by Depp and Jeste[6] who identified as many as 29 different definitions of SA during the course of reviewing 28 quantitative studies of SA. By far, the most often included component of SA in more than half of the studies reviewed was physical functioning/disability. Other components included, albeit in fewer study definitions, were cognitive ability, social functioning, life satisfaction, and absence of disease. As a result of the variability in how SA was defined, vastly different proportions of study participants were categorized as aging successfully (1%–94%, median 35%).

In other studies that have explored the construct of SA using qualitative methods of inquiry[7] (i.e., older adult perceptions of SA) or mixed-method approaches that combine objective and subjective criteria of SA,[8–10] the proportion of older adults categorized as aging successfully has again varied widely. Using the objective criteria set forth by Rowe and Kahn in their model of SA, Strawbridge et al.[9] found that only 18.8% of the 867 older adults (65–99 years) who comprised their sample would be categorized as successfully aging. In contrast, 50.3% of the same sample was similarly categorized on the basis of a single question that asked them to rate the extent to which they thought they were aging successfully.

Moreover, when researcher-based criteria was compared with the perceptions of older adults as to what attributes they thought defined SA, a more encompassing definition emerged.[7] While the majority of older adults who responded to a mailed survey considered two-thirds (13/20) of the already listed attributes to be important to SA, additional attributes were identified that could be broadly divided into four larger dimensions of health—physical, functional, psychological (mental), and social health.

On the basis of these divergent findings, a number of researchers have argued that the perceptions of older adults need to be included in any definition of SA.[7,11,12] McLaughlin et al.[3] have also called for a broader definition of SA, particularly if the concept is to be used as a benchmark for assessing the health and functional status of the older adult population. The authors argue that if the term continues to be narrowly defined, "we are likely to classify many older adults with good health and functioning as being in an unhealthy state for what might be relatively minor reasons" (p. 225). By way of a compromise to the current controversy over how best to define SA, Depp et al.[13] suggest that future research endeavors "focus on the determinants of success as independent components and investigate the extent to which risk factors and interventions impact these components" (p. 532).

MODELS OF SUCCESSFUL AGING

To date, the most popular model of SA that has been used to guide gerontology research is one first conceptualized and collaboratively investigated by an interdisciplinary team of scholars assembled by the MacArthur Foundation and chaired by Dr. John Rowe,[4,5] a geriatrician and physiologist at Mt. Sinai Medical Center. The development of this model was to herald a dramatic paradigm shift in aging research from one that focused on the negative aspects of aging such as disease and disability to one that emphasized the positive aspects of aging and the important role that lifestyle and other psychosocial factors play in helping older adults retain and/or enhance their ability to function well into their later years.

The ability to maintain three key characteristics formed the basis of Rowe and Kahn's SA model: a low risk of disease and disease-related disability, high mental and physical function, and active engagement with life.[4] In order to be categorized as aging successfully, however, older adults needed to display high levels of all three of the aforementioned characteristics. A sample of 1189 older adults aged between 70 and 79 years who met the objective criteria established for SA (i.e., top 33rd percentile across all three domains) were subsequently followed for the next 8 years.[4,5] In all, the many related studies that followed produced close to 100 scientific publications and a best-selling lay publication,[5] in which a number of myths previously associated with the aging process were successfully debunked.

Baltes and Baltes[14] developed a complimentary model of SA known as the Selective Optimization with Compensation (SOC) model. The SOC model was based on findings emerging from the original Berlin Aging Study[15] that followed a sample of 516 persons aged between 70 and 100 years between 1993 and 1998. In contrast to the Rowe and Kahn model of SA, the SOC model focuses more on describing the behavioral and psychological processes involved in adapting to age-associated reductions in physiological reserve and breadth of neural plasticity. The basic assumption of the SOC model is that individuals engage in behaviors that are aimed at optimizing their general reserves as they age while also compensating for restricted plasticity or adaptive potential. Subsequent research demonstrated that different combinations of the SOC mechanisms are used by adults of different ages to regulate their lives and that higher engagement in SOC-relevant strategies is associated with indicators of SA such as positive psychological functioning, life satisfaction, and emotional well-being, irrespective of age.[16]

More recently, Pruchno et al.[17] have begun testing a two-factor model of SA. Central to their conceptual model of SA is the contention that adults can experience chronic disease and disability and still believe that they are aging successfully and that SA is a characteristic that should not be delimited by age. Unlike the two previous models of SA described, the assumptions of the two-factor model proposed by Pruchno et al. were tested in a large sample of middle-aged adults (50–74 years). Using a mixed-method approach, wherein SA was defined using both objective and subjective criteria, the authors sought to understand how and to what extent the objective and subjective aspects of SA were related to each other, as well as the role of age and gender. Their preliminary results provide support for a model of SA that includes both objective and subjective criteria. Moreover, their findings further suggest that certain factors such as cognitive function, social engagement, and psychological well-being, previously identified as components of SA, might be better viewed as predictors or antecedents of SA, respectively.

LIFE-COURSE APPROACH TO THE STUDY OF AGING

In recent years, a major shift toward the adoption of a life-course approach to studying aging has begun that capitalizes on data derived from historical and birth-cohort studies. The life-course approach,[18] as it is called, is being driven by a growing consensus that adult function has its roots in early life experiences and that aging is "driven by the rate of accumulation of molecular and cellular damage" (p. 717).

According to Kuh et al.,[18] addressing two fundamental questions is central to a life-course research approach to aging. The first (question) seeks "to identify what factors across the life course, from the molecular to the societal level, independently, cumulatively, or interactively influence whether people as they age maintain their physical and cognitive capability and stay intellectually and socially connected," whereas the second addresses the question of how best to "transfer this knowledge to people themselves and the institutions that exist to improve human health" (p. 720). It is worthy to note here that the first question being addressed

specifically identifies two of the three components that Rowe and Kahn[4,5] identified in their model of SA. Preliminary findings suggest that early movement experiences in childhood can predict changes in motor and cognitive abilities in mid- and later life as well as the risk of mortality.[18,19]

DETERMINANTS OF SUCCESSFUL AGING

Key determinants of SA that have been described in a number of review articles on the topic can be broadly divided into the following categories: genetic, biological, psychological, and social/environmental. As Depp and Jeste[6] noted in their review, the predictors of SA appeared to vary as a function of the definition of SA used in each study. The strongest and most consistent predictor emerging was younger age (closer to 60 years) with other strong predictors being health related (e.g., absence of arthritis, higher Activity of Daily Living levels, hearing problems, abstinence from smoking). Engaging in higher levels of physical activity, having fewer medical conditions, global cognitive function, absence of depression, and lower systolic pressure were moderately supported as predictors of SA with only minimal support being provided for higher levels of education, income, being married, and white.

Although the once prevalent belief that the secret to SA was to choose your parents wisely has since been found wanting as a result of the MacArthur studies of SA[5] and more recently published molecular genetic studies,[20] one's genetic makeup does play a role in the onset of disease[21–23] and changes in mental function,[24] two important components of the Rowe and Kahn SA model. The good news is that as we age, the influence of genetics appears to become less influential, while environment and lifestyle factors become much more important. The aging process also results in a number of changes occurring at the cellular level that affect the rate at which cells multiply and how they function. These changes can result in compromised immune system responses, the onset of certain diseases (Alzheimer's disease and cancer), and an inability to regulate important body functions. Age-related dysregulation of the hypothalamic–pituitary–adrenal (HPA) axis, which can result in the secretion of glucocorticoids (e.g., cortisol) and the subsequent damage to important brain structures such as the hippocampus, has also been reported.[25] This dysregulation of the HPA axis has been associated with decreased cognitive function and increased depression.[25] The influence of allostatic load[26] (AL) on indices of SA was first investigated during the course of the MacArthur studies of SA and conceptualized as an index of wear and tear on the body resulting from environmental challenges, both internal and external, that are repeatedly placed on the physiological systems of the body across the lifespan. Seeman et al.[27] found higher AL scores to be associated with poor physical and cognitive function as well as an increased risk for cardiovascular disease in a sample of older men and women.

Cross-sectional and longitudinal studies have identified a number of psychological attributes that have been associated with SA. These include such things as intelligence and cognitive capacity or reserve, self-efficacy, affect (positive or negative), and attitudes toward the aging process.[28] Although less well studied, there is some evidence to support a role for positive spirituality in SA,[29–31] particularly as it relates to one's physical and mental health. Spirituality has been shown to be positively related to measures of physical and mental health, psychological well-being, and life satisfaction in older adulthood.[31]

Important social and environmental factors that have been cited in the literature as important for SA include such things as the physical environment and the level of social support available. Living in an environment that is safe, clean, and affords access to both desired and essential services is believed to be fundamental to aging successfully. Socioeconomic disparities also influence how well an older adult ages. Older adults with fewer financial resources available to them have less access to health care, healthy foods, opportunities for continued education, and a host of other services and/or resources required for aging successfully.[32]

While each of the variables described in this section have been shown to correlate, to a greater or lesser extent, with how well an older adult functions, it is likely that the complex interplay that occurs among these many variables, combined with the influence of individual lifestyle factors (e.g., physical and cognitive activity, nutrition, social engagement), best determines how older adults are and/or perceive that they are aging successfully.

BUILDING PATHWAYS TO SUCCESSFUL AGING: THE RESULTS OF INTERVENTION RESEARCH

Exercise or Physical Activity

A mounting body of empirical evidence has demonstrated that exercise or physical activity plays an important role in shaping many of the physical, psychological, and cognitive changes that occur across the lifespan. Certainly, structured exercise- or physical activity-based interventions are at the core of most, if not all, attempts to prevent the onset of disability, slow the progression of disease or system impairments, or restore function to a level that optimizes independence following a traumatic event. Pope and Tarlov[33] refer to these as the primary, secondary, and tertiary roles played by physical activity in promoting health.

For each of the components identified in the SA model developed by Rowe and Kahn, physical activity has the potential to serve as the primary vehicle for enhancing and/or maintaining each of the three key characteristics identified. Indeed, a substantial amount of research has demonstrated an important primary role for physical activity in the prevention of a number of chronic diseases[34] (e.g., cardiovascular disease, type II diabetes, osteoporosis, certain types of cancer), functional limitations,[35,36] and premature disability.[37–39] Moreover, regular engagement in physical activity is associated with the retention of substantially higher levels of cognitive health as characterized by preserved executive control function well into later adulthood.[40–42] Finally, regular

engagement in physical activity, particularly in socially supportive group environments, facilitates "active" engagement in life.[43] This is particularly true for older women who are just beginning an exercise program.[44,45]

Despite the wealth of research evidence that has identified physical inactivity as a key risk factor for a number of chronic medical conditions that result in premature disability and/or mortality in the older adult years, only 51.2% of older adults (≥65 years) reported participating in the currently recommended level of physical activity (i.e., at least 150 min of moderate-intensity aerobic activity per week or 75 min of vigorous-intensity activity per week).[46] Older adults aging with a disability are even less likely to engage in any type of leisure-time activity when compared with older adults without disability. This is a particularly troublesome finding given that individuals with disability who regularly engage in physical activity derive similar health benefits. A reduction in the level of functional impairment and improvements in perceived quality of life have also been demonstrated for individuals with disability who participate in physical activity, even at different levels of intensity.[47,48]

A review of the research investigating the efficacy of different types of physical activity interventions as they influence health in the older adult population, suggest that a "one type suits all" physical activity intervention is not effective.[49–51] As the different roles for physical activity identified earlier in this chapter suggest, relatively healthy older adults can derive significant health benefits and/or a reduced risk for disability by participating in many different types of physical activity interventions (e.g., walking, cycling, structured exercise classes), whereas older adults living with one or more chronic diseases and/or system impairments that adversely affect their health and restrict their mobility appear to benefit more from a physical activity intervention that is more individually tailored to their needs and specifically addresses the impairments that are contributing to a more rapid decline in their health. While the overall intensity of the designed intervention may not differ between these two groups, how the major exercise principles (i.e., overload and specificity) and related exercise variables (i.e., frequency, intensity, time, and type) are manipulated may be very different. Finally, for older adults who are frail or transitioning into frailty, individualized physical activity interventions that manipulate the major exercise principles and variables in yet another way and are delivered in combination with other intervention strategies (e.g., medication management, environmental modifications to living environment) appear to be a more effective intervention approach.[52] Growing evidence also suggests the need for including a behavioral counseling or social-cognitive component within a physical activity intervention as a means of developing self-regulation skills and better long-term compliance with a physical activity intervention.[45,52,53]

The benefits of exercise on cognitive function among older adults, considered as important as maintaining physical capacity by Rowe and Kahn, have also been explored in a number of clinical trials over the past decade. Using meta-analytic techniques, Colcombe and Kramer[54] evaluated the effects of 18 clinical trials that investigated the impact of different fitness interventions on cognitive function in healthy older adults ranging in age from 55 to 80 years. The benefits of exercise were most apparent for higher order executive functions such as planning, abstraction, and the selection of relevant sensory information. Larger and more reliable improvements in cognitive function were noted for those fitness interventions that combined aerobic exercise with resistance training and were longer in duration (6+ months). Of further note was the finding that clinical populations showed similar improvements with exercise as did the non-clinical populations studied. It is presumed that the mechanisms by which exercise exerts its primary influence on brain function lies in its promotion of neurotrophic factors and reduced oxidative stress and inflammation.[55,56]

Cognitive Training and Stimulation

Intervention strategies that specifically target higher order cognitive processes have also demonstrated significant improvements in the cognitive function of both healthy older adults and those already experiencing mild cognitive impairment.[57–60] The Advanced Cognitive Training for Independent and Vital Elderly trial[61] investigated both the short- and long-term benefits of a cognitive training program that targeted specific cognitive skills in a sample of 2000 healthy, community-dwelling older adults. Participants were randomly assigned to one of three different training groups (i.e., verbal episodic memory, inductive reasoning, or processing speed) or a no-contact control group. Immediate posttraining improvements in the specifically targeted cognitive skills were observed after only 10 training sessions and continued 2 years after completion of the initial training.[57]

Cognitive training interventions have also been shown to be effective in reversing intellectual decline with age. This was nicely demonstrated in the Seattle Longitudinal Study.[62] Approximately two-thirds of study participants identified with declining cognitive function demonstrated significant improvements in multiple indices of executive function, with approximately 40% of those who had experienced significant declines over the course of the 14 year period they were monitored, returned to predecline levels of function.[58] Moreover, the positive training effects continued to be observed 14 years posttraining.[59]

Other innovative cognitive training programs that have been tested include Senior Odyssey,[63] a cognitive enrichment program that engages older adults in complex problem-solving activities in a team-like atmosphere that also promotes social connectedness. Participation in the program has been shown to enhance cognitive functions such as verbal fluency, speed of processing, and mindfulness.[63–65] Studies investigating the benefits of computer-based cognitive training programs have also demonstrated positive effects on a number of important domains of executive function (e.g., processing speed, memory, selective attention) as well as improved performance in their everyday lives.[66,67] Many of these programs are now commercially available and being widely used in rehabilitation, community, and retirement settings.

Dietary Influences

Both the adequacy and quality of food consumed by the older adult will influence their ability to age successfully. Numerous studies have demonstrated the impact of an inadequate diet on physical health,[68,69] cognition,[70–72] and the prevention or control of chronic disease[69] in older adulthood. For optimal health across the lifespan, the consistent consumption of a healthy diet that is high in fruits and vegetables, dietary fiber, and essential vitamins and minerals while low in saturated fats is strongly recommended according to the recently published *Dietary Guidelines for Americans, 2010*.[73] Adults over 50 years are also encouraged to consume foods fortified with vitamin B12.

Maintaining a healthy diet is also essential for weight reduction or maintenance. Research studies have shown that obese or overweight adults are at a higher risk for developing high blood pressure, diabetes, heart disease, arthritis, and certain forms of cancer.[74] Decreased mobility and daily function are also negative outcomes associated with being overweight or obese. Unfortunately, maintaining a proper diet is not always easy for many older adults as a result of physiological changes that result in compromised organ function, difficulties with chewing or swallowing, or diminished interest in food as a result of sensory changes affecting taste and smell.[74] Living alone has also been associated with an older adult's inability to meet his or her nutritional needs.[75]

In addition to the consumption of a well-balanced diet, findings from a small number of clinical and epidemiological trials have also demonstrated the benefits of calorie restriction (CR), reduced food intake, on multiple indices associated with SA. In addition to reducing the incidence of many age-related diseases,[76] other favorable findings include reductions in blood pressure, body mass index, triglyceride levels, and improved cholesterol profiles.[76–78] Improvements in memory have also been demonstrated after relatively short periods (3 months) of caloric restriction.[79]

More recently, an alternative strategy to CR has become the focus of growing attention by a number of research groups.[80] The development of CR Mimetics (i.e., compounds that target metabolic and stress response pathways and, thereby, mimic the effects of CR) is under way. These drugs (e.g., metformin, resveratrol) are intended to mimic the metabolic, hormonal, and physiological effects of CR without the need to actually restrict caloric intake. Although more longitudinal studies are needed to more fully evaluate the long-term influences of CR Mimetics on the aging process, preliminary findings are promising with respect to CRM's enhancing and neuroprotective effects.

Other nutrients that are essential to the physical health and cognitive function of older adults include calcium, which is critical for lowering the risk of bone loss and osteoporosis in both men and women,[81] folic acid, omega 3 fatty acids, and other antioxidant vitamins.[82] Some evidence also exists for the positive benefits of added vitamin D supplementation, particularly for older adults showing below-average baseline levels.[83] Inadequate vitamin D levels have been associated with increased risk for falls and related fractures that will significantly undermine the older adults' physical and emotional health.[84] Finally, some evidence suggests that dietary supplements in the form of enriched drinks can have positive benefits on selected measures of cognition.[85]

Social Engagement and Volunteerism

The importance of being socially engaged and having a strong social support network in older adulthood has been frequently cited as an important characteristic[4] or determinant of SA.[13] Recent intervention research, in particular, has focused on the benefits of involving older adults in a variety of different productive activities (e.g., working for a salary, caregiving), including volunteering.[86–91] One highly successful program that has been demonstrated to benefit both the older adult volunteers as well as those served is the Experience Corps (EC), a program that trains older adults to assist at-risk elementary school students learn math and other skills in a school setting.[86] In one of the first studies conducted to evaluate the program's efficacy, Fried et al. assigned 149 new older adult recruits to either an EC or control group. The older adult volunteers assigned to the EC group worked with elementary school students to improve their math and reading skills for a minimum of 15 h a week throughout the academic year. Outcomes at 1 year showed that the EC volunteers demonstrated significantly higher levels of physical activity, strength, cognition, and breadth of social support networks. What is perhaps most noteworthy about this program is that similar health benefits were derived by older adult volunteers categorized as being in only fair-to-good health.[87] Having older adults engage in productive activities has also been shown to be positively associated with physical and psychological health as well as survival rates of older adults.[89–91] Collectively, the results of these studies provide support for the value of older adults engaging in meaningful volunteer activities as a means of improving their level of physical, cognitive, and social health—all important determinants for SA.

IT'S NEVER TOO LATE: FACT OR FICTION?

While considerable research has demonstrated the negative effects of physical inactivity, obesity, smoking, excessive alcohol, and poor diet on morbidity and mortality,[92–94] there is evidence to suggest that much can be done to reverse many of the adverse effects associated with unhealthy lifestyle behaviors.[95] In fact, one of the many myths debunked as a result of the MacArthur Foundation studies was that it is too late for older adults to lower their risk for premature morbidity and mortality after decades of engaging in unhealthy (e.g., eating fatty foods, not exercising) or risky behaviors (e.g., smoking, excessive alcohol) once older adulthood is reached.[5] Research has also shown that most age-associated declines in physical performance can also be reversed with regular participation in even moderate levels of physical activity.[96,97] For example, the Lifestyle Interventions and Independence for Elders pilot

study, a multicenter, randomized clinical-controlled trial involving 424 sedentary persons aged between 70 and 89 years at risk for disability, has demonstrated both immediate[97] and longer-term improvements (2 year follow-up)[98] in physical performance and mobility disability following completion of a 12 month moderate-intensity physical activity intervention. As Rowe and Kahn[5] aptly state "Physical activity is at the crux of SA, regardless of other factors (p. 98)."

Research evidence also shows that smoking cessation, even in the case of previously heavy smokers, significantly lowers the risk for cardiovascular disease, lung cancer, and stroke.[99,100] According to the American Lung Association, within a year of quitting, former smokers reduce their risk of coronary heart disease by 50% with the risk further declining with each passing year.[99] The adverse effects of a poor diet can also be reversed through nutritional interventions that combine dietary screenings with individualized nutrition plans designed to address the specific needs of the older adult (e.g., malnourishment, obesity).[101,102] Bowen and Beresford,[103] following their review of 80 published dietary intervention studies, concluded that more intensive dietary interventions that set high goals for participants and recruited more selectively (i.e., more highly motivated participants) yielded the better outcomes.

ROLE OF HEALTH CARE PRACTITIONERS IN THE PROMOTION OF SUCCESSFUL AGING

Health care professionals can play an integral role in promoting SA among older adults. Health care providers are viewed by the majority of older adults as the primary source of health information and, therefore, have the credibility needed to be an influential force in getting older adults to embrace a healthier lifestyle. The very fact that adults in the United States visit a physician's office an average of three times per year provides the opportunity needed to implement successful health-promoting practices.[104] In spite of this knowledge, the percentage of older adults (65 years or older) who report receiving counseling about health-promoting behaviors such as regular physical activity are very low (approximately 31%).[105] In this final section of the chapter, I will briefly review the research evidence that supports a role for the health care provider and the types of intervention strategies that have yielded successful outcomes.

A number of research studies have explored the benefits of physician-based counseling of patients, particularly as it relates to physical activity,[106] smoking cessation,[107] alcohol consumption,[108] and nutrition.[109] Calfas et al.[110] demonstrated that previously sedentary patients provided with in-office structured counseling sessions as short as 3–5 min resulted in positive short-term changes in their patients' physical activity levels as well as their readiness to adopt physical activity. Other studies that have individually tailored the PA counseling by matching it to a patient's stage of motivational readiness for physical activity[111] (e.g., precontemplation, contemplation, preparation) have also proven effective, at least in the short term.[112,113] Patients enrolled in the Physically Active for Life project who received individually tailored PA counseling were more likely to be in more advanced stages of readiness for PA 6 weeks following their initial counseling appointment when compared with a group receiving standard care. Unfortunately, these gains were no longer evident after 8 months with no differences in physical activity levels evident between the two groups.[113]

In order to achieve more long-term behavior change among previously inactive older adult patients, Pinto et al.[114] supplemented a brief PA counseling session (approximately 3 min) delivered by the physician during the course of an office visit with regular telephone counseling by a health educator. Significantly higher levels of physical activity were reported for the group receiving the additional telephone counseling (additional hour/week) after 3 months when compared with a group receiving a single in-office counseling session (12.45 min/week). More importantly, the physical activity gains were sustained in the extended counseling group through 6 months of follow-up. In addition to counseling, providing older adult patients with a motivational tool in the form of a pedometer may also prove to be an effective intervention strategy. Findings from a study conducted by Bravata et al.[115] showed that pedometer use by adult outpatients resulted in higher physical activity levels and other health benefits (decreases in body mass index and blood pressure), at least in the short term. Given the knowledge that older adults can attenuate the progression of functional impairments by up to 55%, even by engaging in only moderate levels of physical activity,[116] providing physical activity counseling to all older adult patients, irrespective of health status, should be a high priority for the health care professional.

Physician-based counseling focused on alcohol consumption,[108] smoking cessation,[107,117] and improved nutritional practices[109] has also yielded successful outcomes. The efficacy of physicians providing two brief (10–15 min, 1 month apart) counseling sessions supplemented with follow-up phone calls from a nurse has been demonstrated to significantly lower alcohol use, episodes of binge drinking, and frequency of excessive drinking, in groups of at-risk patients reevaluated at 1 and 2 years after the first counseling session.[108] Similarly, physician counseling, often combined with nicotine replacement therapy or telephone quitlines, also constitute effective smoking cessation strategies.[107,117] Intervention strategies aimed at improving dietary behaviors have also yielded successful outcomes when delivered by health care providers in primary care settings. The most effective interventions appear to combine patient education, behavioral counseling, patient reinforcement, and follow-up. The interventions also tend to be more intensive, are conducted over a longer period of time, and are directed at patients at increased risk for chronic disease.[109]

Routine counseling of patients relative to the physical and cognitive benefits of social engagement as well as engaging in cognitively demanding activities should also be an integral component of the health care services provided to older adults. Encouraging older adults to add new cognitive, physical, and social activities into their daily routines and providing examples of appropriate types of activities

will be important. As indicated earlier in this chapter, certain types of computer-based cognitive training programs have been demonstrated to improve multiple domains of cognition (e.g., processing speed, memory, visuospatial orientation) in controlled trials conducted with older adults.[66] Although more controlled studies are needed, limited evidence also suggests that improvements in certain cognitive domains transfer to the performance of routine daily activities.[118] Indeed, many community-based centers and retirement communities have begun installing computer-based "brain fitness" training programs and other types of interactive video games (e.g., Nintendo Wii) aimed at improving the physical, cognitive, and social health of older adults.

Older adults who report unusual changes in their physical or cognitive health concerns to their health care provider should undergo further testing to distinguish between changes that are associated with age versus pathology. Because age-associated changes in muscle and bone predispose older adults to injury, additional care needs to be taken when prescribing physical activity for older adults and referring them to community-based classes. In the case of those older adults who are already experiencing significant changes in their functional abilities and are at heightened risk for falls, it will be especially important to have the appropriate health care professional conduct a thorough assessment of their physical abilities so that the exercise prescription can be appropriately matched to their ability level. While referrals to local community-based physical activity programs or directions on how to begin a self-directed walking program may be sufficient for more healthy patients, others will require more tailored and multifactorial interventions.[52] While some hospitals and outpatient centers currently offer on-site programs that include educational programs directed at improving chronic disease self-management skills as well as structured exercise programs focused on primary or secondary prevention of disease, many more are needed to address the growing needs of the middle-aged and older adult populations.

What are the core ingredients necessary for implementing interventions aimed at enhancing the health of older adults? Haber[119] recommends that in order to be successful, health promotion interventions aimed at older adults should include the following core elements: the development of short- and long-term health goals that are both modest and measurable, strategies for building and maintaining the patient or client's motivation, techniques for addressing barriers that have prevented success in the past and/or might become an issue in the future, fostering compliance so that the new behavior becomes a habit, and assisting the patient/client garner the social support needed to continue in the face of adversity. To accomplish these outcomes, an interdisciplinary team approach is going to be necessary.

SUMMARY

Despite the controversy that the term "successful aging" has sparked in the literature, both with respect to how it is defined and/or measured, research evidence strongly indicates that aging is not synonymous with an inevitable decline in one's physical and cognitive health. Modifiable lifestyle and behavioral factors clearly play a greater role in shaping the older adults' overall quality of life, both as it is perceived and actually experienced, than one's genetic inheritance. While making healthy lifestyle and behavior choices early in life are clearly important to optimizing health and well-being in later adulthood, the research shows that it's never too late for an older adult to alter the trajectory of his or her lifespan. The health care professional has the potential to serve as both an important catalyst for change as well as a mediator of that change. Regularly counseling older adult patients about the benefits of physical activity, eating a balanced diet, not smoking, and avoiding excessive alcohol intake can do much to improve their physical health. Similarly, encouraging older adults to engage in stimulating cognitive and social activities on a daily basis will also benefit them psychologically and emotionally.

The early identification of unusual physical and cognitive changes is an important first step in preventing or delaying the onset of more serious impairments that will threaten an older adult's ability to remain independent and socially engaged. This can be accomplished through regular screenings conducted by the appropriate health care provider and immediate referral for additional testing, if warranted, or to programs and/or services available in outpatient or community settings. In order to ensure long-term success, a systematic and collaborative team approach will be necessary because no single health care provider has the knowledge, skills, or resources available to address the many factors that contribute to whether an older adult does or does not age successfully. Building wellness teams that interface primary care physicians, physician assistants, physical and occupational therapists, and clinical nurse specialists, with health educators and other community- and home-based service providers will be needed if long-term behavior change can be expected. Added incentives in the form of allocating time for health care providers to receive the necessary training, providing additional resources and personnel to implement effective interventions, and providing financial reimbursement linked to outcomes may be necessary to help primary care providers, in particular, overcome many of the barriers that currently exist to the implementation of regular health-promoting practices with their older adult patients.

INTRODUCTION

Is functional decline an inevitable and inescapable consequence of growing older? Or can we play an active role in determining the path that aging takes? There is a growing body of evidence to suggest that we may be able to postpone some of the negative consequences of growing older by maintaining a high level of physical activity. Avoiding a sedentary lifestyle and eating a healthy diet may be one of the most effective means of postponing the onset of functional decline, promoting independence, and maintaining high-quality of life in old age. During the past century, many developed countries have experienced an epidemiological transition in which the impact of infectious diseases has steadily declined and noncommunicable diseases (NCDs) have become the leading causes of disease, disability, and death [1]. Because chronic diseases and conditions typically take many years to develop, the increased levels of NCDs are disproportionately borne by older adults, many of whom have

increased risk of developing and dying from cardiovascular disease, type 2 diabetes, obesity, and certain cancers [1–5]. Many chronic conditions share common preventable causes that are both lifestyle related (unhealthy diets, physical inactivity, smoking, and alcohol abuse) and biological (hypertension, obesity, and dyslipidemia). In addition, there are also a number of social, economic, and environmental factors linked with chronic diseases, including education, availability, and affordability of healthy food, access to health services, and policies and infrastructures that support a healthy lifestyle.

Despite the complex relationships among the many determinants of chronic disease, the World Health Organization (WHO) has identified regular physical activity as an effective means by which an individual can reduce the risk of developing chronic diseases and conditions and, thereby, promote independence and age successfully [6]. Epidemiological research has consistently shown significant decreases in the relative risk of cardiovascular and all-cause mortality among persons who are classified as highly active compared with those in a similar age range who are classified as moderately active or less active [7].

In this chapter, we present an overview of current research and recommendations concerning the relationship between regular physical activity and successful aging. In "Benefits of physical activity for older adults" section, we briefly review some of the benefits that accrue to older individuals who adopt a physically active lifestyle. In "Recommendations and guidelines for frequency, intensity, duration, and type of physical activity" section, we summarize current U.S. government guidelines regarding the frequency, intensity, duration, and type of physical activity recommended for older adults. Next, in "Motivating older adults to initiate and maintain a physically active lifestyle" section, we focus on evidence-based strategies to help motivate older adults to initiate and maintain a physically active lifestyle. Finally, in "Communicating with patients about exercise and physical activity" section, we discuss how clinicians should talk to their patients about physical activity, focusing on the need to help patients to learn how to "be active their way." We conclude by providing answers to frequently asked patient questions about physical activity. Throughout the chapter, the Institute of Medicine definitions of physical activity and exercise and related concepts are adopted, where, physical activity refers to body movement that is produced by the contraction of skeletal muscles and that increases energy expenditure. Exercise refers to planned, structured, and repetitive movement to improve or maintain one or more components of physical fitness.

BENEFITS OF PHYSICAL ACTIVITY FOR OLDER ADULTS

Over the past 20–30 years, a very substantial number of studies have confirmed that there are many benefits for older adults who participate in regular physical activity. In 2008, the Department of Health and Human Services (DHHS) published, for the first time, official U.S. Government Physical Activity Guidelines (PAG) [8]. The DHHS PAG for Americans conclude that, compared with less active persons, more active men and women have lower rates of all-cause mortality, coronary heart disease, high blood pressure, stroke, type 2 diabetes, metabolic syndrome, colon cancer, breast cancer, and depression. In addition to these biomedical benefits, there are many other reasons older adults should be encouraged to find a way to build physical activity into their everyday lives. Regular physical activity can help to improve quality of life in old age. Physical activity can help older adults remain active and engaged within their families and communities.

A detailed review of the benefits of physical activity for older adults is beyond the scope of this chapter; however, several recent review articles are available, which provide excellent summaries of the existing evidence [9,10]. For example, the American College of Sports Medicine (ACSM) recently published a Position Stand on Exercise and Physical Activity for Older Adults [9], which summarizes the benefits of both long-term exercise and physical activity and shorter-duration exercise programs on the health and well-being of older adults. The ACSM Position Stand concludes that although no amount of physical activity can stop the biological aging process, there is evidence that regular physical activity can minimize the physiological effects of an otherwise sedentary lifestyle and increase healthy life expectancy by limiting the development and progression of chronic disease and disabling conditions. Importantly, physical activity not only benefits our physical health but there is also strong evidence that it can improve psychological health and well-being. Regular physical activity can favorably influence a broad range of physiological systems and may be a lifestyle factor that discriminates between those individuals who have and have not experienced successful aging.

In October 2007, the American Medical Association and the ACSM launched a major new initiative called Exercise is Medicine (EIM). The major goal of the EIM project is to make physical activity and exercise a standard part of a global disease prevention and treatment medical paradigm. The initiative recognizes that regular exercise can be an important element in the management of numerous medical conditions including coronary heart disease [11–13], hypertension [11,14,15], peripheral vascular disease [16], type 2 diabetes [17], obesity [18], elevated cholesterol [11,19], osteoporosis [20], osteoarthritis [21,22], claudication [23], and chronic obstructive pulmonary disease [24]. A joint statement from ACSM and the American Heart Association [10] concludes that physical activity is valuable in the treatment and management of depression and anxiety disorders [25], dementia [26], pain [27], congestive heart failure [28], syncope [29], stroke [30], back pain [31], and constipation [32]. In addition, there is some evidence that physical activity prevents or delays cognitive impairment [33] [34,35] and disability [36–38] and improves sleep [39,40].

TABLE 105.1
Individual Benefits of Physical Activity for Older Persons: Physiological Benefits

Immediate benefits
- *Glucose levels*: Physical activity helps regulate blood glucose levels
- *Catecholamine activity*: Both adrenalin and noradrenalin levels are stimulated by physical activity
- *Improved sleep*: Physical activity has been shown to enhance sleep quality and quantity in individuals of all ages

Long-term effects
- *Aerobic/cardiovascular endurance*: Substantial improvements in almost all aspects of cardiovascular functioning have been observed following appropriate physical training
- *Resistive training/muscle strengthening*: Individuals of all ages can benefit from muscle strengthening exercises. Resistance training can have a significant impact on the maintenance of independence in old age
- *Flexibility*: Exercise which stimulates movement throughout the range of motion assists in the preservation and restoration of flexibility
- *Balance/coordination*: Regular activity helps prevent and/or postpone the age-associated declines in balance and coordination that are a major risk factor for falls
- *Velocity of movement*: Behavioral slowing is a characteristic of advancing age. Individuals who are regularly active can often postpone these age-related declines

The WHO Guidelines have been placed in the public domain and can be freely copied and distributed (WHO, 1996).

TABLE 105.2
Individual Benefits of Physical Activity for Older Persons: Psychological Benefits

Immediate benefits
- *Relaxation*: Appropriate physical activity enhances relaxation
- *Reduces stress and anxiety*: There is evidence that regular physical activity can reduce stress and anxiety
- *Enhanced mood state*: Numerous people report elevations in mood state following appropriate physical activity

Long-term effects
- *General well-being*: Improvements in almost all aspects of psychological functioning have been observed following periods of extended physical activity
- *Improved mental health*: Regular exercise can make an important contribution in the treatment of several mental illnesses, including depression and anxiety neuroses
- *Cognitive improvements*: Regular physical activity may help postpone age-related declines in Central Nervous System processing speed and improve reaction time
- *Motor control and performance*: Regular activity helps prevent and/or postpone the age-associated declines in both fine and gross motor performance
- *Skill acquisition*: New skills can be learned and existing skills refined by all individuals regardless of age

The WHO Guidelines have been placed in the public domain and can be freely copied and distributed (WHO, 1996).

EIM strongly advocates that physical activity should be considered by all health care providers as a vital sign in every patient visit and that all patients are effectively counseled and referred with respect to their physical activity needs. The WHO suggests that the benefits of physical activity for older adults can be divided into two broad categories: (1) benefits of physical activity for the individual and (2) benefits of promoting physically active lifestyles among older persons for society [41]. Under the WHO schema, the individual benefits can be summarized into four general areas: physiological benefits (Table 105.1), psychological benefits (Table 105.2), social benefits (Table 105.3), and the benefits for society in an additional table (Table 105.4). As long ago as 1996, the WHO was recommending that virtually all older persons should participate in physical activity on a regular basis and that society has a responsibility to advocate for broad-based participation in physical activity whenever possible. The WHO Guidelines conclude that regular physical activity provides substantial health-related benefits. In addition, it is cheap, safe, and readily available.

TABLE 105.3
Individual Benefits of Physical Activity for Older Persons: Social Benefits

Immediate benefits
- *Empowering older individuals*: A large proportion of the older adult population voluntarily adopts a sedentary lifestyle, which eventually threatens to reduce independence and self-sufficiency. Participation in appropriate physical activity can help empower older individuals and assist them in playing a more active role in society
- *Enhanced social and cultural integration*: Physical activity programs, particularly when carried out in small groups and/or in social environments, enhance social and intercultural interactions for many older adults

Long-term effects
- *Enhanced integration*: Regularly active individuals are less likely to withdraw from society and more likely to actively contribute to the social milieu
- *Formation of new friendships*: Participation in physical activity, particularly in small groups and other social environments, stimulates new friendships and acquaintances
- *Widened social and cultural networks*: Physical activity frequently provides individuals with an opportunity to widen available social networks
- *Role maintenance and new role acquisition*: A physically active lifestyle helps foster the stimulating environments necessary for maintaining an active role in society, as well as for acquiring positive new roles
- *Enhanced intergenerational activity*: In many societies, physical activity is a shared activity, which provides opportunities for intergenerational contact thereby diminishing stereotypic perceptions about aging and the elderly

The WHO Guidelines have been placed in the public domain and can be freely copied and distributed (WHO, 1996).

TABLE 105.4
Societal Benefits of Promoting Physical Activity for Older Persons

- *Reduced health and social care costs*: Physical inactivity and sedentary living contributes to a decrease in independence and the onset of many chronic diseases. Physically active lifestyles can help postpone the onset of physical frailty and disease thereby significantly reducing health and social care costs
- *Enhancing the productivity of older adults*: Older individuals have much to contribute to society. Physically active lifestyles help older adults maintain functional independence and optimize the extent to which they are able to actively participate in society
- *Promoting a positive and active image of older persons*: A society which promotes a physically active lifestyle for older adults is more likely to reap the benefits of the wealth of experience and wisdom possessed by the older individuals in the community. A large proportion of the older adult population voluntarily adopts a sedentary lifestyle, which eventually threatens to reduce independence and self-sufficiency

The WHO Guidelines have been placed in the public domain and can be freely copied and distributed (WHO, 1996).

RECOMMENDATIONS AND GUIDELINES FOR FREQUENCY, INTENSITY, DURATION, AND TYPE OF PHYSICAL ACTIVITY

DHHS PAG for Americans recommendations for the frequency, intensity, and duration of exercise and physical activity for older adults are summarized in the subsequent sections. The PAG recommend 150 min/week of moderate-intensity aerobic activity for health benefits. However, the DHHS Guidelines note that additional benefits occur as the amount of physical activity increases through higher intensity, greater frequency, and/or longer duration. The DHHS PAG stress that if older adults cannot do 150 min of moderate-intensity aerobic activity a week because of chronic conditions, they should be as physically active as their abilities and conditions allow. The following recommendation for older adults describes the amounts and types of physical activity including endurance, resistance, and flexibility exercise.

Endurance Exercise for Older Adults

Frequency: For moderate-intensity activities, accumulate at least 30 or up to 60 min/day (for greater benefit) in bouts of at least 10 min each to total 150–300 min/week or at least 20–30 min/day or more of vigorous intensity activities to total 75–150 min/week or an equivalent combination of moderate and vigorous activity.

Intensity: On a scale of 0–10 for level of physical exertion, 5–6 for moderate intensity, and 7–8 for vigorous intensity.

Duration: For moderate-intensity activities, accumulate at least 30 min/day in bouts of at least 10 min each or at least 20 min/day of continuous activity for vigorous intensity activities.

Type: Any modality that does not impose excessive orthopedic stress, walking is the most common type of activity. Aquatic exercise and stationary cycle exercise may be advantageous for those with limited tolerance for weight-bearing activity.

Resistance Exercise for Older Adults

Frequency: At least 2 days/week.

Intensity: Between moderate (5–6) and vigorous (7–8) intensity on a scale of 0–10.

Type: Progressive weight training program or weight-bearing calisthenics (8–10 exercises involving the major muscle groups of 8–12 repetitions each), stair climbing, and other strengthening activities that use the major muscle groups.

Flexibility Exercise for Older Adults

Frequency: At least 2 days/week.

Intensity: Moderate (5–6) intensity on a scale of 0–10.

Type: Any activities that maintain or increase flexibility using sustained stretches for each major muscle group and static rather than ballistic movements.

Balance Exercise for Frequent Fallers or Individuals with Mobility Problems

Currently, balance exercise is recommended for individuals who are frequent fallers or for individuals with mobility problems. Unfortunately, due to a lack of adequate research evidence, there are currently no specific recommendations regarding the frequency, intensity, or type of balance exercises for older adults. However, the most balance and fall prevention programs include (1) progressively difficult postures that gradually reduce the base of support (e.g., two-legged stand, semi-tandem stand, tandem stand, one-legged stand), (2) dynamic movements that perturb the center of gravity (e.g., tandem walk and circle turns), (3) stressing postural muscle groups (e.g., heel stands and toe stands), or (4) Reducing sensory input (e.g., standing with eyes closed).

Special Considerations for Prescribing Physical Activity for Older Adults

If older adults have been sedentary for many years, it may be necessary to start out slow when beginning a new exercise program, particularly for older adults who are frail or who have chronic conditions that affect their ability to perform physical tasks. Increases in exercise intensity and duration should be gradual and tailored to tolerance and preference. Taking it easy and being patient are good strategies for deconditioned seniors. For some older adults, muscle strengthening activities and/or balance training may need to precede aerobic training activities. If chronic conditions prevent activity

at the recommended minimum amount, older adults should perform physical activities as tolerated so as to avoid being sedentary.

MOTIVATING OLDER ADULTS TO INITIATE AND MAINTAIN A PHYSICALLY ACTIVE LIFESTYLE

Developing the best, most well-rounded physical activity program is not going to be sufficient if we do not also pay attention to motivating older adults to participate in the program! In recent years, a great deal of attention has focused on the study of behavioral factors that increase the likelihood of an individual initiating and maintaining a regular program of exercise and/or physical activity. ACSM has summarized the Best Practices for Physical Activity Programs and Behavior Counseling In Older Adult Populations [42]. The ACSM Best Practice Statement suggests that incorporating a comprehensive behavioral management strategy in physical activity interventions can help maximize recruitment, increase motivation for exercise progression, and minimize attrition. The following behavioral strategies can increase the likelihood a person will sustain a new physical activity behavior.

Social Support—Involving Friends and Family

Social support from family and friends has been associated with long-term exercise adherence in older adults [43]. Examples of social support strategies include peer support (e.g., tell a friend and bring a friend, exercise buddy system) and professional health educator support (telephone counseling, mail follow-up).

Self-Efficacy—You Can Do It! We Can Help!

For many seniors, aging is associated with a loss of perceived control [44]. There is growing evidence that people are more likely to initiate and maintain physical activity if they feel confident about their ability to succeed and if they are afforded a variety of opportunities to actively participate in physical activity. Health contracts, practice/mastery experiences, modeling, and having choices enhance self-efficacy.

Active Choices—Finding the Program That Works For You

As part of a comprehensive behavioral strategy, tailoring the exercise program to the needs and interest of participants has successfully motivated older adults to initiate and maintain a routine of regular physical activity [45]. Therefore, physical activity leaders should work closely with individuals to design a physical activity regimen that reflects the person's preferences and capabilities. There is growing evidence that providing choices concerning exercise program characteristics (such as group-based vs. individual activity programs and choice of exercise location) contributes to greater adherence.

Health Contracts—Making a Commitment

A health contract is a written agreement negotiated between the participant and a health professional to accomplish a health goal [46]. The contract usually includes challenging but realistic goal setting and a measurable, specific, time-delimited plan or course of action for reaching the health goals. The use of a health calendar to record physical activity provides a means for the participant to monitor the targeted physical activity and to reinforce a commitment to the exercise routine. Self-monitoring is most effective when completed frequently (as it occurs or daily), focuses on the behavior (not absence of), and it is specifically defined.

Perceived Safety—It's Safe, It's Fun

Concerns for safety have been identified as a barrier to exercise by many older adults [47]. Physical activity programs can help alleviate inappropriate concerns about safety by educating participants about actual risks of physical activity and by helping individuals understand how to self-monitor their exercise intensity levels.

Regular Performance Feedback—How Are We Doing?

Providing regular and accurate performance feedback can assist older adults in developing realistic expectation of their own progress [48]. Performance feedback should be positive and meaningful to the individual. Observation of meaningful positive changes in performance and success in achieving expected outcomes are associated with exercise adherence in older adults.

Positive Reinforcement—Keep It Up, You're Doing Great!

Positive reinforcement is any procedure introduced in an intervention that increases the likelihood of maintenance of the activity [49]. Examples of effective reinforcement strategies in physical activity settings include recruitment incentives, rewards for reaching targeted goal, and public recognition for attendance and adherence. To maximize the effect of reinforcement, it should be valued by the individual being targeted.

COMMUNICATING WITH PATIENTS ABOUT EXERCISE AND PHYSICAL ACTIVITY*

It is important to help your patients understand that there are many different ways for older adults to be physically active. For some individuals, structured exercise programs led by certified exercise professionals will be the preferred option, whereas, others may wish to find other ways to build physical activity into their everyday lives. The notion that there is a single best way to exercise is no longer tenable, and it is increasingly clear that individuals will need to

* *Source*: DHHS, *Be Active Your Way*, 2008.

select the form of physical activity that works best for them. The DHHS "Be Active Your Way" guide that accompanies the 2008 PAG invites members of the public to select physical activities that meet their personal needs and preferences. The steps outlined in the "Be Active Your Way" guide provide an excellent framework for clinician patient discussions around exercise and physical activity.

Step 1—Getting Started

Before beginning an exercise or physical activity program, the "Be Active Your Way" guide recommends that older adults to first focus on identifying a personally meaningful motive for increasing their activity levels. You should discuss with your patients some physical activity goals that are personally meaningful to them. Among the possible reasons identified for increasing physical activity are the following:

- Be healthier
- Increase my chances of living longer
- Feel better about myself
- Have less chance of becoming depressed
- Sleep better at night
- Help me look good
- Be in shape
- Get around better
- Have stronger muscles and bones
- Help me stay at or get to a healthy weight
- Be with friends or meet new people
- Enjoy myself and have fun

Step 2—Making Physical Activity Part of Your Life

You should encourage patients who are considering a physical activity program to think about reasons why they have not been physically active in the past and to try to develop strategies for overcoming these barriers. The "Be Active Your Way" guide encourages people who have been sedentary for many years to choose something they already like to do and to try to build a physical activity component into the activity. For example, many people like to go shopping or to attend dances and other social events; by increasing the time they spend walking (or dancing), they can gradually combine their fun activity with a healthy dose of physical activity. Older adults should be encouraged to select an activity program that is personally meaningful. Among the strategies recommended are the following:

- Pick an activity you like and one that fits into your life.
- Find the time that works best for you.
- Be active with friends and family. Having a support network can help you keep up with your program.

Step 3—Keeping It Up, Stepping It Up

Once your patients have successfully integrated physical activity into their everyday lives, you should encourage them gradually increase the intensity and duration of physical activity until they are meeting the physical activity recommendations for older adults. This can be achieved in the following ways:

- By being active longer each time. Older adults already walking for 30 min, three times a week, could go longer—walking for 50 min, three times a week.
- By being active more often. If an older adult is biking lightly 3 days a week for 25 min each time, he or she could build up to riding 6 days a week for 25 min each time.

Step 4—Being Active for Life

Once older adults are successfully meeting the PAG, they should be encouraged to consider adding new elements to their physical activity regimen in order to keep physical activity interesting and fun. For example, once older adults are comfortable sustaining moderate-intensity activities on a regular basis, they could begin to add higher intensity activities. The "Be Active Your Way" Guide lists a number of moderate and vigorous physical activity options that are available to older adults.

"Be Active Your Way" moderate physical activity options:

- Biking slowly
- Canoeing
- Dancing
- General gardening (raking, trimming shrubs)
- Tennis (doubles)
- Using your manual wheelchair
- Using hand cyclers—also called arm ergometers
- Walking briskly
- Water aerobics

"Be Active Your Way" Vigorous Physical Activity Options:

- Aerobic dance
- Basketball
- Fast dancing
- Jumping rope
- Martial arts (such as karate)
- Race walking, jogging, or running
- Riding a bike on hills or riding faster
- Team sports
- Swimming fast or swimming laps
- Tennis (singles)

ANSWERING YOUR PATIENT'S QUESTIONS ABOUT EXERCISE AND PHYSICAL ACTIVITY

For those of us who make our living advocating for healthy and physically active lifestyles, it may come as a surprise to realize how little many older adults know about physical activity. However, many older adults were educated at a time

and in a culture in which little was known about the health benefits of physical activity and professionals and members of the public were skeptical about the need to remain physically active after retirement. In the final section of this chapter, we consider some frequently asked questions that older adults ask about exercise and physical activity with the goal of assisting you to provide succinct but accurate responses that will serve to motivate and inform your older clients.

Patient Question: Why Should I Be Physically Active?

Clinician response: There are many reasons you should build physical activity into your everyday life. Regular physical activity can help to improve quality of life in old age. Physical activity can help you stay active and engaged with your family and community. It can help you to manage or postpone some of the chronic diseases and conditions many of us have come to expect from old age. Aging does not have to be something that "happens to us"—on the contrary, being physically active can help us to play a more active role in our own aging. Physical activity can help us to live happier, healthier, and more productive lives.

Additional comment: For many years, exercise professionals have tended to focus on the health or medical benefits of exercise and physical activity when trying to motivate sedentary individuals to become more active. For some individuals, motives such as decreasing cholesterol levels, improving cardiac output, and increasing bone mineral density are effective motivators, but for many seniors, they are not. As a clinician, you should also stress that regular physical activity can be fun, can increase quality of life, and can help seniors continue to do the things that they like to do. It is doubtful that a single motivational strategy will work for all older adults. You should ensure that your clients are exposed to a variety of different motivational strategies in order to find the technique that works best for each of their clients.

Patient Question: How Much Physical Activity Do I Need?

Clinician response: Ideally, you should aim to do at least 150 min of moderate-intensity aerobic activity per week as well as 2 days/week of resistance exercises. However, start by doing what you can and gradually look for ways to do more. If you have not been active for a while, start out slowly. After several weeks or months, build up your activities—do them longer and more often.

Additional comment: The current PAG for Americans summarize the best available scientific recommendations, and a health professional should be prepared to summarize this information for their patients. However, it is important to understand that, for many older adults, 150 min of moderate-intensity aerobic activity per week can be an extremely intimidating target that may leave them discouraged or unwilling to even try to increase their physical activity. It is important that clinicians help patients understand that it is perfectly acceptable to gradually increase physical activity levels starting at easily achievable, nonthreatening levels, and slowly increasing as they become more comfortable with exercise and physical activity.

Patient Question: What Is the Best Exercise for Older Adults?

Clinician response: There is no single best exercise that works for all older persons. Depending on how you define it, "old age" can cover as much as a 50 year age span, ranging from 50 to 100 years of age and older. For this reason, it is impossible to recommend single set of activities that is best for all older persons. Some seniors can run marathons or compete in triathlons, whereas others may be more comfortable walking, gardening, or doing tai chi. Still others will get their exercise in a chair or in bed! The most important thing is to do regardless of your age is to avoid inactivity. The specific type of physical activity will always vary from person-to-person. A good idea is to select activities you enjoy. If possible, mixing up activities that promote stamina, strength, flexibility, and balance is a good idea.

Additional comment: The best exercise or physical activity program is the one that your patients are willing and able to do regularly, that they enjoy, and that adds to their quality of life. For some individuals, this will be a structured group exercise program at the local senior center or YMCA, but for others, it will be something much less structured, possibly involving activities such as healthy commuting, gardening, or walking the dog. Many health professionals grew up enjoying games and sports and are extremely comfortable "working out" in traditional exercise environments. It is important to remember that not all older adults have enjoyed similar positive experiences with traditional exercise programs. Work with your patients to understand their goals, aspirations, and personal preferences. For some individuals, identifying options for active living may be a much more successful strategy than simply referring an individual to an exercise program at a local fitness center or community agency.

Patient Question: How Many Times a Week Should I Exercise?

Clinician response: Generally, it is better to spread out physical activity throughout the week with a goal of being active on at least 3–5 days/week. By choosing activities that you enjoy, that are convenient and affordable, you may be able to find a way to be active on almost all days of the week. Try to mix up your physical activity program so you are not doing the same thing everyday. On some days, you might go for a walk in your neighborhood with a friend or family member, on other days, you might take advantage of a more structured exercise program at the senior center or church. Many people find that wearing a step counter can help them keep track of their activity levels. On days where you have not accumulated

many steps, an after-dinner walk can help you maintain your commitment to maintain an active lifestyle.

Additional comment: As a clinician, one of the most important things you can do for your clients is to empower them to be independently physically active and not to depend solely on you or other health professionals for advice about their physical activity. Clinicians should work with patients to help them develop activities that they can do on their own time and in their own space. By helping seniors understand that there are many different ways to be active, health professionals can help them develop a well-rounded, personalized activity program that selects from a menu of physical activity choices and helps them to be active on most if not all days of the week.

Patient Question: I Have Not Exercised for Many Years, Where Should I Start?

Clinician response: Forget the old saying "no pain, no gain"—it is simply not true! Too many of us learned in childhood that physical activity has to be painful or exhausting if it is going to do us any good. There are many excellent options for those of us who cannot or do not want to exercise vigorously. Walking is a wonderful way to increase your activity level. Stretching, tai chi, and water exercise are also good options. For example, the Arthritis Foundation offers excellent aqua exercise programs designed especially for those with arthritis and joint disorders. Gardening and working outdoors can also be a good form of physical activity. Remember—the most important thing is not what you do—rather—it is most important to avoid complete inactivity.

Additional comment: Prescribing exercise and physical activity is as much an art as it is a science. The most successful clinicians are those that have mastered both of these elements. Simply informing patients about the current scientific guidelines may not be sufficient to motivate them to change their behavior. Understanding some of the principles of behavioral change, discussed earlier in this article, can help you develop greater insight into how to identify the right place for an individual to start on their journey toward an active lifestyle.

Patient Question: Will Physical Activity Help to Reduce My Risk for Specific Diseases and Conditions?

Clinician response: Physical inactivity is a major risk factor for many physical and psychological conditions. Sedentary living is associated with heart disease, obesity, diabetes, and many other conditions. Inactivity is also linked to low self-esteem and psychological depression. Regular physical activity can positively influence all of the aforementioned conditions. Many studies have shown that activity can also help slow the loss of muscle and bone mass that often occurs with advancing age. In addition to these physical and psychological benefits, physical activity can often have significant social benefits. Many seniors enjoy group exercise programs where they have a chance to interact with fellow exercisers of all ages. Even for those individuals who prefer to be active alone or with a partner, physical activity can help them retain the strength and stamina necessary for playing an active role in everyday life.

Additional comment: One of the areas in which more scientific research is needed pertains to the specific mode, intensity, and duration of exercise and physical activity needed to bring about a particular clinical outcome. When approached by an older person with a specific disease or condition, it is especially important for a clinician to recommend an exercise or activity regimen that has been shown to be effective in the treatment and management of that particular condition. For example, when approached by an older woman with osteoporosis who was looking for an exercise program to increase her bone mineral density, it would probably not be optimal to recommend a low-intensity walking and calisthenics program conducted at the local senior center. Clinicians should familiarize themselves with the variety of exercise and physical activity options available in their community and be prepared to work together with their patients to help identify the most appropriate choice for each individual. The online Exercise Assessment and Screening for You (EASY) screening tool, http://www.easyforyou.info/, is an excellent resource for clinicians wishing to tailor physical activity to the needs of a particular client.

Patient Question: Is Exercise Safe?

Clinician response: Yes! Almost everyone can find a safe and effective exercise program tailored toward his or her health status, physical activity goals, and personal preferences. It is far more risky to your health to be sedentary than it is to begin a program of light-to-moderate-intensity physical activity. The greatest risk is that your muscles will be sore in the first few weeks of an exercise program. There are some things that you can do to reduce these risks. Learn to read your body's signals. On days that your body feels tired or weary—take it easy. On good days, take advantage of your body and enjoy yourself! Once we learn how to read our body's signals and respect its needs, we get a better sense for how to adjust our activity programs as we grow older. Very few individual will be able to (or would want to) run or dance as energetically in their seventies as they could in their twenties. Many believe that the secret of successful aging is learning how to adjust to changing needs and circumstances while remaining an active and vibrant member of society.

Additional comment: While there are some risks associated with participation in regular physical activity, the risks of being sedentary are much greater! Physical activity risks are related to level of intensity, with lower-intensity physical activity being associated with the lowest risk. Low-intensity physical activity reduces the risks of injury and muscle soreness and may be perceived as less threatening than moderate-to-high intensity routines. While lower risk is associated with lower-intensity exercise, the consensus is that moderate

physical activity has a better risk/benefit ratio, and moderate-intensity physical activity should be the goal for older adults. Although speaking with a health care provider is always a good idea, the involvement of a primary care provider prior to beginning a program of physical activity may not always be necessary and depends on a person's health condition and the level of intensity and mode of physical activity they plan to pursue. The ACSM Best Practice Statement recommends that before starting or increasing their level of physical activity, older adults should have a strategy for risk management and prevention of activity-related injuries.

Recently, an online website has been developed to help older adults identify the physical activity program most suited for their personal needs, preferences, and health condition [50]. The EASY (http://www.easyforyou.info) is a tool developed to help older individuals, their health care providers, and/or exercise professionals identify different types of exercise/physical activity regimens that can be tailored to meet the existing health conditions, illnesses, or disabilities of older adults. The EASY tool includes six screening questions that were developed based on an expert roundtable and follow-up panel activities. The philosophy behind the EASY is that screening should be a dynamic process in which participants learn to appreciate the importance of engaging in regular exercise, attending to health changes, recognizing a full range of signs and symptoms that might indicate potentially harmful events, and becoming familiar with simple safety tips for initiating and progressively increasing physical activity patterns [51]. The EASY screening philosophy represents a paradigm shift from traditional screening, which excludes individuals from participating in exercise in favor of a more inclusive approach that tailors physical activity to meet the needs of virtually all older adults.

Patient Question: Am I Too Old to Exercise?

Clinician response: No! You are never too old to exercise! Physical activity has been shown to be of benefit for individuals of all ages including persons as old as 90 and 100 years. Many people just like you are active on a daily basis. You can find a physical activity program that you will enjoy, that will make you feel better, and that will increase your quality of life. Think about what you most like to do in life and what you hope to gain from being active. An exercise professional can help you to develop a physical activity program that will help you to achieve these goals.

Additional comment: It is increasingly clear that beneficial effects of regular physically activity can be observed at all stages of the life course ranging from the very young to the oldest-old. In recent years, many excellent and well-publicized studies have focused our attention on the benefits of regular physical activity in those cohorts of seniors who were previously thought to be "too old" or "too frail" to partake in physical activity. There are a number of reasons why the frail and the oldest-old tend to be the most sedentary members of society. First, many of the oldest-old do not think of themselves as candidates for physical activity. They are unaware of the many benefits that can accrue to them if they increase their physical activity levels, and they do not realize that many people just like them enjoy activity on a regular basis. Second, for many years, exercise and physical activity professionals were reluctant to expose the oldest-old to the rigors of even the most modest physical activity regimens. It is only recently that professional organizations and Institutional Review Boards have begun to recognize that the benefits of physical activity are much greater than the very small risks they pose. Third, many of the exercise and physical activity programs traditionally employed with the middle-aged and young-old are poorly suited for use with the frail and the oldest-old. However, there are now an ample number of effective evidence-based programs that have been proven to work in frail and older adult populations.

Patient Question: Do I Need Special Clothing and Equipment?

Clinician response: No! Special clothing and equipment are seldom needed. Safe and effective physical activity can be performed wearing comfortable street shoes and loose fitting everyday clothes. Effective strength training can be achieved with inexpensive equipment such as elastic bands and water-filled jugs.

Additional comment: Many older adults have significant discretionary income and are ready and willing to spend it on club memberships, exercise equipment, and clothing; however, many others are in less fortunate financial circumstances and do not have a lot of money to invest in physical activity. Clinicians should be sensitive to the resources available to their patients and tailor their advice and recommendations accordingly. In my own clinical experience, probably the most important equipment needed to maintain an active life style is a well-fitting pair of shoes, which are both comfortable and provide adequate cushioning to minimize the risk of muscle and joint injuries.

SUMMARY

Although no amount of physical activity can stop the aging process, there is strong evidence that regular physical activity can minimize the physiological effects of aging and increase active life expectancy by limiting the development and progression of non-communicative diseases and promote independency and quality of life in older age. A combination of aerobic and resistance training activities appear to be more effective than either form of training alone in counteracting the detrimental effects of a sedentary lifestyle on the health and functioning of the cardiovascular system and skeletal muscles. While there are clear fitness, metabolic, and performance benefits associated with higher intensity exercise training programs in healthy older adults, it is now evident that such programs do not need to be of high intensity to reduce the risks of developing chronic cardiovascular and

metabolic disease. Social support, self-efficacy, perceived safety, and regular feedback are important behavioral factors that can help increase the likelihood of an individual initiating and maintaining a regular program of physical activity. Physical activity risks are often related to level of intensity, but the risks associated with a sedentary lifestyle far exceed them.

In 2010, the International Obesity Taskforce (IOTF) estimated that approximately 1 billion adults worldwide were overweight, with an addition 475 million obese. Among school-aged children, overweight and obesity are estimated to affect approximately 200 million children. This chapter will review the rapidly changing prevalence of child overweight and obesity, variations in the prevalence of child obesity, key environmental determinants affecting youth eating and activity behaviors, and the health, social, and economic impact of the burden of obesity in young people.

DEFINING OVERWEIGHT AND OBESITY AMONG CHILDREN AND YOUNG PEOPLE

Body mass index (BMI) is a well-accepted measure of adiposity for children and young people [1] and is used extensively internationally. Several approaches of categorizing BMI to define overweight and obesity among children and young people have been developed and are important to acknowledge, particularly when comparing prevalence statistics across populations. The Centers for Disease Control and Prevention (CDC) [2], the IOTF, and the World Health Organization (WHO) [3] have all developed BMI-based definitions of overweight and obesity for child and adolescent populations, and these definitions have been used throughout the academic literature to describe the prevalence of overweight and obesity among populations.

Comparisons of the prevalence of overweight and obesity given by these measures suggest that the definitions give similar but variable results. Compared with the CDC definitions of overweight, the IOTF definitions give lower prevalence statistics of overweight for younger children and higher estimates for older children [4]. The WHO definitions for overweight and obesity give higher rates of overweight and obesity than the CDC and the IOTF definitions [5]. For example, the prevalence of obesity among New Zealand adolescents is 10% when defined by IOTF criteria and 14% when defined by WHO criteria [6]. Given these variable results, acknowledging how overweight and obesity are measured among children and young people is important when comparing population-level estimates.

PREVALENCE OF CHILD AND ADOLESCENT OBESITY

In 2004, it was estimated that the prevalence of overweight and obesity among school-aged children and adolescents was 10% globally [1]. Available data suggest that the prevalence of overweight and obesity is highly variable by country and region of the world with the highest prevalence observed in

the United States (>30% of children), followed by Europe (20%), and lowest in sub-Saharan Africa (<0.5%) [1]. The burden of childhood overweight and obesity has developed rapidly. Between the early 1970s and 2003, the prevalence of overweight (BMI for age ≥95th percentile) for 12- to 19-year-old adolescents in the United States increased threefold, from 6% to 18% [7,8]. Over the past 20 years, the prevalence of child obesity has increased 0.5% per annum in the United States and Brazil and nearly 1% per annum in Canada, Australia, and the United Kingdom [1]. Trends in childhood obesity follow closely with adult obesity. Between 1980 and 2008, the average BMI among adults increased markedly (approximately 0.5 kg/m^2 per decade), with the highest rates of adult obesity now in the United States and many countries in Oceania [9].

Data from the 2003–2004 National Health and Nutrition Examination Survey (NHANES) survey estimated the prevalence of overweight and obesity among American young people at >35% (IOTF) [10]. A national health survey of Mexican young people (10–17 years old) reported that approximately one-quarter of children were overweight or obese (IOTF), but children living close to the U.S. border had a much higher prevalence [11].

National survey data for the United Kingdom in 1997 reported 19% of young people (age 4–18 years) were overweight or obese (IOTF) [12]. A more recent survey in Ireland (2002) found that approximately one in four children (4–16 years) were overweight or obese (IOTF) [13]. Prevalence estimates in Europe are similar but variable with Northern European countries tending to have lower prevalence levels of overweight and obesity than Southern European countries [14].

Data collected in Australia in 1995 estimated the prevalence of overweight and obesity (IOTF) to be 20% for children aged 2–18 [15]. In New Zealand, the prevalence of overweight and obesity (IOTF) among children (ages 2–14 years) in 2007 was 29% [16] and for adolescents was 34% [6]. Smaller studies conducted in the Pacific have estimated the prevalence of overweight and obesity to be approximately 40% among Tongan adolescents and 30% among Indigenous Fijians [17].

RECENT TRENDS IN CHILD AND ADOLESCENT OBESITY

Several countries around the world have begun to report that the prevalence of child obesity has begun to stabilize. In the United States, there were no appreciable increases in the prevalence of overweight and obesity among children and young people between 2003 and 2006 [18]. Likewise, reports from Australia [19] and France [20] have reported minimal or no increases in the prevalence of child overweight/obesity in the early 2000s. Moreover, a decline in the prevalence of overweight among children in Switzerland was observed between 2002 and 2007 [21].

While these recent reports look promising for public health, it remains unclear as to why a leveling of childhood obesity may be occurring. Many countries have implemented numerous nutrition and activity interventions and policies to address the issue of childhood obesity and it may be that these are having an effect. Overall, however, it is probably too soon to assume that childhood obesity has reached a plateau and will not worsen.

There are numerous factors that affect population variations in the prevalence of obesity (see subsequent sections). While national averages in the prevalence of child obesity may not change year to year, these averages may not capture fluctuations among subpopulations who bear the greatest burden of obesity. In New Zealand, data from nationally representative samples showed that there were no changes in the prevalence of child overweight/obesity between 2002 and 2007 [16]. However, a smaller study of adolescents attending high schools in high deprivation areas of New Zealand experienced a significant increase in obesity alone, from 19% in 1997 to 31% in 2005 (average annual increase of 7%) [22]. In the United Kingdom, the overall prevalence of overweight and obesity was steady from 2002/2003 to 2006/2007, but the socioeconomic gradient in obesity widened [23]. Thus, relying on reports of national averages may result in a worsening of the problem for segments of the population at greatest risk.

Population-Level Variations in the Prevalence of Obesity

The extent of the obesity epidemic is more prevalent among certain population groups. Demographic characteristics and socioeconomic factors associated with the prevalence of child and adolescent obesity are described in the subsequent sections.

Age

Isolating the developmental stages or periods in which children and adolescents are likely to become overweight/obese has important public health implications for targeting prevention efforts, but reviews of the evidence suggest this is difficult to achieve [24]. Large epidemiologic studies generally suggest that the prevalence of overweight/obesity increases throughout childhood and adolescence, but these findings are not consistent. For example, among the young people (4–18 years) participating in the 1997 National Diet and Nutrition Survey (United Kingdom), the prevalence of overweight/obesity significantly increased with age among boys, but not girls [12]. Pooled data from the 2003–2006 NHANES surveys reported that 24% of 2- to 5-year-olds had BMI values indicating overweight/obesity compared with 33% among 6- to 11-year-olds and 34% among 12- to 19-year-olds [25]. Of more interest, a 5 year longitudinal study of overweight/obesity during adolescence in the United Kingdom found that, among their sample of nearly 6000 students (11–12 years at baseline), few new cases of overweight or obesity emerged during adolescence, suggesting that persistent obesity may develop prior to adolescence [26].

Ethnicity

Ethnic and racial disparities in child and adolescent obesity have been documented in most Western countries. In the United States, the prevalence of overweight (CDC) based on the most recent NHANES survey data is significantly higher among African American (21%) and Mexican American (21%) children compared with white children (15%) [25]. The prevalence of overweight has increased significantly among these two population groups of children in the United States between NHANES III (1988–1994) and NHANES 1999–2000, while no significant increases were observed among white children [8]. Studies involving Pima Indians (United States) show that the median BMI of Pima Indian children compares with the 90th–97th percentiles of the CDC reference values for the general population of American children [27]. In the United Kingdom, the prevalence of overweight and obesity is considerably higher among Indian (38%) and Pakistani (35%) boys and Afro-Caribbean (46%) and Pakistani (34%) girls than children in the general population (27% for boys and 28% for girls; IOTF) [28]. In New Zealand, the prevalence of overweight/obesity is highest among children of Maori and Pacific Island ethnicities, with >40% of Maori children and young people and >60% of Pacific children and young people meeting the definition of overweight and obesity (IOTF), compared with approximately 25% of those of European ethnicity [6,29].

One of the most discussed evolutionary theories explaining the ethnic disparities in obesity and type 2 diabetes is the thrifty gene hypothesis. The theory was first introduced by James Neel in 1962 [30] and poses that, over time, populations who were exposed to periods of famine experienced genetic changes to maximize their ability to store energy. When food is abundant, these populations would then store more energy, which would result in higher rates of obesity in the modern context. The theory continues to attract academic support and further research in some quarters, but there are several problems with this theory from biological and ethical perspectives. First, current evidence suggests that genetic variation among humans is homogenous [31]. While genetic variation is geographically structured, and certain ethnic population groups have long been geographically isolated, substantial overlap has occurred between populations meaning that ethnic populations do not have discrete genetic types [31]. Second, the obesity epidemic has occurred too rapidly for changes in the genetic makeup of a population to be a sole factor [32]. The obesity epidemic has become most evident over the past 30–40 years; complex genetic adaptations do not happen that quickly. Third, it has been argued that any contributions that genes make to the obesity epidemic did not adapt in response to periods of famine since severe famines have actually been very rare and mortality due to starvation has been very low [32].

Several criticisms of the thrifty gene hypothesis from an ethical perspective have been made and are important and relevant to public health [33]. First, reliance on hypotheses like the thrifty gene hypothesis to explain ethnic disparities in disease assumes that ethnicity is a proxy measure for genetics, and as a result, ethnicity becomes an unmodifiable risk factor for obesity. Second, the thrifty gene hypothesis also perpetuates attributions to ethnicity that may be explained by other overlooked social factors, such as socioeconomic factors. Last, discussion of the thrifty gene hypothesis precludes any prevention efforts that may be culturally appropriate or beneficial to susceptible populations. It is reasonable to conclude then that the thrifty gene hypothesis is contentious and has the potential to further widen ethnic disparities in health.

Socioeconomic Position

In economically developed countries, childhood obesity is inversely associated with socioeconomic status, while in less economically developed countries, the burden of obesity has affected young people in urban areas and more affluent families [1,14]. Findings from the 1997 National Diet and Nutrition Survey (United Kingdom) demonstrated that young people from poorer social classes were significantly more likely to be obese than those from the wealthier social classes [12]. Likewise, studies of household income [34] and parental education [35] also show inverse relationships between socioeconomic indicators and child obesity. Research is now emerging to document the effects of neighborhood deprivation on child obesity [6,29,36,37]. These studies demonstrate that children living in poorer neighborhoods are significantly more likely to be overweight, even when controlling for individual measures of socioeconomic position and other demographic characteristics.

ENVIRONMENTAL DETERMINANTS OF CHILD OBESITY

Unhealthy weight gain is simply understood as the consequence of an energy imbalance where people consume more energy than they expend. What is less simple to explain are the underlying causes of this energy imbalance. That is, why is the greater population suddenly (within the past few decades) eating more and exercising less? Given the short time period over which population body weights have increased, particularly for children, great academic interest has been devoted to understanding the environmental factors underlying the behaviors promoting increased body weights. Specifically, the focus has highlighted the changes in the availability, affordability, and marketing of unhealthy foods (e.g., fast food, soft drinks, snack foods, and sweets) and increasing opportunities for sedentary activities.

At the core of the major changes to population eating behaviors is the shift to the modern food system. A food system is the entire set of components that link agriculture to human consumption, including food production, processing/packaging, distribution/transport, and consumption. The modern food system is characterized by large-scale, industrialized production methods that emphasize high yields and

low price, globalized distribution networks, high processing and packaging, minimal cooking, and excessive waste [38]. This is in comparison with traditional food systems, which emphasize small-scale, limited, and seasonal production, local distribution networks, and home cooking with limited waste [38].

Food systems exert an enormous influence over how and what populations eat. The modern food system encourages the consumption of highly processed, convenience foods as these foods have a long shelf life and are more profitable than fresh foods [39]. Furthermore, multinational food companies invest heavily in food marketing; a large body of evidence demonstrates that marketing routinely promotes unhealthy foods and is extremely effective in changing human behavior [40].

This transition to our modern food system is recent. While the industrialization of the food system globally has occurred throughout the twentieth century, the most dramatic changes have occurred over the past few decades. Between 1950 and 2000, the number of farms in the United States decreased by >60%, while the average size of farms increased by more than half [41]. The vertical integration of farming was accompanied by an emphasis on producing corn and soy resulting in a massive loss of diversity of crops [41]. Corn and soy became cheap ingredients for animal feed and processed foods, and their abundant supply created a global market for highly processed, convenience foods and mass-produced low-priced meat [42]. Advances in intensive agricultural methods, biotechnology, and national and international policies also facilitated this transition.

Evidence of the impact of the modern food supply on the American diet is notable. Between 1970 and 1990, the consumption of foods and ingredients most commercialized (snack foods, fats, and sugars) increased in the United States, while consumption of fresh foods decreased (eggs and dairy) [43]. Approximately one-third of the total food budget for married couples in the United States is spent on commercially prepared foods outside the home [44], and fewer than half of all main dishes served during the main meals are "fresh" or "homemade" [45]. The impact of the industrialization of the food supply on population body weights is evident through studies of the nutrition transition in developing countries [46] and the effects of migration or urbanization in Western countries [47–50]. These studies consistently demonstrate that as the food supply becomes Westernized, population diets change dramatically and risks of obesity increase markedly.

Within Western countries, however, research of the impact of the immense changes to the food supply on child eating behaviors and obesity has largely been focused on behavioral aspects of nutrition and physical activity. Soft drinks and snack foods have received substantial attention with regard to child obesity given their ubiquity in the diets of young people. Findings from analyses of the U.S. Nationwide Food Consumption Surveys between 1977 and 1996 reveal that the total amount of energy consumed as part of meals decreased, while the energy consumed as snacks increased by >70% [51]. Furthermore, the proportion of energy that children consumed as fast food, soft drinks, candies and desserts, and modern snacks increased during this time span, while the proportion of energy consumed as fruits and vegetables; meat, fish, or poultry; and milk products all remained constant or decreased [51].

Research examining the role of soft drink consumption on child overweight and obesity is convincing. Soft drinks are thought to have a unique contribution to child and adolescent obesity given their high energy content, low satiability, pervasiveness in the environments of children and young people, heavy investment in marketing to this age group, and low cost. A meta-analysis by Vartanian et al. [52] found that soft drink consumption among young people was associated with increased energy intakes, increased body weights, and increased risk of other poor health outcomes (e.g., diabetes).

Snacks contribute approximately 20%–25% of energy to the total diet [51,53,54]. Analyzing data of 10-year-old children from the Bogalusa Heart Study, Nicklas et al. [55] found that consuming snacks and consuming low-quality foods were both positively associated with overweight status. The research on snacking, snack foods, and child obesity is suggestive but inconclusive in the contribution of snack foods to weight gain [56]. Overall, it is likely that the state of the science on the relationship between food intakes and child obesity is limited by inconsistent and weak dietary measures, a rapidly changing food environment (especially in the highly processed food categories), and the relatively narrow line of scientific inquiry, which attempts to attribute significant weight gain to single foods.

Like energy intake, energy expenditure is a key component of weight control. With regard to energy expenditure and child and adolescent obesity, the key limitation in the research is a lack of valid measures of energy expenditure that are feasible for population-level studies and that have been consistently used for monitoring purposes over an extended period of time. Factors like reductions in active transport and reductions in overall physical activity patterns have been suggested as having an important contribution to child obesity, but the overall effect is likely to be small [1].

The environmental changes encouraging sedentary behaviors among children and young people, particularly television viewing, appear to play a far more convincing role in child obesity. American children, on average, consume 3 h of television each day [57]. Television use is thought to promote unhealthy weight gain in numerous ways, e.g., by displacing time spent being active, affecting metabolic rate, increasing snacking behaviors while viewing, or increasing exposure to advertising for unhealthy foods. It has been estimated that up to one in three cases of child obesity is attributable to the effects of television advertising [58]. Numerous studies have reported a positive relationship between television use and child obesity [59,60]. At least one intervention study has demonstrated that reducing television use among young, overweight children results in healthier body weights [61].

IMPLICATIONS FOR HEALTH AND OTHER OUTCOMES

Obesity during childhood results in a wide range of poor outcomes for children and young people, some of which have long-term consequences. Obesity during childhood affects a young person's psychological well-being, physical health, and has long-term social and economic implications for the wider community [1,62,63]. Health implications of unhealthy weight gain during childhood affect most systems of the body, with reasonable evidence suggesting child obesity adversely affects the cardiovascular, metabolic, pulmonary, gastrointestinal, skeletal, and hormonal systems [63].

The poor outcomes for young people resultant from unhealthy weight gain are compounded by the persistent nature of obesity. That is, young people who become overweight are much more likely to remain overweight into adulthood [62]. Several longitudinal studies have shown that overweight occurring as early as 6 years of age is predictive of overweight well into adulthood [64–68]. In a cohort study of American young people, >80% of those who were obese at 10–14 years were obese as adults [68]. Similarly, 83% of Canadian young people who were obese during childhood (7–18 years) remained obese as adults, 22 years later [67].

Cardiovascular Risk Factors

Reviews of the health impacts of obesity consistently conclude that child obesity negatively affects the cardiovascular system [1,62]. A large study of 5- to 17-year-old children found that overweight was associated with poorer indicators of higher total cholesterol, low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol, systolic blood pressure, and triglycerides, even among the younger children [69]. Additionally, there have been numerous studies that have suggested that childhood obesity predicts cardiovascular disorders later in life [70,71]. Findings from the Bogalusa Heart Study showed that overweight during adolescence persists into young adulthood and increases the risk of multiple cardiovascular risk factors [71]. Overweight adolescents were significantly more likely to have hypertension, high total serum cholesterol, high LDL serum cholesterol values, and low HDL serum cholesterol values at ages 27–31 years than their lean counterparts. It has been suggested, however, that child obesity does not independently predict adult cardiovascular events, rather it is dependent on the persistence of obesity into adulthood [72]. Given that such a high proportion of obese young people become obese adults, these distinctions may be less relevant for public health.

Type 2 Diabetes

Until recently, onset of type 2 diabetes among children and adolescents was extremely rare but has become more common in the wake of the obesity epidemic. Complications of type 2 diabetes include accelerated development of cardiovascular disease, renal disease, vision impairment, circulatory problems, and premature death [73,74]. Limited data that document trends in the incidence and prevalence of type 2 diabetes among children and adolescents suggest this is a rapidly growing problem affecting countries worldwide. For example, one study of a regional pediatric diabetes referral centre in Ohio found that the incidence of type 2 diabetes increased 10-fold between 1982 and 1994 [75]. A similar study in Arkansas also found a dramatic increase in the number of new cases of type 2 diabetes among youth between 1988 and 1995 [76]. This study also showed that youth with type 2 diabetes were significantly more likely to be overweight/obese compared with those with type 1 diabetes. Annual studies of hundreds of thousands Japanese school children have also documented increases in the incidence of type 2 diabetes that mirror the prevalence of obesity [77]. In 1975, there were between one and two new cases of type 2 diabetes per 100,000 per year, increasing to more than seven new cases per 100,000 per year in 1995. During this time span, the prevalence of obesity among the population also increased from <5% to >8%.

Sleep Apnea and Asthma

Sleep-disordered breathing is a well-accepted, but underacknowledged, complication of obesity in both children and adults. Several studies have documented that children and young people who are obese are at increased risk for sleep-disordered breathing and snoring [78–80]. The relationship between child obesity and asthma has also been documented [81–84], but the underlying mechanisms are less clear. This is an important point as much of the research on the relationship between obesity and asthma is based on cross-sectional research and it may be that children with asthma may do less physical activity or take medication that may affect weight gain. That said, at least one longitudinal study has found that the incidence of newly diagnosed asthma among school-aged children was significantly higher in those who were overweight compared with those who were not [83] indicating that the overweight precedes the onset of asthma.

Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) is a largely asymptomatic condition in which fat is deposited into the liver, which is not attributable to alcohol use. NAFLD is one of the most common liver conditions affecting children [85] and is considerable more problematic among obese young people. It has been estimated that NAFLD affects approximately 10% of children and adolescents; among obese young people, up to 80% are affected [86]. The most effective therapeutic strategies for NAFLD are lifestyle modification, similar to what is indicated for weight loss. Exercise and dietary changes, which result in weight loss can result in significant improvements in the progress of NAFLD [1,86].

Life Expectancy

The increasing prevalence of obesity and its health-related complications pose a serious threat to life expectancy. It has been projected that obesity could stop or decrease the mean life expectancy in the United States that has been on a slow, steady increase for a thousand years [87]. In a cohort of American Indian children without diabetes, rates of death (from endogenous causes) among the heaviest children were more than double that of the leanest children over time [74]. This has serious implications for the current generation of children and adolescents as they may, on an average, live shorter lives than their parents. Among adults, the risk of death from all causes increases with BMI throughout the overweight classifications [88], but this area of research is the topic of ongoing debate. A systematic review of cohort studies found better health outcomes among adults in the overweight and mildly obese groups [89], though the authors suggest that this was likely due to the limitations of the BMI as a specific measure of adiposity rather than a reduced risk attributable to adiposity. Another study of a nationally representative sample of adults in the United States found that the association between BMI and mortality varies by cause of death [90]. For example, being overweight was associated with a decreased risk from all-cause mortality, but an increased risk of death from diabetes and kidney disease combined.

Psychosocial Issues

Obesity during childhood and adolescence can result in numerous psychological and social issues that present an immediate and ongoing concern for young people. Depression is common among adolescents and can persist into adulthood. Given that adolescence is a critical period for the development of both depression and obesity, research has been unclear as to whether depression is a risk factor for later depression or vice versa. A recent meta-analyses of 16 studies found that depression during adolescence was a significant predictor of adult obesity, particularly among females [91]. Conversely, a longitudinal study of adolescents found that obesity was predictive of depressive symptoms (but not clinical depression) in the following year [92]. Thus, identifying the direction of the relationship between depression and obesity is difficult, but available evidence suggests that adolescent obesity is a risk factor for depressive symptoms among young people.

Children and young people who are overweight experience numerous difficulties with peer relationships and social stigmatization. As early as the 1960s, research revealed that young children viewed overweight body shapes negatively (e.g., lazy, naughty, mean, and dirty) [93]. A nationally representative survey of Canadian young people found that overweight young people were more likely to be the victims of bullying, teasing, and violent behaviors than their healthy weight peers [94]. Furthermore, overweight young people who experience weight-based teasing and bullying are at greater risk for disordered eating behaviors, depressive symptoms, anxiety, and low self-esteem than those who are not teased [95].

Recently, several population-based studies have documented that overweight young people are significantly more likely to engage in weight-control behaviors, especially unhealthy weight-control behaviors, than healthy weight or underweight young people [96–98]. Weight-control behaviors are pervasive among adolescents and include a wide spectrum of behaviors from eating more fruits and vegetables to purging or starvation [99,100]. Adolescent dieting results in psychological, physical, and nutritional disturbances with limited sustained benefits to body weight. Adolescents who employ extreme dieting behaviors have high levels of depression and anxiety [101] and are more likely to develop suicidal behavior into young adulthood [102]. Likewise, adolescents adopting unhealthy weight-control behaviors have poorer nutrient intakes [103] and poorer eating behaviors [104]. Adolescents who diet are more likely to develop binge eating behaviors [105] and gain more weight [106] over time. Approximately 20%–25% of unhealthy dieters develop partial or full syndrome eating disorders [107].

Health-related quality of life is a multidimensional concept, which captures a person's subjective view of their physical, emotional, and social well-being. Children and young people who are obese report markedly lower ratings for all dimensions of quality of life [108–111]; one study found that obese children reported the same level of quality of life to children with cancer [109]. The dimensions of life that appear to be most affected by obesity are physical competencies, appearances, and social functioning [108]. The long-term impact of obesity during childhood on health-related quality of life is largely unknown, yet emerging studies suggest that treatment of obesity results in better quality of life for young people. A 4 week weight loss program for adolescents demonstrated that weight loss is associated with improvements to quality of life [112]. Moreover, a study of the effectiveness of laparoscopic adjustable gastric banding of severely obese young people resulted in significant weight loss as well as significant improvements on indicators of quality of life [113].

Economic Costs of Child Obesity

The most recent estimates suggest that the medical costs of obesity in the United States are close to $150 billion [114]. Direct costs of adult obesity account for 2%–7% of total health care costs in developed countries [115]. Identifying the economic burden of child and adolescent obesity alone is difficult to do given the few medical treatments provided for child obesity, the inconsistent recording of body weights during clinical assessment, and the undiagnosed related disorders [1]. Between 1979 and 1999, hospital discharge records documented drastic increases in obesity-related diseases among children adolescents [116]. Available research has confirmed that obese children and young people have higher health care costs than normal-weight young people, including greater expenditures on prescription drugs and emergency room visits [117].

Indirect costs of obesity—those related to reductions in economic opportunity—are also difficult to quantify for children and young people because the contribution that children and young people make to an economy is variable. It has been suggested that child obesity may have high indirect costs through time off of school for illness or costs to schools and the education system for special resources [1,63]. Indirect costs of child obesity may also be quantified through parental time off work to care for a sick child or costs of premature death due to early onset obesity.

Child obesity may also result in high intangible costs which, again, are difficult to quantify. As mentioned earlier, losses in quality of life and psychosocial stresses may result in an economic burden resultant from childhood obesity. Furthermore, several studies have demonstrated that obesity during adolescence is also associated with less educational achievement [118–120] and lower earning potential as adults [119,120].

CONCLUSIONS

Given the poor outcomes for children and young people who are overweight, the persistent nature of childhood obesity and the costs of the burden to the wider population, strategies to prevent or treat obesity early on are warranted. Though there has been some suggestion that the prevalence of child obesity may be stabilizing, it would be prudent to ensure disparities in obesity-related behaviors and health disorders were not worsening. Targeting the excessive consumption of highly processed and unhealthy foods, promoting physical activity, and reducing the excessive use of sedentary behaviors (e.g., television) appear to be the most relevant behaviors for maintaining healthy body weights. Early treatment of obesity could have wide-ranging and long-term benefits as many of the adverse effects of childhood obesity could be ameliorated if the obesity were resolved prior to adolescence [110]. Child and adolescent obesity is one of the most urgent and important health issues facing the current generation of young people and, if unabated, will continue to bear a great cost to the health and well-being of young people, their families, and the wider community.

INTRODUCTION

Diabetes has emerged as one of the most important global health threats due to its increasing prevalence and the excess disease and economic burden that its comorbid complications carry with it. The current type 2 diabetes problem is a prototypical chronic disease epidemic in that its rise appears to be linked to cultural change, and its public health response will have to be multifactorial. New surveillance reports indicate that at least 11% of American adults (or 25.6 million) now have diabetes and prevalence approaches 20% among minority ethnic groups [1–2]. The rate of new cases continues to increase substantially (Figure 107.1). This, when combined with continued decreases in mortality rates [4], has led to projections that the proportion of adult Americans with diabetes will exceed 20% of the adult population by the year 2030 [5]. The implications of this increased diabetes on morbidity of the population is extensive due to the well-documented risks of coronary heart disease, stroke, vision loss, amputation, end-stage renal disease, and mortality, as well as nontraditional outcomes ranging from dementia to certain cancers [6,7]. Although type 2 diabetes appears to develop through multiple physiological mechanisms and numerous risk factors, increases in obesity, aging, and detection are the predominant factors in the ongoing increases in type 2 diabetes incidence observed both in the United States and worldwide [5,8]. Fortunately, strong evidence exists for the role of lifestyle interventions, when applied to high-risk adults, to reduce type 2 diabetes incidence by 50% or more [9–11]. In this chapter, we review the primary modifiable risk factors for type 2 diabetes, the factors explaining the current trends in the disease, and the health system and policy-based interventions most likely to impact trajectories in the current epidemic.

DIABETES DEFINITIONS, ETIOLOGY, AND BURDEN

Diabetes is a metabolic condition characterized by high levels of blood glucose due to impaired insulin production or action, or both [12]. More than 90% of diabetes cases are type 2, which is typically preceded by insulin resistance, wherein the body's cells don't use insulin properly. Although type 2 diabetes has received the most attention for its increasing incidence, type 1 diabetes, characterized by a virtual lack of insulin production, and gestational diabetes (GDM), defined as glucose intolerance only occurring during pregnancy, have both increased in frequency in the United States and many regions of the world [13,14]. Diabetes is diagnosed when one has an elevated fasting plasma glucose (FPG; ≥126 mg/dL), a postchallenge or random blood glucose >200 mg/dL, or an elevated hemoglobin A1c (≥6.5%) on two separate occasions. Prediabetes, a condition referring to elevated glucose levels below the diabetic threshold, associated with subsequent diabetes and macrovascular morbidity, is defined as FPG 100–125 or an A1c of 5.7%–6.4% or a 2 h plasma glucose in a 75 g oral glucose tolerance test (OGTT) 140–199 mg/dL.

The pathogenesis of type 2 diabetes is complex, involving at least 20 genes, diverse pathophysiological processes, and multiple environmental exposures [15,16]. However, for the vast majority of cases of type 2 diabetes, excess adiposity plays a central role, leading to excess nonesterified fatty acids, release of proinflammatory cytokines, which affects insulin action on cells, and ultimately affecting beta cell function. Excess glucose ultimately results from a failure of insulin secretion to adequately compensate for declining insulin sensitivity [15,16].

Consistent with its role in the pathogenesis of type 2 diabetes, obesity is the strongest modifiable risk factor for type 2 diabetes. Each standard deviation of body mass

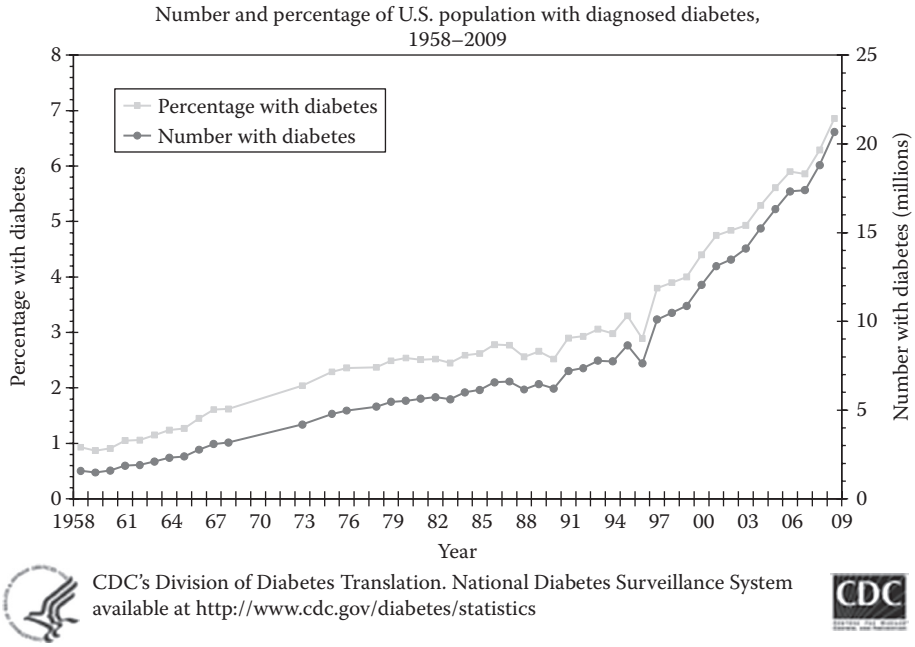

FIGURE 107.1 Number and percentage of U.S. population with diagnosed diabetes, 1958–2009.

index (BMI) (about 3–5 kg/m^2 in most populations) or waist circumference (about 10 cm) is associated with an approximate 80%–90% increased risk of type 2 diabetes [17,18]. In the United States, diagnosed diabetes incidence ranges from about 0.2% per year among normal weight adults to about 0.5% (2.2 times as high) among overweight adults to about 1.7% per year among obese adults (i.e., eight times as high) [4]. Increasing age also carries a large magnitude of diabetes incidence, since incidence increases from 0.3% per year among adults aged 18–44 years to 1.1% (i.e., three times as high) per year among those aged 45–64 years, to 1.3% (i.e., four times as high) among those aged 65 years [4]. As a result, compared with young adults, the prevalence is about three times as high among middle-aged adults (13.7%) and seven times as high among older adults.

After obesity and age, physical inactivity, poor diet, hypertension, and non-white race/ethnicity are the next set of common risk factors that carry a high magnitude of risk. Increasing physical activity levels [19] has been consistently associated with a reduced incidence of type 2 diabetes. Although part of this relationship is explained by obesity, moderate intensity physical activity is associated with reduced risk even after adjusting for BMI [19]. The relationship appears to follow a dose-response relationship with energy expenditure and total duration of physical activity. People who engage in more vigorous physical activity appear to have a particularly reduced incidence, but whether that reduction in risk is truly independent of energy expenditure has not been confirmed. In other words, people who engage in more vigorous physical activity may have a greater reduction in risk because they also spend more time in physical activity.

Having a family history, known hypertension, low birth weight, being a smoker [20], having depressive symptoms [21], dysfunctional sleep [22], and exposure to environmental pollutants have each been associated with elevated type 2 diabetes risk [23], while coffee intake and moderate alcohol consumption have each been associated with decreased risk [24]. However, there have not been intervention studies to determine whether acting upon any of these risk factors with specific interventions is effective or practical. Modification of smoking risk, for example, may actually lead to some weight gain and thus counteract the benefit of removing smoking as a diabetes risk factor [20]. Similarly, there is no evidence that treating hypertension, depressive symptoms, or poor sleep influences disease risk although each is plausible.

Several nutritional factors may influence insulin resistance or type 2 diabetes risk above and beyond their effects on obesity [25]. Some of the most consistent findings exist for whole grains and cereal fibers, as consuming at least 8.8 g/day (the highest quintile) has been associated with a 37% lower diabetes risk than those who consume fewer than 3.8 gm/day (i.e., the lowest quintile) adjusting for other nutritional and body composition factors [26,27]. The quality of fats in the diet also appears important; consumption of polyunsaturated and monounsaturated fats may reduce risk, whereas saturated fats and total intake have been associated with increased risk [25].

Consumption of sugar-sweetened beverages (SSBs), including soft drinks, sweetened carbonated beverages, and fruit drinks, have more than doubled in the U.S. population over the past two decades and have been implicated as important risk factors for obesity, insulin resistance, and type 2 diabetes [28,29]. Several mechanisms have been proposed for linking SSBs and type 2 diabetes, including inadequate satiation of SSBs leading to greater compensatory and overall caloric consumption, along with hypotheses that SSBs have direct effects on insulin resistance through their glycemic properties. Longitudinal evidence is, however, spotty.

Data from the Nurses' Health Study found that women reporting more than seven servings per week of SSB had an 80% greater diabetes risk than those reporting <1 serving/week [30]. However, other cohort studies found only modest or nonexistent associations with diabetes risk. There is also insufficient evidence from randomized control trials that replacing SSBs or supporting policies of SSB reduction will result in appreciable reductions in type 2 diabetes incidence [28,29].

Type 2 diabetes is strongly associated with family history and genetics. Numerous common genetic markers have been identified, many of which have significant but modest associations with type 2 diabetes incidence [31]. In a study of 18 single-nucleotide polymorphisms among adults in the Framingham Heart Study, a genotype score was developed and shown to be highly predictive of subsequent diabetes, such that persons within the top decile of a continuous genotype score had about two and half times the incidence of adults in the bottom quarter of the genotype score. However, the ability of the genotype score to discriminate between cases and non-cases was only slightly more predictive than a conventional risk score composed of self-reported risk factors along with glucose and triglyceride levels. Genotype-based scores may still become an important part of risk prediction in the future, but this is likely to depend upon a better understanding of how genes interact with lifestyle and environmental factors.

Estimation of county-level diabetes prevalence indicates that diabetes in the United States appears to cluster within specific regions and belts (Figure 107.2). Counties with a high diabetes prevalence (defined by diagnosed diabetes prevalence >10.6%) were clustered in a belt extending from the Mississippi river valley in the South to the coastal Carolinas and the Appalachian Mountain region. Almost three-fourths of counties in Alabama, Georgia, Louisiana, Mississippi, and South Carolina had high diabetes prevalence, while almost two-thirds of counties in West Virginia and Tennessee had high prevalence. In addition, counties in the Western and Plains states with large populations of Native Americans also have high prevalence. This clustering of counties with high diabetes prevalence is largely a function of the classic factors described earlier. However, high levels of poverty both at the individual and community level appear to play a particularly important role in increasing the amount of clustering of diabetes risk [32,33].

In addition to the multitude of risk factors for type 2 diabetes described earlier. Presence of elevated FPG (100–125 mg/dL), impaired glucose tolerance (IGT) or A1c are associated with yearly diabetes incidence of 2.5%–3%, compared with about 1% per year in the overall population and <0.5% per year in people with normal glucose tolerance [34]. As will be described in more detail in the subsequent sections ("Translation of Intervention Evidence" section), measures of glycemia and GDM are increasingly recommended as efficient ways to risk stratify the population for intervention referral.

EXPLAINING RECENT TRENDS IN DIABETES

Despite the large number of risk factors explaining variation in type 2 diabetes risk for individuals, the principal factors underlying increases in type 2 diabetes in the population as a whole are not necessarily the same factors that explain risk in individuals. For example, exposure to several of the risk factors for type 2 diabetes, such as smoking levels, saturated fat intake, or organic pollutants, are unlikely to explain the recent increases in incidence in the population because exposure to those factors have been declining steadily for several

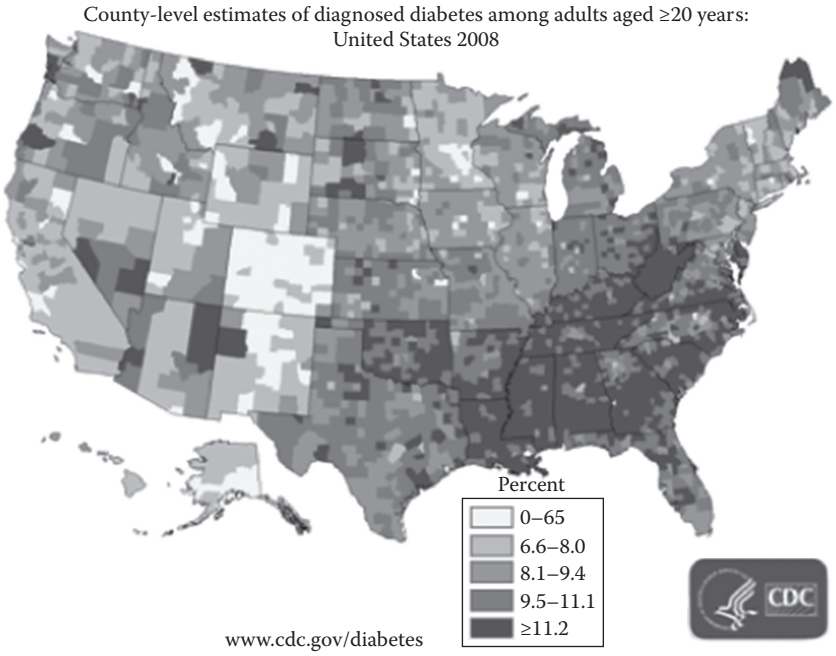

FIGURE 107.2 County-level estimates of diagnosed diabetes among adults aged ≥20 years: United States 2008.

decades. Even the contribution of physical activity levels to the changes in type 2 diabetes prevalence is unclear. However, it appears that the increase in obesity occurring in virtually all segments of the population has explained the majority of prevalent and incident cases. When diabetes prevalent cases are partitioned into BMI categories, it is apparent that 25% of new cases relative to the previous decade came from the overweight segment of the population, 75% came from the obese population, and none of the increase came from the lean population [35]. This is consistent with a similar analysis showing that, within BMI strata, there has been no increase in diabetes risk; instead, there are simply many more people with moderate and severe obesity [36].

Several secular trends and cultural factors have been proposed as possible explanations for the change in obesity of the population, including increased portion sizes [37–39], refined carbohydrates and corn syrups, and increased SSBs. Sleep duration has decreased, and treatment for depression using s*elective serotonin reuptake inhibitors* have increased dramatically, but whether and how much these have affected obesity or diabetes trends is not known.

In addition to the behavioral and social factors affecting diabetes incidence rates through their impact on obesity, the increases in diabetes prevalence in the adult population may have also been fueled by increases in the detection rate of undiagnosed diabetes, declining mortality of the diabetic and nondiabetic populations, and possibly increases in the immigration patterns, increasing the proportion of higher-risk ethnic groups in the United States [40].

EVIDENCE FOR PREVENTION

The observational evidence associating lifestyle factors with type 2 diabetes risk led to a series of large randomized controlled trials beginning in the late 1990s [9,41]. To ensure adequate number of events (i.e., incident diabetes cases) in these trials, virtually all were conducted among high-risk populations, defined as presence of IGT and/or elevated FPG. To maximize intervention effectiveness, most studies tested multifactorial interventions, combining reduced caloric intake, increased physical activity, increased fiber and whole grain intake, etc. [9–11,41].

The first randomized trial of lifestyle intervention screened the entire adult population of Da Qing, an oil city in Northeastern China, to find adults with IGT [42]. Thirty-three clinics were then randomized to four conditions: control, diet, exercise, and diet plus exercise. The dietary intervention involved counseling to reduce fat, simple sugars, and alcohol intake, while the exercise condition involved counseling to increase moderate and vigorous leisure-time exercise and sports activities. The study found significant 31%, 46%, and 42% reductions in type 2 diabetes incidence in the diet, exercise, and diet plus exercise conditions, respectively. The study was also notable, however, in that it was conducted among a fairly young population and, more importantly, had its effects with essentially no weight loss achieved over 6 years by the intervention conditions [42].

Four and five years later, findings from the Finnish Diabetes Prevention Study (DPS) and the U.S. Diabetes Prevention Program (DPP) were published [10,11]. Each study randomized adults with IGT to intensive group and individual-based lifestyle interventions, defined by reduced total and saturated fat intake and increased leisure-time physical activity and behavioral support. The Finnish study was also notable in that it employed a high fiber diet. Both studies achieved 58% reductions in diabetes incidence. The benefits of lifestyle interventions were observed across diverse age, sex, and race-ethnic groups. Follow-up studies reported by both studies [43,44] highlighted the importance of modest weight loss (7 and 4.2 kg at year 1 in the DPP and DPS, respectively) as a central factor along with the importance of the multifaceted aspects of the interventions. In the DPS, for example, the number of goals achieved was strongly inversely associated with the incidence of diabetes, such that incidence was about 8% per year for those meeting zero goals, about 5% per year for those meeting two goals, and about 2% per year for those meeting four or more goals [45,46].

In subsequent years, similar studies were published from Japan [47], India [48], Iran, and Italy [49,50]. These studies further expanded the geographic scope of evidence of these trials, indicating that structured, lifestyle interventions can be effective in diverse settings and populations. Formal quantitative meta-analyses have estimated that lifestyle interventions result in a 49% reduced incidence of diabetes, a magnitude of risk reduction that is significantly stronger than the effect observed with pharmacologic interventions [9,41]. Further, of all the putative benefits of a healthy lifestyle, the magnitude of effect from these studies is arguably the strongest effect of lifestyle interventions observed for any chronic condition. Common characteristics of these interventions included an intensive, multi-visit educational curriculum covering 6–12 months and an extended period of counseling support for 2 years of more. Perhaps, most importantly, the successful programs employed a comprehensive set of behavioral strategies, including staging of information over multiple sessions, tailoring of lifestyle change to the individual, observational learning for dietary change, and self-monitoring of key behaviors and goals.

Three of the lifestyle intervention trials have examined the extended impact, or the "legacy effect," of lifestyle interventions several years beyond the completion of the primary intervention [43,44,51]. The Finnish DPS found that 4 years following the completion of the trial (7 years from baseline), adults randomized to the intervention condition still had a significant 43% reduction in diabetes incidence [43]. The Da Qing DPS found that 14 years following the intervention (20 years after baseline), intervention was still associated with a 43% reduction [51]. Most recently, the DPP reported a 24% reduced incidence 8 years following the completion of the trial (10 years after baseline). Only one of these trials has reported effects on long-term complications of diabetes. Gong et al. reported a significant reduction in incidence of severe retinopathy associated

with the intervention, a nonsignificant reduction in cardiovascular disease (CVD) mortality but no association with CVD incidence [52].

At the same time, the limitations of these studies limit the implications and raise other questions. First, all studies were limited to the selected adult population with IGT and, in some cases, people with impaired fasting glucose and IGT. Thus, it is unknown whether structured lifestyle interventions also reduce incidence of prediabetes or progression in people below the prediabetes threshold, leading to debate about who should be identified for interventions. Second, the degree to which implementation of the isolated subcomponents of the diabetes interventions can also be expected to affect risk is not known. Although post hoc analyses indicated that meeting individual goals reduces risk, it should not be interpreted as an indication that implementation of single component interventions will be similarly effective. This has led to debate about whether dietary or exercise interventions in the absence of multidisciplinary behavioral support are likely to be effective uses of resources. One randomized controlled trial of high-risk adults randomized to Mediterranean diets had 52% reductions in diabetes incidence. These data, combined with findings from the Da Qing Prevention Study, suggest that dietary interventions can be effective without an aggressive weight loss component [53].

The evidence for type 2 diabetes prevention has led to considerable debate about how best to identify people for public health interventions. Although most of the prevention trials used OGTTs to identify people with IGT, many consider OGTTs to be impractical and IGT unnecessarily exclusive for practical real-world interventions. Fasting blood glucose and A1c are commonly accepted alternatives as are multicomponent risk scores that use demographic, behavioral, health status, and glycemic data to separate screened populations into those at low and high risk of subsequent diabetes. Others have begun to explore multicomponent assays that incorporate several metabolic markers, including inflammatory factors, insulin, and glucose into prediction scores.

TRANSLATION OF INTERVENTION EVIDENCE: A PYRAMID FOR PREVENTION OF DIABETES AND ITS COMPLICATIONS

Changing the course of the diabetes epidemic will ultimately require a multi-tiered strategy in which evidence-based interventions are tailored to the level of risk and morbidity (Figure 107.3). The principal objective among the 19 million adults who already have diagnosed diabetes is to reduce the incidence of diabetes complications and related morbidity by improving diabetes management and achieving optimal levels of glycemic, blood pressure, and lipid control and performing regular screening for early foot, kidney, and eye disease. The second tier involves efficient early identification of adults with undiagnosed diabetes so that the evidence-based therapies can be initiated to reduce the incidence of complications.

The remainder of the prevention pyramid (Figure 107.3) involves several tiers designed to reduce the incidence of type 2 diabetes. The first step involves efficiently identifying adults who are at high risk for the development of type 2 diabetes. While population-wide haphazard screening is not recommended, diagnostic testing of adults with risk factors (family history, overweight or obese, age >45 years, hypertension, non-white race/ethnicity, or history of GDM) is recommended to identify people with prediabetes or undiagnosed diabetes. Those with prediabetes or a history of GDM (primary prevention tiers 1 and 2) should ideally be referred to community-based structured prevention programs to reduce their risk.

The Centers for Disease Control and Prevention has recently developed a recognition program to promote and certify evidence-based prevention programs for community settings. As a prototype for such an approach, it has

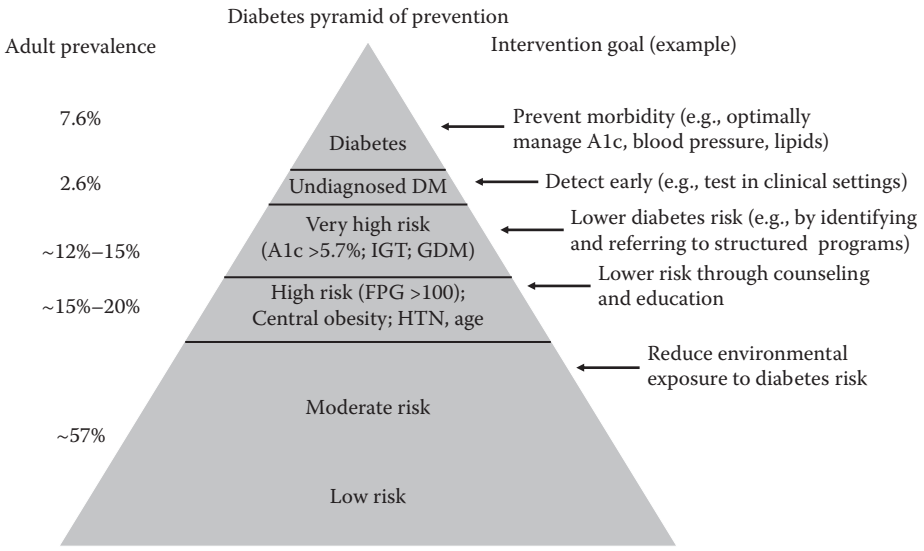

FIGURE 107.3 Diabetes pyramid of prevention.

also partnered with the national Y (formerly YMCAs) and United Health Care to provide reimbursement and a centrally recognized training and recognition program of prevention programs. The *National Diabetes Prevention Program* is based on observations that structured lifestyle programs in community settings such as Ys YMCAs and churches have achieved 1 year weight loss ranging from 2% to 7% among adults at high risk for diabetes [54–56], levels of weight loss that have been consistently associated with reduced diabetes incidence. Since access to effective community programs for diabetes is lacking in many parts of the United States and reimbursement remains spotty, it is important for primary care settings to enhance efforts at awareness, counseling, and referral to program with trained staff to stimulate and support changes in lifestyle to achieve a healthier diet, weight, and pattern of regular physical activity.

Since the majority of the population and roughly half of eventual diabetes cases over a 10 year period will come from the population without established prediabetes or GDM, additional population-wide strategies will be necessary to change incidence trends. At least three general targets of population-wide policy targets exist: the food environment, the physical environment, and the social environment. Plausible interventions for the food environment include food and menu labeling, crop subsidy and pricing strategies to encourage whole grain content of foods and healthy portion sizes and discourage refined carbohydrates, sugared sodas, and saturated fats. Incentives for communities to support diverse healthy foods and farmers markets have also been proposed. Policies recommended to improve the food environment included increasing availability and affordability of healthy foods in public areas, improving geographic availability and giving incentives for supermarkets and healthy foods in underserved and poor areas, instituting smaller portion sizes in public settings, limiting advertisements of unhealthy foods and beverages, and discouraging consumption of sugared beverages. Changes to the food environment may ultimately require direct engagement with private industry to change the content of available foods in grocery stores. Recommended strategies to improve the physical activity environment include requiring school physical education and increasing the amount of physical activity in school physical education, increasing opportunities for extracurricular physical activity and access to recreational facilities, reducing screen time in public settings, improving access to public transportation, promoting access to mixed use development, and enhancing personal and traffic safety in public areas [57].

Unfortunately, rigorous research that would support the prioritization of the multitude of policy-level interventions that have been proposed is lacking. Although numerous innovative policies are regularly developed by health systems, communities, business organizations, and legislatures, rigorous empirical examinations of such initiatives are scarce. As a result, there are few clear evidence-based policies for preventing or controlling the progression of diabetes that can be targeted at large segments of the population [58–61]. This has led to calls for new research platforms, including natural experiments and comparative effectiveness research for health services interventions to improve the science base for health system and policy-level interventions. Ultimately, changing the course of the current diabetes trends will require improvements in both the evidence base as well as the delivery of established interventions across individual, health system, and societal levels.

The findings and conclusions in this report are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention.

INTRODUCTION

The purpose of this chapter is to synthesize the existing literature on physical activity as it applies to older adults. In the process of doing this, there are several concepts that need to be explored. First of all, the term "older" adult will be discussed and the question of how to apply a standard definition when the field and the participants are so diverse. Next, the concept of health as applied to aging will be discussed, and the focus will be on measurements issues. Paramount among these ideas will be the concept of length of life versus quality of life and the important role of physical activity at every stage. To explore this, the type and form of physical activity that can accommodate aging-related physical changes and comorbidities will be shown for the most common chronic conditions. Surveillance data will be used to identify declines in physical activity typically associated with aging, and when available, for adults with particular chronic conditions. The final section includes a discussion of the barriers to being physically active that are most relevant for older adults along with specific suggestions for dealing with these barriers and increasing physical activity.

WHO IS AN OLDER ADULT?

One of the challenges in working with the aging population is how to characterize these adults. While "years of age" is an easy marker, the differences that exist among individuals as they age preclude using chronological age as an optimal method to classify older adults. A more practical way would be to classify adults according to functional markers, which is possible to do for an individual but difficult to do on a population level. While age has many dimensions, surveillance

reports, such as those documenting physical activity, are limited to categorizing individuals by chronological ages or by presence of chronic conditions. The usual classification defines an older adult as age 65 years and older, although the exact cut point can vary.

The growth in the number and proportion of older adults is unprecedented in the history of the United States. Two factors—longer life spans and aging baby boomers—will combine to double the population of Americans aged 65 years and older during the next 25 years. Estimates suggest that by 2030, there will be 71 million American older adults (larger than the current combined population of the entire states of California, Texas, and New Jersey), and these older adults will comprise about 20% of the U.S. population [1]. Recognizing these trends, several public health initiatives (such as those designed to increase physical activity) are focused on keeping older adults healthy and active.

CONCEPT OF HEALTH AS APPLIED TO AGING

The diversity of older adults leads to another important issue: health. There are several ways to conceptualize health including absence of disease, absence of activity limitations, or physical and mental well-being, with each concept providing important information on some aspect of health. Whatever way health is conceptualized, measuring this construct is the challenge. For older adults, the assessment tool should take into account aging-related declines that may not be diseases but may contribute to a poor quality of life. Examples of contributors to poor health that are common among older adults are joint pain, visual problems, and hearing problems. Over one half of adults over age 65 years reported joint pain in 2009 [2]. In addition, 13% of U.S. adults over age 65 years reported visual problems and 7% reported having hearing problems or being deaf [2].

Because of this, assessing health status involves more than just documenting the presence of particular diseases but should include quality of life issues as well. Among the tools that have been used to measure overall health status is a survey item that asks adults to rate their health on a 5-point scale ranging from poor to excellent. This question can also be asked as "rate your overall health status for your age" or "rate your overall health status compared to others your age." The question without mention of age or comparison with others has been shown in numerous countries and populations to have an association with mortality such that those who rate their health as fair or poor have a higher mortality rate than those who rate their health as good, very good, or excellent [3,4]. Unfortunately, data from the United States in 2009 found that 24% of adults aged 65 years and older rated their health as fair or poor [2]. Among adults of any age, those who report a disability (defined as being limited in any activities because of a physical, mental, or emotional problem or a health problem that requires use of special equipment such as a cane, a wheelchair, a special bed, or a special telephone) are more likely to report fair or poor health than those without such a disability [1]. Adults aged 65 years and older reported an average of 5.5 physically unhealthy days in the past month according to 2004 Behavioral Risk Factor Surveillance System (BRFSS) data [1].

Quantity versus Quality of Life

Life expectancy in the United States has increased from 47 years for Americans born in 1900 to 78 years for those born in 2007. For adults who were already aged 65 years in 2007, the additional life expectancy was 19 years and for those already aged 75 years in 2007, the additional life expectancy was 12 years [2]. While all adults would like to extend their life spans, the goal should be not to live longer but to live healthier. This is where physical activity can be an important component of aging. It is known that several diseases develop or become worse due to physical inactivity. While these diseases (an example is arthritis) may not directly cause mortality, they play a huge role in quality of life. Data from 2008 to 2009 found that among community-living adults aged 80 years and older, 15% of women and 10% of men needed health with personal care activities (eating, bathing, dressing, getting in or out of bed or chairs, using the toilet, or getting around inside the home). The most common need for personal care activities was with bathing or showering or dressing [5].

Disability

One of the best measures of quality of life is the ability to live independently and perform necessary activities of daily living. However, over time, many adults develop functional problems that limit their ability to live independently. Because this process occurs in stages, it is useful to use a standard nomenclature to assess disability [6]. One system commonly used is the Nagi [7] classification of disability, which describes four stages beginning with pathology and ending with disability. These stages are shown in Table 108.1 using knee osteoarthritis as an example. While every person may incur some degree of impairment

TABLE 108.1
Stages of Disability and Example of Each Using Knee Osteoarthritis

Label	Description	Consequence
Pathology	Underlying changes have occurred with or without clinical symptoms	Joint changes in knee
Impairment	Dysfunction in specific body systems	Pain when bending knee
Functional limitation	Restrictions in physical/mental function	Unable to walk long distances
Disability	Unable to conduct activities of daily living without assistance	Unable to walk; may not be able to continue working

or functional limitation over time, the goal is to keep complications at a minimum to prevent or delay disability. Physical activity can play a major role in preventing disability, but among adults aged 65 years and older, only 26% are physically active compared with 42% of adults without disabilities [1].

CHRONIC DISEASES AND PHYSICAL ACTIVITY

Lifelong physical activity is important in maintaining functional health and independence. However, over time, the type and form of physical activity may change to accommodate related physical changes and comorbidities as well as age-related changes. About 80% of older Americans (aged 65 years and older) are living with at least one chronic condition [1], meaning that the type and intensity of physical activity must be modified to reflect presence of these conditions. The leading cause of death among adults aged 65 years and older is heart disease, followed by cancer, and stroke, while the most common chronic conditions are high blood pressure, affecting just over half of older adults, followed by arthritis, affecting about half of older adults. At lower prevalence, the rest of the top six chronic conditions include coronary heart disease and stroke, cancer, diabetes, metabolic syndrome, osteoporosis, and depression. Some of these conditions for which physical activity has been shown to be beneficial are described in this section.

High Blood Pressure

Also known as the silent killer, elevated levels of blood pressure are usually asymptomatic while causing major damage to many organs. High blood pressure is a major risk factor for stroke as well as coronary heart disease [8]. Data from 2005 to 2008 identified 70% of adults aged 65 years or older with elevated blood pressure. Although there is treatment to lower blood pressure, only 79% of those with elevated blood pressure were being treated. However, 46% of those with treated elevated blood pressure did not have it under control. In addition to medication, increasing physical activity is often recommended as a way to control blood pressure.

Arthritis

Although the term arthritis includes over 100 separate diagnoses characterized by joint degeneration, over 95% of all arthritis is osteoarthritis. Based on U.S. data from 2007 to 2009, about 50% of adults aged 65 years and older have arthritis and almost half of them (46%) have some arthritis-attributable activity limitation. Because there is evidence that sports injuries eventually lead to the development of arthritis at the site of the injury, many individuals assume that physical activity is not recommended. Just the opposite is true. Participation in physical activity keeps joints moving and flexible, bringing much needed blood circulation to the affected joint(s).

Coronary Heart Disease

Most of the early work on physical activity began with its role in preventing the leading cause of mortality, heart disease. Although the mortality rates have consistently decreased since the 1980s, coronary heart disease is still the leading cause of death among adults over age 65 years and continues to be a problem for older adults. The lifetime prevalence of coronary heart disease in 2009 for men was 31.2% among those aged 65–74 years and increased to 45.8% among those aged 75 years and older compared with 14.5% for those aged 54–64 years. The lifetime prevalence of coronary heart disease in 2009 for women was 21.1% for those aged 65–74 years, 30.7% for those aged 75 years and older, compared with 11.7% for those aged 45–64 [2]. Even at older ages and after the disease has developed, participation in physical activity reduces the risk of additional complications.

Cancer

Although there are many types of cancer, each with its own set of risk factors, physical activity has a documented effect on the development of cancer of the colon and the breast. There is a strong possibility that physical activity can reduce the risk of endometrial, lung, and prostate cancers. Cancer is one of the leading causes of death among older adults, and the number of people living with cancer increases with age. A lifetime prevalence of cancer among men in 2009 was found to be 4.8% among adults aged 45–64 years and increased to 18.9% among adults aged 65–74 years and to 22.7% among adults aged 75 years and older. Among women, the lifetime prevalence of cancer was found to be 15.3% for those aged 65–74 years, 16.9% for those aged 75 years and older compared to 8.7% compared to those aged 45–64 years [2]. These numbers reflect persons who were alive in 2009 and who had been diagnosed with cancer.

Diabetes

Diabetes prevalence increases with age. In 2005–2008, 4% of adults aged 20–44 years, 14% of those aged 45–64 years, and 27% of those 65 years of age and over had diabetes. From 1988–1994 to 2005–2008, diabetes prevalence increased among adults who were 65 years of age but not among adults 45–64 years of age [2]. Diet, weight loss, and medication have been used individually or together to control diabetes. For many years, it was assumed that physical activity had no direct effect on diabetes, but an indirect effect mediated by weight loss. However, meta-analyses and systematic reviews of the literature provide evidence that physical activity can have a beneficial effect on the control of diabetes and subsequent complications, even in the absence of weight loss [9]. In spite of these findings, a recent study found that older adults with diabetes were less physically active than similarly aged adults without diabetes and that the prevalence of physical activity among them decreased within each age group (65–70 years; 71–74 years; and 75 years and older) [10].

Metabolic Syndrome

The metabolic syndrome is usually defined as the presence of at least three of the following symptoms: fasting glucose at or above 110 mg/dL; blood pressure at or above 130/85 mm Hg; high density lipoprotein below 40 mg/dL for men and below 50 mg/dL for women; triglycerides at or above 150 mg/dL; or waist circumference more than 102 cm for men or more than 88 cm for women. People with this syndrome have an increased risk of developing and dying from chronic diseases, most notably, diabetes and cardiovascular disease. Data from the National Health and Nutrition Examination Survey III, 1988–1994, found that the prevalence of metabolic syndrome among adults aged 60 years and older was over 40% [11]. A physically active lifestyle can positively improve the symptoms associated with the metabolic syndrome.

Osteoporosis

Osteoporosis is a common problem among older adults that causes bones to become abnormally thin, weakened, and easily broken (fractured). Women are at a higher risk for osteoporosis after menopause due to lower levels of estrogen, a female hormone that helps to maintain bone mass. Estimates from the staff at the National Osteoporosis Foundation suggest that by 2010, about 12 million people over the age of 50 years are expected to have osteoporosis and another 40 million to have low bone mass. By 2020, the numbers are expected to increase to 14 million cases of osteoporosis and over 47 million cases of low bone mass. Hip fractures are one of the major problems associated with low bone density. Weight-bearing exercise, especially resistance exercise, can help to maintain bone mineral density among older adults.

Depression

A common mental health problem, depression, occurs in the United States and worldwide and often accompanies other chronic diseases. Although the prevalence of major depressive disorder is lower among older adults than younger adults (5% for adults aged 50 years and older compared with about 8% for adults aged 18–49 years), in 2009, 10% of men and 17% of women over age 65 years reported a prescription for antidepressant drugs [2]. Physical activity has been shown in numerous studies to be useful in preventing and managing depression and also to protect against development of subsequent depression [12].

HOW MUCH PHYSICAL ACTIVITY?

One question that is often asked pertains to how much physical activity is necessary for health benefits. While the exact amount and type of physical activity varies depending on a person's functional age, there are additional differences related to physical abilities and comorbid conditions. For healthy older adults with no limitations, a good approach is to follow the guidelines for adults as presented in the 2008 Physical Activity Guidelines project [13] and summarized in Table 108.2.

TABLE 108.2
Key Physical Activity Guidelines for Adults

General statement: All adults should avoid inactivity. Some physical activity is better than none, and adults who participate in any amount of physical activity gain some health benefits

- For substantial health benefits, adults should do at least 150 min (2 h and 30 min) a week of moderate-intensity or 75 min (1 h and 15 min) a week of vigorous-intensity aerobic physical activity, or an equivalent combination of moderate- and vigorous-intensity aerobic activity Aerobic activity should be performed in episodes of at least 10 min, and preferably, it should be spread throughout the week
- Adults should also do muscle-strengthening activities that are moderate or high intensity and involve all major muscle groups on 2 or more days a week, as these activities provide additional health benefits
- For additional and more extensive health benefits, adults should increase their aerobic physical activity to 300 min (5 h) a week of moderate-intensity, or 150 min a week of vigorous-intensity aerobic physical activity, or an equivalent combination of moderate- and vigorous-intensity activity. Additional health benefits are gained by engaging in physical activity beyond this amount

The Key Guidelines for Adults also apply to older adults. In addition, the following guidelines are specific for older adults:

- When older adults cannot do 150 min of moderate-intensity aerobic activity a week because of chronic conditions, they should be as physically active as their abilities and conditions allow
- Older adults should do exercises that maintain or improve balance if they are at risk of falling
- Older adults should determine their level of effort for physical activity relative to their level of fitness
- Older adults with chronic conditions should understand whether and how their conditions affect their ability to do regular physical activity safely

The guidelines go on to say that adults (of any chronological age) with chronic conditions need to participate in regular physical activity, according to their abilities and ensuring that the physical activity is safe. These activities should be selected with help from their health care provider. However, for general situations, Table 108.3 provides guidance or a starting point for several common conditions. Note that for all conditions, overweight or obesity adds more stress to the body and physical activity can help maintain weight.

SURVEILLANCE DATA

Surveillance of physical activity behavior among U.S. adults is conducted through a number of national surveys. The National Health Interview Survey (NHIS) is an annual "in-person" interview with a representative sample of U.S. noninstitutional adults. Questions on the type, frequency, and duration of various physical activities are obtained, and these prevalence data are statistically weighted to represent the U.S. population. The BRFSS is a state-based

TABLE 108.3
Commonly Recommended Physical Activities for Selected Chronic Conditions

Condition	Why Physical Activity Is Important	Type of Activity
Arthritis and osteoarthritis	Improves blood flow through joints and keeps them lubricated. Improves flexibility and range of motion	Aquatic or land-based programs Low-impact aerobic and/or resistance training
Osteoporosis	Weight-bearing activities promote bone health and help maintain bone density	Climbing stairs, walking, Tai Chi, dancing, hiking, aerobics and step classes, jogging, racquet sports skipping rope, lifting weights
Cancer	Helps build endurance to combat fatigue	Activities suited to individual; start slowly with both aerobic and resistance activities
Diabetes	Improves insulin resistance	Walking and resistance training
Cardiovascular disease	Helps reduce risk factors of hypertension, high cholesterol	Walking and other aerobic activities
Depression	Help stabilize mood	Aerobic and resistance activities

survey using standard measures so that state-specific data as well as national estimates can be calculated. The BRFSS is conducted annually and is telephone-based. Questions on physical activity range from doing "any" leisure-time physical activity for at least 10 min at a time to more detailed questions assessing the frequency and duration of physical activity. This is one of the few surveillance systems that assesses occupational activity through one question regarding the amount of time during work spent sitting, walking, or doing heavy labor. The NHIS and the BRFSS are the two major sources of national data on the prevalence of physical activity.

Recognizing that individual differences apply, it is generally known that physical activity decreases with age. Recent data from the NHIS survey found that 12% of men and 9% of women over age 65 years meet the 2008 federal guidelines for all aerobic and muscle-strengthening activities [2]. Using BRFSS data and looking only at aerobic activities, about half of adults over age 65 years meet the 2008 federal guidelines [14]. Data published prior to 2008 may use previous guidelines, but regardless of the system used, older adults are less active than younger adults. Using data from the 2004 BRFSS, 28% of adults aged 65–74 years and 36% of adults aged 75 years and older report no physical activity in their leisure time in contrast to only 19% of those aged 18–29 years who report no physical activity [1].

Note that the statistics reported here are based on physical activity performed outside of an occupational setting. As more adults reaching the "magic" age of 65 years continue to work, the contribution of occupational physical activity should not be ignored. Recent data from the state-based BRFSS suggest that including occupational physical activity increases overall prevalence of meeting the physical activity guidelines among adults aged 65 years and older by a modest 1.8% among men and 1.1% among women compared with about 10% for men and 6% for women aged 18–54 years [15].

MEASURING PHYSICAL ACTIVITY

The best way to collect information on physical activity is to use simple questions that can be compared with published national data. Although objective methods of measuring physical activity are thought to obtain more accurate measures than pencil and paper tests, there are major limitations to using these methods. Accelerometers measure heart rate and activity in multiple planes but cannot be worn when doing water activities. In addition, they must be worn correctly, cost several hundred dollars, and the data collected by the device must be downloaded and analyzed for interpretation. These problems make accelerometers more appropriate for research studies than for measuring physical activity in a community or clinical setting. Pedometers are a much cheaper alternative that counts steps while being worn around the waist. While they also cannot be used around water, they are much cheaper (can be found for less than $20) and give instant feedback to the user. Because of these issues, the best use of a pedometer is as a motivation tool to encourage individuals to be more active (increase daily step counts to reach a goal). For a quick assessment and subsequent recommendation, simple questions about the time spent doing aerobic activities are efficient ways to determine adequate physical activity. Questions should include some measure of intensity (e.g., type of activity such as walking or running), time spent doing activity, and how often the activity is done. These questions do not need to be too detailed in order to get a rough idea if the person meets the guidelines for physical activity.

BARRIERS TO BEING PHYSICALLY ACTIVE

Although most adults are well aware of the need to participate in physical activity, about half do not, and this proportion is even higher among older adults. Physical activity can prevent or delay the occurrence of many chronic diseases, including arthritis, hypertension, diabetes, heart disease, for example, which become more common as individuals age. Even when chronic diseases are present, participation in physical activity can prevent worsening of the condition or developing new conditions related to physical inactivity. However, surveillance data consistently report that participation in physical activity decreases as people age. Reasons

for this decrease are varied but some are particularly relevant for older adults, such as functional problems limiting mobility, lack of safe venues for activity, and lack of knowledge about appropriate activities. For all adults, the most common barrier to being physically active is lack of time. However, for older adults, the barriers to being physically active include such things as chronic illnesses, injury, and lack of skill [16]. For example, those with chronic back pain reduce activity levels out of fear of worsening the pain, even though physical activity has been shown to improve the condition [17]. In addition, motives for exercising differ among older adults. A study of community-dwelling older adults in Finland found that those with mobility limitations exercise for disease management, while those without mobility limitations exercise for health promotion and positive experiences [18]. For older adults, the barriers become much more complex and are summarized in Table 108.4 along with some strategies that may facilitate physical activity.

Injury

While injuries occur with many sports, they are often minor and do not represent a major shift in the direction of an active lifestyle. However, for older adults, even minor injuries may involve a prolonged period of recovery. During this recovery period, significant deconditioning may occur, leading to difficulty in resuming physical activities. In addition, the type of injury could be devastating and may discourage future activity. For some older adults, the fear of injury, rather than an actual injury is a major barrier.

Environmental

The newest area of research on physical activity prevalence has to do with the role of the environment. Several features of the environmental design can promote physical activity, especially among older adults. Access to safe walking areas, free from crime and traffic, is important for all adults but essential

TABLE 108.4
Common Barriers to Physical Activity for Older Adults

Type of Barrier	Major Concern	Strategies
Injury	Slow recovery time	Encourage cross-training to let injured body part heal
		Promote low-impact activities
	Deconditioning	Restart minimal activity after injury and increase slowly to pre-injury levels
	Falls	Develop and use safety checklist
		Use proper footwear
	Fear of injury	Educate on safe exercise practices
Environmental	Crime	Identify safe areas for walking or other activities
	Traffic	Ensure that crossing lights allow enough time for older adults to cross
	Falls	Ensure sidewalks are available and in repair
	Fatigue	Identify areas with benches or resting places
	Extreme heat or cold	Identify climate-controlled areas for walking (e.g., malls)
Urinary incontinence	Lack of facilities	Identify areas with appropriate facilities
Arthritis pain	Fear of increasing pain	Educate on benefits of physical activity for arthritis
	Unable to perform usual activity	Identify alternative activities
Medications	May cause dizziness and balance problems	Identify walking or exercise partners, identify safe exercise venues that are well lit with solid pathways
Chronic conditions (ear or hearing problems)	May cause balance problems	Identify walking or exercise partners
Surgery	Limited mobility and fatigue during recovery	Educate on alternative physical activities, start minimally and increase activity slowly
Cancer treatments	May cause dizziness, fatigue	Identify walking or exercise partners, start activity program slowly
Obesity	Inability to participate in many types of physical activity	Start with conditioning, work up to aerobic activities, such as walking
	Embarrassment	Find clothes that fit, join groups with same problem

for older adults who may not be able to travel to other areas just to be active. The nature of physical activity changes as a person ages and opportunities to walk for transportation (errands) or gardening (own or community gardens) become more important. To encourage walking, street connectivity, stores in proximity to housing and public transportation, and places to sit along the way are characteristics that promote activity.

Urinary Incontinence

While many older adults, women in particular, have some form of urinary incontinence, it is difficult to obtain exact prevalence data. Although about 25% of older adults report problems with urinary incontinence, it is estimated that less than half of women with urinary incontinence mention it to their provider. This has a particular impact on physical activity. Although urinary incontinence is a barrier for participating in physical activity, there is evidence that suggests physical activity actually reduces the risk of urinary incontinence among older women.

Arthritis/Osteoarthritis

Arthritis is a disabling disease that results in joint pain as the cartilage degenerates. Although pain may limit some activities, it is important for adults to know that physical activity is important in maintaining joint function. Adults with arthritis should also know how to provide alternative exercises so that painful joints are not unduly stressed. Because there is no known cure for orthrictis research focuses on prevention and symptomatic treatment of the disorder. In this regard, a beneficial effect has been shown for aerobic and strengthening exercises on pain relief and joint function [19].

Medication

Overall, about 80% of adults have at least one chronic condition [1]. A recent study of adults aged 57–85 years found that 75% of them had one or more comorbid conditions (including high blood pressure, stroke, myocardial infarction, heart failure, diabetes, thyroid problems, Alzheimer disease or dementia, cancer, and any type of arthritis) [20]. The same study found that among adults aged 65–85 years, 80% took at least one medication per day, while 29% used five prescription medications per day. Over-the-counter drugs were also common with almost half of those aged 65–85 years using a combination of at least one prescribed medication along with an over-the-counter drug or supplement. Surveillance data for the United States in 2005–2008 found that 65% of adults 65 years and older used three or more prescription drugs in the past month [2]. In addition to the known side effects for a particular drug, there is the possibility for unforeseen problems due to interactions among multiple medications, including over-the-counter drugs or supplements. The most common side effects include sleepiness, dizziness, or visual problems, all of which could lead to falling. Persons taking a number of medications should still exercise, but the form may be dependent on personal cognitive and functional conditions. There are several preventive techniques that can be applied in this situation. Physical activities should be low impact and done with a partner who can watch for any problems. The venue should be safe with good lighting.

Chronic Conditions

A number of chronic conditions, in and of themselves, can affect physical activity directly or indirectly. For example, ear problems may affect balance and preclude activities where there is a risk of falling. Persons with visual problems, such as macular degeneration, may have to give up their usual forms of activity and may need assistance in developing alternative exercises. Muscle problems such as Parkinson's disease and muscular dystrophy may limit the types of activity that can be done. There are numerous resources for promoting appropriate physical activities for people with chronic conditions.

Surgery

Often the fatigue associated with recovery from surgery may limit the type and volume of physical activity. To avoid the deconditioning process, mild activities, such as standing and taking a few steps, should be started soon after surgery as feasible. Then increasing the duration and intensity of the activity should occur slowly over the next few weeks, as healing allows. There is evidence to suggest that physical activity actually promotes healing and should be an integral part of recovery.

Cancer Treatments

Cancer treatments including chemotherapy and radiation take a toll on the body. While exercise may not be high on a patient's priority list, a slow return to physical activity may help combat the effects of treatment. The most common activity that cancer patients do is walking. Because of the safety of walking and the ability to adjust walking speed from a low to a high intensity, this is a very reasonable type of activity to begin a program of physical rehabilitation after cancer treatment. Strength training is an often overlooked activity that will help build endurance.

Obesity

Becoming involved in any type of physical activity and increasing endurance over time is an important adjunct to diet when trying to lose weight or to prevent weight gain. However, to start, an extremely overweight individual may have particular issues including finding clothes that fit and dealing with the embarrassment about exercising in public, even in pools. Once these issues are successfully overcome, perhaps by connecting overweight individuals with others in the same situation, a physical activity program that starts off slowly and builds endurance can have important implications for self-esteem and health benefits over and above any weight loss that might occur.

SUMMARY

While much is known about the general decline in physical activity associated with age and the related adverse health events that can accompany this inactivity, there needs to be more emphasis on the variety of activities that are appropriate for adults of any age. The Physical Activity Guidelines specify that older adults need aerobic as well as strengthening and flexibility activities to prevent or delay aging-related physical decline. The strategies to achieve these guidelines will vary depending on the functional status and comorbidities present among older adults. The key point is that physical activity is essential at any age and maintaining functional health and independence is the major goal. Several themes emerged regarding the particular issues older adults face with regard to keeping physically active. These themes include special attention to safety issues around the home and outside the home where physical activity is usually performed. With the projected increase in the proportion of the U.S. population over the age of 65 years, low participation in physical activity among older adults becomes an important public health problem that will need to be addressed.

INTRODUCTION

There is an increasing body of literature detailing sex differences in the development, prevention, and treatment of cardiomyopathies throughout the human lifespan. This indicates that more research is being undertaken in single cohort studies in both the clinical science and pharmacologic fields. The results of these comparative studies can now be used to provide the most beneficial course of sex-specific clinical treatment. This chapter will present some of the recent data detailing sex differences in response to acute and chronic resistance and cardiovascular exercise. Since cardiovascular disease (CVD) is associated with the greatest morbidity and mortality worldwide and there are sex differences with the treatment of the disease, this chapter will also delve into the effects of exercise on resting hemodynamics and vascular responsiveness in a hypertensive cohort.

EPIDEMIOLOGY OF THE DISEASE

CVD is the largest single cause of mortality among women, accounting for 38% of all deaths among females. For example, in the United States, 42.1 million (36.6%) women live with CVD, and the population at risk is even larger. While CVD is a large public health issue in women, it is not solely related to mortality due to the recent advances made in sex-specific research allowing women to have greater chances to survive CVD. Hypertension is a large contributor to CVD and is defined as a systolic blood pressure (BP) greater than 140 and/or a diastolic BP greater than 90 mmHg (respectively). Hypertension has been diagnosed in 76.4 million U.S. adults, and as our population ages, this figure will increase since hypertension prevalence increases with age [1]. A nonclinical diagnosis of prehypertension may be considered when your systolic pressure is between 120 and 139 mmHg and/or your diastolic BP is between 80 and 89 mmHg most of the time [2]. If you have prehypertension, it has been shown you are more likely to develop hypertension.

SEX DIFFERENCES

Sex differences are detected during puberty as differential effects of sex steroids give rise to the differences of primary and secondary sex characteristics. While previously unthought of, the development of these sex differences may start the inflection point for increases in the incidence of CVD increasing the need for more cardiovascular studies in adolescents. It has been shown that in females, follicle-stimulating hormone (FSH) and luteinizing hormone (LH) cause estrogen production from the ovaries, which instigates pelvis broadening, increased bone growth, targeted fat depot sites, and breast development. However, puberty in males is a result of FSH and LH causing testosterone production from the testes, which upregulates bone formation and muscle mass as well as increased erythropoietin production from the kidneys. This hormone shift leads to physiologically divergent responses in both the cardiovascular and skeletal muscle systems within the human body. Perhaps the greatest impact of sex differences are shown in a population of chronic diseased individuals (i.e., hypertension) where men progress from normotensive to prehypertensive to hypertensive from their thirties when few women present with this disease; however, women catch and surpass men in the incidence of hypertension by their sixth decade of life [1]. This is disturbing information since

women do not respond to many of the antihypertensive medications in the same fashion. Women reported twice as many adverse effects than men during the Treatment of Mild Hypertension Study, prompting sex-specific adverse effects profiles for many antihypertensive medications. Common medications such as angiotensin-converting enzyme inhibitors (ACEi) and AT_1-receptor blockers (sartans) have shown fetal development complications making these drugs contraindicated for women who are or wish to become pregnant. Further, ACEi treatment results in twice as many coughs reported in women than men. Diuretics, commonly a drug of choice in elderly women due their propensity to decrease hip fractures, have shown a greater incidence for women to develop diuretic-induced hyponatremia and hypokalemia. Lastly, women have reported more cases of peripheral edema while taking a calcium channel blocker as an antihypertensive.

HYPERTENSION

Aside from what can be explained with kidney disease, the etiology of hypertension is mostly unknown, yet there are several contributors to the disease that research has elucidated within the last several years. Some of these risk factors point to microvascular dysregulation due to several functional and structural adaptations. Increased sympathetic outflow, pulse pressure, and endothelial dysfunction are mechanisms leading to hypertrophic remodeling. When normalized, the internal diameter of the artery shows a decreased lumen diameter, increased reactivity, increased arterial stiffness, and an increased wall to lumen ratio. All of these negative remodeling factors brought about by uncontrolled hypertension lead to functional changes within the arterial matrix giving rise to deleterious consequences. Further, vascular smooth muscle cells may be separated from endothelial cells leading to decreased vasodilatation and a microvessel loss (microcirculatory rarefaction). Also, endothelial cells are attenuated and there is some evidence that they may become separated from their basement membrane. Therefore, understanding endothelial-dependent vasoactivity and oxidative stress are important to furthering our knowledge of possible contributors to hypertension. The increased vascular resistance caused by the narrowing of the arterial lumen results in a baroreceptor resetting to the higher pressures, making the baroreceptor less sensitive, further increasing BP variability.

SEX DIFFERENCES IN HYPERTENSION

Dr. Kathryn Sandberg's laboratory recently has shown that the sex chromosome complements are factors in sex differences in hypertension regardless of gonadal sex, meaning the X chromosome may have a greater role in BP control throughout adult life [3]. Documented studies of individuals with X chromosome inactivation have shown cardiovascular complications ranging from vessel complications to hypertension [4,5]. Little is known regarding the sexual dimorphism of CVD; however, some recent animal studies by Sandberg et al. have shown tissue-specific enzyme expression that may contribute to the differences in the evolution of hypertension. Sandberg and colleagues have shown that renal angiotensin-converting enzyme 2 (ACE 2), which synthesizes the vasoconstrictor angiotensin 2, exhibits higher activity in the male kidney under basal conditions [6]. This is an important finding as it demonstrates that ACE 2 is lower in the kidney of the female counterpart due to ovarian effects, which may start to explain the sex differences in the etiology of CVDs such as hypertension. With this new knowledge, therapeutic prescriptions that target sex-specific hormone milieu may be more beneficial for the prevention or treatment of CVD. Women show a slightly greater percentage of awareness and ability to control their disease as shown in the NHANES III data from 1991. However, there is an alarming disparity in the rates of awareness as only about 60% of the hypertensive population is aware they have the disease and only about 20%–30% of those aware have their BP under control [7]. Men and women alike are at risk for developing CVD, underscoring the importance of a heart-healthy lifestyle to prevent or treat CVD. Included in lifestyle changes are weight loss, improved eating habits including a substantial decrease of sodium and alcohol in the diet, and increased amount of physical activity. Since the microcirculation is involved in the genesis and sustainability of hypertension, more research in this area needs to be completed to better elucidate the functional changes that may be prevented with lifestyle changes such as weight loss and exercise.

EXERCISE

It has been shown that exercise confers its benefits on the vessel wall through sheer stress, which increases the bioavailability of endothelial nitric oxide, in turn increasing vasodilatation [8]. Therefore, exercise may be as or more beneficial to a particular sex than the current potpourri of pharmacological interventions. In relation to acute exercise, males and females exhibit similar mechanisms of motor control and similar muscle quality and show no difference in lower-body muscle strength when it is expressed relative to body weight [9]. However, women have been shown to posses less upper body strength than their male counterparts [10]. Yet, women show greater resistance to fatiguing contractions, which may, in part, be the result of increased muscle blood flow during contraction and the differential responses in muscle metabolism between males and females [11]. Since women have less muscle mass, the muscle contraction may not occlude blood flow, thus enabling the muscle to maintain the exercise longer than males [11]. Another potential mechanism may be a difference in motor unit discharge rate as women show greater recruitment synergism

and relative muscle activation of the muscle compartment than age-matched men and a lower rating of perceived exertion during the task [12]. In relation to muscle mass, older women may show a blunted response to hypertrophic resistance training that may be related to an attenuation of protein synthesis [13]. Further data to support this evidence suggest that women have decreased muscle protein synthesis following the ingestion of a meal [14]. However, even though women have less muscle mass on average, they still show considerable strength gains following a progressive resistance training regimen [15]. Taken together, women show greater fatigue resistance to acute exercise; however, they exhibit a resistance to skeletal muscle hypertrophy via an attenuation of protein synthesis with resistance training compared with men.

Women are consistently improving their world record times in events that are related to cardiovascular fitness (i.e., track and field and marathoning) at a faster rate than their male counterparts. The cardiovascular responses to acute exercise show dissimilarities that are mostly reflective of stature and mass differences between the sexes. Women show higher heart rates yet similar cardiac output responses at relative and absolute submaximal loads, respectively. Women show no difference in maximal heart rates; however, they have a lower stroke volume due to sheer size of the internal ventricular volume. On average, women have lower hemoglobin content and less potential for increasing the arterial to venous oxygen difference [16]. These factors along with the fact that women have more sex-specific body fat storage translate into a VO_{2max} that is 70%–75% of their age-matched male counterpart.

With cardiovascular training, both men and women increase their fat-free mass and decrease their relative fat mass leading to decreases in total body mass. However, the magnitude of changes in body composition (fat mass to fat-free mass) is correlated to the amount of energy expended over time than to the individuals' sex. With cardiovascular training, both sexes show increases in stroke volume due to increased heart contractility and blood volume. The increases in VO_{2max} has been shown to result from increases in maximal cardiac output accompanied by small increases in arterial to venous oxygen differences. Ventilation differences are more of a result of differences in size, not necessarily sex; however, maximal ventilation can be increased with either sex following cardiovascular training. These data show that most cardiovascular and respiratory changes following training do not exhibit sex specificity.

Perhaps the greatest sex differences lie in the amount of studies completed in men than their female counterparts. With the recent creation of the Organization for the Study of Sex Differences and more attention given to women's health initiatives, increased knowledge of the physiological and mechanistic differences between males and females will be elucidated, lending to better prevention and treatment of disease by sex specificity. As with the progression of most diseases, the cornerstone of treatment is lifestyle intervention, which usually starts with an increase of physical activity. CVD is the leading cause of mortality worldwide [17], and while the trend of reported CVD for men has recently leveled off, it continues to climb for women. Further, women experience longer hospital stays and greater disability and show less successful response to antihypertensive medications than men [18,19]. Aerobic exercise has been shown to reduce cardiovascular events by 30%, which is equivalent to the reduction in cardiovascular risk following antihypertensive and lipid lowering therapy [20]. In addition to lowering cardiovascular risk, aerobic exercise lowers BP and improves vascular reactivity, thought by primarily increasing the bioavailability of nitric oxide [21]. Resistance exercise has also been shown to reduce BP to the same extent as moderate intensity aerobic exercise; however, weight training has been shown to increase arterial stiffness in young healthy and hypertensive populations [21,22]. Recently, sex differences in vascular parameters have been shown following the inclusion of weight training in a fitness regimen [23,24]. Females have not shown significant increases in arterial stiffness following resistance training when compared with their male counterparts. These protective benefits are still seen in women following menopause when estrogens can no longer provide active cardioprotective benefits. Therefore, females reap the benefits of resistance training without any significant increases in arterial stiffness, which is important in an aging hypertensive population. Women can include resistance training, which will also help prevent and treat osteopenic and osteoporotic conditions, without any further increases in arterial resistance.

Subtle sex differences exist following acute and chronic exercise training. While most of these differences can be explained by stature and mass, the mechanisms that underlie arterial changes following resistance exercise may provide windows into how we can make our arterial tree more resilient as we age.

CONCLUSION

Lifestyle changes are the cornerstone for the prevention and treatment of hypertension. Aerobic exercise has been shown to reduce BP by employing its effects on the endothelial wall via increases in sheer stress making it as effective as antihypertensive medications with few side effects. Increasing the amount of moderate intensity exercise to at least 120 min per week has shown to be effective at decreasing ambulatory BP. Considerations should be given when prescribing exercise so women can derive more cardiovascular and skeletal muscle benefit such as the addition of a progressive, weight-bearing resistance training regimen. However, aerobic exercise should be prescribed by physicians and backed by incentives from insurance companies as a way to decrease the incidence of hypertension and decrease out-of-pocket insurance costs to companies that provide wellness initiatives for their employees.

INTRODUCTION: THE IMPERATIVE TO ACHIEVE HEALTHIER PEOPLE AND HEALTHIER ECONOMICS IN HEALTH CARE

From obesity and tobacco use to diabetes and cardiovascular disease—the current overall health situation in the United States is not a positive story. Rising costs are not sustainable, and the health implications are staggering.

Health promotion in the workplace is a critical tool, both in terms of enhancing employee health and company economics. Successful programs can advance business goals and corporate social responsibility commitments while delivering highly valued services to employees. By implementing dynamic, effective health programs in the workplace, we can help our people and our companies become healthier.

This chapter focuses on workplace health promotion programs, the rationale for their adoption, as well as a case study on The Dow Chemical Company's (Dow) positive experience with them.

RATIONALE FOR CORPORATE AND WORKPLACE HEALTH PROMOTION PROGRAMS

As a vital component of a true health system, companies can make a positive difference in the health of their people, and they can have a peripheral impact in the communities where they operate. Well-conceived workplace health promotion programs can improve health and quality of life for employees, reduce their risks for disease, control unnecessary health care utilization, limit illness-related absenteeism, and decrease health-related productivity losses.

The worksite is the right place to tackle many of our health problems because adults spend so much of their active waking hours at work. As Dr. Ron Goetzel—a nationally recognized expert in health and productivity management, return on investment (ROI), program education, and outcomes research—points out, health promotion programs at work make sense because of the following:

- They can reach large segments of the population not exposed to and engaged in organized health improvement efforts.
- Workplaces contain a concentrated group of people who share a common purpose and culture.
- Communication with workers is straightforward.
- Social and organizational supports are available.
- Certain policies, procedures, and practices can be introduced, and organizational norms can be established.
- Financial or other types of incentives can be offered to gain participation in programs.[1]

Further, there is a direct, logical basis for workplace health prevention:

- Many of the diseases and disorders are preventable.
- Many of these diseases and disorders are triggered by modifiable health risks.
- Many modifiable health risks are associated with increased health care costs and decreased worker productivity.
- Modifiable health risks can be improved through health promotion and disease prevention programs.
- Improvements in the health risk profile of a population can lead to reductions in health care costs and absenteeism, and heightened productivity.
- Well-designed and well-implemented worksite health promotion and disease prevention programs can save money and produce a positive ROI.[2]

Health Promotion Programs Provide Value for Employers

Investing in workplace health promotion programs provides value to organizations through a number of dimensions. Financial estimates indicate that a company can save $350 annually when a low-risk employee remains low risk and $153 annually when a high-risk employee's health risks are reduced.[3] One meta-review of 56 published studies of workplace health promotion programs shows the following benefits[4]:

- Average 27% reduction in sick leave absenteeism
- Average 26% reduction in health care costs
- Average 32% reduction in workers' compensation and disability management claims costs
- Average $5.81-to-$1 savings-to-cost ratio

After closely examining their organizations' data, many large U.S. companies have also concluded poor health increases employees' utilization of health care services and diminishes employee performance, safety, and morale—thus incurring higher costs to their employer. For a business, workers in poor health—as well as those with behavioral risk factors—mean greater medical expenditures, more frequent absenteeism, increased disability, more accidents, and suboptimal productivity.[5–13]

In terms of the bottom-line value, for a Fortune 50 company, simply keeping U.S. direct dollars in the lower end of projected inflation for health care costs can save hundreds of millions of dollars over a 10 year period.

CASE STUDY: THE DOW MODEL

The Dow Chemical Company has offered an employee occupational health program for 90 years and has had a focused health promotion program for more than 20 years. This outcomes-focused, data-based program aims to enhance the health of the Dow population, including the prevention of injury and illness, through education and support for healthy lifestyle change. It addresses the health issues that Dow people face, on and off the job.

Dow's long-term vision for its health promotion program is to improve health, reduce health risks, positively impact health-related costs of Dow people, improve employee performance, and achieve a high level of satisfaction—with improved health being the highest priority. This will be achieved through a strategy that ensures that "Total Health"-related programs and services are established, prioritized, leveraged, and implemented on a global basis, in the most cost-effective and efficient way. These objectives are consistent globally—at all of Dow's 214 work locations located in 37 countries. They are supported by regional targets and plans that provide local prioritization and focus to the objectives.

Dow's Business Case for Health

In 2004, at the request of Dow's CEO and executive team, Dow Health Services and Healthcare Benefits groups developed a business case analysis of the situation related to the health of Dow people. Here is a simplified summary of the business case:

- Dow has a very large economic impact associated with the health of its people, and the inflation on this large base typically increases at a rate greater than general inflation or economic growth.
- Translating this economic impact into cents/share demonstrates it as a significant priority.
- There is strong evidence that Dow has an opportunity to change the situation through improved quality, through addressing waste and ineffectiveness in the system, and through prevention.
- Health advocacy is a priority as reform agendas are vital to the future.

This business case drove development of a simple yet powerful corporate-level health strategy.

The Dow Health Strategy

It is imperative to have a long-term view for and commitment to health. Company leadership at Dow approved a corporate Health Strategy in 2004, which confirmed health as a corporate priority. Dow's Health Strategy is built on four pillars:

1. Prevention
2. Quality and effectiveness
3. Health system management
4. Advocacy

The strategy includes all aspects of the impact of health for "Dow family" members (including employees, dependents, and retirees). It is reflective of Dow's belief in the alignment between the health of its people and the success of the

company and the view that health spending is an investment. Based on a long-term commitment, Dow Health Services and Benefits have set multiyear goals as well as annual objectives for each pillar of the strategy.

Preventive Health Promotion Program: A Fundamental Choice

Focusing on the prevention aspect of the health strategy, Dow's comprehensive health promotion program incorporates best practice design and implementation characteristics: awareness, motivation strategies to engage employees, skill-building programs, and supportive environments. It includes a variety of health-related company policies and initiatives: periodic health examinations, Dow-directed testing, consultation, referral and follow-up, health education through intranet and Internet channels, small group programs, health/disease risk topic-focused campaigns, on-site wellness centers, self-care and consumer education, and tools such as an electronic personal health record.

In addition, Dow offers strong prevention coverage in its health benefit plans as well as initiatives—such as the Healthy Workplace Index (HWI)—to create a supportive environment.

Dow launched the HWI in 2007 at its domestic and global worksites to reinforce the connection between workforce culture, environment, and health. The HWI measures the health parameters of a worksite, such as access to healthy food, access to exercise, participation in programs, and a tobacco-free campus. A site's status on all of the parameters is ranked by its level of achievement and assigned points accordingly. The cumulative index score of all individual elements is used to classify worksites as achieving bronze, silver, gold, or platinum levels.

The global strategy features a blend of corporate efforts and local plans to ensure Dow meets the needs of its diverse workforce, and it emphasizes shared responsibility between the company, local leadership, and employees for improved health.

People Resources: A Global Health Promotion Team

In alignment with Dow's Health Strategy and overall health services package, an updated Global Health Promotion team was chartered in late 2009 to provide strategic leadership to the program. The team is lead by the global health promotion leader and includes regional health promotion coordinators from five different regions, plus subject matter experts for the priority health targets of weight management, tobacco, resiliency, and physical activity.

It is important to note that health promotion occurs throughout all service lines within Dow's Health Services organization, such as Clinical Care and Health Assessment. The intent is that achievement of prevention and health promotion is accomplished across all service lines.

Formal subject matter experts and/or teams are in place for a wide variety of health topics and technologies (e.g., counseling, measurement/evaluation). These contacts monitor internal and external practices, research, and trends to help drive best practices in the program. They also take ownership in developing and updating communications and programs on their topics—to help ensure consistency of message and integration of best practices.

Regional health directors, regional health promotion coordinators, and other Health Services staff prioritize and customize base and local programming to meet regional needs with available resources.

Only one-quarter of Dow work locations have an on-site Health Services staff member. Reaching the entire workforce thus requires the active involvement of employees across the company. This includes Dow's global network of site and workgroup health contacts. The primary purpose of this network is distribution of programming and information. These contacts provide feedback and customize the program to ensure that central or regionally developed strategies are implemented.

In addition, a small core group of staff provides support with language translations, data management, and communication.

A Key Focus: Shared Responsibility

One of the premises of Dow's health promotion program is that individual health is most effectively achieved when there is a shared responsibility between employees, company leaders, and the company. While individual behavior is inevitably essential, a healthy culture and environment established through policies, benefits, and leadership behaviors is also essential. This results in shared benefits for both the company and the employee: improved health, personal performance, and lower costs:

- Employees need to be educated medical consumers, make decisions and take actions to improve their personal health, and utilize the tools and resources provided by the company.
- Company leaders need to proactively facilitate a supportive environment, such as supporting access to healthy foods and physical activity.

Health Services communicates regularly and consistently to both leaders and employees across Dow, constantly striving to build a health-centered culture and promote various programs. It is widely recognized that leaders are essential to creating a culture that encourages employees to live healthy lifestyles. Communications methods thus target both leaders and employees.

Health Services uses various tools to reach these two audiences. Broad communications include internal news resources; reports with important findings, updates, and successes; and newsletters and web casts/videos. A health intranet site has a vast amount of information and resources for employees. Dow's external website contains additional health resources that are available to employees

and their dependents, retirees, and community members. Communications delivered on-site include messages on TV monitors, posters, presentations, safety meetings, discussion panels, and awards. Health Services also communicates more personally to the individual through home mailings and e-mails.

Communications are consistent across the globe, with the flexibility to adjust for cultural differences and program plans. This allows for customization of messages as appropriate, whether that means releasing a communication in the local language and/or communicating about local events and promotions. Most of Dow's global programs and communications are translated into 13 languages. Dow is fortunate to have a corporate translation department to manage initial translations and use local contacts for review and adjustment of content, examples, and measures.

The following are some examples of programs Dow has implemented globally, often with local customization, to enable employees to take a more active role in their health.

Reducing Tobacco Use

The Dow Corporate Smoking Policy was first enacted in the United States in 1993. It has been updated, and since January 1, 2003, all Dow property and meetings in the United States have been smoke-free. Outside the United States, all Dow buildings and meetings have been smoke-free since January 1, 2004. The difference in the two policies represents the necessity for utilizing a multicultural approach. The global policy was written as a minimum standard with room for flexibility in implementing at a local level.

One example is Dow's annual No Tobacco Day, which urges tobacco users to make a commitment to quit using tobacco for at least 1 day. Communicated in 15 languages across all Dow sites globally, tobacco users are asked to commit online. Participants then receive motivational messages and the chance to win gift card prizes. In the inaugural year of 2007, 6% of tobacco users (representing 27 different countries) committed to quit and 56% of those met the 24 h challenge. At 6 months, 11% of participating employees remained tobacco-free. Site leaders from 30 sites also committed to making their work environment more supportive and sponsored activities like tobacco cessation workshops, tobacco-free worksites, free "cold turkey" lunches, educational sessions for employees' families, and free massages. In 2010, 7% of tobacco users (representing 28 sites and 18 different countries) committed to quit using tobacco and 34% met the 24 h challenge. This event, combined with internal health counseling efforts and improved medical benefit plan design, has resulted in a 3% point reduction in prevalence of tobacco users since its inaugural year (2007).

Eliminating the negative impacts of tobacco use requires more than a policy and program. As part of Dow's comprehensive approach, the company has strengthened internal health counseling efforts and improved its U.S. medical benefit plan to cover tobacco cessation consultation and pharmacotherapy at 100%, using evidence-based, best practice recommendations from the National Business Group on Health and U.S. Preventive Services Task Force.

Increasing Physical Activity

Dow implemented a global year-long physical activity challenge, MOVE for Good Health, to increase emphasis on regular physical activity at both an individual and organizational level. Nearly 5000 people from 53 countries registered for MOVE and made sustained changes in their physical activity level:

- 89% of previously sedentary participants became active (i.e., were sedentary at baseline and now exercise at least once per week).
- 47% of high- to moderate-risk participants moved into low risk during the program (i.e., started at high or moderate risk and now exercise three or more times per week).
- MOVE contributed to a 2008 Dow global population improvement in physical activity level—a 1% point reduction in high risk (from 26% to 25%) and 1% point increase in low risk (from 39% to 40%).

Since 2005, efforts to improve access to physical activity at Dow worksites, global physical activity challenges, and partnerships with groups like the U.S. President's Council on Physical Fitness and Sports have helped support a 12% point increase in Dow's low-risk population and a 6% point reduction in high risk for physical activity in the United States alone. Globally, the improvements were 7% points and 7% points, respectively.

Impacting Overweight and Obesity Issues

Dow participated in National Heart, Lung, and Blood Institute-funded research to examine the health and economic benefits of worksite and environmental interventions on overweight and obesity. The environmental interventions, called LightenUP, aimed to decrease unhealthy eating and increase physical activity among workers. Interventions included the following:

- Moderate-level treatments that introduced relatively inexpensive environmental changes to the physical environment, such as walking paths, healthy food choices, nutritional information in vending machines and cafeterias, and employee recognition
- More intensive-level treatments that encouraged an organizational culture of healthy behaviors through leadership training, top management involvement, integration of behavior change programs into the company's established business practices, and leadership accountability
- Control sites continued to receive the core health promotion programs, including individual-based programming (e.g., counseling), but did not receive the environmental interventions

After 1 year of the study, researchers found employees who participated in the LightenUP interventions reduced their blood pressure risk and maintained a steady weight when compared with employees at control sites who received only individual-focused interventions. After 2 years, Dow saw an increase in physical activity, better nutrition habits, reduction in tobacco use, increase in leadership support, and increase in employee awareness. These results suggest even moderate changes to the work environment can have a positive impact on employees by reducing at least one health risk and helping the well stay well.

Analysis of Dow's year 3 data indicates statistically significant results. Average weight loss at the intervention sites was significantly greater than at control sites, as were the reductions in mean blood pressure and cholesterol levels. Intervention sites also achieved significantly greater improvements in diet and exercise. These results indicate that adding environmental interventions to individual-level programs improves biometric and behavioral risk factors.

Improving Dow Family Health

In addition to addressing modifiable risk factors, Dow health promotion efforts engage employees, retirees, and family members as active participants in their health care. Dow provides health resources and information on the company's external website that are available to employees and their dependents, retirees, and community members. It includes benefits information, engaging programs, and more.

Dow's Positive Action health care consumerism program increased awareness of the consumer's role, helped participants become more comfortable with the U.S. health care system, and taught valuable skills such as self-care and adequately preparing for a doctor's visit. In the 9 months following the program pilot, participants experienced fewer health care claims than nonparticipants, which equated to a half million dollars in savings to employees and approximately $300,000 in savings to Dow within the first year after the program.

Since Dow still bears partial responsibility of health care costs for early retirees in the United States and Dow retirees help to shape the health culture in communities where Dow operates, a focused Retiree Health Empowerment Program is also implemented in the United States. Health promotion deliverables are extended to retirees in other geographies, as appropriate.

Measuring Success

The success of The Dow Chemical Company in establishing and maintaining a global culture of health can be seen as a systematic process. The support of leadership is unquestionably ingrained, and the health of employees is directly linked to business goals and objectives. This approach and strong focus on prevention translates to comprehensive worksite health promotion that is uniquely tailored to Dow employees.

Dow has a standard process and definitions for capturing, recording, and reporting participation. Hard copy forms and/or a web-based registration portal are used for global and local programs. Each country and/or region maintains a database for coding participation in health promotion as well as other employee health services. Rates are calculated and reported annually. Participation can be assessed by location, participant, topic, type of intervention, and actual intervention name.

Dow also identified the health risks with the greatest potential to impact its health strategy objectives. Ten-year targets were established to support the business case. These targets are tracked globally and regionally each year. Progress is also reported to the company executive leadership and the Board of Directors. As such, the targets are a significant driver for the program. They also serve as a unifying force across regions. While each region may have a slightly different prioritization, all regions share this common set of targets.

Dow tracks satisfaction, awareness of services, costs of services, participation, percentage of population reached, and progress in the HWI. The HWI quantifies site adherence to best practice recommendations for establishing a supportive work environment that contributes to the reduction of health risk, health-related injury/illness risk, and employee productivity. A formal customer satisfaction survey is conducted for each service component every 3 years to a random sample of the employee population.

Dow's Results

Driven by the 2004 strategy, many of Dow Health Services' recent program dimensions are still young, but indicators are already demonstrating the positive health impact. Here are a few, as of year-end 2010:

- The company has seen increases in the percent of Dow people who believe Dow sincerely cares about their health and well-being. Using global assessments, Dow saw an improvement of 11% points in 2010 versus 2005 in employee perceptions.
- Approximately 89% of global employees and 82% of U.S. employees voluntarily participate in health assessments. According to satisfaction surveys, 93% value this option—which is why Dow is able to attain such high participation rates without direct financial incentives to participate.
- Eighty-one percent of Dow's people globally and 79% in the United States participate in one or more internal Dow health services each year.
- Ninety percent of Dow's sites with >200 employees are engaged in the HWI. This represents approximately 57% of the Dow global employee population. Sites report total scores and are recognized for various achievement levels—bronze, silver, gold, and platinum. Through 2010, 61% of these sites reached the bronze level or above, which equates to

a 152% improvement since the 2008 baseline. Five sites were recognized by senior EH&S and Health Services leaders for achieving the silver level, and one was recognized for reaching the gold level.

- Dow tracks 11 key health risk indicators, which are measured from information obtained in periodic health assessment exams: blood pressure, total cholesterol, high-density lipoprotein (HDL) cholesterol, fasting glucose, body mass index (BMI), physical activity level, tobacco use, stress, depression, nutrition (fat consumption), and nutrition (fruit and vegetable consumption). Using an established baseline of global employees from 2004, Dow has seen a decrease in the high-risk level for 6 of the 11 health risk factors (total cholesterol, BMI, tobacco use, physical activity, depression, and nutrition [fruit and vegetable consumption]). Over this same period, Dow has increased the number of employees in the low-risk category in 8 of the 11 measures (total cholesterol, HDL cholesterol, BMI, tobacco use, physical activity, depression, nutrition [fat consumption], and nutrition [fruits and vegetables consumption]).
- In 2010, Dow continued its trend of reducing health risks in the employee population for the company's top three risk targets of tobacco use, physical activity, and obesity. Between 2004 and September 2010, there was a 25% reduction in high-risk people and a 19% increase in low-risk people in these three categories.
- Using U.S. data, Dow can illustrate the impact of one of its key services, health advocacy case management, in total economic benefit. In 2010, Health Services reported 14,533 absenteeism days saved resulting in $18 million in direct and indirect savings.

These results affirm the value of Dow's specific efforts and of corporate health programs generally. With a sustained focus, Dow will continue to have an impact on the health of its people because corporate health strategies offer one of the best opportunities to effectively engage adults to maintain and improve health.

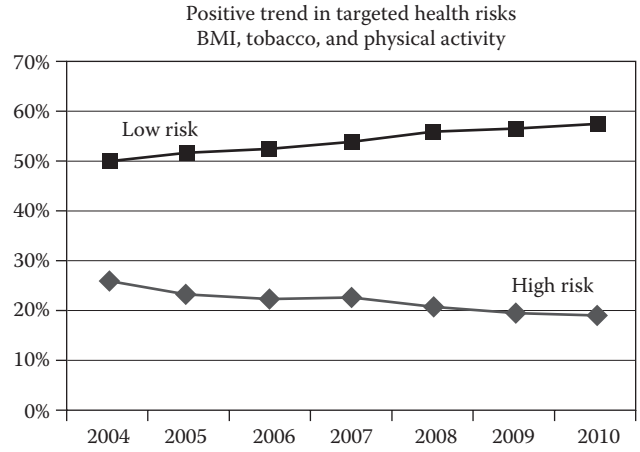

FIGURE 110.1

Community Impact

Beyond Dow employees and their families, the company has a long-standing commitment to the health of the communities in which Dow operates, tracing back to founder Herbert H. Dow. Over the years, Dow has worked hard to establish

- Employee health programs that are recognized for their excellence
- Community advisory panels at all major production locations
- Direct financial contributions to health needs in communities as an integral part of corporate giving
- Medical departments at major sites that work closely with local community health services
- Public health value, because Dow performs and publishes important health research

One example of community partnership is Dow's investment to help establish the Michigan Health Information Alliance (MiHIA), a multistakeholder collaborative covering 14 counties in central Michigan that is dedicated to improving the health of the people in the region through the innovative use of health information. MiHIA is also a Chartered Value Exchange as designated by the Department of Health and Human Services through the Agency for Healthcare Research and Quality. Aligned with the mission is a commitment to advance the cornerstones of value-driven health care through the development and implementation of interoperable health information technology and the dissemination of price and quality information.

LESSONS LEARNED

Worksite health programs, such as those implemented by Dow around the world, are key components of empowering people to take control of their health. The reality is that it is not any single resource, policy, or initiative that works—it is the combination of efforts and a long-term, strategic, and well-integrated program that adds the greatest value. The following aspects are key lessons that have contributed to Dow's success in implementing and maintaining an effective health promotion program:

- *Corporate requirement and strategy*—helps insure that the program is available to all employees and sites and implemented consistently worldwide
- *Strong, detailed business case*—essential to secure management commitment
- *Economic impact*—determine the total economic impact of all health-related costs, both direct and indirect
- *Extensive metrics and evaluation*—complement these by a focus on outcomes and reporting on progress and value delivered
- *Multi-year targets*—metrics and required multi-year strategic plans drive program growth and encourage regions and sites to tailor the program to their critical targets

- *Truly comprehensive program*—prioritize and adjust through regular review of data and best practices, maintain integrity, and focus on serving the health of individuals
- *Organizational integration*—organize into core of the company (leader development, site goals, safety, HR, integrated medical model)
- *Engage stakeholders*—includes local health contacts, internal partnerships, labor organizations, as well as internal company stakeholders
- *Shared responsibility and healthy culture norms*—develop and nurture at individual, workgroup, and leader levels
- *Standard cycle of programming*—a set of global interventions initiate behavior change, develop lifestyles, and create a supportive environment for the priority health targets, focus on continual improvement, and implementation excellence
- *Balance of central and local influence*—a global base of deliverables, which can be easily customized, provides consistency, and allows for local application; this also helps maintain cultural sensitivity
- *HWI*—this supports the creation of a supportive environment that allows individuals to practice and maintain their healthy habits
- *Subject matter experts*—experts for each key risk factor can monitor performance, evidence, and best practices and consult on program improvement
- *Confidentiality*—ensure absolute privacy and confidentiality of all personal health data

Every company has its own unique objectives and challenges. A company-wide health promotion program that addresses these strategic needs while balancing standardization with local customization can lead to healthier people and a healthier company.

INTRODUCTION

The relative importance of a healthy lifestyle on the protection of health and prevention of illness cannot be overstated. On the one hand, chronic diseases are recognized as a major global burden to public health. On the other hand, most of the chronic diseases are preventable in nature as one of the main underlying causes of this premature mortality is modifiable lifestyle behavior. Chronic diseases, such as heart disease, stroke, cancer, chronic respiratory diseases, and diabetes, are by far the leading cause of mortality in the world, representing 60% of all deaths. Out of the 35 million people who died from chronic disease in 2005, half were younger than 70 years and half were women [1]. In the year 2000, the top 10 leading causes of death accounted for more than 1.9 million of the 2.4 million deaths in the United States [2]. Among these leading causes, heart disease (29.6%) and cancer (23%) top the list of reasons for premature mortality.

The notion that modifiable lifestyle behavior represents a causal factor for premature death has been well documented by the Centers for Disease Control and Prevention in the United States [2,3]. Smoking, physical inactivity, poor diet, and alcohol consumption combined account for approximately 40% of all preventable deaths. Research has demonstrated that nearly 90% of the impact from perfect care for heart disease would accrue from interventions before and between acute events—with most impact coming from primary prevention. Risk-factor interventions before or between acute heart disease events is amplified by the fact that these interventions also reduce the risk of death from other chronic diseases [4,5]. Obviously, it is important to ensure the best quality of care for people with diagnosed conditions. However, preventing or delaying the onset of chronic disease would protect at-risk individuals from increased illness burden; reduced physical, emotional, and psychological functioning; increased health care expenditures; as well as lower quality of life. In fact, not only would individuals benefit, others, including children, spouses, and families, employers, health plans, and the community at large, would reap rewards as well.

From a population health perspective, health plans across the United States are in a unique position to reach a vast majority of Americans with health promotion messages. For example, America's Health Insurance Plans (AHIP) is the national association representing nearly 1300 member companies providing health insurance coverage that reaches at least 200 million, or about 65%, of all Americans through its member organizations [6]. Health plans have the opportunity

and capability to influence individuals, groups, decision-makers, policy-makers, and other community stakeholders to direct more attention to the integration of lifestyle behaviors into strategies that address awareness of the importance of healthy living, engagement into actions and programs, behavior change toward healthier activities, and the creation of supportive environments that lead to sustainable solutions [7]. Health plans tend to play an active role in their communities and have obvious relationships with purchasers of health care (government, employers), care delivery organizations (care systems, clinics, physicians, and others), and their members. In this context, health plans have large potential to influence the health care system as a whole toward enhanced focus on the important role of modifiable health behaviors.

Purpose

It is the purpose of this chapter to consider and discuss the opportunity that resides within health systems to integrate modifiable lifestyle behaviors into their products and services, their relationships with other stakeholders, and the potential benefits that may be gained by doing so.

POPULATION HEALTH PROMOTION IN HEALTH SYSTEMS

Promotion of population health makes good sense for health plans. Health in itself may be regarded as a central objective since lack of health is associated with increased health care expenditures. Health plans first and foremost represent an insurance function. As such, health plans are interested in optimizing the management of the financial risk associated with their covered population.

Economic Rationale

In law and economics, insurance is a form of risk management primarily used to evade the risk of a potential loss. Insurance is defined as the equitable transfer of the risk of a loss, from one entity to another, in exchange for payment. Insurance involves pooling funds from many insured entities (known as exposures) to pay for the losses that some may incur. The insured entities are therefore protected from risk for a fee, with the fee being dependent upon the frequency and severity of the event occurring [8].

Specific to health care, health insurance policies will cover the cost of medical services and treatments. If financial risk exposure is lowered, better managed, or more predictable as a result of health promotion efforts, the promotion of better health of the population becomes a business opportunity for health plans.

A treatment-only strategy is not sufficient—strategies that protect and promote health need to be implemented alongside each other in a complementary and integrated manner. Primordial prevention efforts are needed to reduce the likelihood that risk factors for disease occur in the population; primary prevention efforts are needed to reduce incidence of new disease and diagnosis and reduce mortality; and secondary and tertiary prevention efforts are needed to find and treat disease early, prevent exacerbations of existing disease, and reduce mortality [9]. However, disease prevention and health promotion strategies that improve health, reduce the need for health care services, and increase the affordability of health care lie with services that focus on the preservation of health rather than those that disrupt disease progression [10].

As efforts move from primordial to tertiary prevention, per person medical care costs increase. Furthermore, individuals at lower risk tend to have lower overall health care costs for the population (as they are below average), whereas those with health risks or diagnosed disease experience higher health care costs due to their need, demand, and consumption of medical care resources [11]. Those at higher risk tend to incur more costs. Moreover, more than 50% of the highest cost group in a given year is replaced in the following year by people at lower cost in the current year. This concept is depicted in Figure 111.1. Hence, a treatment-only strategy without a comprehensive prevention strategy is not sustainable from a cost perspective and does not shut down the pipeline of disease. Today, the United States spends more than 95% of its health care expenditures on treatment of those with health risks and disease—less than 5% is spent on prevention [12]. The approach of waiting for people to get sick and then treating the ailments is a very expensive one. As Americans see health care expenditures continue to increase, it is important to focus on strategies that reduce the incidence, prevalence, and cost of preventable diseases. Health plans interact with multiple audiences (members, employers, payers, providers, etc.) in a variety of settings (community, workplace, clinic, home, etc.) over an extended period of time and are well positioned to make a meaningful impact on the health of the population. They also have the technical capability to reach their enrollees with health promotion and disease prevention technology [7].

Whereas the discussion so far has centered on health care costs, other economic reasons to worry about ill-health exist as well. Cost drivers besides medical, hospital, and pharmacy costs include disability, workers' compensation, absenteeism, presenteeism (reduced on-the-job effectiveness due to ill-health), recruitment, retention, morale, safety, emergency preparedness, and national security [13–15]. Evidence of effectiveness for many approaches to address these issues exists in the literature today. For example, the Task Force on Community Preventive Services has published recommendations related to worksite health promotion efforts based on strong evidence of effectiveness that shows such programs improve health [16]. This evidence of effectiveness is supported with an economic rationale that indicates a positive return on investment for employers. Several reviews and meta-analyses point to a return on investment for health care costs of approximately 3.25:1 [17,18], absenteeism-related savings of approximately 2.75:1 [18], and intangible, but not less important, returns on higher morale and the organization's culture [19].

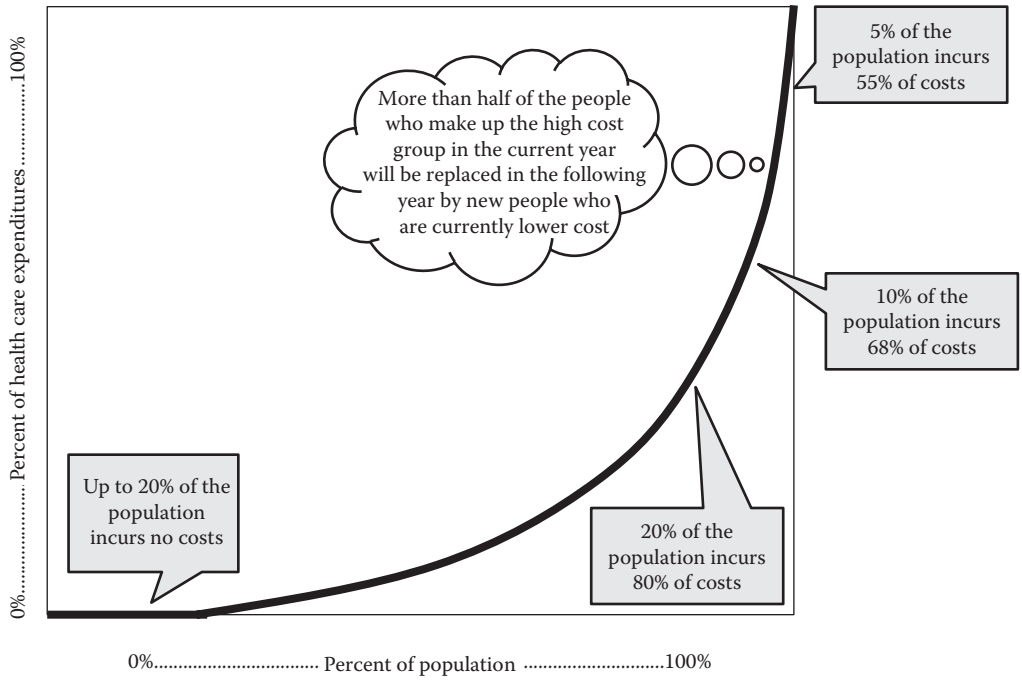

FIGURE 111.1 Health care expenditures by population percentile.

From a societal perspective, cost-effectiveness analysis of community-based physical activity interventions ranged between $14,000 and $69,000 per quality-adjusted life year (QALY) gained, relative to no intervention [20]. In this analysis, interventions exemplifying each of four strategies strongly recommended by the Task Force on Community Preventive Services were evaluated: community-wide campaigns, individually adapted health behavior change, community social-support interventions, and the creation of or enhanced access to physical activity information and opportunities. Each intervention was compared to a no-intervention alternative. All of the evaluated physical activity interventions appeared to reduce disease incidence, to be cost-effective, and based on comparative effectiveness, to offer good value for money. Maciosek et al. [21] carefully considered the cost effectiveness of clinical preventive services in the United States that are likely to be delivered by health plans. In this study, the few services that actually appear to be cost saving included daily aspirin use for men (age 40 years and older) and women (age 50 years and older), childhood immunizations, and advice and support to help adults quit smoking. Considering these results, many stakeholders may benefit greatly from a strategic focus on health promotion as implemented through health care systems. Such a strategic approach would benefit from a framework designed to align the interests of key stakeholders.

Framework for Multistakeholder Alignment

Arguably, for an organization to invest resources into any strategy, the strategy has to generate positive net value. Ideally, this value proposition extends to all of the stakeholders involved—the organization itself as well as its customers. In the context of health systems, four key stakeholders are identified: (1) the individual *person* who receives insurance coverage (and their dependents when applicable), (2) the health *plan*, (3) the *providers* of health care services and treatments (physicians, nurses, care systems, clinics, etc.), and (4) the *payers* of health care (employers, government, individuals). These stakeholders all come together in the context of a larger community, which is influenced by factors such as local or national policies, legislation, and social norms. To make the argument related to the integration of health promotion and disease prevention efforts into a health care system's products and services, a clearly defined set of outcomes is needed that resonate with the value proposition of the entire effort. Here, we argue that those outcomes need to include several domains that come together in a synergistic manner, namely, the simultaneous improvement of population health, per capita costs of care (health care affordability), and individual experience of care and service. This set of outcomes has been introduced in the health care context by the Institute of Healthcare Improvement (IHI) and is aptly named the "Triple Aim" [22]. A framework that is centered on the needs and experiences of the user, generates improvements in health, reduces health care costs, aligns the interests of key stakeholders, and is implemented with explicit goals to connect to the larger community is arguably a strong model for multistakeholder and multisectoral collaboration. Figure 111.2 depicts the framework.

Organizing around the Triple Aim

In 2008, leaders at the IHI introduced an important new and elegant strategy for improving health care [22]. In order to

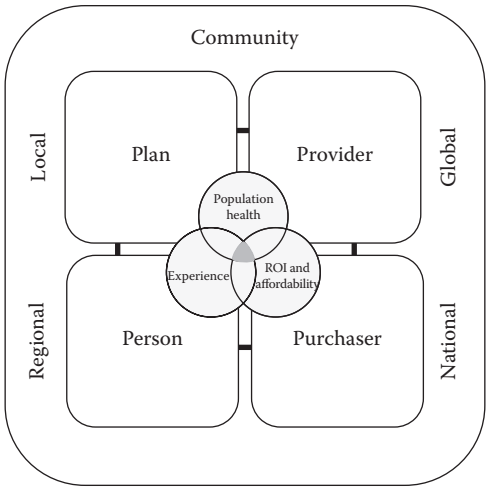

FIGURE 111.2 Alignment of stakeholder and outcomes for health promotion in health care systems.

achieve high-value health care, the IHI proposed the pursuit of a system of linked goals called the "Triple Aim." The IHI Triple Aim defined this set of interdependent health care delivery goals as follows: the simultaneous improvement of population health, per capita costs of care, and individual experience of care. This pursuit of high-value health care as the central objective of the IHI Triple Aim may in itself be seen as a major innovation in stimulating improvements in health care delivery. Since population health is prominently featured as one of the three aims, the IHI Triple Aim provides a significant opportunity for clinical care delivery to move beyond the clinic walls and reach deeper into the community. Such action would represent a departure from traditional care delivery roles, which are largely limited to clinic-based care.

Extending deeper into the community will provide significant potential to pursue and incorporate novel approaches that affect nonmedical determinants of health. Given that estimates of the impact of health care on the health of populations range between 10% and 20% [23,24], it seems reasonable to suggest that the IHI Triple Aim would benefit greatly from a nonmedical determinants of health agenda to increase the likelihood of achieving breakthrough success in population health improvement. Furthermore, in order to achieve significant and sustainable reductions in per capita cost of care following initial elimination of unnecessary care costs, population health improvement is a prerequisite since changes in health care expenditures represent a lagging indicator that *follows* changes in health status of the population [25,26]. Finally, any programs that are implemented in a manner that generates an exceptional experience for users are likely to be rewarded with high participation rates, high satisfaction ratings, and many people willing to refer others into the programs.

One might wonder whether it is possible to actually achieve this notion of the Triple Aim, i.e., simultaneous achievement of population health, exceptional experience, and reduced cost. One successful example comes from the worksite health promotion literature and is the result of a health system collaborating with an employer [27]. In this case study, a successful multiyear employer–health plan partnership generated measurable improvements in population health, high levels of program participation and satisfaction, and an overall return on investment of approximately 3:1. Expressed in medical cost savings, the 3 year program impact accumulated to almost U.S.$1 million, or 3.3% of overall expected medical care costs. In addition, the program savings related to reductions in excess health-related productivity losses were estimated to be in excess of U.S.$1 million.

Another successful example of progress toward the achievement of the IHI Triple Aim includes the experience from the HealthPartners Medical Group related to population-based care for diabetes. Since 2004, HealthPartners has reduced its total cost index from slightly above the Minnesota statewide average to nearly 10% points below the statewide average [28]; HealthPartners Medical Group has increased optimal diabetes care (defined as achieving goal for hemoglobin A1c, blood pressure and cholesterol, the patient is taking aspirin daily, and the patient is not using tobacco) for its diabetes population from 9% to more than 42% of all patients being at goal, and the proportion of patients who would recommend HealthPartners clinics is consistently greater than 95%. This experience is depicted in Figure 111.3.

Four Key Stakeholders

The four key stakeholders identified in the framework are the person, the plan, the provider, and the purchaser—in short, the "4 Ps." Collaboration among the 4 Ps may be facilitated by approaches designed to meet the interests of all—interests represented by the Triple Aim.

The Person

From an individual perspective, health in and of itself is clearly an important goal. Health of all family members is also important. Health insurance is one of the best known and most common means used to obtain access to health care. Increasingly, the evidence points to the negative health and economic consequences related to being uninsured [29]. The integration of additional health promotion services into health insurance products would provide additional value.

Second, when health promotion and disease prevention programs reduce the need and demand for more expensive and invasive clinical care delivery services, the individual will enjoy cost savings as a result of fewer co-payments, avoidance of deductibles, and reduced use of pharmaceuticals. In addition, healthier people tend to miss less work, are less likely to be disabled long term, and return to work faster after injury or illness [25]. Higher physical and psychological functioning brings rewards to the workplace in terms of performance [13] that may benefit the employee beyond wages and employment, per sé.

Furthermore, when the program experience is rewarding, engagement with the program components, participation

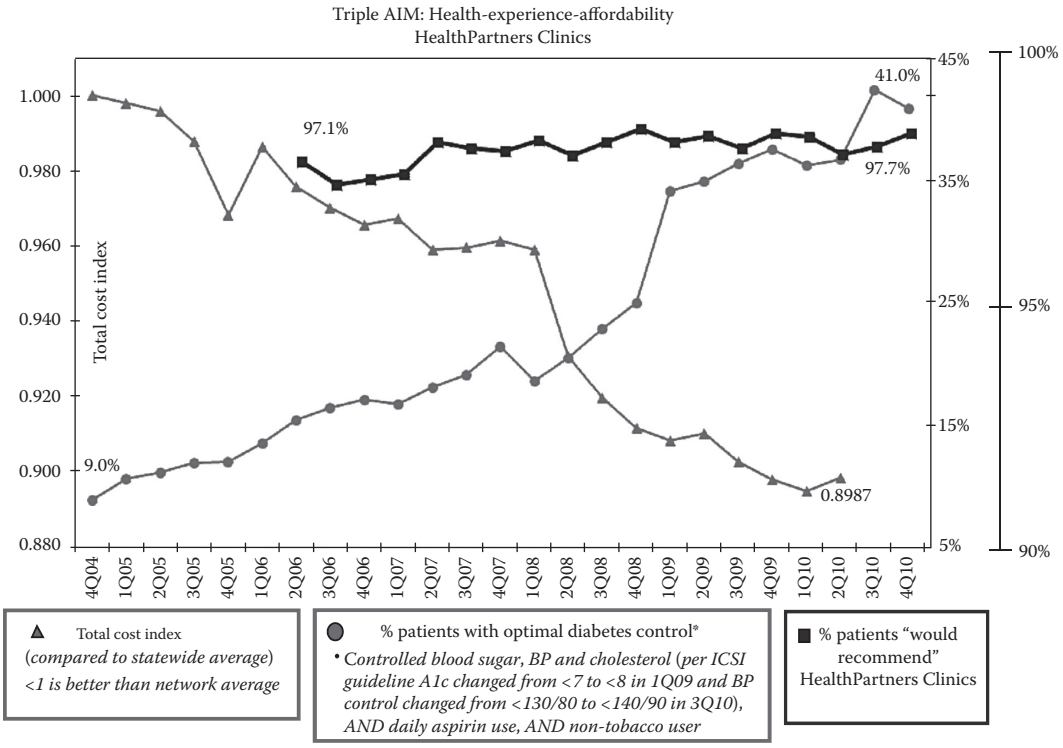

FIGURE 111.3 TRIPLE AIM: Health-experience-affordability. HealthPartners Clinics.

intensity, and adoption of new behaviors is more likely to occur. This is especially important as adoption and maintenance of new behaviors is challenging, but critical, to achievement of long-term health outcomes. A good experience should be associated with ongoing access to health promotion services instead of only linked to short-term, campaign-like experiences. Rather than a focus on programs that last 6–8 weeks and calling out short-term impact on behaviors, ongoing programming should promote long-term participation in healthy behaviors that builds intrinsic motivation for continued engagement. Obviously, a positive experience is a key driver for both short-term and longer-term health outcomes. As the value proposition also attempts to generate cost savings, ongoing engagement and participation in health promotion programs and healthy behaviors will eventually allow for a quantification of a positive return on investment [25,27]. A decision to "do nothing" has been shown to generate significant health care expenditures even in the short-term [25,30].

The Plan

The decision for a health plan or health care system to integrate health promotion into its products and services would first and foremost be related to the potential for reductions in health care costs. The notion that healthy people cost less in terms of health care has been clearly described [11,25,30]. Less agreement exists around the idea that less healthy people can improve their health through adoption and maintenance of healthy lifestyles and thereby lower overall costs. Despite increasingly convincing scientific evidence that has emerged over the past decade indicating that health promotion can improve population health and reduce per capita health care costs, health care systems and health plans have been relatively slow to adopt such strategies. However, as many plans include evidence-based approaches to resource allocation, the fairly recent emergence of evidence of effectiveness based on systematic reviews of health promotion programs will allow barriers to be reduced and innovations in health improvement solutions to occur [31].

The integration of health promotion into health plan services also supports health care delivery services. For example, an overweight, sedentary smoker who, following treatment for cardiovascular disease, attempts to quit using tobacco may find excellent resources in the form of health coaching, access to covered quit aids, weight management programs, or financial incentives to join a local fitness center that are supported by the health plan [32,33]. Providing such services supports clinical care delivery, prevents repeat medical events (such as a repeat myocardial infarction), and avoids repeat hospitalizations among those at high risk and, as a result, saves money.

The Provider

Health promotion services can directly support the efforts of care delivery. In essence, when care teams attempt to optimally manage the health of their patients, consideration needs to be given to the relative role of healthy behaviors, including lifestyle behaviors such as healthy diet, physical activity, no tobacco use, rethinking drinking,

and regular sleep, as well as behaviors more directly related to the care process such as medication adherence and regular preventive maintenance through primary care. In fact, many clinical care guidelines include advice and referral to health promotion services and in many cases consider these services to be first line of intervention [34]. Unfortunately, healthy lifestyle interventions are difficult to deliver in the clinical setting. The reality of busy clinical practices oftentimes limits the physician in time spent with their patient, and prevention may only receive a minute or less during the course of a clinic visit [35]. It is also highly unlikely that physicians will ever have more time to devote to counseling their patients around health behaviors due to the high cost of physician time and the time pressures under which they do their work [36]. As such, many barriers exist for providers to effectively and efficiently incorporate advice and access to follow-up programs and, as a result, this practice occurs far too little. Barriers related to addressing healthy lifestyles in care delivery include, among others [37,38]

- Lack of time to provide counseling
- Lack of financial reimbursement
- Lack of training and background in subject matter (nutrition, physical activity, obesity, etc.)
- Lack of training in counseling techniques
- Lack of organizational support to deliver the services
- A perception that patients do not want the service
- A perception that intervention does not change patient risk or behavior
- A perception that intervention is not the clinician's job
- Lack of confidence to deliver the service
- An overwhelmingly large number patients that need these services
- Perceived lack of referral services in the community
- Perceived lack of scientific evidence that lifestyle interventions are effective
- Lack of commitment to deliver the service

Yet, given the relative importance of healthy lifestyles on outcomes of both prevention and treatment effects of many chronic diseases, it would behoove providers, and especially patients, to engage more fully in such practices. Patients are known to appreciate receiving dietary advice, help in setting realistic goals, and exercise recommendations from their physician [39]. Furthermore, when the goal is to achieve the IHI Triple Aim as delineated earlier and depicted in Figure 111.2, the integration of lifestyle medicine becomes paramount in clinical practice.

The Purchaser

In considering health care coverage, two major purchasers are considered: employers and the government. Certainly, promoting health among the employee (and dependents) population has become a major interest of employer groups in the past few years. Whereas worksite health promotion was recognized over 2 decades ago for its health- and cost-management potential [3], it took longer to generate the data that substantiate the promise of improved health and reduced costs. Major reviews on this topic have painted an increasingly clear picture over the past several decades that worksite health promotion programs improve health and productivity, reduce health care expenditures, and create a positive image for the company that offers them [9,17,40–45]. However, despite enthusiasm and interest in such programs, according to the most recent national survey in 2004, only 6.9% of all worksites in the United States have actually implemented a comprehensive worksite health promotion program according to standards as defined by Healthy People 2010 [46]. Based on the literature, components associated with success include screening and assessment with appropriate feedback and follow-up, health education programming, supportive social and physical environment, integration of the program into the organizational structure, and linkages to related programs such as employee assistance programs (EAPs), work-life balance resources, and others [44,46]. In short, comprehensive multicomponent programs that offer individuals access and choice and are implemented at multiple levels of the company, may be considered informed by evidence of effectiveness [9,44]. In supporting employers in efforts to develop effective programs, the National Institute for Occupational Safety and Health (NIOSH) created a list of 20 essential elements of effective workplace programs and policies ([47]; Table 111.1).

The second major purchaser (also a payer), the government, has traditionally focused on coverage of treatment for disease and clinical preventive services. Disease prevention through support for healthy lifestyle behaviors has not been a focus until the Patient Protection and Affordable Care Act ("the ACA") was passed in 2010 [48]. A major prevention provision of the ACA is the new Medicare Annual Wellness Visit. A fundamental and statutorily mandated component of the Annual Wellness Visit is administration of a health risk assessment (HRA), which is used to gather and analyze much of the information referenced in the statute's menu of elements (e.g., family and medical history, behavioral risks) prior to the office visit, allowing clinicians to spend the bulk of their time during the visit on a personalized and comprehensive conversation about the patient's risk profile and the steps the patient can take to modify that risk. The law specifies that Medicare will cover, without cost to beneficiaries, an Annual Wellness Visit that includes an HRA. Table 111.2 identifies the elements that may be included as part of the Annual Wellness Visit. Despite its appropriateness and comprehensiveness, the preceding list of required procedures and screening activities is not likely to be easily implemented within the context of a time-limited office visit appointment.

TABLE 111.2
Elements of the Medicare Annual Wellness Visit as Directed by the "ACA"

- Establishment of a beneficiary's medical/family history
- Establishment of a list of current providers and suppliers who are regularly involved in providing medical care to the beneficiary
- Measurement of an individual's height, weight, BMI (or waist circumference, if appropriate), blood pressure, and other routine measurements as appropriate, based on the beneficiary's medical/family history
- Detection of any cognitive impairment that the individual may have
- Review of the individual's potential (risk factors) for depression, including current or past experiences with depression or other mood disorders, based on the use of an appropriate screening instrument for persons without a current diagnosis of depression, which the health professional may select from various available standardized screening tests designed for this purpose and recognized by national medical professional organizations
- Review of the individual's functional ability and level of safety based on direct observation, or the use of appropriate screening questions or a screening questionnaire, which the health professional may select from various available screening questions or standardized questionnaires designed for this purpose and recognized by national professional medical organizations
- Establishment of a written screening schedule for the individual, such as a checklist for the next 5–10 years, as appropriate, based on recommendations of the United States Preventive Services Task Force (USPSTF) and the Advisory Committee on Immunization Practices (ACIP), as well as the individual's health status, screening history, and age-appropriate preventive services covered by Medicare
- Establishment of a list of risk factors and conditions for which primary, secondary, or tertiary interventions are recommended or are underway for the individual, including any mental health conditions or any such risk factors or conditions that have been identified through an Initial Preventive Physical Examination (IPPE), and a list of treatment options and their associated risks and benefits, Furnishing of personalized health advice to the individual and a referral, as appropriate, to health education or preventive counseling services or programs aimed at reducing identified risk factors and improving self management, or community-based lifestyle interventions to reduce health risks and promote self management and wellness, including weight loss, physical activity, smoking cessation, fall prevention, and nutrition

ACA, Patient Protection and Affordable Care Act.

Community Context

The proposed framework (Figure 111.2) recognizes the community context in which the stakeholders operate. This context is represented by the local, regional, national, and global community representing an environment in which not only local (site-based, townships, cities, etc.) policies and protocols influence activity but also the larger aspects of civil society, the competitive marketplace, the relative influences of a community's health and welfare, and the context of global forces that influence the health and well-being of a population. In the context of community, multiple determinants of health should be considered—not only those that may be considered in the context of health care or health systems.

Clearly, there are more to health than health care alone. In fact, most of a population's health status is not determined by the health care sector [23,24]. Whereas access to health care is in itself an important determinant of health, other determinants, such as the social gradient, early-life experiences, education, employment, poverty, access to transportation, clean air, clean water, and a built environment conducive to healthy living, represent factors that, when acted upon, are of vital importance to population health improvement [49]. Gross inequalities in society influence the opportunities that people have and the choices that they make. These opportunities and choices, in turn, have a direct impact on the health of the population—to quote the Commission on Social Determinants of Health's report: "Social injustice is killing people on a grand scale" [50]. Furthermore, health inequalities significantly impact costs to society associated with managing the ill-health effects of such disparities. As a result, health disparities negatively impact the economic prosperity of society and addressing them improves not only population health but also the economic vitality of communities,

regions, and the nation as well. As outlined by Dr. Joseph Stiglitz and colleagues, the establishment of healthful natural and built environments and equitable social and economic policies and institutions not only ensure happiness and harmonious relations among the population but also address security among people [51]. Hence, nonmedical determinants of health extend their impact beyond health-related outcomes alone and reach economic, interpersonal, and safety outcomes and experiences. These important nonmedical determinants cannot be assigned to a medical diagnoses code or tied to reimbursement, and they are not mentioned in the list of most important clinical preventive services [21]. Even so, they must be addressed as part of an integrated multisectoral health policy agenda.

Approach to Healthy Lifestyle Integration

Based on the early work of Dr. Michael O'Donnell [52] and adapted to reflect a more contemporary context, an approach for the integration of lifestyle medicine in health systems may be organized around four components: (1) awareness, (2) engagement, (3) behavior change, and (4) supportive environments. These four components provide a powerful organizing principle to improve the health of populations since together they can act complementarily, additively, or synergistically. One component by itself may have some success, but only by taking them together can optimal impact be achieved. In particular, the creation of supportive environments is paramount since this level of programming will enable and support individuals to adopt and maintain changes in behavior.

Awareness

Awareness programs are designed to increase a person's level of knowledge, awareness, or interest in a certain health topic. Whereas these programs may affect an individual's belief, attitude, and knowledge on the topic, they usually do not result in significant increases in the desired behavior. Hence, awareness programs by themselves are not effective. However, they improve outcomes when offered in conjunction with programs that engage people in health actions and behavior change. This issue has been clearly demonstrated by the recent worksite reviews conducted by the Task Force on Community Preventive Services [16,45]. The assessment of health risk with feedback (AHRF) may be considered an awareness program as it is defined as the collection of health information, translation of this information into a risk status or category, and the provision of such risk information to the participant. The Task Force found insufficient evidence to determine the effectiveness of AHRF when implemented by itself as a primary intervention. However, the Task Force found sufficient or strong evidence that AHRF plus health education programs generates significant health outcomes in the areas of tobacco use, alcohol use, physical activity, seat belt use, dietary fat intake, blood pressure, total cholesterol, summary health risk scores, number of lost days from work, and use of a variety of health care services.

Engagement

Whereas awareness programs relate to a person's knowledge and interest in a health topic, engagement goes deeper and refers to the degree of motivation and participation in health actions. Engagement is a necessary step in bridging the gap between awareness and successful behavior change. Individuals need to try new behaviors, model those behaviors in their own environments, and adapt to such new situation in a positive manner. Indicators of engagement may include participation, time spent in the health activity or new behavior, degree of interest expressed in feedback, general satisfaction with the program, and willingness to refer others into the program, among others.

Health systems have direct relationships with individual members and those members also represent patients in the clinical setting. Members may also be employees in the workplace setting. The effective use of benefit design, communication methods, incentives, and behavioral economics [53] has the potential to spur people into action and create supportive environments in the clinical, occupational, and economic environments of the member.

Behavior Change

Adoption and maintenance of new lifestyle behaviors is a challenging task for most people. The successful and long-term adoption of new behaviors such as nonsmoking, regular exercise, healthful eating, or to discontinue harmful drinking requires personal motivation, support from others, continued reinforcement, and positive feedback. Despite such challenges and difficulties, population-based programs designed according to identified success factors have shown to positively move the entire population to an improved level of health status over the short-term as well as over the longer-term. Edington [54] has shown a natural flow of risk transitions over the course of 3 years—the natural flow is negative in that an increase in health risks are experienced over time in the absence of health-promoting interventions. Loeppke et al. [26] used a similar risk transition format to describe the intervention effect of a prevention program and reported a net improvement in population health level of 13.5% as compared to the natural flow expected based on Edington's model, which would have been −7.1%. Another population-based example of a multiyear program reported a net improvement of 6.1% in modifiable behaviors over the course of 3 years of intervention although this change model used different parameters than the Edington model and they can therefore not be directly compared [27]. One of the strongest reports providing evidence that it is possible for populations to improve their level of health through lifestyle modification comes from the diabetes prevention program [55]. In this study, conducted as a randomized controlled trial, a lifestyle intervention of 3 years induced 5.6 kg of weight loss, and 58% of the group had increased their levels of physical activity enough to meet guidelines for health benefit. The result was a 58% reduction in risk for type 2 diabetes.

Supportive Environments

Supportive environments are critical for adoption and maintenance of healthy lifestyle behaviors. Physical and social environments are the context in which individuals work, play, and live their lives. Humans are affected by characteristics of their physical, cultural, social, and economic environments. When the environment makes healthy choices the easy choices, it is more likely that larger numbers of people succeed in living healthfully and, thereby, successfully prevent or delay premature morbidity and mortality. The food that is eaten depends largely on the food that is available and accessible—it is not merely a matter of personal preference. Food preference is very much related to marketing and pricing and how people perceive its value [56]. The level of physical activity is related to the environment, too, not only to an individual's intention to be active. Prolonged sitting, an emerging independent health risk factor, is largely a result of the continued decline in occupational physical activity over the past 50 years [57]. Tobacco use has decreased dramatically since policies were instituted that banned smoking from public places, including worksites [16,31]. Hence, attitudes, beliefs, and value are affected by the macroenvironment in which individuals live. When this macroenvironment remains a barrier to the adoption and maintenance of healthful living, programs aimed at influencing individual behaviors may be expected to have little impact. Figure 111.4 represents the concept that individual efforts made toward optimizing one's health potential are supported, or hindered, in large part by the public policies that shape the physical, social, and economic environments of communities.

Health systems have many opportunities to create supportive environments. Examples include health benefits designs that create incentives for individuals to engage in their own health, employers (purchasers) to promote health, and providers to focus on health. Prompts that come from the plan to remind people to come in for their clinical preventive services (these may be sent electronically using secure web-mail or as a simple mailing), reminders regarding access to services to support smoking cessation, enhance physical activity levels, or achieve a healthy weight.

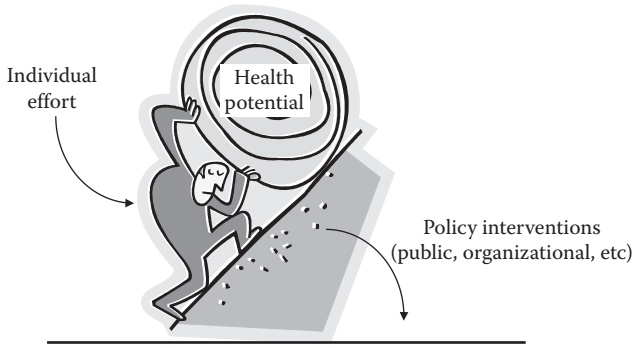

FIGURE 111.4 Making healthy choices the easy choices.

STRATEGIES AND TACTICS

Framework for Action

One component of the National Physical Activity Plan is a framework for promoting physical activity in the business and industry sector [58]. This framework has been adapted here to reflect a focus on health in general and an introduction of example tactics. The result is depicted in Table 111.3. Horizontally, the factors outlined ensure that health improvement can happen, is likely to happen, and may be adopted and sustained by considering the notion that it is possible for individuals and groups to improve health, recognize that they are incented to do so, and connecting the efforts to ongoing activities within the larger community. Vertically, the framework recognizes the importance of action at multiple levels. Strategies to promote, adopt, and maintain healthy lifestyle behaviors long-term need to be supported by specific tactics that can be implemented at the level of individuals, groups, organizations, and the environment (physical, social, economic, etc.). It is important to carefully select individual, team, organizational, and environmental-tactics in order to ensure a balanced approach to successful implementation. In the words of Sun Tzu, "Strategy without tactics is the slowest route to victory. Tactics without strategy is the noise before defeat." [59]. Taken together, strategies and tactics create a powerful method to generate successful outcomes of initiatives to improve the health of the population. Considering the grid outlined in Table 111.3, several specific tactics are inserted in the cells of the grid which may be helpful to envision how this framework may be used to create a strategic and tactical plan.

The framework outlined in Table 111.3 also serves to connect the tactics to the overall strategic approach depicted in Figure 111.2. In order to successfully implement programs that simultaneously generate an exceptional experience, population health, and a positive return on investment (i.e., achieve the Triple Aim), the process of implementation should be carefully considered since participation in health improvement programs is paramount to successful outcomes. In the absence of participation, nothing happens to population health. Without population health, any economic outcomes observed cannot be attributed to health promotion efforts. As such, to paraphrase Elliot Freidson [60], "the process used to improve health constitutes a dimension quite as distinct and fully as important as the outcomes it generates."

Program Mix

Besides the process used, the choice of interventions also needs to be carefully considered. Here, it is important to consider multiple program topics that address a variety of health needs, to provide choices for individuals, to deploy multiple modalities for program implementation, and to select those interventions that show the highest likelihood for success.

TABLE 111.3
Framework to Support Connecting Strategies with Tactics to Improve Population Health

		Make Being Healthy …						
		Possible	**Simple**	**Socially Rewarding**	**Financially Rewarding**	**Personally Relevant**	**Organizationally Relevant**	**Community Connected**
Level of influence	Individual	Easily accessible program options		Individuals recognized for achievement		Choice of program tailored to personal need		
	Inter-individual			Groups recognized for achievement				
	Organizational						Health system analyses indicate lower cost as health improves	
	Environmental		Opt-out design facilitates exposure and engagement		Participation linked to preferred health benefit differential			Health actions include community resources

Note: Examples of tactics are inserted for illustrative purposes only.

Evidence-Based Approaches

When it comes to implementing health promotion programs, following evidence-based practices is increasingly recognized as a prudent way to optimally use scarce resources. Many programs have been identified as being "evidence-based" and health systems should take full advantage of available resources that outline such programs. In general, when faced with resource allocation decisions, preference should be given to those interventions that come with evidence of effectiveness versus those that do not. Decisions to apply resources toward programmatic solutions are often challenged by demands and cycles of accountability within the political context that are based on a need to satisfy short-term demands or interests. Many health systems, however, have already built evidence-based principles into their decision-making processes that relate to clinical care delivery. Since 1984, the U.S. Preventive Services Task Force (USPSTF) is a well-known reference for that purpose [61]. When considering community preventive services, the Task Force on Community Preventive Services [31] systematically reviews the evidence of effectiveness for interventions in the realm of health promotion and disease prevention. The Task Force on Community Preventive Services leads the development of the Guide to Community Preventive services ("the Guide") and makes its recommendations and reviews available via the web (see: www.thecommunityguide.org), publications, presentations, and other tools, products, and services. Other institutions that provide excellent recommendations based on systematic reviews of all the scientific literature related to a given intervention include the National Institute for Health and Clinical Excellence in the United Kingdom (see: www.nice.org.uk) and the Cochrane Collaboration (see: www.cochrane.org).

Program Topics

Depending on the setting in which the health system supports the implementation of programs, selection of program topics and interventions needs to be carefully considered. For example, if a health system partners with an employer group, a comprehensive, multicomponent, and multilevel program tends to be most likely to generate successful outcomes [58]. On the other hand, if the health system implements a direct-to-member strategy to improve health, a more tailored or topic-specific approach may be preferred. As such, topics for health improvement may be selected from a long list, and a wide variety of activities may be associated with any given topic. Topics may include physical activity, tobacco cessation, weight management, sleep hygiene, stress management, resilience, healthy nutrition, rethinking drinking, preventive services, and medication adherence, among others. Within each topic, activities may range from pedometer walking programs to half-marathon training programs for physical activity or pay-for-performance programs for care delivery to reduce tobacco use among members to supporting referral to state quit lines for tobacco cessation.

From a health system's perspective, it may make sense to focus on those topics that are most strongly related to member health burden, avoidable health care costs, and for which effective interventions exist. Physical inactivity, poor diet, heavy alcohol consumption, and cigarette smoking have been identified as actual causes of death in the United

States since they cause type 2 diabetes, cardiovascular disease, stroke, elevated blood pressure, certain cancers, back pain, high cholesterol, and other chronic conditions [3]. Occurring in clusters, these behaviors are responsible for approximately 40% of all deaths, nearly 80% of chronic diseases, and, through their association with chronic disease, are related to nearly 75% of all medical care expenditures in the United States [62,63]. Simultaneous adherence to these four lifestyle behaviors is associated with lower mortality from cardiovascular disease and all-causes in both men and women [64,65]. Furthermore, among adults, adherence to these four behaviors is associated with short-term, 2-year incidence of chronic disease in a dose–response manner [66], and also correlates with indicators of emotional health [67]. Whereas these associations are certainly bi-directional, messaging around the adoption of a lifestyle that is physically active, where an individual does not use tobacco, misuse alcohol, and eats five servings of fruits and vegetables daily is very much common sense. Simply put, adherence to one of these four is better than none, more is better than some! Alternatively, a "just add one!" message would be right on target.

PATIENT PROTECTION AND AFFORDABLE CARE ACT

At the time of this writing, health systems, employers, care delivery organizations, and a host of other organizations dealing with health care in the United States are working to understand the implications and changing to ensure compliance with the PPACA [45]. When considering the opportunity for health promotion and modifiable lifestyle behaviors to be addressed in the health systems setting, a lot will depend on the incentives that will drive the actions of each of the 4-Ps identified as the four stakeholders in this chapter. Alignment of their incentives around health objectives or, perhaps more importantly, around the Triple Aim, will present opportunities for health promotion strategies to be deployed. Whereas cautious optimism exists that this may be the case, it is too early to tell and it remains far from clear to delineate how this may happen.

One promising development delineated in the ACA is the introduction of Accountable Care Organizations (ACOs) in the community. The ACA requires the secretary of health and human services to establish a shared savings program for groups of health care providers that join forces, with or without hospitals or health plans, to form legal entities that agree to take responsibility for the quality, cost, and overall care of a population of patients [68]. In case the savings of such a program will be related to the "total cost of care" related to a defined group of people receiving services from an ACO, it would make a lot of sense for such ACOs to ensure that the healthy people of this population stay healthy, those who are ill receive high-quality care, and those at risk for costly care receive close monitoring to prevent avoidable hospitalizations.

SUMMARY

This chapter has presented an overview of the opportunities that reside within health systems to integrate modifiable lifestyle behaviors into their products and services, their relationships with other stakeholders, and the potential benefits that may be gained by doing so. An economic rationale has been presented supporting this approach, and frameworks that may guide this work have been introduced. In order to position health promotion as an integral part of what heath systems do, the incentives need to be aligned with those of several other key stakeholders, most importantly the providers of health care, the purchasers of health benefits, and insured persons. As health care in the United States moves into its next iteration, integration of health promotion remains understated in its importance to help achieve the central objectives of cost containment and improved population health. Yet, in this age of dramatic change in the health care industry, health systems are uniquely positioned to draw upon the potential health promotion offers to align the stakeholders and generate outcomes of mutual interest.

INTRODUCTION

This chapter reviews the financial impact of worksite health management (WHM) programs and the quality of the evidence in light of the utilized study methodology. The authors will provide a brief overview of WHM and then focus the majority of the chapter on a review of the literature demonstrating the financial impact as well as the issues associated with evaluating such programs. WHM can be understood as a type of population health management focused on the worksite. Pronk[1] defines population health management at the worksite as "the strategic and operational processes used to generate the health outcomes of a defined group of individuals collectively associated with a company's health improvement efforts." WHM has been in place for several decades. As an example, O'Donnell's first textbook on WHM was published in 1984.[2] WHM has gained increasing popularity over the past 5–10 years as noted by the Mercer National Survey of Employer-Sponsored Health Plans findings on program prevalence. The 2010 Mercer National Survey of Employer-Sponsored Health Plans is the longest running survey of its kind and indicated increases in prevalence of health risk assessments, disease management, and lifestyle management programs of employers with 500–20,000 employees[3] (see Figure 112.1).

The rationale behind the increasing implementation of WHM programs involves several factors. One of the most common motivations among employers to implement WHM program is in an effort to mitigate increasing medical costs. While the overall rate of increase in medical costs has varied over time, trends are consistently two or more times greater than the Consumer Price Index (Figure 112.2).

Another reason for WHM promotion as a cost management strategy is that employers realize cost shifting is a short-term strategy and that eventually they will have to stop placing additional costs on the employee. Furthermore, with the U.S. health care reform phasing in, employers cannot shift costs too much or they will violate regulations around plan affordability, and if overall premiums become too high, employers face an excise tax. Therefore, given the limitations to cost shifting and the constraints of health care reform, more employers will continue to seek WHM strategies. In addition to the health care cost containment issues, WHM activities have impact on health care outcomes such as absence and productivity[4–10] serving as another piece in the business case rationale.

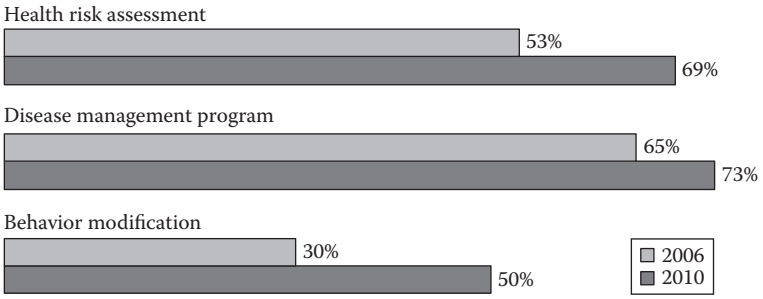

FIGURE 112.1 Rate of growth in WHM activities.

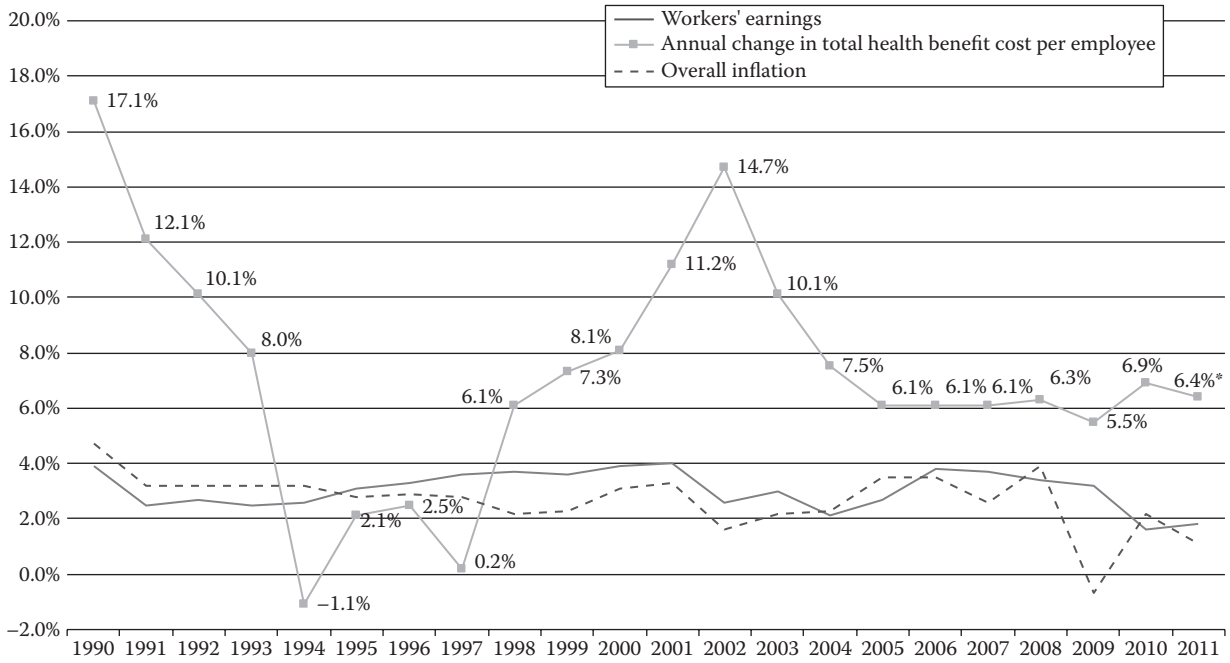

FIGURE 112.2 Health care cost trends and benchmarks. Source: Mercer's National Survey of Employer-Sponsored Health Plans; Bureau of Labor Statistics, Consumer Price Index, U.S. City Average of Annual Inflation (April to April) 1990–2010; Bureau of Labor Statistics, Seasonally Adjusted Data from the Current Employment Statistics Survey (April to April) 1990–2010.

Finally, the worksite is an ideal location for population health management interventions because it provides a(n)

- Cohesive audience
- Ability to modify physical environment and organizational policies such as tobacco use
- Opportunity for repeated exposure
- Chance to influence behavior through incentives and cultural norms

While there is a healthy skepticism by some business leaders as to the value of WHM, there has been a tremendous amount of knowledge accumulated over the past 30 years to help employers implement effective programs.[4,6,7,11] For example, one researcher with a long-term historical perspective, talks about the past 25 years in health promotion and the positive results of programs in both commercial and public sector.[12] However, some skepticism stems from poor past experiences potentially related to ineffective programs that were not implemented according to best practice approaches or that did not have a chance to benefit from more recent advances in the industry. There have been a number of articles that document WHM best practices.[13–16] One research study describes the relationship between identified best practice characteristics of WHM programs with increase program engagement and greater reduction in health risk.[16] Nine best practices were identified: comprehensive program design, integrated incentives, integrated comprehensive communication plan, strong senior management support, dedicated on-site staff, multiple program modalities (phone, mail, online), population-based awareness building activities, biometric health screenings, and vendor integration.

The Health Enhancement Research Organization (HERO, www.the-hero.org) Scorecard is another example of quantifying best practice approaches and benchmarking among employers. The scorecard is a tool that assesses WHM programs on the following dimensions: corporate culture and leadership commitment, strategic planning,

communications/marketing promotion, program components, benefit design, incentives, program coordination, data management, and evaluation. Each area is given a score and weighted to combine for an overall score. Participating employers can compare their scores with other employers as well as use the tool as a planning guide. Other organizations, such as the National Committee for Quality Assurance (NCQA, www.ncqa.org), URAC (formerly the Utilization Review Accreditation Commission; www.urac.org), and the National Business Group on Health (NBGH, www.wbgh.org) also have tools to review program quality and whether the programs meet standards associated with a higher probability of success.

Understanding best practice approaches helps program evaluators determine whether the reason for the lack of program outcomes was a result of a truly faulty program design or due to poor implementation. In many cases, poor outcomes and lack of return on investment (ROI) are a product of less than best practice implementation rather than a flaw in the WHM science and rationale. As an example of strong best practice implementation and outcomes, one can note the programs that qualified to win the C. Everett Koop Health award. Those winners all report impact on both health improvement and health care cost savings. Likewise, the Centers for Disease Control and Prevention (CDC) funded research on WHM best practice approaches and found few companies take advantage of key practices toward assessing the need for services, attracting participants, using behavioral theory as a foundation, incorporating multiple ways to reach people, and making efforts to measure program impact.[17]

FINANCIAL IMPACT OF DISEASE MANAGEMENT PROGRAMS

It is important to remember the initial definition of WHM as we consider the research on the financial impact of these programs. The definition is general in nature and encompasses programs that range in scope from focusing on chronically ill populations for disease management to those at risk for illness by virtue of lifestyle, as well as wellness populations that need to be reinforced for healthy behaviors. WHM programs may include some or all of these programs and target some or all of the population described. This variation in program offering and population target can add to the complexity of comparing research. For example, research conducted by Goetzel et al.[18] on disease management is an important follow-up to the Congressional Budget Office study that found limited positive financial evidence supporting disease management programs,[19] although they did find evidence showing programs improved clinical and process-related measures. This study focused on research with financial impact measures of disease management programs and more specifically, those articles where an ROI was calculated or could be calculated based on the data presented. The study covered asthma, congestive heart failure (CHF), diabetes, and depression.

The authors' review indicated an overall positive ROI for CHF programs and programs covering people with multiple conditions. Evidence for diabetes seemed to indicate a positive ROI, but studies on asthma and depression looked as though they might cost more than they save. Although the authors' conclusions are consistent with the data reviewed, they acknowledge that the analysis is highly limited as noted in the following list:

1. The number of studies reviewed was small and generally 2001 or earlier.
2. Sample sizes tended to be small.
3. There was tremendous variation in types of programs implemented. Most programs were not "population based" as there were any number of exclusion criteria used in the analysis.
4. Age and gender of the population varied across studies.
5. Studies' designs and evaluation methods were very limited and subject to bias such as regression to the mean, selection bias, poor financial metrics, and lack of baseline or appropriate comparison group.
6. Review methodology grouped studies according to whether they were randomized clinical trials (RCTs), controlled before and after studies, or descriptive before and after studies. There were very few RCTs that reflect the current implementation models.

General skepticism on limited impact might also be fueled by another review of disease management[20] until one notes several key points regarding the article:

1. The author's main theme is that there are inconclusive published data available to determine the savings impact of disease management programs.
2. Methodology used by researchers is not rigorous or sensitive enough to detect financial program impact.
3. The author only found three large-scale published studies to review. Two studies focused only on diabetes and did show net savings. The third study covered multiple diseases and showed improved care and lower increases in the participant group but no net savings.
4. The other studies reviewed tended to be small demonstration projects focusing on high-risk groups that don't easily generalize to commercial populations.
5. The study was a review of reviews, so there may have been something lost in the translation.
6. The dates of the studies go back to 1990, which are not representative of today's approach.
7. There were no long-term studies available. One year was the typical study period.
8. Key findings:
   a. Improved quality of care and disease management process
   b. Net savings in two of the three large studies
   c. Inconclusive evidence, to date, to "prove" disease management yields net savings

Bottom Line: More Research and Better Methodology Are Needed to Evaluate Programs

If the program can improve the clinical process, we assume that the outcomes will also improve. Disease management programs seem to improve the process (i.e., quality of care) for those engaged in the program. Contacting, reaching, enrolling, and engaging identified populations are major challenges for disease management. The cost associated with the engagement process can outweigh the benefit if only a few members are engaged. More effective outreach and incentives for participation will help drive a positive ROI at the population level.

Interestingly, these articles are focused on disease management, which is sometimes generalized to WHM, but there is more evidence for positive savings for wellness programs than for disease and case management. Furthermore, it is very important to note that the disease management studies rarely report net positive savings in year 1. Disease management studies occasionally report positive impact in years 2 and beyond, which is consistent with what the theoretical models would suggest (i.e., uncovering problems, which generate short-term increase in utilization but avoidance of high cost services). As further support of the disease management model, Mattke et al. note that depression disease management increases costs and utilization, which is exactly what they are designed to do in the short term.[20] In that way, they reduce costs for other comorbid disease states as well as mitigate any long-term catastrophic costs.

One major challenge to determining the impact of WHM programs is the limited number of published studies on program impact within the past 5 years. This is an understandable phenomenon given most WHM programs are implemented by employers with a business motive to contain costs and improve productivity. While employers want to measure their program impact to justify program investment, they have limited motivation to publish the findings in peer-reviewed journals. Most studies on WHM are conducted by academics, vendors, and the rare employer willing to invest in the cost of conducting a rigorous analysis. Therefore, given the limited number of studies available on the topic, this section of the chapter will recap the literature reviews in the field and then discuss several studies conducted within recent years to give a start to what will be the basis for a critical mass of evidence for modern best practice programs as well as further documentation of health management financial impact.

LITERATURE REVIEW ON THE FINANCIAL IMPACT OF WHM PROGRAMS

There has been an increasing need for a review and synthesis of the impact of WHM programs given the growing interest by employers and policy makers to use WHM as a primary health care cost containment and productivity enhancement strategy. There have been a number of literature reviews conducted in the past 10 years that tend to focus on the wellness programs within WHM and some have included disease management as well.[4,6–8,18,20–22] The problem is that with few new studies being published, these reviews tend to review the same studies, include reviews in the review, and cover commercial (WHM) and public sector (Medicare and Medicaid) populations in the same review without differentiating the very different program challenges present in the varying populations. One review that conducted a meta-analysis did not take into account the quality of the evaluation being conducted, the difference in program scopes, or the variation in populations.[21] Other reviews reported out the study findings in an objective format, but again took the findings on face value. One review attempted to weight the study findings by research design quality and convert the outcomes to total population metrics such as impact on total health care costs.[22] Those researchers looked at health promotion programs separately from disease management programs as well as combining the two (Table 112.1).

TABLE 112.1
Health Care Cost Impact and ROI from WHM Programs

	Health Promotion		Disease Management		Employee Health Management	
	Low Range	High Range	Low Range	High Range	Low Range	High Range
Average savings (% impact on medical costs)	2.20	2.76	1.01	1.27	3.22	4.02
Average ROI	3.0:1.0		2.0:1.0		2.5:1.0	

The earlier review of reviews indicates consensus of positive ROI and health impacts based on reviews that span at least two decades. Research still needs to refine these program impacts over time, program types, populations, and settings. While not being reviewed here, there have been some studies on the relationship of organizational culture and program impact that have also showed a powerful effect of factors beyond program services.[16,23]

The following is a review of recent studies that demonstrate strong methodology, analyze a specific program intervention, and provide evidence for program impact. They also reflect the latest best practices and program innovations in a rapidly evolving program landscape. Few studies are conducted of comprehensive interventions but most address the total population in one way or another.

DISEASE MANAGEMENT

Review of recent studies in the disease management arena has revealed several interesting studies, but as a review by de Bruin et al. indicates, the evidence is inconclusive.[24]

There are studies that demonstrate impact on specific programs. For example, one recent study conducted by Wennberg et al. provides strong evidence for the impact of telephone-based coaching for those with chronic conditions.[25] This study used a randomized control design to document the incremental benefit of enhancing the standard care disease management approach to predictive modeling, outreach, and frequency of contacts. The intervention arm of the studied termed "enhanced care," which entailed outreach to a larger portion of the population by lowering the threshold for eligible participants, was compared to an existing commercial program. The findings indicated that in the population with the enhanced care, average monthly medical and pharmacy costs per person were 3.6% ($7.96) lower than the population with the usual support ($213.82 vs. $221.78, $P = 0.05$). A 10.1% reduction in annual hospital admissions ($P < 0.001$) accounted for the majority of savings. These findings may seem modest but are compared to those in standard disease management who may also be experiencing savings. The authors did not compare the enhanced care group to population of individuals with chronic conditions who did not receive some level of treatment. In addition, the savings are presented "per member" not per participant. Given roughly, 10% of the members have a chronic condition, and only a portion participated; the savings per participant would be significantly higher. The authors indicate the cost of this intervention program was less than $2.00 per person per month and therefore provides a strong return on the investment. Again, it is important to note that the price is per all members, not just those with a chronic condition. This raises another complexity when comparing research—the measurement of savings is not consistent. Savings are reported in a variety of ways including per member, per identified, and per participant. When comparing results, it's important to be aware of these nuances.

Another disease management study that looked at cost of care, utilization, and quality used a strong evaluation approach in a fee-for-service environment and also included complex care management as part of the intervention.[26] The evaluation of the difference in utilization was based on the difference in the cost per-member-per-month (PMPM) in a 1 year measurement period, after adjusting for differences in fee schedules, case-mix, and health care benefit design. After adjustments for both case-mix and benefit differences, the study group was $63 PMPM less costly than the comparison population. Interestingly, the effect increased with age. Cost differences are largest in the 55–64 years and 65 years and above age groups. The study group was $115 PMPM lower than the comparison population for the age category of 65 years and older.

Most of the published research included in literature reviews tends to be on either mail- or phone-based delivery channels. A rapidly growing program modality involves the web-based delivery of disease and lifestyle management programs. This study examined the impact of a web-based disease management program on medical cost among health plan members.[27] The study used a matched cohort design in a retrospective quasi-experimental approach. The sample size was 413 participants and 360 nonparticipants, all members of the same health plan. The web-based program was a rigorous program requiring ongoing engagement and program interaction, all within a broader health management context that, in some cases, included telephonic support. The researchers considered participants, only those members who completed all requirements of the program and for whom claims were available during the evaluation period. The results yielded significant financial impact of $757 per year less for participants as compared to matched nonparticipants. Authors indicate this is a ROI of almost 10:1. It is important to note that self-management web-based program may not be applicable to all members, but of those that engage in them, there appears to be a significant impact although this type of return is considerably greater than those typically reported and may be a function of the methodology used to assess program impact.

Another form of medical management involves the process of medical claims monitoring and alert systems. While technically not a disease or lifestyle management program, these activities often serve as the basis of outreach for disease management nurses and provider compliance programs. The interventions tend to involve direct communication with providers and, in some cases, the employee or health plan member. The intent is to increase provider and patient compliance with evidence-based medicine. One study done in 2005 and then a follow-up in 2008 used a claims data-based sentinel system to improve compliance with clinical guidelines.[28,29] The evaluation used a randomized prospective design and found among those in both intervention and control groups who triggered recommendations 19% fewer hospital admissions in the intervention group compared with the control group ($P < 0.001$). Health care charges among those whose recommendations were communicated were $68 PMPM lower among controls compared with the baseline values ($P = 0.003$). Paid claims for the entire intervention group (with or without recommendations) were $8.07 PMPM lower than those for the entire control group. The authors note that the intervention cost $1.00 PMPM, suggesting an eight-fold ROI. In a follow-up study, the researchers analyzed the effect of a decision support tool designed to help physicians detect and correct medical "missteps." The key findings were that the new information technology lowered average charges by 6% relative to the control group. This area of intervention has grown into what is also known as "gaps in care" interventions and is often used as a basis for how programs prioritize care management plans.

The focus of this chapter is on financial impact; however, it seems relevant to acknowledge the clinical basis upon which the financial impact is said to follow. In addition to the aforementioned studies on increasing compliance with evidence-based guidelines, a study conducted by Pimouguet et al. reviewed the effectiveness of disease management programs specific to diabetes that focused on improving glycemic control in adults found consistent results.[30] Programs on average provided about 0.51% reduction in hemoglobin

A1c levels. One theme of this meta-analysis was that they found a positive relationship between program impact and patient contact. A second and recurring theme throughout the literature was the relatively modest clinical impact of the programs.

LIFESTYLE MANAGEMENT

Lifestyle management programs address behavioral risk factors typically identified and targeted through screenings and health risk assessments. Lifestyle management has been a core element of WHM programs for more than a decade. Targeted programs aimed at those members at moderate and high risk is thought to be an effective approach to population health management. One review of the research on the impact of using health risk assessments and follow-up feedback indicated a positive impact on health risk change but did not evaluate financial impact.[9] However, a study by Naydeck et al. assessed the impact of a comprehensive WHM program for Highmark employees on health care costs over a 4 year period.[31] The study used an external control group to compare the participant change versus similarly matched nonparticipants. The results of the multivariate *models estimated health care expenses per person per year as $176 lower for participants. Inpatient expenses were lower by $182. Four-year gross savings were $1,335,524 compared with program expenses of $808,958, therefore yielding an ROI of $1.65 for every dollar spent on the program. This study contributes to the limited data on evaluations of multiyear programs. Another study of a program that has been in place for 30 years looked at the past 6 years of program impact on health care costs.*[32] *The evaluation measured the participant company's, Johnson & Johnson, health care cost experience* against similar large companies. Johnson & Johnson experienced average annual growth in total medical spending that was 3.7% points lower than the similar large companies. Company employees benefited from meaningful reductions in rates of obesity, high blood pressure, high cholesterol, tobacco use, physical inactivity, and poor nutrition. Average annual per employee savings were $565, producing an ROI equal to a range of $1.88–$3.92 saved for every dollar spent on the program. The most recent study available on a comprehensive population health management program was conducted for three years of program operation and included lifestyle and disease management as well as nurse line (Serxner et al. 2012).[33] The authors used multivariate regression to control for selection bias and understand the independent as well as incremental contributions of each program to the overall cost impact. While the ROI in year 1 was not positive, the following 2 years were positive which yielded an overall 3 year ROI of $2.45:1. By year three the participant health care cost increase was 8% compared to increases for the non-participants of 11.4%.

Further evidence for positive impact of WHM programs comes from the Healthy Lifestyle Incentive Program conducted with Salt Lake County, Utah, government employees over a 5 year period.[34] That comprehensive program, aimed at improving health behavior as well as preventing and controlling chronic disease, showed that over a 5 year study period, the cost savings in lower prescription drug and medical costs was estimated to be $3,568,837. A study of health promotion in a health plan population looked at the impact of health assessment, biometric screening, follow-up counseling, and online lifestyle management programs. The results of this 4 year evaluation showed that participants incurred consistently lower costs than risk-matched nonparticipants. Predictive modeling of upward cost trajectories relative to actual health care costs for participants and risk-matched nonparticipants indicated a savings of $350 per participant per year. These four studies, Johnson & Johnson,[32] Highmark,[31] Salt Lake County,[34] and HMSA,[27] combine to show a promising trend for sustained long-term program impact on health care costs.

A study by Nyman et al. found significant savings for disease management but not for lifestyle management.[35] Only small savings were detected for reduction absence with disease management participation. Interestingly, they only found disease management impact on the "big 5" conditions (asthma, diabetes, coronary artery disease, CHF, and chronic obstructive pulmonary disease), not all 11 conditions for which they had programs. In the case of musculoskeletal conditions, there was an increase in cost. Also of note was while the second year of program participation produced cost reductions, they were lower than the first year. Participation in the general disease management program over 2 years was associated with significant reductions in expenditures (approximately $1000 per year per participant averaged across conditions and various analyses), as was participation in programs for certain specific diseases. No consistently significant absenteeism or lifestyle management effects were found. Overall, the program (combined disease and lifestyle management) did not generate a positive ROI.

As noted earlier, a rapidly growing intervention modality is web-based programming. A 2011 study by Williams and Day attempted to assess whether an insurer-provided web-based wellness program resulted in cost and utilization improvements.[36] The web-based programs ranged from disease condition topics to self-care to lifestyle risks such as stress and smoking. The evaluation involved comparing participating employees to nonparticipants using generalized linear mixed models to study changes in costs and utilization while matching for differences between the two groups. Costs of program participants showed a lower rate of increase in 2004 and then dropped below those of the nonparticipants for the duration of the study. Between 2003 and 2007, the increase in medical expenditures of the participant group was significantly less than that of the nonparticipant group (31% vs. 46%). In addition, the participant group showed a lower increase in professional service expenditures and greater utilization of preventive services. The authors conclude that web-based insurer-provided wellness programs may decrease health care costs and encourage preventive service utilization. Another web-based WHM program looked at the effects of an incentive-based physical activity on health care costs.[37]

The employer (IBM) analyzed a matched sample of participants and nonparticipants on medical and pharmacy costs prior to program participation against program years. The results showed that participants average annual health care costs increased by $291 compared with an increase of $360 for nonparticipants ($P = 0.09$). Participants had significantly lower inpatient hospital costs as well as cost related to hear disease and diabetes. It appears that web-based WHM programs and disease management programs may have a positive impact on reducing health care costs.

In addition to telephone, mail, and web programming, there has always been on-site programming since the advent of WHP. Historically, on-site clinics focus on occupational issues and dealt with regulatory health surveillance and workers' compensation issues. More recently, the role of the on-site clinic has evolved to become more prevention and primary care oriented. Employers see on-site programming as a way to further engagement their population as well as reduce time away from work for medical visits. One study examined the impact of on-site nurse practitioner program on employee health care costs.[38] The researchers evaluated the program using two methods. One method compared actual to projected claims and the second method looked at nine major diagnostic areas accounting for almost 90% of the total claims. The first method yielded 8.7:1 ROI and the second yielded a 2:1 ROI. Taking a conservative perspective and adding any reduction in time away from work would indicate that the program provided a worthwhile benefit to the employee and employer.

Based on the earlier selected review of studies, there seems to be continued evidence that WHM does provide financial savings and a positive ROI, albeit modest in many cases.

WHM EVALUATION METHODOLOGY CHALLENGES

While the earlier review has served to provide a good context for estimated program impact, the discussion only briefly noted the methodological considerations that go with those study findings. This section will highlight major challenges involved with evaluation of WHM programs and make recommendations for enhanced approaches. One factor contributing to the limited number of published WHM outcomes studies is the degree of difficulty in conducting a rigorous program evaluation study. Another key factor is the applied nature of the environment in which the intervention occurs. This applied context poses a number of challenges as compared to a more controlled environment. The following are a few examples:

- *Interventions can change during the measurement period*—Employers are more concerned about results, employee experience, and budget than maintaining a consistent intervention to preserve study quality. Often employers will modify the intervention during the study period to improve participant experience, drive improved results, or be more efficient with limited resources.
- *Carriers/provider change*—Based on pricing, contracts, business relationships, and perceived or demonstrated performance, employers may change one or more of the vendor partners providing the program and services. This change introduces data issues as well as program continuity issues.
- *Data quality/access*—Financial impact studies of comprehensive WHM programs are data intensive requiring multiple years of data and involve many variables (demographic, program participation and outcomes). Each set of data may be located in with a different vendor and when located with a data aggregator may still have data integrity issues. Gaining access to multiple sources of data and linking them to a unique identifier require significant effort to assure data quality while maintaining individual-level confidentiality. Additionally, health care claims data can take months to mature, which can delay reporting and analysis.
- *Employee tenure*—Most outcomes studies involve some form of cohort design. However, in the worksite setting the members are constantly coming and going. Organizations experience varying degrees of turnover and even have different turnover rates within divisions. Employee tenure can introduce bias in the study and must be addressed in the analysis as well as in the extrapolation of findings.
- *Business environment*—The business environment is the overriding context in which the WHM program and evaluation occurs. If the business needs to shift priorities toward increasing production, containing costs, or marketing products, they may increase or decrease the workforce, reduce the WHM budget (and interventions), postpone the interventions, or limit the evaluation budget. All of the issues can affect the nature of the intervention, the study design, and the ability to conduct a rigorous analysis.
- *Benefits mentality*—WHM programs are provided as an employee benefit and as such are made available to all eligible employees/members. Withholding services is inconsistent with that philosophy and a general sense of fairness, all of which makes random assignment difficult or not an option in most worksites. Without random assignment, a number of threats to validity, such as selection bias and regression to the mean, require solutions.

Supporting data must also be considered as context to understanding findings on program savings and ROI. Often program impact and savings will be presented without information on the number of participants identified, targeted, enrolled, and engaged in a given program. Without information on the "participation cascade" the link to gross savings is difficult. Credible outcomes require having measures on leading indicators such as program engagement, risk reduction, and health service utilization. Furthermore, generalizability

analyses comparing the study sample to the total employer population must be conducted in order to understand the validity of extrapolating the savings from the study sample to the broader employer population.

Other challenges in WHM program evaluation and determining an ROI have to do with incorporating broader measures to address productivity and absence. In many organizations, quality absence data are not available and self-report productivity measures are viewed with less credibility by many employers. Productivity is acknowledged as a key impact of WHM programs, but employers are reluctant to include productivity savings in the ROI calculation. The focus tends to be impact on total medical and medication spending.

Working with claims data is a specialized skill set in addition to those required to conduct program evaluation analyses. Health care claims tend to be highly skewed with a large portion of the distribution having zero or small claim and a small portion of members having very large claims. Analysis needs to account for both ends of the distribution by addressing outliers as well as the skewed distribution. This topic will be addressed in the recommended methodology section of this chapter.

Two other issues that can introduce variation across studies are how key metrics are operationalized and the employers vary in terms of populations and programs, which can make generalization of findings difficult. One example of the operationalization issue is that of defining participation. Is an individual considered a participant if they register for a program, take one call with a coach, two calls or "graduate"? Employers, program providers, and researchers have no standard definition of participation for interventions or by modality such as what constitutes participation in web-based or mail-based programs. These definitions have important implications since many studies compare participants to nonparticipants, but if in one study, a participant is someone who simply enrolls and in another study a participant must graduate, comparing the two analyses would be challenging. Likewise, the control groups will be very different since the nonparticipant group might include some "participants" in one study but not in another.

WHM EVALUATION METHODOLOGY RECOMMENDATIONS

The discipline of WHM promotion has evolved dramatically of the past two decades. Probably one of the most important additions is that of disease management programs. With the advent of disease management programs, WHM began a full population health management approach; however, the disease management industry used very different evaluation and reporting approaches than the health promotion management industry. Most notably is the wide application of a trend-based evaluation for disease management compared to a statistical or health impact model for the health management industry. As the prevalence of disease management grew so did the interest in documenting ROI and the concern with the credibility and accountability of the standard practice methodology. To further the concerns of employers, as programs began to cover the health continuum, multiple program providers were implementing programs and claiming savings, which lead to a double counting or overestimation of savings. Recently, there has been movement in the industry to raise the standard of methodology. Several major program providers have started to adopt more rigorous approaches.[39] One of the industry organizations, the Care Continuum Alliance (formerly the Disease Management Association & America), has issued version 5 of their outcomes guidelines that provide a broad review of best practices that include a statistical approach to WHM program evaluation but make no specific recommendation on which methods provide the most credible evaluation results under which circumstances.[40] At least one major benefits consulting firm has been promoting an individual-level multivariate approach over the population-based trend methodology.[41]

Individual-level multivariate analysis—The following description of WHM evaluation guidelines is an enhancement to work published by Serxner et al.[42] Some of the key enhancements are the focus on using a two-stage regression approach to address selection bias. The recommendations discuss various options for creating a matched case control or using the propensity score in a regression model to predict "difference in difference" health care costs, utilization, and productivity changes. This approach is based on creating an individual-level database that includes detailed program participation information, demographics, and outcomes. The analysis involves using non-participant-derived financial outcomes compared to participant-derived financial outcomes prior to program implementation and for program years. The difference between this approach and the comprehensive population-level trend approach is that this approach involves using multivariate statistics analyzing individual participation records to document the program experience of each member, and then linking that intensity of participation with outcomes measures such as medical costs, prescription drug costs, and productivity measures. In addition to creating unique categorical participation variables, demographic variables such as age, gender, plan type, and geographic location should be part of the individual member record and controlled for in the analysis. For organizations that have detail participation data, this approach assesses the independent contribution of each discrete program component and eliminates any overlap in savings calculations or "double counting." A dose-response type of relationship can then be established to determine the incremental or additive benefit of each program component. The following is a description of the recommended approach; however, each evaluator will have to adapt the methodology to the specific situation based on available data, programs being evaluated, and the nature of the claims and participation data. Therefore, the following are guidelines to help evaluators and reviewers of literature determine the most rigorous approach for each context.

This approach is for a two-stage individual-level, multivariate analysis to measure the savings estimate for the ROI calculation. Outlined in the following is an overview of the methodology that the program evaluator will use to conduct the annual analysis. The proposed multivariate methodology assumes, through the use of statistical matching or propensity score weighting methods and covariates (e.g., adjusting the groups for differences in age, gender, and health risk burden), that the analysis can create a statistically valid (i.e., no statistically significant differences between participant and comparison groups on key variables) comparison model for nonparticipating and participating members.

Methodology Overview

The methodology compares nonparticipant outcomes to participant outcomes prior to program implementation and for each program year. Multivariate statistics are used to analyze the relationship between individual participation and outcome measures such as medical and prescription drug claims over time. Stage 1 of the process involves creating a comparison group using one of several methods (i.e., multi-pass matching, propensity score matching, propensity score weighting, or propensity score as a covariate). Stage 2 regression analysis involves comparison of participant and nonparticipant groups on financial, utilization, and productivity outcomes along with a robust covariate selection to control for differences that may not have been fully addressed in the matching process (i.e., stage 1). Through these methods, a quasi-experimental design will be constructed based on variables related to significant differences between the participant and nonparticipant groups controlling for selection bias as well as regression to the mean and other threats to validity. The final design and operationalization of the methodology should be mutually agreed upon by the parties in writing.

Eligibility

1. Eligibility should be defined in an identical manner between the Base Period and Reporting Period based on client benefits eligibility or program specific guidelines.
2. Individuals will be included in the analysis only if they have 6 months or more of continuous eligibility in both the Base Period and Reporting Period. In addition, an individual must be identified for inclusion in the program during the Reporting Period for at least 3 months.
3. The Base Period and Reporting Period group eligibility should be a minimum of 12 months. Individual eligibility requirement should include a minimum of 6 months of eligibility in both the Base Period and Reporting Period. Additionally, exposure (i.e., months identified for inclusion in the active care management portion of the program) should be included as a primary covariate in the analysis.
4. Analysis will be on active members between the ages of 18 and 65 years.
5. Individuals may be excluded entirely from the analysis for the following reasons:
   a. Coverage through Medicare carve-out
   b. Retired persons
   c. Certain procedures or conditions such as:
      i. Diagnosed with end-stage renal disease
      ii. Diagnosed as HIV positive or have AIDS
      iii. Received an organ transplant
6. Active participation in any program results in qualifying as a participant.
   a. Participation in any year qualifies as participating in that year
   b. In order to be considered as a participant in a program, the participant must engage in one or more counseling calls with a nurse/coach and meet the eligibility requirements listed earlier (note: definition of program participation may vary by vendor).

Base Period and Reporting Period Timeframe

One year of eligible member level claims costs (major service areas such as inpatient, outpatient, emergency room visits, professional services, and prescriptions for at least 6 months) prior to program launch will form the base period. Reporting population claims included should be symmetrical with the 12 month base period and reporting period eligibility. Baseline and measurement periods may be conducted on a calendar year or indexed basis (i.e., based on the participation engagement date). In general, indexing is preferred.

Trend and Cost Assumptions

Participant medical and pharmacy costs will be converted into an average per PMPM cost.

Regression Models

1. *Stage 1*: Comparison group: Using a multipass or logistic or multinomial regression process, an equivalent nonparticipant group will be developed. Results of the regression (propensity score) may be used to create a matched group or as a weighting variable that can be applied to eliminate differences between participant and nonparticipant groups.
2. *Stage 2*: Independent variables: The following variables are not meant to be a comprehensive list of factors to be considered and instead a subset of those most likely to be included in the multivariate model.
   a. *Participation*: Mutually defined in non-overlapping mutually exclusive categories
   b. *Demographics*: Age, gender
   c. *Clinical profile*: Including, but not limited to, disease state, level of comorbidities, health risk level, clinical standards of care compliance

   d. *Utilization history*: Including count of inpatient stays, outpatient visits, and emergency department utilization. Additionally, ICD-9 and CPT utilization, both the specific occurrence of and combination of
   e. *Participant risk*: Risk score derived from proprietary predictive models, episode risk score, resource utilization band, weighted average comorbidity index, or similar proxy
3. *Dependent variable*: Total and PMPM medical and prescription drug claims costs, utilization (inpatient, average length of stay, emergency department visits, etc.), and productivity measures.
4. *Modeling fundamentals*: Since the analysis involves repeated measures or longitudinal data, panel data and models appropriate to the distribution of the data (e.g., generalized estimating equations with gamma distribution) will be used. The inclusion of both participant and nonparticipant data within the same econometric model and the effect of the program by the parameter estimate for the interaction of group membership and time will be valid if the participant group and nonparticipant group are shown to be balanced on key demographic and cost variables.

As noted earlier, program evaluations have adopted the two-stage regression approach and the use of propensity scores to address the potential selection bias between participants and nonparticipants. The use of matching, weighting, or the score as a covariate has potential merits. The key enhancement to prior individual-level multivariate analyses is that the evaluator be able to demonstrate that process was employed that equalize the two groups on critical variables such as demographics, baseline costs, and health service utilization prior to conducting the second-stage regression analysis to determine impact on outcome measures of interest. Additionally, the second-stage regression should take into consideration the distribution of the data on their original scale (i.e., without logging the dependent variable, which presents retransformation issues) and the correlation of data over time, where appropriate.

DISCUSSION

Reviewing the studies of WHM seems to provide general consensus that these programs tend to provide a positive ROI. However, the results of any WHM study need to be considered within the context of detailed understanding of the exact nature of the program and the methodology used for evaluation. For example, the programs reviewed in this chapter ranged from medical data surveillance to lifestyle management. Some programs were delivered telephonically and others used web-based technology. Even within a given program area, such as disease management, there is tremendous diversity in the frequency, content, and quality of coaching calls across different program providers and worksites. The point is that sweeping generalizations about whether WHM has a financial impact can be misleading since the category of programs is broad, and the variability within program offerings can be significant. Additionally, evaluation methods do matter and have a dramatic effect on results. While enhanced two-stage statistical models have been accepted as the standard in the peer-reviewed literature they have not been widely adopted in the program provider community. Lack of consistency in programs offered and methods for evaluation creates a major challenge in summarizing the state of the art in WHM program impact.

Given the cautions about understanding the nature of the programs being offered and the methods used for evaluation, there was a theme across many of the programs reviewed. Overall, the programs provided positive but modest impacts. For example, a. 5% reduction on H1c means that an individual with a 10 only brings her level to a 9.5 when the target for most diabetics is 7 or less. The study on disease management by Wennberg et al. reported a 3.6% cost reduction in the participant group, but savings where limited to only five conditions.[25] The modest savings reported in many of these studies for participants or for a select group of participants need to be spread across the total program cost to justify the investment.

The business decision with regard to whether to invest in WHM programs is complicated and as with most business decisions involves weighing the costs against the opportunity. The level of rigor involved in this decision varies by organization, but in the case of WHM is also constrained by the lack of available quality studies on the topic. Estimated savings opportunity can be assessed by reviewing prevalence of risk and chronic conditions in a population, but estimating the probability for having an impact is more difficult. In addition, there are new considerations in calculating the cost of WHM programs. For example, recently, many programs include incentives for members to participate in WHM programs. Incentives have evolved from simple gifts to cash to lower health care premium contributions to richer plan designs. It can be difficult to assign a specific cost to the later incentives and many studies neglect to include any incentive costs in the ROI calculations. Other costs that may be overlooked are the costs of changing a culture by engaging leadership, implementing robust communications, and modifying the physical environment. Also difficult is assessing the potential success in changing the culture and, in turn, the effect that may have on driving positive program outcomes.

There are limitations to the published literature on the WHM that go beyond those of methodology or consistent program implementation. One such limitation is termed the "file drawer effect" of the phenomenon whereby only studies with positive results are published creating a publication bias in the literature. It is unclear how many unsuccessful program evaluations have not been disseminated, but clearly, this absence of balanced findings adds to the challenge of estimating program impact. One other challenge in deciphering results is that each analysis uses a different unit of analysis (e.g., per member, per identified, per participant, per employee but with spouse costs included as employee costs). The different units of analyses make it difficult to compare savings when the savings basis changes dramatically across studies.

WHM is growing in prevalence and continues to be considered a valuable method for improving population health as well as managing costs. Reported results of these programs have varied widely and, in some cases, been met with skepticism. The challenge for WHM is translating science into practice and in turn into a viable value proposition for business. The science of WHM draws on public health, psychology, economics, and many other disciplines. The multidisciplinary science used to develop programs that help people make positive behavior change serves as the framework for WHM but can be difficult to operationalize or provide programmatically on a population-level scale. The field of WHM has evolved over the past few decades to serve larger and more diverse populations through leveraging data, enhanced technologies, multidisciplinary training for practitioners, and robust clinical systems. However, there is still tremendous variability in WHM program design, implementation, and quality. All these factors provide a challenge when comparing one program to another. Continued program measurement and monitoring against best practice targets can begin to yield light on which programs and components are providing the most impact to support the credibility of the value proposition being made to business.

Going forward, quality and consistent implementation will be the key to participant engagement and ultimately to driving positive outcomes. Programs need to be data driven and science based to yield the highest probability of success. As worksites solve engagement issues through the combination of incentives, communications, and culture, the focus will increasingly be on quality and efficacy of the WHM programs. Commitment to quality measurement methodology and the resources required for the evaluation will serve providers by helping them improve their programs and generate a credible basis for their value proposition while at the same time serving the participant by providing relevant quality programs that ultimately help to improve their health.

EXECUTIVE SUMMARY

A Tale of Two Stories

This chapter is our view, as told through two stories: the twentieth century maturing of health promotion and the twenty-first century transformation of health promotion into a serious mandate for creating positive health and high-performing populations. At the University of Michigan Health Management Research Center (HMRC), the two stories represent our focused research direction first from 1978 to 2010 and second from 2006 to present.

A focused research direction (story) begins with an intuitive or simplistic concept based on previous data and proceeds through the complexity of verifying (or not) the original concept and emerges on the back end as a simple easily understood conclusion. As Einstein said, "… if you can't explain it in simple and easily understood terms, you don't understand it well enough …."

The two stories are related in that they cover the development of the past and future of healthy and high-performing workplaces, workforces, and countries worldwide. Our prediction is that healthy and high-performing workplaces and workforces will be the competitive and cooperative advantage of the twenty-first century, whereas labor costs were the competitive advantage during the past three decades. Anything less than healthy and high-performing workplaces

and workforces in the twenty-first century will threaten sustainability of the organization and put the future of that population (workforce, community, and country) at risk of becoming irrelevant.

First Story

This story extends from the early formulation of worksite health promotion programs in the late 1960s and early 1970s, with their initial objectives of disease prevention, to their maturation in the early years of the twenty-first century. Health promotion programs at the worksite have traditionally focused on the reduction of health risks and improvements in healthy behaviors defined as the opposite of the precursors to disease. These precursors to disease were formulated by the early population studies at Framingham, MA [1]; Tecumseh, MI [2]; and other large-scale studies. The recognition of the complexity of the risks and behavior precursors and formulation of the Health Risk Appraisal was by an Indianapolis physician, Dr. Lou Robbins, after observing his own patients and the results of the population studies; the work in Canada; and the further development of algorithms and computerization by the Centers for Disease Control and the Carter Center in the United States [3].

The details of the first story can be found in the first section of *Zero Trends: Health as a Serious Economic Strategy* [4]. Table 113.1 documents the progression of understanding about three critical concepts: the natural flow of a population, the development of the business case for health promotion (worksite wellness), and the beginnings of transformational strategies for the twenty-first century.

Second Story

The second story arose out of the serious questioning of the outcomes and fundamental approaches developed by the practitioners of health promotion during the 30 years captured in the first story. In February 2008, we asked a team of experienced analysts, "Other than the precursors to disease, what could be the determinants of a healthy and high-performing workplace and workforce?" The answers we got were then pursued in the scientific literature to satisfy four criteria: can it be measured; is it connected to short and long-term costs to an employer; is it suitable to a questionnaire; and can it be reduced to one or two questions (for a paper questionnaire). If so, we included that determinant in the draft of the next-generation HRA. This work took 3 years. In the fall of 2010 and spring of 2011, we asked a similar question to every group we encountered, "If you worked for a very high-performing organization, how would you describe the workplace and workforce." In every case, we got the same responses we heard in early 2008. We feel these expanded health and business determinates of health plus a systematic, systemic, and sustainable business strategy will dominate the future of health promotion in the twenty-first century.

TABLE 113.1
University of Michigan Health Management Research Center Progression of Learnings: 1980–2010

Timeframe	Learnings
1980–1990	Establish the integrated data warehouse and databases for several companies
	Implement health risk appraisals
	Move from mortality to utilization and cost outcomes
1991–1992	High-risk persons are high cost by individual and/or cumulative risk (0–2, 3–4, 5 or more)
	Absenteeism shows same relationships to risks as medical costs
1993–1994	Excess costs are related to excess risks
	Cost changes follow risk changes (medical and pharmacy)
1995–1996	Risk combinations are the most dangerous predictors of cost
	Low-risk maintenance
	Resource optimization—targeted, specific risk combinations drive change in costs (Trend Management System)
1997–1998	Benchmarking by wellness score and company health score
	Participation relates to risk and cost moderation
	Program opportunities: preventive services, low-risk maintenance, high-risk intervention, and disease management
1999–2000	Presenteeism as a measure of productivity and influenced by risks and disease
	Total value of health defined to the organization
2001–2002	Natural flow established for risks and costs (the do-nothing strategy)
	Cluster identification
	Focus on the person, not risk or disease
	Cost changes follow risk changes
	Time away from work respond the same as medical costs
2003–2004	Improved population health status results from employer sponsored programs
	Proof of concept must bend the cost trends
	Health Management Scorecard: 90%–100% participation; 75%–85% low risk; and 85% stay low risk over time
2005–2006	Preretirement participation influences postretirement participation
	Presenteeism cost changes follow risk changes
	Interventions have severe "stepdown" participation
	Zero trends as an outcome
2007–2008	Don't get worse
	Help healthy people stay healthy
2009–2010	Zero trends: health management as a serious economic strategy
	Champion companies
	Culture of health
2010–2012	Best practices to next practices
	New cultural and community assessments
	Next-generation healthy life assessment

The purpose of this chapter is to introduce the reader to a transformation in the way health promotion approaches a positive healthy and high-performing workplace and workforce in America and across the world. The things we have done in the past fell short of an optimal outcome measures capable of fulfilling the promise of worksite health promotion. Therefore, we need an expanded transformational strategy if we intend to impact the health, well-being, and performance levels of the workplace and workforce around us. First, we'll briefly review the field of health promotion so we can determine why all of our efforts yielded limited positive results. Then we'll discuss the changing landscape of the twenty-first century. Finally, we'll describe the strategic systematic, systemic, and sustainable model that will drive the future of health promotion into the coming decades of the twenty-first century.

CONSIDERING THE PAST AND PRESENT OF HEALTH PROMOTION

Brief History of Health Promotion

Before we discuss the future of health promotion, it is important to recognize the history of this field. While health promotion efforts existed in even the most ancient of civilizations (such as devising methods to provide clean drinking water or dispose of sewage), we will limit our discussion to the modern efforts of health promotion, which began in the 1950s as the medical profession became aware of how health behaviors were linked to health risks, disease, morbidity, and mortality through studies such as the Framingham Heart Studies [1].

The World Health Organization currently defines health promotion as "the process of enabling people to increase control over their health and its determinants, and thereby improve their health" [5]. This broad definition encompasses many different facets of health promotion, while our discussion will mainly be restricted to the efforts of organizations such as corporations, municipal organizations, health insurers, and care providers.

As noted earlier, the Framingham Heart Study and others like it were the first indicators that our lifestyle as Americans might be contributing to early morbidity and mortality. In the initial stages of this field, it was thought that as soon as individuals were educated about how their health behaviors might negatively impact their health, they would take steps to change those behaviors. This was the driving force behind early efforts, which mainly consisted of health education. The health risk appraisal (HRA) tool was conceived by Louis Robbins [6] and further developed by Canadian and the U.S. Centers for Disease Control [7] as the primary source for gathering health risk information in a given population. Usually, a report was returned to the participant that acted as a principal health education tool. Corporations, health insurers, physicians, municipalities, and other groups began to offer health education classes, activities, or printed information to further edify individuals. These programs typically focused on individual health risks. Weight management classes were recommended to an overweight individual, while smokers were encouraged to attend cessation programs, for example.

Several theories of behavior change were proposed in the early decades of health promotion research. Examples include the Health Belief Model [8], the Theory of Reasoned Action [9], the Social Cognitive Theory [10], and others. There was no shortage of ways to explain why and how people might change their behaviors. One of the most popular was (and continues to be) the transtheoretical model of behavior change, also called the Stages of Change model [11]. This theory states that for any single behavior, individuals exist along a continuum of six stages of change ranging from precontemplation to contemplation, preparation, action, maintenance, and termination. Behavior change was adopted as the intuitive health promotion strategy and was the dominate strategy for several decades. As diagramed in Figure 113.1, behavior change was positioned as the central strategy for changes in lifestyles, healthier individuals, better employees, and gains for the organization. But if we've learned anything from these models, it's the fact that changes in behavior are very complicated; just like the people who are making, or not making, them.

Since corporations were the main payers of health care in the late twentieth century in the United States, they often led the efforts to provide health promotion activities for employees. While there were altruistic motives for instituting these programs, a chief goal was also health care cost control. Some of the landmark studies were those that established the link between health risks measured by commonly used HRAs and economic outcome measures such as health care costs, pharmacy costs, and productivity costs [12–15]. The evidence for this association justified the cost of providing health promotion activities for employees and also provided ways to measure the success of those efforts.

Health Maintenance Organizations (HMOs) have a long history [16] but really caught the attention of employers

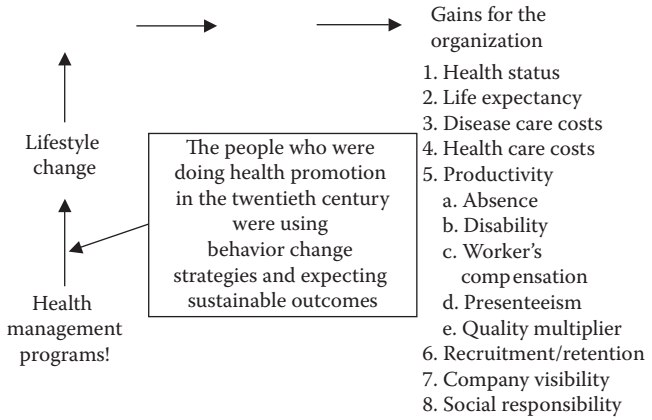

FIGURE 113.1 Health promotion using behavior change as the dominate strategy in the twentieth century.

in the late 1980s and early 1990s. They are prepaid health plans that enroll members and provide care through a designated provider network. HMOs marketed themselves as being prevention-oriented and a better way to help people stay healthy rather than waiting to treat them until they were sick. By the end of 1996, about a quarter of the U.S. population was enrolled in one of the more than 600 HMOs. However, participant dissatisfaction with managed care led insurers to alter their key cost-containment strategies such as closed panels of doctors, primary-care gatekeeping, and preadmission authorization [17]. Furthermore, HMOs abandoned their original goals of providing wellness management rather than simply sickness care in favor of strategies to directly control costs.

During this same period, corporations made concerted efforts to improve workplace safety and return-to-work programs as strategies to lower accident rates and disability leave costs. These programs generally achieved great success. The Occupational Safety and Health Act of 1970, which created the National Institute for Occupational Safety and Health and the Occupational Safety and Health Administration, likely, were the impetus for improvements that many companies made [18]. A literature review supports the concept that employee safety training creates hazard awareness and safe work practices at a wide variety of worksites [19].

Outcome measures that were used to gauge the success of health promotion efforts in the 1970s through the year 2000 were prevalence of health risk factors, avoidable deaths, mortality rates, infectious disease rates, incidence of disease, injury rates, environmental hazards, preventive services compliance, and disease management process measures. As programs progressed and the research base was established, organizations were able to move toward the use of economic outcomes to measure the success of their health promotion efforts. These measures included health care costs, productivity costs, cost-effectiveness of interventions, pharmacy costs, recruitment, and employee morale. Return on investment (ROI) research compared the cost of programs with the avoided cost of disease and showed some promise in a few cases, but evidence of widespread success was still lacking [20–22]. This deficiency of evidence was caused by many factors but primarily by a lack of understanding of the impact of the individual as a complex interrelated system rather than a collection of single risk factors that could be addressed one by one.

Despite the efforts of government, corporations, and other organizations in health promotion and safety, health spending as a percentage of total compensation increased from 5.6% in 1987 to 8.3% in 2003 [23]. Household spending on medical care as a percent of adjusted personal income also rose during that time from 4.8% in 1987 to 5.9% in 2003 [23]. The United States has experienced double-digit increases in health care spending for many years [23] with only occasional decelerations in the growth of health services spending [24,25].

So, why did the efforts of health promotion and managed care make little to no impact on rising health care costs? The medical community has always focused on sickness care. "Good health" has typically been defined as the "absence of disease." A strategy of waiting for people to become sick and then treating them is unsustainable, however. What is needed is a shift in thinking. True wellness is achieved when individuals have a high level of health, vitality, resilience, and performance, not simply the absence of disease. Behavior change and risk reduction strategies had only modest success as the cost of medical care escalated. Not only did few individuals participate in these programs, but if someone was able to make a change, it was only a short time until recidivism occurred. Thus, we observed a continual march toward increasing numbers of Americans who were obese and not physically active, as well as increases in the number of individuals with metabolic disease such as diabetes.

Five important lessons were learned from the history of health promotion thus far [4]:

1. One cannot solve a fundamental problem by waiting for defects and then attempting to fix the defects.
2. Only the actions that are rewarded are the actions that are sustained.
3. Anyone in business knows that you take care of your champion customers before going to find new ones.
4. One cannot put a changed person back into an unchanged environment and expect the change to be maintained.
5. Successful health promotion systems require continuous improvement through immediate and strategic quality assurance metrics.

A paraphrase of Einstein was finally heard: "The level of thinking that got us into these unsatisfactory results is not the level of thinking that will get us out of the situation." It is clear to us that the future of health promotion will be dependent on finding a framework or systems approach rather than the relatively isolated programs that attempt to fix defects one risk or disease at a time. These important learnings will propel health promotion to the top of strategies used to achieve and maintain high health status and performance in our corporations, towns, and countries, worldwide.

Business Problem and Solution of the Twentieth Century

Another line of thinking got us to a similar conclusion as in the previous paragraphs. The universal business problems of the final two decades of the twentieth century and first decade of the twenty-first century were the continuously increasing and unsustainable costs related to medical and pharmaceutical utilization, time away from work, worker's compensation, and other issues that led to lower performance and productivity.

Twentieth-Century Health Promotion Solution

The solution presented by the health promotion field was predominantly an ever increasing number of independent and single-focused risk reduction programs such as weight reduction, smoking cessation, physical activity, safety belts, and stress reduction. Behavioral change was the predominant tactic delivered one-on-one, telephonic, or via the Internet. By the first decade of the twenty-first century, the health promotion field was adding additional programs, looking for additional delivery methods to present behavioral change, and searching for the lowest-cost methods of delivery but continuing to emphasize single-focused risk reduction programs. Evaluation methods continued to be focused on the ROI methodologies.

It is clear to us that the assumptions and methods of the twentieth century will not be the solutions for the twenty-first century. We contend that Einstein and Covey would suggest, "… more of the same level of thinking that got us into this unhealthy and low performing situation will not be the level of thinking that will get us out of it … and we are also insane if we continue to do the same. …" Health promotion needs a transition from the past to the future and eventually a transformation from "best practices" to "next practices."

TRANSITION: SETTING THE STAGE FOR A TRANSFORMATION

Changing Landscape in the Twenty-First Century

Whereas the prevailing theme for medicine and wellness in the twentieth century was to wait for defects and then fix them, the prevailing theme for the twenty-first century will be to fix the systems that lead to the defects.

Whereas the prevailing strategy for wellness in the twentieth century was individual behavioral change, the prevailing strategy for the twenty-first century will be population health through supportive cultures and environments.

Whereas the standard of program efficacy in the twentieth century was evidence based and best practices, the standard in the twenty-first century will be evidence-based next practices.

Whereas the competitive advantage in the last half of the twentieth century was discovering ways to find lower costs of materials, production, labor, and other factors, the competitive and cooperative advantage of the twenty-first century will be with those organizations that can develop and maintain a healthy and high-performing workplace and workforce.

Finally, "What's the point?" This is a question that we raise with every audience we have the opportunity to address. Of course, the point is cost control in the organization and health and performance for individuals. But far beyond those, we believe the next practices of the twenty-first century will be "… our promise to provide each member of our organization and their families and work group an equal opportunity to obtain the highest possible level of health and performance. …" It is the right thing to do for the individual, their family, their work group, their organization, their community, and eventually their country.

Major Transitions in Health Promotion

As we noted in the previous section, during the twentieth century, health promotion, as identified by behavior change and risk reduction strategies, had only modest success, while the cost of medical care continued to rise and with only marginal improvements in quality of health care. In the early 2000s, health promotion stakeholders demanded more rigorous outcome measures and methods. Steps were taken to quantify the "total value of health" to organizations and communities. This includes a combination of several outcomes such as health care costs, pharmacy costs, productivity costs, absenteeism, presenteeism, job effectiveness, recruitment, turnover, morale, and socioeconomic measures. Programs were evaluated for ROI, but little for cost-effectiveness of interventions.

Other changes were taking place in companies and communities during these years of transition. These included a decrease number of jobs in the manufacturing sector as more jobs were created in knowledge-based work. Furthermore, many workers began telecommuting, and workforces became widely dispersed rather than concentrated at a single worksite. These changes presented challenges to the field of health promotion as it tried to reach people in new ways and through new technologies.

Going forward, corporations will continue to be the major stakeholders in defining the value of a healthy and high-performing workplace and workforce. Corporate and community leaders are only beginning to make the assessment that delaying the initiation of care to when sickness or high risks become apparent is an unsustainable strategy. It is in the employers' best interest to convince health plans to address the health status issues that lead to sickness. When insurance companies shift their sole focus from illness to, at least, considering wellness, they transition to a health plan and able to partner with purchasers of health benefits (companies) by having aligned incentives. Communities also have begun to realize the economic advantage of healthy and high-performing populations. The recession of 2009–2010 altered the pace of this transition and possibly delayed it due to acute budgetary consideration resulting in more short-term thinking.

However, the problem remains that health promotion and the entire medical establishment is focused on fixing sick people and addressing high risks. It is certainly a bad situation for the United States and many other countries of the world when one of the largest and fastest growing industry sectors is devoted to taking care of sick people. The implications for society as we know it is not good.

One physician has correctly stated that "Medicine (U.S.) has become a pig trough" and that trough is a reimbursement system that pays on a fee-for-service basis using a diagnostic and procedural coding system [26]. There are many examples that demonstrate this assertion. Gallstones are one example. Generally, in the absence of complications, patients

should be educated about the condition and encouraged to modify their diet. After those changes are made, a gallstone may dissolve on its own or shrink so that it no longer causes symptoms. However, the choice to operate immediately has become increasingly more common. There are several reasons for this. Operating increases revenue, satisfies patients' desire for action, and reduces the need for patients to make changes in their own behaviors. Even if a physician does not explicitly realize the reasons for his or her choice, the incentives are stacked up in a way to immensely encourage the decision to operate.

A second example would be diabetes. The insurance system will reimburse a hospital for amputating a limb afflicted with gangrene caused by diabetes complications. But it pays little or nothing to help a patient avoid developing diabetes in the first place, which obviously would have prevented the amputation. Billing occurs at the individual patient level and reimburses for services and procedures, a reflection of what the system presently values. This is like watching a soccer match through a pinhole: you see a single player in isolation, but you are blind to the strategy and dynamics of the larger picture. Similar economic models fit for health promotion as it is now practiced.

The future of health promotion must be redefined. Waiting for people to get sick and then working to make them better is a failed strategy if the objective is to take the population to a healthy and high-performing society. We can transition the twentieth century conversation about health and productivity for organizations to the twenty-first century conversation by considering the following five transitions:

1. From health as the absence of disease to disease as the absence health
2. From only caring for the sick to enabling healthy people to stay healthy
3. From the cost of health care to an investment in the total value of health
4. From individual participation to population engagement
5. From behavior change to a culture of health

These transitional conversations will help focus health promotion for the twenty-first century.

Business Problem and Solution of the Twenty-First Century

If one continues to ask the same or similar questions and can't get to a solution, then it could be that it is time to change the question. The unsustainable cost part of the twentieth-century business problem remains the same, but it is now complicated by a more competitive world and competition for high-performing people and, perhaps more importantly, competition for healthy and high-performing populations. Unsatisfactory results plus expanding or changing the questions clearly requires a new level of thinking.

Going forward, the competitive advantage for companies, communities, and countries will be healthy and high-performing individuals and populations working in healthy and high-performing workplaces and living in healthy families and communities. The health promotion field will struggle unsuccessfully if it continues to rely on twentieth-century solutions and maintains a continual emphasis on independent and stand-alone single-focused programs targeted at high-risk individuals with a behavior change solution.

New Century, New Decade, Changed World: New Journey

New world economics will require organizations to grow and maintain a healthy and high-performing workplace and workforce if they are to meet the economic challenges of the worldwide competitive marketplace. This awaking and new journey is alive in all countries of the world. The world now needs a few leading edge companies to begin to focus on achieving zero growth in their costs and an increase investment in a highly engaged and resilient workplace and workforce. Not only will the aforementioned costs be lowered but the clinical measures will also be improved, for example, fewer new cases of chronic diseases such as diabetes and heart disease.

It is clear we need a transformational change in the way we take care of healthy people and the environments and cultures we establish to maintain their health and to welcome others back into a healthy and high-performing quality of life. The outcomes from the past 40 years of twentieth-century health promotion should have taught us it is time for a transformation and it is only a matter of commitment within the organizations (and communities) to allow this new way of doing business to flourish in our lives.

Twenty-First-Century Health Promotion Solution

The solution for the twenty-first century must be created by strategically applying systematic, systemic, and sustainable business and economic viable solutions. Almost all organizations (public and nonpublic) take their lead from senior management balanced by agreement throughout the organization and bottom-up feedback (systematic). The process is continuous and sets the expectations and "rules" on how all members feel and act (systemic). The final (sustainable) part of the process comes through immediate and appropriate feedback to each level in the organization and movement in the outcome metrics.

Challenge Is to Grow Champion Companies or Remain on the Periphery

We are totally convinced that either the effort in creating healthy and high-performing workplaces and workforces will be carried into the core business strategy of organizations or this field will be left irrelevant and on the periphery of business success, only providing a series of single-focused programs, which touches only a very small percentage of the population.

Going forward into the twenty-first century, we see four levels of engagement for organizations to select as their desired state:

- Level 1. A do-nothing company
- Level 2. A traditional company doing health assessments, lunch and learn programs, and risk reduction programs
- Level 3. A comprehensive company doing Level 2 plus additional programs and some measurements related to ROI
- Level 4. A champion company recognizing health as a serious business and economic strategy and employing strategically implemented systematic, systemic and sustainable strategies.

Using Three Learnings from Successful Business Strategies

Best Practices or Next Practices

C.K. Prahalad, one of the world's most influential business leaders, used a concept attributed to Peter Drucker that often innovation and advances in business comes about by "seeing what is not visible." This advice is similar to hockey great Wayne Gretzky's advice: "go to where the puck will be." Prahalad advocates spotting opportunities and inventing "next practices."

Best practices are important if one wants to stay abreast of the competition and to move within the inherent limits of current circumstances. Best practices do not advance innovation or continuous improvement except at the margin. If the goals of business are relatively static, the results of its efforts are 100% achieved, and if nothing changes in the business or social environment, then best practices may be the right objectives. However, as we all know, these assumptions within the context of worldwide competition are far from realistic in the business (or society) equation.

It seems clear to us that to achieve continuous improvement in bringing about healthy and high-performing workplaces and workforces, the current best practices are not the road to innovation and success going forward. The primary component that is lacking in those who base their strategy on best practices is a vision of the future: "seeing what is not visible" and "going to where the puck will be." They also find that when they achieve the best practices, "someone moved the cheese," as described by Spencer Johnson [27].

The current best practices in the health and wellness field are built upon a series of individual interventions that one assumes will magically bring about a healthy and high-performing population. The degree of success over the past 30 years is marginal at best and when one uses population metrics as the measure of success one finds nearly no success. Our friend Albert Einstein would again remind us, "… if the current level of thinking is continuing to produce unsatisfactory results, more of that same level of thinking will not lead to satisfactory results." Thus, it is time for a higher level of thinking.

As a solution, Deming, Prahalad, Blanchard, and Drucker advocate the integration of individual strategies into systems thinking. In our opinion, this transformation creates a powerful approach where everything in the organization is focused on a common objective: a healthy and high-performing organization. In this approach, the healthy workplace and workforce become one with a healthy and high-performing organization.

System thinking is what drove the creation of the transformational approach advocated in *Zero Trends*. The system that leads to a healthy and high-performing organization begins with the vision of senior leadership connected to the mission of the organization; handing off to operations leadership to create the environment that begins to lead to a culture that allows the vision to come alive, continuing to manage expectations and creating consistent messaging at every touch point; providing resources for each and every employee to grow to all they can be, including family members; providing various forms of recognition for positive actions; and maintaining a quality assurance real-time process to measure, evaluate and provide for decision support at each point in the system.

The operational nature of a system is that the output of one part of the system is the input into the next part of the system. In no other way can each part be working together to move along the journey to a healthy and high-performing organization. It is the "next practices" that we should seek.

Keep a Good Customer or Go Find a New One?

The field of health promotion has been focused on ignoring the good customers and solely focused on those individuals with high risks. Although this seems intuitively correct, it violates one of the learnings of the "natural flow" of populations and one of the learnings of any business: take care of your good customers first, utilizing exceptional customer service.

It seems to us that the "low-risk, low-cost, and high-performing" individuals are the good customers and champions. Why ignore them and focus all of the health promotion efforts on the high-risk, high-cost, and poor-performing customers? The problem becomes how to identify the good customers and find a supportive process to help them remain in the good customer cohort.

There are at least two strategies that work to help achieve this goal. First, reward the positive actions taken by the individuals through intrinsic and extrinsic recognition of those actions. Second is to create an environment (structure and culture) that supports the desired behaviors and supports those who change from high risk to low risk, high cost to low cost, and low performers to high performers.

Recognition of positive actions is a fundamental precept of behavioral science: what is recognized and rewarded is the action that is sustained. Blanchard and Johnson in the One Minute Manager emphasize the point of "… catching people doing something right …" and the thought is that if one catches someone doing something right and then recognizes and rewards that behavior, it is likely they will do

it again [28]. Not only should the individuals be recognized and rewarded for positive actions but recognition and rewards can also be effective at the unit level: workgroup, department, division, location, etc. There are opportunities to reward groups that are even more sustaining than that of individual recognition.

Tom Golaszewski and Judd Allen have led the way in describing the influence of the environment on the workplace and the workforce [29]. The environment can be somewhat artificially separated into structure and culture and each has a complementary impact on the environment. The effectiveness of the structure and culture interventions is likely the most impactful on creating and maintaining the high-performing champions and in creating a best place to work company.

Strategic Systematic, Systemic, and Sustainable Strategies

We are convinced that there is a major disconnect between the high level of expectation and potential of health promotion programs and the current performance of these programs in workplace settings. Our 30 years of work at the University of Michigan's Health Management Research Center collaborates the high promise of the wellness strategy; however, the programs are under delivering on that promise.

The missing component to the twentieth-century health promotion programs is a business strategic strategy and an operational framework that results in a serious business and economic approach. After learning from our 30 years of work, we formulated such an approach in *Zero Trends: Health as a Serious Economic Strategy:*

The focus of the systematic framework is to incorporate the vision of a healthy and high-performing workforce into the systemic part of the organization. That is, incorporate wellness into the environment and culture of the organization. Most organizations already have incorporated Safety and Quality into the culture of the organization. These two examples provide a roadmap for us to do the same with a healthy and high-performing workplace and workforce.

Once high-performing workplace and workforce are systemic, then the culture is set to make it sustainable. After all, if any initiative in not sustainable, it will likely die out of the organization within a few years. This is not necessarily a major organization development issue; it is just follows the teachings of [28,30,31], and many other leaders of systems and leadership thinking. The strategic systematic, systemic, and sustainable strategy will move us beyond "fixing defects" and get us to "fixing the systems that lead to the defects."

Einstein gave us the framework to solve the safety and quality issues that troubled American businesses in the past with the next level systems thinking and that same systems level thinking will help us solve the overpromising and underperforming medical and wellness promises. In addition, systems thinking will allow behavior change to finally reach its full potential, so that we have supportive environments and cultures for changed behaviors to be sustained.

FUTURE OF WORKSITE HEALTH PROMOTION IN THE TWENTY-FIRST CENTURY

Population Health Management: Next Assumptions

Most current wellness or health promotion programs are based on the theories that corresponding risk-related behavior change will lower the chance of disease which, in turn, decreases health care, disability, and productivity costs. These theories seem reasonable; however, their real-world application to impact the health of a population (worksites or communities) have led to strategies proven to be largely ineffective—witness the increased percentages of the population with diabetes, obesity, other chronic diseases, and unhealthy risks and behaviors.

The current assumptions will still hold in the twenty-first century. However, other and more advanced assumptions related to population health and a framework for implementation at the worksite will be needed. The fundamental question for the twenty-first century is, "What are the major individual and social determinants of health for individuals and populations?" We project that the most influential assumptions for the twenty-first century will revolve around individuals, workplaces, workforce, family and friends, communities, and the overall impact of the environment and culture.

Framework for Health Promotion in the Twenty-First Century

In the first decade of the twenty-first century, the field of health promotion as applied to populations was more appropriately called wellness. It became clear to us in 2006–2009 timeframe that wellness, as defined by low-risk lifestyles, is insufficient to describe a healthy and high-performing individual and especially a population such as a workforce or citizens of a community. Either a redefinition of the current describers or another name needs to be found or created to represent a higher level of health and performance. Well-being, positive health, or health and well-being and other descriptors are being tested in several countries to represent a higher level of performance for individuals. Population health is a reasonable term to use to describe the health of a population.

Implementation of the Next Practices for the Twenty-First Century

We are convinced that the future of health promotion depends on finding a remedy for the five important twentieth-century learnings discussed previously (see p. 7). The obvious solution for worksites is to integrate health status into the organizational environment and culture. Our research over the past 30 years has provided us with the transformational framework: five fundamental pillars that support a culture of health in an organization and enables workplaces and their total workforce to maximize the potential of optimal health and performance.

The five pillars are designed to

1. Drive the vision from the level of senior and strategic leadership
2. Create a supportive environment via the operations leadership
3. Formulate the objectives through employee self-leadership
4. Reward and encourage positive actions that promote self-leadership
5. Provide quality assurance measures for the purpose of assessing and improving the success of the objective

In the worksite setting, the ultimate objective is to facilitate a high-level positive health status and high performance for all members, which benefit both the individuals and their employers. Figure 113.2 shows how the behavior change strategy diagramed in Figure 113.1 has been replaced with the strategic strategy (the five pillars). Behavior change remains a key tactic, especially in Pillar 3, but it is no longer the only or dominate tactic.

The strategic strategy has the potential to engage the total population and enable companies, health promotion practitioners, and individuals to capture the total value of health. A positive healthy and high-performing champion organization will have the features listed in Table 113.2, which create and support a culture of health.

We've touched on how the future of health promotion will change from focusing on individuals and individual health risks to a population-level approach. What does this mean exactly? Population-based programs are those which impact the entire spectrum of an organization or community. They offer something for everyone, not just the high-risk individuals. And, population-based programs are the only way to avoid the continuing development of high-risk individuals. This is accomplished by helping low-risk people stay low risk, helping others not get worse, encouraging all employees to develop a winning attitude, nurturing the champions,

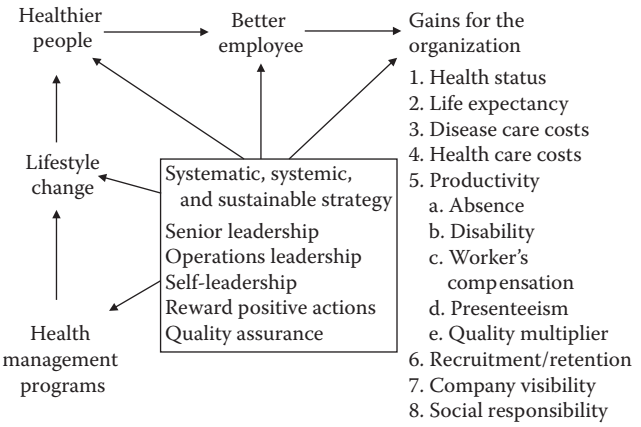

FIGURE 113.2 Health promotion using integrated and strategic systematic, systemic, and sustainable strategies as core business in the twenty-first century.

and beginning to engage higher risk individuals in the culture of health.

The systematic solution and framework represented by the five pillars are discussed in the following sections.

Create the Vision

It is fitting that this first pillar was illustrated in the publication of an article coauthored with Ken Blanchard: "Averting the Collision between Rising Health Care Costs and Corporate Survival" [32]. The message of the article is that CEOs have to recognize that health and health care are core business and economic survival issues in these times of global competition. If CEOs and other senior executives do not recognize this and do not create environments where they grow healthy and high-performing companies, someone else in the world will and they will lose competitive advantage as well as their overall way of life.

In the future, CEOs will provide a vision for organizations and people where everyone shows up for work, regardless of their work location, on time and with high energy, enthusiasm, creativity, optimism, resilience, and vitality; they are high performers during the whole work period; and, when they finish their work period, they leave with high energy, enthusiasm, creativity, optimism, resilience, and vitality. These employees will then apply that same energy and high performance to their home life and to their community. In addition, they will show up at work the next day with renewed energy enthusiasm, creativity, optimism, resilience, and vitality and the other traits that fit the company's vision of a positive, healthy, and high-performing workplace and workforce.

The earlier description is what we consider an ideal vision for the future work situation where the workplace and the workforce act synergistically to produce a high-performing organization that will be able to compete in an increasingly highly competitive local and worldwide marketplace. Currently, there are only a few organizations that create and sustain this type of workplace. In fact, many organizations are set up to create a workplace where employees arrive with energetic characteristics but leave the workplace with an empty tank of energy, even if they are well paid.

The gap between these two work situations focuses the question: "How will organizations create a workplace that expects and supports healthy and high performance from employees?" The enlightened employers will realize that they have to give energy back to the employee to allow those daily high-energy–high-performance work characteristics to be renewable and sustainable over time. This renewable and sustainable energy will create a work environment that feeds high performance and often exceeds all expectations of the company.

The role of the CEO and other senior leaders will be to create the vision, similar to that describe earlier; connect the vision to the business strategy; be the role models they want the employees to see; provide adequate resources; engage all senior leaders in a visible participating role; and have the ultimate courage to support the vision throughout the implementation of the strategy.

TABLE 113.2
Health Promotion Program Features of a Champion Organization

Senior Leadership	Operations Leadership	Self Leadership	Reward Behavior	Quality Assurance
Emphasizes the role of senior leadership in creating the vision	Emphasizes the role of operations leadership in impacting the culture	Emphasizes self leadership among employees	Emphasizes rewarding positive behaviors and developing the culture of health	Engages in quality assurance activities to get to results-driven programming
Vision connected to company strategy and people	Brings integrated health policies into alignment with a healthy culture	Provides for a health assessment system, including coaching and wellness activities for all	Rewards the champions	Understands the distinction between data, measurement, information, and decision support
Senior leadership is visible and committed	Brings all policies and procedures into alignment with a healthy culture	Provides educational programs for understanding of the value of health management to the company and to the employee	Cultivates individual respect, care, and growth	Tracks the percent of total population engaged and the percent of the total population at low risk
Senior leadership delegates and then transitions to cheerleaders	Modifies benefit design to focus on company values	Offers appropriate resources to all employees, including dependents, if possible	Corporate culture emphasizes an abundance mentality that engages the total population	Compares the program results with the expected natural flow of risks and costs
Provides adequate funding for programs	Integrates management of disease, crises, absence, disability and workers' compensation, and other resources		Incentives follow actionable items	Tracks employee and company satisfaction indicators
Assigns responsibility for implementation	Emphasizes branding of the program and direct marketing to the employee Encourages meetings with all managers and employees to manage expectations Provides incentives for all, including the low-risk individuals Engages external partners (health enhancement companies, health plan, benefit consultants, pharmaceutical companies, primary-care physicians, health systems, and communities) in accordance with vision			Examines the trends of the relevant outcome measures

Create a Supportive Environment and Culture

The vision will not be implemented without a planned and integrated strategy initiated at the senior leadership level and seamlessly implemented by the operations or local leadership. The vision from the senior level will come alive in the environment created by the operations people (typically human resources). The combination of vision and environment/culture will be the heart and soul of a champion company and will create the structure and culture of a healthy and productive great place to work.

The structure part of the environment will include fair wages, integrated and well-designed value-based health care, resilience training, self-leadership training, and healthy choices throughout the worksite. The culture piece of the environment will start at the top and permeate throughout the organization as positive role models, peer support, supervisor support, mutual trust, positive norms, and positive expectations. The culture will need local champions listening at the employee level for success stories or sometimes barriers to success and feeding that de-identified information up the

organizational structure for consideration. This bottom-up communication will complete feedback loop cycle.

Once everyone in the organizations understands the vision realizes the intent of the environmental factors and sees and feel trusts the individual and organizational support, the culture will reach a point where individual and corporate energy is renewable and sustainable. Although the concept of addressing cultural issues in health promotion is not new, the identification of a workplace health initiative as a cultural phenomenon departs dramatically from the long-standing intervention practices of the twentieth-century health promotion efforts. This new focus, i.e., creating a culture of health, represents a major breakthrough in both evaluation and intervention design.

Creating a supportive environment and culture will require a major effort to communicate the message throughout the organization (managing expectations), align and integrate all internal policies and procedures, align and integrate all external partners to be consistent with the organization's objectives, brand the vision where everyone in the organization recognizes the vision and the objective, and engage all members (employees and dependents) in the vision.

The transformation to a twenty-first-century vision of a champion company's health promotion strategies will require a new set of tools: next-generation health risk assessments, which include components related to positive health and well-being components and issues related to the workplace, community, and family environments and cultures. The transformation will require a move from best practices as the standard to "next" practices, which incorporate a higher level vision and more organizational strategies.

Develop Self-Leaders

Champion companies are going to need self-leaders in order to be competitive in the twenty-first century. This will be accomplished by additional recruitment criteria and on-the-job training. The organization will need to create a supportive environment and opportunities for employees to become winners; help employees not get worse; and help the low-risk and healthy employees stay low risk and healthy.

The needed tactics will include communications to manage expectations at all levels of the organization; special orientation and training opportunities (learning modules) centered around the characteristics of positive, healthy, and high-performing individuals; low-risk maintenance programs; and some of the common twentieth-century risk reduction programs.

One of the tactics for all employees (population-based program) will be the completion of core modules illustrating the basic concepts of self-leadership, consumerism, resilience, change, and self-efficacy. In addition to the modules, health promotion coaches will need to be trained in motivational interviewing (advanced form of the twentieth-century strategy) including coaching for low-risk individuals and how to develop self-leaders.

We've touched on how the future of health promotion will transform from focusing on individuals and individual health risks to a population-level approach. What does this mean? Population-based programs are those which impact the entire culture of an organization or community. They offer something for everyone, not just the high-risk individuals. Population-based strategies are the only way to avoid the migration of individuals with low-risk health status to high-risk status. In the future, this will be accomplished by helping low-risk people stay low risk, encouraging all employees to develop a winning attitude and nurturing the champions. This low-risk strategy will be supplemented by enhancements of the more traditional high-risk reduction programs that were used in the twentieth-century health promotion programs.

An example of a population-based approach where everyone can win includes a goal of walking 1000–3000 steps a day, a campaign to learn your blood pressure and cholesterol numbers, and an agreement to maintain body weight (just don't get worse!). Every individual or preferably every work group will earn the recognition because everyone can do these activities (or get appropriate substitutes). The organization can now celebrate its winners. What's next? The next step might be to ask individuals what they would like to undertake for the next 6 months. Perhaps it will be 4000 steps/day, still don't gain weight, and still just know your numbers. The organization will continue to be on the journey to more positive health and high performance, which benefits each person in the organization and the organization itself.

A health-oriented environment and culture will reinforce the population-based strategy and engage everyone in skill development and motivational opportunities. In the twenty-first century, strategic positive, healthy, and high-performing workplaces and workforces will be recognized as an integral part of a high-performing champion company. A highly productive employee is not only healthy but one who also has competitive skills for their job and is highly motivated to be a champion within the champion company. In addition to the "don't get worse" challenge, more traditional risk reduction programs are needed for those who decide they want to undertake more intense self-improvement.

Recognize Positive Actions

When companies in the twenty-first century take the important step of making a healthy and high-performing workplace and workforce a core business strategy, as a first incentive, they may only choose to pay for health care only for those employees who engage in the self-leadership program. Employees who decide not to engage will pay for their own health care benefits. This significant incentive (positive reward or recognition) will be discussed with all employees, and the options openly explained during preprogram meetings. The purpose of these meetings is an attempt to manage company and employee expectations.

Once motivated by the initial incentive, the workplace and workforce will need another series of rewards, or more preferably recognition, to maintain corporate and employee interest and engagement. This second level of positive recognition is necessary because initial activity in the twentieth

century often took place at the time of benefit selection and was focused only on increasing participation. An emphasis on self-leadership must continue throughout the year in order to reach the desired outcome of a positive healthy high-performing individual working in an environment and culture that supports positive and healthy actions. Constant communication and work group recognition keeps the momentum going and keeps participants engaged, either maintaining their health status or making improvements. Another effective recognition strategy will be to have activities in the current year lead to a qualification threshold for the recognitions for the following year. Regardless of the type of motivation that will be used, it is crucial that they are not viewed as entitlements: that is, effective incentives will follow positive actions such as an investment for future returns.

Measure and Share all Strategies and Outcomes

The quality assurance pillar involves data-driven decision making and performs the critical function of integrating a positive healthy high-performance workplace and workforce into the culture of the organization. The highest level objectives are those organizational and individual traits identified in earlier parts of this section. The senior leaders and the leaders of each of the pillars will have identified three metrics they each need to give them confidence of the progress of moving the organization toward a champion company and moving individuals toward self-leadership.

There will be a need for preliminary and intermediate objectives (early indicators) of company and individual engagement, such as program participation rates or the prevalence of health risks or gaps in communications. A champion company, however, will take the major steps of measuring, evaluating, and making decisions process to a much higher level of company performance. The data sources needed to create the metrics are unlimited and could include employee satisfaction, changes in the environment and culture, management and alignment of policies and procedures, employee progress on completing the learning modules and coaching, employee engagement, maintenance or reduction in health risk status, family and community involvement, shift from a focus on costs to a focus on investments, beating the natural flow, bending the cost trend lines, relevant company productivity measures, and less utilization of medical, absence, and disability claims.

Each company, regardless of size or industry sector, will measure accomplishments and successes through the creation of a real-time quality assurance system. The data systems will be integrated to create data information systems from which the appropriate metrics will be provided upon request in order to facilitate effective and timely decision support.

WHAT WILL WE BE ABOUT IN THE TWENTY-FIRST CENTURY?

The twenty-first-century health promotion programs will have learned from the first 40 years of experience that the only strategy that addresses the fundamental positive health and high-performance objectives is a strategy of fixing the culture and environment of the workplace and the self-leadership needs of the workforce. The outcome of this transformational approach will result in all of the economic cost outcome measures approaching a zero trend line and the investment outcome measures approaching an optimal productivity of the company. However, companies and other organizations will not be able to solve the fundamental issues by themselves. They will need integrated help in public policy from the federal government, state governments, optimal company products and services, communities, families, and individuals. In addition, the quality and cost of a high-performing workplace and workforce will be within reach but it will require an equal effort of both sides of the economic and social equations. It will take a synergistic set of strategies for each company or country to remain on track to fulfill its promises to its clients, employees, and citizens for effective positive, healthy, and high-performing systems.

We've covered a lot of ground and presented numerous ideas and concepts about our view of the future of health promotion strategies and outcomes. The take-away message is that health promotion has evolved at the margins over the past 40 years, but now there is an urgent and passionate need to generate a major transformation if health promotion is going to remain relevant and effective. The lessons learned from the less than optimal approaches in the twentieth century can be put to good use augmenting the transformational and effective methods necessary for the optimal future of health promotion.

Following the organizational strategy of a strategic systematic, systemic, and sustainable strategy will help organizations transform themselves into champion workplaces and help individuals live positive, healthy, and high-performing lives in their families, workplaces, and communities. The vision of the future will only come alive by a transformation in our thinking to a new and higher level of thinking. Only the view from that level will create the positive, healthy high-performing future workplace and workforce. Twenty-first-century health promotion will show that the "investment in doing something" (successfully) is less than the "cost of doing nothing."

In the previous edition of *Lifestyle Medicine*, I (S.J.P.) wrote a chapter on mind-body understandings [1]. Given that more than 10 years have passed since that chapter appeared, we thought it might be interesting to see how far things have (or have not) progressed since that publication. What follows is a revised and updated accounting of that 1999 chapter, but rather than presenting more generic studies, we have focused primarily on what has evolved in the exercise domain since that time.

The Latin phrase "Mens sana en corpore sano"—a sound mind in a sound body—was (and perhaps still may be) the mantra for exercise psychology. It clearly suggests that mind and body are intimately related to one another. Careful consideration of the available literature, however, often leads to the conclusion that mind and body are distinct entities, with the latter serving only as a place within which the former resides. Since the early seventeenth century, science has operated on the notion that mind and body can be separated. As Melnechuk [2] put it,

> Back then, dualism made the body, as a ghost-free machine of mere meat, a permissible object of empirical investigation at a time when the Inquisition was dangerous to scientists, as shown by the contemporaneous trial of Galileo. In modern times it reinforced the biomedical avoidance of studying emotions as factors in health and disease. (p. 183)

This dualistic thinking still permeates much of science, and particularly exercise science, although it is difficult to defend the position that mind and body are separate. What results from the continued distinction are physiologists studying physiological processes as entities with no influence from the mind and psychologists (or other "mind scientists") studying psychological processes as though they were distinct from physiological sources. Consider the following: "All social cognitive approaches are based on a constructionist metatheory, where cognitively based variables such as intentions, attitudes, and self-efficacy are nonmaterial psychological constructions and not observable in the physical world" [3, p. 1396]. This is a perfect illustration of what Morgan [4] meant when he wrote "… those who rely on cognitive psychology, seem to believe that the head does not have a body" (p. 100).

A more tenable philosophical approach to examining mind-body issues is monism, a central tenet in psychophysiological approaches to understanding human behavior (i.e., perceptions, thoughts, emotions, and actions) [see 5, p. 20, Note 2, for full description]. At its essence, the monistic identity thesis holds that there is a counterpart in the physical domain for every psychological or subjective event. This leads to the realization that events taking place at any level in the individual occur simultaneously at all levels [6]. As such, intentions, attitudes, and self-efficacy are *not* nonmaterial constructs and *can be* observed in the material world. The monistic identity thesis holds then that events of the body are simultaneously events of the mind. Thus, "A mental perception or idea and the initial physical event (brain cells firing, neurotransmitter molecules moving) are not two separate things, but two different ways of describing the same event. An initial mental change *must* entail corresponding physical change…" [6, p. 9]. Indeed, Joseph LeDoux, a prominent neuroscientist, has stated that "your self, the essence of who

you are, reflects patterns of interconnectivity between neurons in your brain. Connections between neurons, known as synapses, are the channels of information flow and storage in the brain" [7, p. 2]. If one espouses such a philosophy, then examining mind-body issues becomes potentially more fruitful. It becomes the challenge of science to find these corresponding physical changes. As Cacioppo et al. [8] noted, at least in most other areas of "psychological" science,

> Monism has replaced any lingering notions of dualism, as psychological states are more likely to be conceived as represented in and acting through cortical, limbic, and brain stem regions, with influences on autonomic, neuroendocrine, and immune activity, which in turn serve to modulate crucial cellular and molecular processes. Afferent information, in turn, travels from the peripheral to the central nervous system to influence the brain and behavior in social contexts. (p. 2)

Unfortunately, dualistic thinking continues to pervade much of exercise psychology. Ekkekakis [9] nicely outlines several instances where this has occurred (and continues to occur) in the field, usually in conjunction with some of the most deeply revered theories and models. Rather than viewing psychological events as embodied phenomena, exercise psychologists instead hold to a disembodied philosophy. This allows investigation at a single level of organization (e.g., psychological) without concern for how such phenomena might extend to other, adjacent levels (e.g., physiological, social). When it is considered, the body is devalued, reflecting what the philosopher Leder referred to as onto-valuational dualism [9,10]. Cacioppo et al. [11; see also 12] have stated,

> Traditionally, investigators have emphasized single levels of analysis of social psychological phenomena with survey and self-report measures being the most common methods used to investigate the mechanisms underlying these phenomena. The predictable yield from isolated research on discrete determinants of multiply determined social psychological phenomena is a portfolio of fact lists and disparate microtheories. These microtheories each provide a limited account for the phenomenon of interest and are at best pieces of a larger conceptual puzzle. Even determinants of a phenomenon that account for a modicum of variance are noteworthy if the goal is to achieve a comprehensive theory of the psychological phenomenon rather than a microtheory of the determinant. In addition, knowledge of the body and brain can usefully constrain and inspire concepts and theories of psychological function, because there are any number of ways in which a particular outcome might be achieved. Knowledge about the functional organization of ordered and disordered mental or social activities, however, can also usefully guide the study of the underlying brain processes because the nature of the particular physiological mechanisms and events could be suggested by the observed mentation, behavior, or interaction. Although there are neurophysiological processes that are affected, for instance, by human association and which underlie the associated psychological and social phenomena, these phenomena shape physiological events in ways that may not be evident from studies of the physiology isolated from the social context in which they manifest. (p. 74)

To be fair, it should be noted the problem cuts both ways. The physiologist, often viewed as reductionistic, typically ignores the influence of psychological and social factors. To once again quote Cacioppo et al.,

> … it [reductionism] undermines multilevel, integrative analyses, alienates scientists working at "unchosen" levels of organization who might otherwise contribute relevant data and theory, and renders it acceptable to ignore relevant theory and data on a phenomenon of interest simply because they were not born from one's preferred level of analysis. [11, p. 75]

While such approaches to viewing the world and answering questions about it are certainly valuable in their own right, the obvious point is that a much greater understanding of phenomena can be gained by examining *across* levels of analysis (i.e., psychological and physiological) [13].

Thankfully, there are seedlings of change cropping up (e.g., transient hypofrontality hypothesis (THH) [14], dual-mode theory (DMT) [9,15,16]). There continues to be a growing effort to uncover the physical events that correspond with psychological phenomena. As way of illustrating the interconnectedness of mind-body, the remainder of this chapter will examine findings from different areas of research, which clearly show the linkages between mind and body or between body and mind. Intriguing findings have come from scientists focusing on cognitions and emotions using a mind-body perspective.

"WINDOWS INTO THE THINKING MIND"

Cognitions and cognitive function have historically held a prominent position in psychophysiology. Cognitive function involves the ability to concentrate, divide attention among several things, learning and memory, action planning, effective execution of that plan, self-regulation of activities, object recognition, to evaluate, to construct in one's mind, logical thinking, and problem solving. Of note, executive control processes [17] constitute a set of cognitive processes oriented toward goal-directed behavior [18]. Such processes include scheduling, planning, working memory (being able to retain relevant information in memory for relatively short periods of time), interference control (dealing with distraction), task coordination, and multitasking; such tasks do not become automatic over time or with practice [19]. Furthermore, they have been shown to decline substantially with advancing age, as do regions of the brain known to support them (e.g., prefrontal cortex (PFC)).

Researchers in motor behavior have long been interested in cognitive function, beginning with the systematic examination of reaction time (RT), or how long it takes an individual to respond to a stimulus presented in the environment (e.g., visual, auditory). This response is assessed behaviorally by measuring the amount of time that elapses from the time a stimulus is presented until the subject makes some overt response (e.g., button press). However, this reveals little

about the how the response comes about. More information is gained if the motor system is examined using electromyography (EMG) recordings, but this still reflects a delay from the time the stimulus is processed by the nervous system to when a response is initiated. In other words, behavioral (i.e., RT) and motor system responses (i.e., EMG) still provide only a limited window through which to "view" the thinking mind (as an aside, some more recent studies are combining behavioral and neuroimaging techniques like functional magnetic resonance imaging (fMRI) to determine the level of convergence between methods).

Fortunately, several other options are available for potentially "better" views. Perhaps the analogy can be expanded to a window with multiple panes, with each pane representing a different way of viewing the thinking brain. Measures of brain activity have been used as "windows on the mind (i.e., cognitive functioning)" [20] for quite some time. Work with such imaging techniques (e.g., electroencephalography [EEG], fMRI) has been able to demonstrate partial information transmission, preparation of the motor system for action of some kind, and processes involved in the inhibition of responses [20]. Perhaps we can think of these different techniques (along with structural MRI) as separate panes of the window, each of which gives a particular view of the brain. What is needed is to get to a point where we are looking through the window as a whole, using mixed methods to determine if we are finding a common picture of what is going on or if we just have these fragmented panes.

Over the past 10 years, there has been an explosion of interest in how exercise might influence cognitive functioning. Much of the credit for this interest is owed to the pioneering work of Waneen Spirduso (examining physical activity/fitness and RTs) and the psychophysiological approach applied to this work by Robert Dustman (see subsequent sections). The effect of exercise on cognitive processing has been primarily examined in older adults and preadolescents given that these are milestones on the developmental continuum where cognitive processing is either in decline or in development, respectively. Thus, these become time points in the lifespan when exercise (if it influences cognitive processing at all) would potentially have its most robust effects.

Psychophysiological measures of brain activity, like EEG, have been useful in examining central inhibition capacity. The ability of the central nervous system (CNS) to inhibit unwanted/undesirable responses typically deteriorates with advancing age. A decrement in inhibitory strength would thus adversely influence physical and cognitive functioning [21]. EEG waveforms have been shown to be more homogenous across electrode sites (i.e., cortical coupling) in older than in younger adults [22], reflecting a loss of inhibition. Greater cortical coupling values are often seen in diseased states (e.g., Down's syndrome, dementia) and with advancing age. Because cortical coupling reflects the degree to which distinct cortical regions function independently from one another, an increase in cortical coupling with age would "suggest that aging is associated with a loss of functional autonomy of brain areas such that the older brain responds in a more homogenous or global manner" [21, p. 146]. Interestingly, physically fit older adults have been shown to be similar to young adults on measures of such functional autonomy (i.e., cortical coupling values), suggesting that endurance exercise can modulate excitation/inhibition relationships.

A more contemporary measure of regional brain functioning is EEG coherence, which measures the similarity between two EEG signals at different brain regions. Like cortical coupling, it is thought to reflect structural and functional coupling of those brain regions [23]. As coherence values approach unity, this reflects increasingly similar responses between different brain regions. Like Dustman's work with cortical coupling, data from our laboratory have shown that older, active individuals had lower mean coherence values than their older, sedentary counterparts [24]. Further elaboration is needed in order to determine how such differences might be manifested at the psychological level (i.e., cognitive function).

Event-related potentials (ERPs) have also been effectively used in the exercise literature as a methodology for indexing cognitive function [25]. Most prominent among the various ERP measures available are the P300 and the event-related negativity (ERN). The P300, or P3, is so labeled because it is a positive-going waveform occurring approximately 300 milliseconds after the presentation of a stimulus. It is thought to reflect the allocation of attentional resources, which can be thought of as the amount of brain activity needed to attend to the task and the updating of memory. Thus, the amplitude of the P300 (i.e., the magnitude of the deflection in a positive direction) reflects the proportion of attentional resources the brain needs to engage in a particular task (i.e., a larger amplitude means the allocation of more attentional resources). The latency of the P300 is a measure of the speed with which a stimulus is classified (i.e., longer latency means longer time to process the stimulus by the CNS). The ERN provides an index of the evaluation and self-monitoring of one's own actions, also referred to as response-monitoring associated with the evaluation of conflict. Thus, the ERN component is thought to reflect the conflict between what a stimulus dictates the response should be and the response that is actually made. Studies have shown the ERN component is generated by the anterior cingulate cortex.

Using exercise as an avenue for providing windows into the thinking mind, early work by Dustman et al. [26] compared ERP measures in younger and older higher and lower fit individuals. Young and old individuals who were more fit had earlier visual evoked potential latencies (i.e., perception of visual stimuli occurred more quickly) and shorter P300 latencies (i.e., they processed information more rapidly) than did their less fit counterparts. In addition, the older fit individuals were similar to the younger subjects in terms of P300 latency, suggesting that maintenance of aerobic fitness may offer some immunity against functional loss often seen with "normal" aging. Similar findings have been reported by numerous investigators since Dustman's work in preadolescents, adults, and older adults [e.g., 17,27–31], although not always [e.g., 32]. Similarly, with the ERN, studies have

shown higher fit younger adults have smaller ERNs after making an error than do their unfit counterparts [33]; this is thought to reflect more efficient allocation of conflict monitoring processes. Behaviorally, this is seen in greater accuracy on trials immediately following an error, something fit individuals exhibit to a greater extent than their less fit counterparts (this finding is consistent with fMRI data showing a less active anterior cingulate cortex in physically active and/or fit individuals—see subsequent sections).

Beyond electrophysiological measures, newer imaging technologies allow views from different panes into the "thinking mind" from slightly different windows. One of the reasons given for the change (often decline) in cognitive function, which is typically seen with advancing age, is the age-related loss of both gray and white matter in the brain, particularly in anterior brain regions (e.g., frontal, prefrontal, and temporal regions). The structural loss itself may not be the absolute reason for cognitive degeneration; however, such losses many times are associated with deafferentation of neurons of closely related structures and the subsequent functional changes that result [34,35]. Kramer and Eriksen [36] noted a relative dearth of studies that have examined the effects of physical activity interventions on the brain itself, more specifically on the structure of the brain and how it operates. Cross-sectional work using high-resolution structural MRI scans of the brains of older adults has shown that in spite of substantial declines in tissue density in the frontal, temporal, and parietal regions of the brain, fitness served to offset (i.e., substantially reduce) these declines [37]. Others have shown that the volume of the hippocampus, a subcortical area of the brain known to influence memory function (i.e., spatial memory) was positively associated with fitness; greater fitness and hippocampal volume were associated with better spatial memory performance [38].

Intervention studies of sedentary but healthy older adults have shown significant increases in brain volume (both gray and white matter) as a function of aerobic training [39]. These results were thought to show that fitness provided a "sparing" effect on brain tissue, an effect confirmed by others [40]. Another study [28] compared the effects of cardiovascular training, which resulted in a significant improvement in aerobic capacity (10% increase), to a non-training control group (stretching and toning; 3% increase) on brain areas implicated in different aspects of executive control and the attentional network (e.g., superior parietal lobule, attentional selection, resolution of response conflict; anterior cingulate cortex, sensitive to response conflict). Consistent with previous research, the aerobic group had significant improvement from pre- to postintervention in reducing their conflict time (11%); the control group essentially did not change. fMRI revealed significantly greater activity in the attentional control areas of the brain (e.g., superior parietal lobule) and significantly less activity in the anterior cingulate cortex in the exercise training group relative to the non-training control group. These results were again interpreted as evidence that exercise training can enhance executive control functioning, even in older adults.

Thus, it appears that regardless of which window or window pane one chooses to look through, physical activity, fitness, and exercise seem to provide the foundation for a "sound thinking mind." It is actually quite striking how consistent the findings generally are across the various levels of analysis.

"WINDOWS INTO THE FEELING MIND"

> Probably more than any other class of behavior, emotion often involves frank biological changes that are frequently perceptible to the person in whom the emotion arises as well as to an observer. [41, p. 361]

It has been suggested by numerous individuals that understanding affect is a necessary task for understanding human behavior. Davidson has been instrumental in advancing what he has termed "affective neuroscience" [42,43], a field of inquiry that certainly captures the essence of multilevel integration. As highlighted by Petruzzello [1], studies using measures of muscle activity (i.e., EMG) [44,45], eyeblink (using EMG [46]), and temperature [47–52]) have demonstrated, and continue to demonstrate (e.g., pupil diameter [53,54]), links between affective responses and physiological measures of such responses. Similar methodologies and paradigms have been extended to the exercise domain to examine a variety of potential explanations for affective change (e.g., temperature [55,56] and eyeblink, again using EMG [57]).

A strong case can be made for the importance of the brain in furthering our knowledge about human affect and affective function, but it is important to note that emotions are not just "in the head" either [58, p. 130]. It is clear that how we feel has direct effects on our central and peripheral physiology; changes in our physiology also influence how we feel. As LeDoux [59] has noted, "understanding emotions in the human brain is clearly an important quest, as most mental disorders are emotional disorders." (p. 19). Much of what is known about affect, particularly in the exercise domain, is often based on self-reports of emotions (e.g., anxiety) or feeling states as a function of manipulations hypothesized to change how we feel. As noted by Davidson and Sutton [43], "Inferences about emotion can be made on the basis of changes in behavior and physiology, and need not rely upon conscious introspective report." (p. 217). Davidson [58] further commented that consideration of the physiological perspective, specifically the brain, could help constrain psychological theory regarding emotion and affect. A similar point was raised by Petruzzello [60] in terms of recognizing what is currently known about the neurophysiology of the CNS and our knowledge of the transactions between the individual and the environment to better understand human emotional behavior. Psychophysiological investigations of affect have provided a much greater understanding that could have never been achieved from an exclusively self-report perspective. Davidson [58] actually refers to the reliance of studying only from a psychological perspective as one of the "seven sins in the study of emotion" (p. 129).

Perhaps as much as any other area within the exercise domain, we have gained much better "views" into the feeling mind over the past 10 years. This is due in no small part to better measures and methodologies, both of which have evolved from better theoretical perspectives to help guide the inquiries. One of the important developments in this domain has been the paradigm shift to examining affective responses from a dimensional perspective rather than what had been the dominant categorical perspective [61]. This led, among other things, to consideration of the activation/arousal and valence (e.g., pleasure/displeasure) dimensions of affective responses to exercise rather than continuing to rely on distinct emotional states (e.g., anxiety, depression), particularly in individuals who were not anxious or depressed. What follows is a summary of some of these theoretical perspectives and some research exemplars that have either directly tested them or indirectly supported them. As Ekkekakis [62] pointed out, there are at least three theoretical propositions that we are in a position to address from a psychophysiological perspective within the affective domain of exercise: anterior hemispheric asymmetry, transient hypofrontality, and the DMT.

Anterior Hemispheric Asymmetry

A rich literature has developed over many years examining the role of the brain in affective responsivity and affective regulation [63,64], a primary measure of which has been the EEG.

> In an era where functional neuroimaging methodologies, such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), have seen an exponential increase in the study of emotion and psychopathology, one might question whether there remains a role for frontal EEG asymmetry in the study of emotion, motivation, and psychopathology. Aside from the obvious advantages of EEG as a measure that is less invasive, less expensive, and more widely available than many neuroimaging modalities, frontal EEG asymmetry has established— by virtue of the nearly 100 studies using this measure— a sizable literature that embeds the measure in a network of psychological and behavioral constructs, thus bestowing frontal EEG asymmetry with sizable construct validity as a measure of an underlying approach-related or withdrawal-related motivational style… As such, frontal EEG asymmetry has greater construct validity as a measure of this motivational style than does any neuroimaging measure to date. [63, p. 1]

EEG, particularly in the alpha frequency range, has been a particularly useful measure in work with humans, specifically in the investigation of affective responses, and has been utilized in a growing number of exercise studies as well. Evidence from numerous fronts has led to the proposal that the anterior regions of the cerebral cortex are particularly important in affective behavior and experience. Davidson has proposed that the right and left anterior regions of the brain are specialized for withdrawal/aversive and approach/appetitive processes, respectively [41,65]. Not only does evidence show that brain activation (as indexed by EEG) changes in response to affect-eliciting events (i.e., state-dependent) but resting anterior EEG asymmetry has also been shown to be a state-independent index of an individual's propensity to respond affectively [for reviews, see 42,66–73].

Exercise has been suspected as an affect-eliciting stimulus for some time, often resulting in reduced negative and/or enhanced positive affect. The perspective espoused here is that the physical changes, which occur with exercise, are intimately linked with these affective changes. Generally, studies that have examined EEG-exercise relationships before and after aerobic exercise have reported an increase in EEG activity (operationalized in a variety of ways) following aerobic exercise, particularly in the slower frequencies (i.e., delta, theta, and alpha) [74]. In addition to its predominantly atheoretical nature, however, this literature has been plagued by numerous methodological shortcomings that make its interpretation difficult. In a programmatic examination of this relationship, we have shown that regional brain activation can predict affective responses to exercise [75–80]. Overall, these studies suggest that both the duration [81] and intensity of exercise may influence the relationship between resting frontal asymmetry and affective responses to that exercise [see 82,83]. When low-to-moderate intensities of exercise are used [walking at a self-selected pace [75]; cycling at 55% VO_{2max} [80]; or cycling at 60% predicted VO_{2max} [84]] frontal EEG asymmetry does not predict affective responses following exercise. However, at higher intensities (cycling at 70% VO_{2max} [80]; running at 70% VO_{2max} [79]; running at 75% VO_{2max} [78]; and graded exercise to exhaustion [76]), frontal EEG asymmetry has been predictive of affective responses, and this relationship appears to be influenced by fitness [78].

While EEG remains a more readily accessible technology in this domain, other emerging technologies could provide even greater insights into the link between physiological processes and affective responsivity. Ekkekakis [62] has described near-infrared spectroscopy (NIRS; see also [85]) as a technology that can provide a better understanding of "what the brain 'does' during exercise" (p. 505) and thus "help reformulate, refine, or place important boundary conditions" (p. 505) on the questions we pose. Basically, NIRS allows an assessment of oxygenation of tissue (including cortical tissue) with evidence indicating an increase in oxygenation (i.e., increased activation) at low-to-moderate levels of exercise intensity and decreases in oxygenation (i.e., decreased activation) during strenuous exercise. Perhaps one of the greatest advantages of NIRS over EEG would be the ability to monitor PFC activity during exercise without the movement artifact concerns present with EEG. Furthermore, understanding the during-exercise affective responses has become an important practical and theoretical issue [16].

Transient Hypofrontality

The second theoretical question noted by Ekkekakis [62] is the THH [14,86,87]. The THH proposes that exercise exerts an inhibitory effect on activation of the PFC, thus providing a possible explanation for both the impairment of certain

cognitive processes during exercise as well as the anxiolytic and antidepressant effects of exercise. There is some behavioral evidence to support the basic tenets of the THH [e.g., 88,89]. However, there is also evidence that does not support it [e.g., 90,91]. Brümmer et al. [90] examined the effects of increasing exercise intensity on EEG current density (measure of brain activity) in the primary sensory and motor cortices and the PFC during the exercise itself. In keeping with the THH, activity in the primary cortex increased in conjunction with increasing intensity, but activity in the PFC (and primary sensory cortex) remained stable throughout. A particularly interesting study was designed to examine whether single bouts of exercise could reduce cravings for cigarettes [92]. Imposing temporary nicotine abstinence on the participants, a substantial reduction of brain activation (assessed via fMRI following exercise or no-exercise control conditions) was seen in the dorsolateral PFC following 10 min of moderate-intensity cycling exercise (compared with scanning done during no-exercise control). In contrast, other areas of the frontal cortex showed increased activation following exercise. van Rensburg et al. [92] pointed to the THH as a potential explanation for their finding. While several psychophysiological methodologies could be used to examine the THH, Ekkekakis [62] makes a cogent argument for the use of NIRS because of its potential application across a range of exercise intensities and its general ability to withstand movement artifact, thus allowing its use during exercise. Coupled with appropriate measurement of ongoing cognition and/or affect, NIRS could be invaluable in furthering our understanding of mechanisms underlying such changes.

Dual-Mode Theory

The final theoretical question concerns what has been called the DMT. Ekkekakis [15,16,62] proposed the DMT as a way of explaining affective responses occurring in response to exercise, taking into account both the evolutionarily adaptive significance of, and the physiological basis for, such responses. Essentially, the DMT proposes that affective responses to exercise are influenced by both cognitive (e.g., self-efficacy) and interoceptive factors (e.g., muscular, respiratory cues). The relative influence of cognitive to interoceptive factors is hypothesized to depend on the intensity of the activity itself. At exercise intensities below the ventilatory threshold (VT), cognitive factors are hypothesized to influence affective responses to a greater extent; at intensities near or above the VT, interoceptive influence becomes increasingly dominant. Such a theoretical perspective would allow psychophysiological examination of affective responses guided by theory, something that has not happened to any great extent in the exercise domain [93]. Evidence to date has been largely supportive of various aspects of the DMT [e.g., 15,94].

As noted by de Geus and de Moor [95] and echoed by Ekkekakis [96], two questions that have puzzled exercise scientists are (1) why exercisers exercise and (2) why non-exercisers don't. de Geus and de Moor presented an interesting case for genetic influence for such individual differences in how exercise might influence affective responses. "We suggest that the genetic make-up of exercisers tips the balance of the appetitive and aversive effects of exercise in favor of the appetitive effects, whereas in non-exercisers the aversive effects may prevail" [95, p. 57]. A tool has been developed to address such individual differences by assessing intensity preferences and intensity tolerances [97]. Defining intensity preferences as "a predisposition to select a particular level of exercise intensity when given the opportunity (e.g., when engaging in self-selected or unsupervised exercise)" and intensity tolerance as "a trait that influences one's ability to continue exercising at an imposed level of intensity even when the activity becomes uncomfortable or unpleasant" [97, p. 354], studies have shown support for both constructs [98,99]. Clearly, with documented large individual differences in the magnitude of exercise-associated affective changes [93,95] and even in the direction of affective responses (positive, negative, and no change to the same exercise stimulus), continued study of individual differences is crucial to developing better exercise prescription so that perhaps even non-exercisers will adopt and adhere to regular exercise programs.

Thinking of affect in terms of both activation/arousal and valence dimensions, examining affective responses during exercise in addition to before and after exercise, and considering individual differences have been productive approaches in examining the role of exercise intensity [93]. Furthermore, the move toward guiding such investigations from theoretical perspectives has yielded, and will continue to yield, noteworthy insights and has provided clearer views through the windows. Yet again, the point is that "mind" issues (i.e., affect/emotion) are intimately rooted in, and inseparable from, "body" issues.

"LOOKING THROUGH 'STRAINED'-GLASS WINDOWS"

Life in the latter half of the twentieth and beginning of the twenty-first centuries has been characterized by ever-growing levels of stress. One of the consequences of this increasingly stressful lifestyle is a concomitant increase in stress-related diseases (e.g., heart disease, cancer, depression, ulcers, irritable bowel syndrome). Sapolsky [100], in a very accessible text, describes how we respond to acute physical crises, chronic physical challenges, and psychological and social disruptions.

An influential framework in the development of our understanding of the stress response involves two related yet distinct neuroendocrine axes: the sympathetic-adrenal-medullary (SAM) axis and the hypothalamic-pituitary-adrenocortical (HPA) axis. The SAM axis response to a stressor results in sympathetic outflow (via the splanchnic sympathetic ganglion) to the adrenal medulla, resulting in the release of catecholamines (norepinephrine [NorE] and epinephrine [E]) into the bloodstream. The HPA axis response involves the release of corticotropin-releasing hormone by

the hypothalamus into hypothalamic-pituitary circulation, which then stimulates the pituitary gland to release adrenocorticotropic hormone into the blood, ultimately stimulating the adrenal cortex and resulting in the release of glucocorticoids (e.g., cortisol in humans). Both axes are involved in the stress response, with the SAM axis responding more rapidly and the HPA axis requiring longer recovery time. As described by Sapolsky, catecholamines (NorE and E) act "within seconds; glucocorticoids back this activity up over the course of minutes or hours" [100, p. 30].

It is a popularly held belief that exercise can act as a buffer against the stress response [101]. Indeed, plenty of anecdotal evidence exists that exercise can help alleviate stress. One basic premise for how exercise could buffer the deleterious effects of the stress response is referred to as the cross stressor adaptation hypothesis (CSAH). Noting that exercise itself is a stressor that invokes many of the same physiological paths as psychosocial stressors but in a beneficial fashion, the CSAH comes from the idea that these beneficial adaptations from exercise manifest themselves when experiencing a psychosocial stressor. Because the exercise-induced adaptations are more positive, they help to attenuate the negative effects of the stressor [102]. As with examination of the affective impact of exercise, an ever-increasing literature has evolved documenting the impact of "body" interventions (i.e., exercise) as a way of buffering the effects of psychosocial stressors. This research has taken the form of studies examining the effects of fitness on various stress indices (e.g., ranging from self-report to cardiovascular to immunological) and studies examining the effects of both acute and chronic exercise on stress. In an oft-cited initial review, Crews and Landers [103] quantitatively summarized the results of 34 studies examining the effects of aerobic fitness on the psychosocial stress response. A variety of stress indices, including heart rate (HR), systolic blood pressure (SBP), diastolic blood pressure (DBP), self-report, and catecholamines (NorE, E), were included. The basic question was simple and straightforward: Do individuals possessing greater levels of aerobic fitness have an attenuated stress response relative to less fit individuals? Crews and Landers concluded that, regardless of the stress index used, more fit individuals had a significantly smaller stress response compared to unfit individuals.

In terms of cardiovascular reactivity to stress, three other reviews of the fitness-stress reactivity literature offer a much less optimistic picture. Forcier et al. [104] examined the effects of fitness on cardiovascular reactivity (HR, SBP, DBP) and recovery from psychosocial stressors. Although their results favored a fitness effect, it was much more muted than that reported by Crews and Landers. Forcier et al.'s analysis essentially showed that physically fit individuals have a smaller HR and SBP reactivity response to psychosocial stressors, estimated at 15%–25%, and also have a faster HR recovery when such stressors are over relative to unfit individuals. In contrast to both investigations, Jackson and Dishman [105] concluded that the evidence does NOT support the hypothesis of reduced reactivity to stressors in more fit individuals. They, like Forcier et al., did find evidence for a slightly faster recovery following stressor offset in more fit individuals, but noted such an effect was rather small. Finally, Hamer et al. [106] reviewed 15 randomized controlled trials that examined the acute exercise effect on blood pressure (BP) responses to psychosocial stressors. The overall effect showed the equivalent of 3.7 and 3.0 mmHg reductions in the SBP and DBP responses, respectively, compared to controls. Hamer et al. concluded that the benefits of regular exercise might come from the fact that the regular exerciser is likely to be in a favorable postexercise window more often when experiencing a daily stressor.

Beyond acute bouts of exercise, it has also been assumed that exercise training would have stress-buffering effects. However, there is no consensus on this assessment. For example, Peronnet and Szabo [107] stated, "Examination of these longitudinal studies suggests that there are no clearly identifiable changes in sympathetic response to psychosocial stress after physical exercise training as revealed by direct sympathetic indices, such as circulating catecholamines" (p. 206). They also suggested that the mechanisms responsible for the sympathetic aspect of the psychosocial stress response are different from the response to exercise stress. Further, Buckworth and Dishman [108] noted that there was little support for the hypothesis that exercise training and/or high levels of cardiovascular fitness translate into a reduced psychosocial stress response, pointing to the lack of evidence demonstrating an effect of exercise training on a reduced sympathetic response (i.e., plasma levels of NorE and E; sympathetic nerve activity). The sympathetic response has been shown to be reduced after exercise training, but only at absolute exercise intensities (i.e., all participants train at the same workload regardless of fitness level); when similar relative intensities are examined (i.e., exercise workload is adjusted based on fitness, age, gender, etc.), the sympathetic response is similar. In other words, "exercise training seems to increase the capacity of the sympathetic nerves to respond to maximal exercise, but does not change their responses to exercise of the same relative strain as before training" [108, p. 83].

While these criticisms may ultimately be true, some research does suggest that aerobic fitness may confer buffering effects to psychosocial stressors. For example, in a cross-sectional comparison, Boutcher et al. [109] found a lower absolute HR response to psychosocial stress (i.e., mental arithmetic, Stroop tasks) in aerobically trained individuals. Utilizing what may be a very important distinction, Boutcher et al. distinguished between absolute reactivity (i.e., the absolute value of HR during stress) and relative reactivity (i.e., a change in HR during stress from a baseline value). As Boutcher et al. noted, the lower absolute HR during stress could be due, at least in part, to a lower resting HR [109]. It has been argued that a lower resting HR is a reason for the smaller reaction to stress in more fit individuals [108]; in reality, their reaction is similar in magnitude to the less fit person. Boutcher [110] argues instead that the lower resting HR and absolute HR during stress may be cardio-protective, an effect resulting from exercise training. More specifically,

he suggested that the lower HR effectively results in the more fit person spending a greater amount of total time in a more "stable" state during the BP cycle (i.e., during diastole, that portion of the cycle when there is less change in the rate of blood flow and when blood flow itself is primarily unidirectional).

As noted by Holmes et al. [102], exercise-stress research is still fairly immature, largely because of a lack of "conceptual sophistication" (p. 501), poor methodological quality, timing of assessments, and the selection of stress indices. For example, "simply" focusing on HR and BP responses has been the norm rather than the exception in the majority of the literature. In addition to his thoughts on the lower HR response to stressors in more fit individuals, Boutcher [110] noted that a reduced absolute HR response may be due to greater dominance of the parasympathetic system at rest, combined with a smaller sympathetic response during the stressor. Using HR variability (HRV), a measure which provides an indirect assessment of parasympathetic influence on the heart, it has been shown that the HR response to a stressor is due more to parasympathetic withdrawal and less to increased sympathetic activity in trained individuals [109,111]. This parasympathetic withdrawal effect has potential importance in terms of catecholamine sparing. That is, if the elevated HR response is due to a withdrawal of parasympathetic influence more so than an increase in sympathetic activity, fewer catecholamines will be released in response to the stressor.

Another example highlights the more real-world nature of the fitness-stress relationship. King et al. [112] examined the effect of a 12 month exercise intervention (compared to a year-long nutrition education program) on cardiovascular stress reactivity in initially sedentary women. These women, who were caring for a relative with dementia, had HR and BP reactivity assessed in response to a 6 min period during which they were asked to discuss those "aspects of her caregiving experience that she found to be most frustrating or disturbing" (p. M29). The assessment was done at the beginning and end of the intervention. Participants in the exercise intervention had significantly smaller SBP and DBP reactivity (4–9 mmHg smaller, approximately twice that reported in the Forcier et al. 2006 meta-analysis [104], following the intervention than did their nutrition education counterparts, reflecting an improvement in the relationship between chronic stress and cardiovascular pathology.

While most exercise–stress research has tended to focus on cardiovascular and catecholamine reactivity, some research has examined the HPA axis response to psychosocial stressors. The stress response has wide-reaching effects and has been shown to have a potent impact on immune function. Several disciplines have developed as a result of such inquiries, including psychoneuroimmunology (PNI). PNI research examines the interplay among a variety of mind-body systems, particularly the nervous and immune systems. Furthermore, and more importantly, special attention is given to psychological and social/environmental factors and the effects these have on mind-body function. To follow up on the work of Davidson [70] presented in the previous section, he and his colleagues [113] have shown that individuals with greater relative right anterior brain activation, as opposed to relative left anterior activation, had significantly lower basal levels of natural killer (NK) cell activity (a measure of immune function), reflective of immunosuppression. The same right-activated individuals showed a greater decrease in NK function in response to a significant stressor (i.e., final examination). Similar results were found earlier in a study by Kang et al. [114], consistent with the framework that greater relative right anterior brain activation is reflective of a vulnerability to negative affective responsivity and dispositional negative affect.

In groundbreaking work in the exercise domain, LaPerriere et al. [115] examined the impact of exercise training as a way of buffering stressors. In a group of asymptomatic men at risk for acquired immune deficiency syndrome (AIDS), LaPerriere et al. showed that those who exercised for 5 weeks prior to receiving notification of their human immunodeficiency virus type 1 (HIV-1) status had little change in psychological and immunological measures when they were notified of testing positive for HIV-1. A control group of men who did not exercise showed significant immunologic changes indicative of reduced immunocompetence (i.e., decreased NK cell activity) along with significant increases in anxiety and depression following positive HIV-1 notification. Thus, the relatively brief exercise training provided, at least in part, significant buffering of the stressful influence of a real-life stressor (i.e., discovering that one has the virus that causes AIDS), both psychologically as well as immunologically.

More recently, Traustadottir et al. [116] examined the CSAH. They examined whether adaptations known to occur within the HPA axis in response to physical stress (e.g., blunted cortisol response to exercise performed at the same absolute intensity, greater maximal capacity of the adrenal glands) also occur in response to psychosocial stress and whether aerobic fitness influenced that response. To examine these questions, Traustadottir et al. had 10 young (19–36 years old) and 26 older (59–81 years old) women perform a battery of psychosocial stressors. All of the younger women were classified as unfit; roughly half of the older women were also classified as unfit, while the other half were classified as fit. The battery of tests was referred to as the Matt Stress Reactivity Protocol (MSRP), which lasted approximately 30 min. It consisted of the Stroop Color Word Test, mental arithmetic, an anagram task (a series of letters needing to be unscrambled to form words; time urgency usually stressed), a cold pressor task (subjects placed their hands in buckets of ice water for as long as they could, up to 3 min), and an interpersonal interview, in that order. HR, BP, and plasma cortisol were assessed 45 min prior to beginning the protocol, at the conclusion of each of the tasks, and during recovery from the protocol.

Whereas the MSRP resulted in significant elevations in cardiovascular and endocrine responses, the cortisol response

was modified by fitness. Older fit women had significantly lower cortisol responses to the MSRP than their older unfit counterparts. This difference in response to stress occurred in spite of there being no significant baseline differences between the groups. It is worth noting that even during the recovery time period, cortisol responses were still elevated above baseline values for the older unfit group. Although the cortisol effects were pronounced, no differences existed for adrenocorticotropin-releasing hormone response, or for any of the cardiovascular measures, between both groups. Thus, aerobic fitness blunted the stress response in the older women. This was interpreted as evidence that aerobic fitness can influence sensitivity to stress, ultimately affecting the HPA axis in the direction of a reduced cortisol response to psychosocial stress [116].

The conclusion reached by Traustadottir et al. has been confirmed in at least two other studies. An initial study by Rimmele et al. compared highly trained (i.e., elite sportsmen) to otherwise healthy but sedentary men in response to a 10 min psychosocial stressor challenge. The Trier Social Stress Test (TSST) consisted of a 5 min public speaking task; in this case, participants had to engage in a mock job interview, followed by a 5 min mental arithmetic task involving serial subtraction. Oral responses were given during the serial subtraction task, and both tasks were performed in front of two evaluators (unfamiliar to the participants). Previous research had shown that the TSST significantly alters both HPA axis and cardiovascular responses. Rimmele et al. [117] found the elite sportsmen had significantly smaller reactivity (i.e., smaller increase) in both HR and salivary cortisol compared to their sedentary counterparts. It could be argued that one reason for the different response was simply due to the fact that elite sportsmen are exposed to socially threatening situations more often through competition and thus have different responses due to this. A follow-up study [118] replicated and extended these findings. Similar groups were tested (elite sportsmen vs. sedentary men), but a third, intermediate group was added—amateur sportsmen. Thus, these participants would likely have the same exposure to the socially threatening situations, but do not train at the same level as the elite sportsmen. The participants were again subjected to the TSST, and the results were similar for the elite sportsmen compared to the sedentary group (i.e., reduced HR and cortisol reactivity during the stressor task). The amateur sportsmen had a similar cortisol response as the sedentary group, but a HR response that was similar to the elite group. Thus, the overall findings from both studies were consistent with the Traustadottir et al. work, namely that physical activity seems to have a blunting effect on the HPA axis (i.e., appears to support the CSAH). Furthermore, it appears that physical activity has more rapid effects on the sympathetic nervous system as both groups of sportsmen showed less reactive HR responses to the stressor.

To further examine the effects of exercise and/or fitness on psychosocial stress exposure, Hamer and Steptoe [119] assessed the association between fitness (estimated from a submaximal test), parasympathetic control of the heart (via HRV), and immune function responses to mental stress. Participants completed two mental stressors (5 min Stroop task, 5 min mirror tracing task), and blood samples and HRV were collected at rest and 45 min post-stressor tasks; HRV was also assessed during the stressor tasks. Measures of immune function [interleukin (IL)-6, IL-1 receptor antagonist] were significantly greater during recovery. Further analyses indicated that, after accounting for several other baseline factors (e.g., age, body mass index, gender, baseline levels of immune function), exercise HR was related to IL-6 and tumor necrosis factor (TNF)-alpha responses to the stressor tasks; exercise HR was also related to the HRV response to stress. Furthermore, higher SBP during exercise was predictive of TNF-alpha responses to the stressors. Hamer and Steptoe noted that a lower exercise HR (an index of greater fitness) was associated with smaller immune response, specifically a smaller inflammatory response, to acute mental stress. This response seems to be mediated, in part, through parasympathetic pathways, a mechanism which may offer an explanation for how fitness buffers against cardiovascular risk.

As mentioned earlier, Holmes et al. [102] have commented on the lack of "conceptual sophistication" (p. 501), poor methodological quality, timing of assessments, and the selection of stress indices. A key issue in this regard, one that has been typically overlooked in exercise research, is the examination of the recovery from the stressor once it has stopped, as opposed to reactivity to the stressor. Gal and Lazarus [120] noted that emotional arousal in response to a stressful event might not be reflected in the magnitude of the hormonal response but rather in how long the response lasts (i.e., the duration). They cite data from a study of combat soldiers, noting that while an "attacking" company had a more marked rise in corticosteroids (i.e., cortisol) in response to combat than a "defending" company, the defending company took much longer to recover from the combat than the attacking company (13 vs. 6 days). This finding not only fits with their thesis that participating in physical/motor activity of some sort, as opposed to being passive, helps to cope with a stressor, but also highlights the importance of recovery from a stressor compared to the actual reactivity to it.

Spalding et al. [121] showed lower HR and rate pressure product (the product of HR × SBP) levels during recovery from a psychosocial stressor in a group of aerobically trained individuals compared to weight-trained or non-trained individuals. Likewise, Traustadottir et al. [116] found elevated cortisol levels in older unfit women during recovery from a stress battery compared to a group of older fit women. Thus, while the evidence for a stress-buffering effect of exercise may not be particularly compelling at present, evidence suggests that fitness or exercise training may provide a more rapid recovery from the stressor once it is no longer present. This shorter duration stress response could have the effect of reducing the overall wear and tear on the mind-body. Again, in this case, better timing of assessments [102] may yield greater clarity of findings.

CLEANING OUR WINDOWS/ LOOKING FOR THE PATTERNS

As one examines mind/body research, it is clear that there is certainly incredible potential to increase our understanding of human functioning. If researchers can be convinced to examine such functioning from multiple levels, as we have argued at the beginning of this chapter, this will most certainly be a step in the right direction. However, human functioning is not going to be easily understood. One need only examine the work of Cacioppo et al., summarized in Cacioppo [122]. In examining neuroendocrine responses to a stressor, he and his colleagues could have easily stopped with the finding that a psychological stressor activates the SAM axis (increased NorE and E) but not the HPA axis (no change in cortisol). However, when these responses were examined within high and low HR responders (i.e., from an individual differences perspective), a different picture emerged. High HR responders had higher levels of cortisol in addition to the elevated catecholamine response; low HR responders did not. As Cacioppo [122] also points out, classifying an individual as a high or low HR responder ignores the origin of this reactivity. For example, high HR reactivity could be due to elevated sympathetic reactivity, vagal withdrawal, or reciprocal activation of both sympathetic and vagal input to the heart. The point is, simply including measures from different levels of analysis alone is not sufficient. There is also the need to look for patterns or profiles of responding as opposed to expecting simple relationships to be found between mind and body measures.

"An integrative, interdisciplinary approach across levels of organization and analysis can add unique perspectives because different levels of analysis *can reveal distinct patterns of order in data* …" (emphasis added, p. 26, [123]). Cacioppo et al. [8] make a logical case for how to examine these multiple measures from the physiological and psychological domains and put them together in a manner that allows us to make sense out of the chaos. They argue that it is probably not realistic to expect to find simple one-to-one relationships between a psychological event and a physiological event (e.g., to expect that HR will give us a physiological measure of anxiety). Such an assumption inevitably leads to frustration because consistent correspondence between such measures will rarely be found. Cacioppo et al. argue instead for examination of patterns or profiles of response. As an illustrative example, they present how two autonomic measures, skin conductance and HR, can be used to infer different psychological processes. The orienting, defense, and startle responses all share a relationship with skin conductance and HR, which would normally preclude the ability to infer the psychological processes from the physiological signals. Such inferences can be made, however, when the patterns particular to each response are examined. The orienting response is associated with a phasic skin conductance response coupled with a deceleration in HR. Both the startle and defense responses can be inferred from a phasic skin conductance response and an acceleration in HR. However, both are differentiated by the fact that the startle response involves an abrupt acceleration in HR while the defense response involves a lingering acceleration in HR. The point is, it is only through the examination of patterns of responding or response profiles that we can uncover the complicated relationships between "body" measures and "mind" constructs. The cost of such an approach isn't cheap, but the payoff is infinitely great.

CLOSING THE WINDOW

Although certainly not exhaustive, the evidence presented in this chapter would make it difficult to argue against the idea that "mind" and "body" are intimately linked and inseparable from each other. Much more information is gained by simultaneously examining human functioning from a mind-body perspective at multiple levels (i.e., psychophysiological, physiological, and social/environmental) than could ever be obtained by looking at mind and body as separate entities and/or from single levels of analysis. It is also worth pointing out that "… in such matters technical progress is likely to outpace refinements in perspective; indeed, technical advances are likely to shape perspective" [124, p. v]. Thus, while it would be foolhardy to discount the advances to understanding that may come from new technologies (e.g., fMRI, NIRS), it would be equally foolhardy to rely on such techniques and technologies without constraining the findings to a theoretical perspective or, at the very least, to the research paradigm that was used to derive the findings. For example, Robinson et al. [125] pointed out that there are numerous factors that could potentially influence the patterning and magnitude of emotional responding in an fMRI paradigm, all of which can lead to different definitions of the phenomenon being examined or to interpretations of the data garnered from such investigations. Another issue with these newer technologies is that the number of participants studied is often rather small (e.g., <10 participants), sometimes only examining one sex, and very often minimizes individual differences (i.e., examining group averages). We know from a growing number of studies [e.g., 97,126] that ignoring such individual differences can lead to erroneous conclusions and the same holds for studies using new techniques.

The major point here is that, as a field, we need to be careful not to get too caught up in the tools that we have available, but to begin with solid research questions that inform innovative research designs. Hopefully this will not lead to a large number of disparate studies with disjointed findings, but instead to a greater likelihood of uncovering patterns and meaning in the relationships between mind-body.

It is our hope that such information will stimulate readers to examine their research questions more thoughtfully and to begin to explore phenomena of human functioning from a multilevel perspective. It is no longer enough to assume that the only reality that matters is that which the individual constructs for her/himself. Such perspectives are important but incomplete. The corporeal basis for such realities will aid in

how we come to understand human behavior. The following quote from Miller [127] sums it up well:

> The body is the medium of experience and the instrument of action. Through its actions we shape and organize our experiences and distinguish our perceptions of the outside world from sensations that arise within the body itself. (p. 14)

INTRODUCTION

Regular exercisers have lower risks for cardiovascular disease, obesity, and type 2 diabetes than non-exercisers [1–3], and the percentage of people at risk because of inactivity is higher than those at risk because of hypertension, smoking, and cholesterol [4]. Despite these well-documented benefits of physical activity, a large proportion of adults in the Western world do not engage in exercise activities on a regular basis [5–7]. As a consequence, a sedentary lifestyle—and the accompanying risk for obesity—remains a major threat to health in today's society. This is reflected in public health recommendations, which unanimously include an encouragement to a more active lifestyle [8].

To increase the success of intervention on this important health behavior, much research has been devoted to the determinants of exercise behavior. The bulk of these studies have attempted to explain low exercise prevalence in terms of social and environmental barriers. These include, among others, poor access to facilities [9], low socioeconomic status [6,10], non-Caucasian race [11], high job strain [12], subjective "lack of time" [13], inadequate health beliefs [6], and low social support by family, peers, or colleagues [13,14].

Although social factors are important, they explain only a small part of the individual differences in regular exercise behavior. In this chapter, we review the evidence that genetic factors play an important role too. Broadly, the genetic research on regular exercise behavior can be classified into twin (family) studies and gene-finding studies. We will summarize the evidence presented by each of these types of studies. As the exact definition of the phenotype might influence heritability estimates, we will first review the different definitions of exercise behavior that have been used across studies.

DEFINITIONS OF REGULAR EXERCISE BEHAVIOR

A first important distinction between studies on regular exercise behavior is whether they query regular exercise activities that are confined to leisure time or whether they count all physical activity (TPA). Leisure-time exercise activities are often specifically aimed to improve cardiorespiratory health such as jogging, exercising at fitness clubs, and participation in team or individual sports [15]. TPA is not limited to these activities and also incorporates occupational physical activity, bicycling to school/work, and household activities.

Even when we restrict ourselves to leisure-time exercise behavior, definitions can differ across studies. Some studies explicitly focus on all "pure" exercise activities (jogging, exercising in the fitness center, and all individual or team sports), while others also include leisure-time behaviors such as gardening, dancing, and walking/bicycling. The differences in the definitions of exercise behavior are further complicated by the varying methods of assessment. Most of the studies on exercise behavior have been survey-based, but rather different questions have been used. Some studies used surveys with only a single YES/NO question [16], whereas others asked about specific exercise activities [7,17] and still others allowed all exercise activities to be reported [18]. The type, duration, frequency, and intensity were sometimes but not always assessed in great detail. This makes it difficult to either pool or compare the prevalence of exercise behavior across survey studies.

Two regular exercise phenotypes are nonetheless easy to define and resemble each other quite well across studies. Sedentary subjects simply do not engage in any type of leisure-time exercise activity, whereas vigorous exercisers perform leisure-time exercise activities above the intensity and frequency thresholds required to maintain a continued

increase in aerobic fitness above their sedentary level. To achieve such an increase, vigorous exercisers engage in large muscle dynamic exercise activities requiring more than 50% of their maximal oxygen consumption for at least three times a week for 20 min or more per occasion [8,19].

Measures of regular light to moderate exercise behavior, i.e., all exercise levels in between sedentary and vigorous exercise, are much harder to compare across studies. Studies use different criteria for the minimum frequency and the minimum intensity that is required to classify participants as "regular exercisers." Criteria for frequency have varied from once per 2 weeks [6,20,21] to five or more times a week [22]. In some studies, the exercise activities were coded for intensity and had to meet a certain minimal intensity to be counted [23–25], whereas in others, no minimum intensity was specified [6,20,21].

In the next paragraph, we describe the prevalence of three different measures of exercise behavior that have been consistently measured in the same way in a large community-based sample from the Netherlands Twin Register (~30,000 subjects) [26]. We compare the prevalence of regular exercise behavior in the Netherlands to the prevalences obtained in five other large studies conducted in industrialized societies [6,7,20–22].

PREVALENCE OF REGULAR EXERCISE BEHAVIOR

Within the Netherlands Twin Register, data on exercise behavior have been collected through surveys in large numbers of twins, their parents, siblings, spouses, and the adult children of twins and siblings. Data collection has started in 1991 when most twins were adolescents. Since then, a survey with data on health, lifestyle, and personality (including data on exercise behavior) has been sent out to the participants in 1993, 1995, 1997, 2000, 2002, 2004, and 2008 [26]. In total, leisure-time exercise behavior and general physical activity data have been collected in about 30,000 subjects. It has been shown that twins are comparable with non-twins and representative for the population at large with regard to their participation in regular leisure-time exercise [18].

Regular exercise in leisure time was measured in detail in each survey. First, the participants were asked whether they exercised regularly in their leisure time ("Yes" or "No"). If participants responded affirmative, they were asked to indicate in which types of exercise activities they engaged. For each activity reported, they noted down the number of months per year, weekly frequency, and average duration in minutes of the activity. Ainsworth's Compendium of Physical Activity [27] was used to assign a metabolic equivalent (MET) score to each exercise activity, reflecting its energy expenditure as a multiple of the basal energy expenditure (~1 kcal/kg/h) in an average subject engaged in that activity. For each participant, a total weekly MET score was computed across all exercise activities by summing the products of the number of hours spent weekly on each exercise activity and its MET score. Activities were only scored if that participant had engaged in them for at least 3 months during the past year. For adolescents, exercise during physical education classes at school was not included in the weekly MET score.

Subjects were classified as moderate to vigorous exercisers if they exercised at least 60 min/week with a MET score of 4 or more. They were classified as non regular exercisers otherwise. In addition, data were collected on the frequency of exercising to sweat during leisure time ("Sweat Index") and the frequency of being physically active during leisure time during at least 20 min in the past 6 months ("Twenty minutes active"). The five answering categories for the Sweat Index were "No," "Yes, once per week," "Yes, 2 times per week," "Yes, 3 times per week," and "Yes, more than 3 times per week." The Twenty minutes active variable had six answering categories, which were "Never," "Less than once per month," "About once per month," "About 2–3 times per month," "1–2 times per week," and "3 times per week or more." The Sweat Index and the Twenty minutes active variable were measured on all time points except 1991 and 2008.

Table 115.1 shows the prevalence of these three regular exercise behavior phenotypes in the Dutch twin family population. To achieve this, we constructed a maximal cross-sectional dataset by selecting the most recent measurement for each individual. This resulted in data from over 21,000 participants for the Sweat Index and Twenty minutes active variable and data from over 29,000 participants for regular exercise status based on the weekly MET score. As can be seen in the table, about 70% of the population exercises at least once per week to sweat or has been physically active during leisure time for at least 20 min at least once per week during the past 6 months. The percentage of the population exercising to sweat or exercising at least 20 min for three times a week or more is much lower and lies around 25%–40%. When taking into account the intensity of the exercise activities in METs, about half of the population engages in moderate to vigorous exercise activities (4 MET or more) for at least 60 min/week.

For the Sweat Index, there are clear sex differences, with men exercising on average more than women. Furthermore, the prevalence of regular moderate to vigorous exercise behavior for at least an hour a week generally declines with age. For example, 55% of the youth between 10 and 20 years old engage in regular moderate to vigorous exercise but this is only 28% in older adults between 60 and 80 years. Interestingly, no obvious sex difference or age-related decline is observed in the answer to the question whether they were physically active during leisure time for at least 20 min in the past 6 months. In contrast to the other two questions, intensity of the exercise activity may not play a role when subjects answer these questions.

Although it is clear that these three exercise phenotypes measure different aspects of leisure-time exercise behavior, they also measured an overlapping construct. A series of univariate ANOVA's showed that the Sweat Index, the Twenty minutes active variable, and Regular moderate to vigorous exercise were all significantly and positively associated with the total weekly MET hours based on the

TABLE 115.1
Prevalence of Different Exercise Phenotypes in the Netherlands Twin Register

	Sweat Index				Twenty Minutes Active				Regular Moderate to Vigorous Exercise		
	N	<1 Time/Week Sweating	≥1 Times/Week Sweating	≥3 Times/Week Sweating	*N*	<1 Times/Week 20 Minutes Active	≥1 Times/Week 20 Minutes Active	≥3 Times/Week 20 Minutes Active	*N*	No Regular Exercise	≥1 h/Week of Moderate to Vigorous Exercise (MET ≥ 4)
Total	21,818	31.0	69.0	23.6	21,896	26.6	73.4	38.1	29,526	56.4	43.6

TABLE 115.2
Association of Weekly MET Hours with the Categorical Sweat Index, Twenty Minutes Active, and Regular Moderate to Vigorous Exercise Variables

	Mean Weekly MET Hours (SD)	*F*-Test
Sweat index		
No	2.79 (8.41)	
Yes, once per week	7.47 (11.55)	
Yes, two times per week	11.99 (14.70)	
Yes, three times per week	18.31 (19.84)	
Yes, more than three times per week	19.93 (26.99)	$F(4.18563) = 743.9$; $p < 0.001$
Twenty minutes active		
Never	2.21 (8.82)	
Less than once per month	2.88 (9.41)	
About once per month	3.32 (8.33)	
About two to three times per month	4.84 (10.24)	
One to two times per week	8.59 (12.59)	
Three times per week or more	14.79 (21.07)	$F(5.18624) = 276.8$; $p < 0.001$
Regular moderate to vigorous exercise		
No	0.63 (4.37)	
Yes	22.19 (21.21)	$F(1.27012) = 14560.9$; $p < 0.001$

questions on type, frequency, and duration of reported exercise activities (Table 115.2).

The prevalence for leisure-time exercise behavior in the Dutch twin families is very consistent with the prevalence reported by five other large-scale studies [6,7,20–22]. Three of these studies were conducted in 10,000–20,000 university students aged 18–30 years from the European Union (EU) and elsewhere [6,20,21]. All three studies found comparable prevalence for leisure-time exercise: about 70% of the students exercised regularly, meaning they engaged at least one time per 2 weeks in exercise (e.g., sports activities and physically active pastime). About 30%–35% of the students were vigorous exercisers (i.e., had exercised on five or more occasions during the previous 2 weeks). The fourth study was a pan-European study of exercise participation in more than 15,000 adults aged 15 years up to more than 65 years old from 15 member states of the EU [7]. They found that 76% of the male and 71% of the female EU population participated in some kind of physical activity during leisure time, a result best comparable with our Twenty minutes active variable. In a fifth study, physical activity levels were assessed in 43,732 men and women from the United States, aged 18 years and older [22]. The average prevalence across adulthood for any form of exercise behavior (five or more times a week and 30 min or more per occasion of any activity, but no intensity specified) varied between 73% for women and 79% for men, a result again comparable with our Twenty minutes active variable.

Overall, a clear picture arises from the six studies described earlier in the text. Despite the well-documented benefits of exercise, a large group of adolescents and adults does not engage in exercise on a regular basis. Across Europe and the United States, the prevalence for sedentary behavior varies between 26% and 34% depending on the exact question used. What factors cause exercisers to exercise and, more importantly, what keeps non-exercisers from doing the same? The remainder of this chapter will review evidence from behavioral genetics for a significant genetic contribution to physical activity behaviors.

TWIN STUDIES ON EXERCISE BEHAVIOR

As with many other traits, exercise behavior appears to run in the family. The familial resemblance observed for exercise behavior can represent environmental influences that are shared within a family ("nurture") or they can represent genetic influences ("nature"). Twin studies can separate these two mechanisms by comparing the resemblance in exercise behavior between monozygotic (MZ) and dizygotic (DZ) twins. When twins are reared together, they share part of their environment, and this sharing of the family environment is the same for MZ and DZ twins. The important difference between MZ and DZ twins is that the former share (close to) all of their genotypes, whereas the latter share on average only half of the genotypes segregating in that family [28]. This distinction is the basis of the classical twin study. If the resemblance in physical activity within MZ pairs is larger than in DZ pairs, this suggests that genetic factors (A) influence physical activity. If the resemblance in physical activity is as large in DZ twins as it is in MZ twins, this points to shared environmental factors (C) as the cause of family resemblance [29].

The extent to which MZ and DZ twins do not resemble each other is ascribed to the unique (or non-shared) environmental factors (E). These include all unique experiences like differential jobs or lifestyle, accidents or other life events, and in childhood, differential treatment by the parents, and non-shared friends and peers. Shared environmental factors are defined as those environmental factors that are shared within a family, such as parenting style, family functioning, neighborhood, or socioeconomic status. Additive genetic factors represent the sum of all linear effects of the genetic loci that influence the trait of interest.

The effect of genetic and environmental factors on exercise behavior in a sample of MZ and DZ pairs can be graphically depicted in a path diagram (Figure 115.1). The heritability of exercise is defined as the relative proportion of the total variance explained by genetic factors. In terms of the parameter estimates obtained from fitting the twin model to the data (see Figure 115.1), the heritability can be expressed as $a^2/(a^2 + c^2 + e^2)$. The heritability can also be represented as a percentage by multiplying this ratio by a hundred. The proportions of variance ascribed to shared environmental and unique environmental factors can be computed in a similar manner and are given by, respectively, $c^2/(a^2 + c^2 + e^2)$ and $e^2/(a^2 + c^2 + e^2)$ [30].

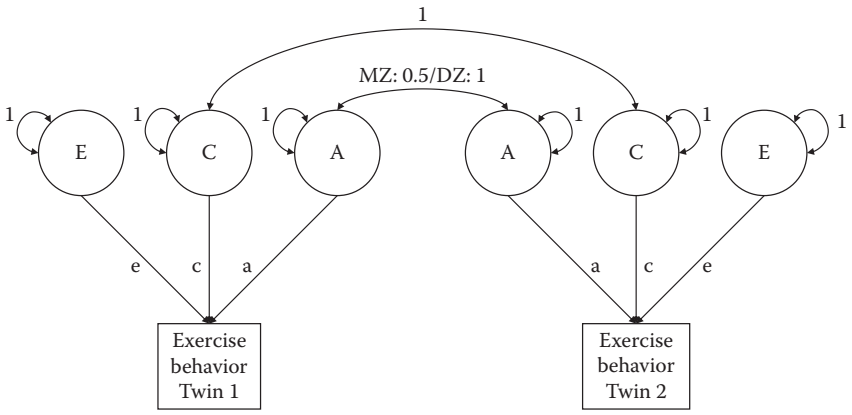

FIGURE 115.1 Path diagram depicting correlated latent additive genetic (A) and shared environmental (C) factors that can cause twin resemblance in exercise behavior, as well as unique environmental (E) factors that are uncorrelated in the twins. We set the correlation of the latent genetic factors for MZ twins to 1 and for DZ twins to 0.5. The correlation of shared environmental factors is set to 1 for both types of twins. The latent unique environmental factors are (per definition) uncorrelated. Unobserved latent variables have no scale: their variance is arbitrarily set to 1 (the double arrows that start and end in the latent factors). Path coefficients a, c, and e represent the factor loadings of exercise behavior on the latent factors.

An overview of twin studies on exercise behavior conducted in adolescents and adults is given in Table 115.3. These studies almost without exception converge on the finding that exercise behavior is heritable, both in adolescence and in adulthood, despite the different definitions of exercise behavior that were used (i.e., leisure-time exercise behavior, TPA, sports participation, or participation in specific high-intensity exercise activities). The heritability of regular exercise in the Netherlands Twin Register has been published in several studies for adolescents of different birth cohorts [17,24] and during adulthood (18–50 years) [31,32]. We extended these studies by estimating the heritability of regular exercise, the Sweat Index, and the Twenty minutes active variable in a sample of 5221 adult twin pairs of a broader age range (18–65 years) and by adding regular exercise data from the most recent survey (sent out in 2008/2009). All three variables were found to be heritable, with the highest heritability for regular exercise (60%; consistent with the previous studies in adults [31,32]). Somewhat lower heritabilities were found for the Sweat Index (38%) and the Twenty minutes active variable (36%). There was no evidence for quantitative or qualitative sex differences in heritabilities. In addition, we computed the phenotypic, genetic, and environmental correlations among the three phenotypes. The three phenotypes were strongly related at the phenotypic (polychoric correlations 0.51–0.67), genetic (0.69–0.78), and environmental level (0.38–0.59). These results confirm that the three phenotypes are not identical but show considerable overlap.

Twin studies in adolescence [17,24,33,34] show that variation in adolescent leisure-time exercise behavior is explained by a combination of genetic, shared environmental, and unique environmental factors. In a study of Dutch adolescent twins aged 13–20 years and born between 1971 and 1987 [34], it was observed that exercise behavior in young adolescents (up to 16 years) is largely determined by shared environmental factors. The influence of these factors rapidly waned when the adolescents became older. In a study of Dutch adolescent twins of the same age but from a later birth cohort (birth year ranged between 1986 and 1994) [17], it was shown that the shared environmental factors in young adolescence (13–14 years) were only present in girls but not in boys, whereas at age 15–19 years again genetic factors accounted for the largest proportion of the variances, and shared environmental factors did no longer play a role in explaining individual differences in boys and girls. Other twin studies confirm that family resemblance in adolescent leisure-time exercise behavior is explained by a combination of additive genetic and shared environmental factors and that shared environmental factors seem most important in young adolescent girls [33,34].

Studies conducted in adult twins aged between 19 and 68 years [31,34–39] show that variation in exercise behavior is almost entirely accounted for by genetic and non-shared environmental factors, with heritability estimates ranging between 35% and 83% of the variance in exercise. Most of these studies included twins of a wide age range, for example, 19–40 years [31] or 18–60 years [40]. A recent study [41] of seven different countries investigated whether the heritability of exercise behavior during adulthood (19–50 years) changes with age. In four of the seven countries (Denmark, Finland, Sweden, and the Netherlands), a significant decrease in heritability was observed with age (from 60%–90% at age 19 years to 0%–40% at age 50 years). In the other three countries (Australia, Norway, and the United Kingdom), the heritability of exercise was found to be stable during adulthood.

Taken together the results from adolescent and adult twin studies, it seems that heritable factors are present at all ages, but that the heritability of exercise behavior peaks during young adulthood [42]. This may also be the period in which the environmental influences on exercise behavior are lowest. For example, most young adults will have left their parent's house and started a more independent life, such that the influences of the home family environment have become less strong. Similarly, young adults may not yet experience some

TABLE 115.3
Twin Studies on Exercise Behavior

Study	Sample	Phenotype	Results
This chapter	2319 MZ and 2902 DZ Dutch twin pairs (18–65 years)	Frequency of engagement in leisure-time physical activities to the extent that it makes you sweat (Sweat index; <1 time/week, 1–2 times/week, ≥3 times/week) Frequency of engagement in leisure-time physical activities of at least 20 min during the last 6 months (Twenty minutes active; <1 time/week, 1–2 times/week, ≥3 times/week) Engage in leisure-time exercise activities with a minimal intensity of four METs for at least 60 min/week (Regular exercise; yes, no)	Sweat index: a^2 = 38%; c^2 = 0% Twenty minutes active: a^2 = 36%; c^2 = 0% Regular exercise: a^2 = 60%; c^2 = 0% Genetic correlations: Sweat index—Twenty minutes active: 0.78 Sweat index—Regular exercise: 0.75 Twenty minutes active—Regular exercise: 0.69
Van der Aa et al. [17]	8355 Dutch MZ and DZ twins (aged 13–14, 15–16, and 17–19 years)	Engage in leisure-time exercise activities with a minimal intensity of five MET hours weekly (moderate exercise) or 30 MET hours weekly (vigorous exercise)	a^2 = 85%; c^2 = 0% for 13–14-year-old boys a^2 = 38%; c^2 = 46% for 13–14-year-old girls a^2 = 80%; c^2 = 0% for 15–16-year-old twins a^2 = 72%; c^2 = 0% for 17–19-year-old twins
Aaltonen et al. [40]	4280 MZ and 9276 DZ twins on wave 1 (18–54 years) and 4383 MZ and 9439 DZ twins on wave 2	Leisure-time physical activity expressed in MET hours/day	Wave 1: a^2 = 44%; c^2 = 0% Wave 2: a^2 = 34%; c^2 = 0%
Duncan et al. [73]	1003 same-sex MZ and 386 DZ adult twin pairs (mean age 30 years)	Total minutes per week of moderate to vigorous activity (more than 60 or 150 min)	60 min criterion: a^2 = 27%; c^2 = 16% 150 min criterion: a^2 = 11%; c^2 = 18%
Nelson et al. [46]	5524 US adolescent twins and siblings on wave 1 (mean age 16.5 years) and 4368 young adult twins and siblings on wave 2 (mean age 22.4 years)	Engage in leisure-time exercise activities with a minimal intensity of 5 METs at least five bouts per week	Age 16.5 years (mean age at wave 1): a^2 = 59%; c^2 = 2% Age 22.4 years (mean age at wave 2): a^2 = 12%; c^2 = 50%
Eriksson et al. [36]	359 MZ and 232 DZ Swedish male twin pairs (19–25 years)	Total physical activity, occupational physical activity and leisure-time physical activity	TPA: a^2 = 49%; c^2 = 0% LTPA: a^2 = 55–56%; c^2 = 0% OPA: a^2 = 54–56%; c^2 = 0%
Carlsson et al. [34]	5334 MZ and 8028 DZ twin pairs (aged 14–46 years)	Frequency of engagement in leisure-time exercise activities in the past year	Age 14–28 years: a^2 = 64%; c^2 = 7% for males a^2 = 51%; c^2 = 15% for females Age 29–46 years: a^2 = 40%; c^2 = 0% for males a^2 = 41%; c^2 = 0% for females
Stubbe et al. [31]	13,676 MZ and 23,375 DZ pairs from seven different countries participating in the GenomEUtwin project (aged 19–40 years)[3]	Engage in leisure-time exercise activities with a minimal intensity of four METs for at least 60 min/week (yes/no)	a^2 = 27%–67%; c^2 = 0%–37% for males a^2 = 48%–71%; c^2 = 0% for females

TABLE 115.3 (continued)
Twin Studies on Exercise Behavior

Study	Sample	Phenotype	Results
Stubbe et al. [24]	2628 complete Dutch twin pairs (aged 13–14, 15–16, 17–18, and 19–20 years)	Engage in leisure-time exercise activities with a minimal intensity of four METs for at least 60 min/week (yes/no)	a^2 = 0%; c^2 = 84% for 13–14-year-old twins a^2 = 0%; c^2 = 78% for 15–16-year-old twins a^2 = 36%; c^2 = 47% for 17–18-year-old twins a^2 = 85%; c^2 = 0% for 19–20-year-old twins
Beunen et al. (2003)	92 male and 91 female Belgian twin pairs (aged 15 years)	Number of hours spent on sports each week	a^2 = 83%; c^2 = 0% for males a^2 = 44%; c^2 = 54% for females
De Geus et al. [42]	157 adolescent (aged 13–22 years) and 208 middle-aged Dutch twin pairs (aged 35–62 years)[3]	Average weekly METs spent on sports or other vigorous activities in leisure time in the past 3 months (≥4 METS)	a^2 = 79%; c^2 = 0% for adolescent twins a^2 = 41%; c^2 = 0% for middle-aged twins
Frederiksen and Christensen [39]	616 MZ and 642 same-sex DZ twin pairs (aged 45–68 years)	Engage in leisure time in any of 11 different exercise activities (jogging, gym, swim, tennis, badminton, football, handball, aerobics, rowing, table tennis, volleyball) (yes/no)	a^2 = 49%; c^2 = 0% for males and females
Kujala et al. [37]	Data on both members of 1772 MZ and 3551 dizygotic same-sex twin pairs (aged 24–60 years)	Participation in vigorous physical activity based on the question: "is your physical activity during leisure time about as strenuous, on average, as (1) walking, (2) alternatively walking and jogging, (3) jogging (light running), or (4) running?" Those who chose alternative 2, 3, or 4 were classified as participating in vigorous activity	a^2 = 56%; c^2 = 4% for vigorous activity
Maia et al. [33]	411 Portuguese twin pairs (aged12–25)	A composite sports participation index (SPI), that takes into account the energy expenditure for a given sport, number of hours practiced per week and number of months per year	a^2 = 68%; c^2 = 20% for males a^2 = 40%; c^2 = 26% for females
Lauderdale et al. [38]	3344 male twin pairs of the Vietnam Era Twin Registry (aged 33–51 years)	Five questions assessed regular participation in specific, intense athletic activities (running, bicycling, swimming, racquet, and other sports) (yes/no)	a^2 = 0%; d^2 = 53% for jogging a^2 = 48%; c^2 = 4% for racquet sports a^2 = 30%; c^2 = 17% for strenuous sports a^2 = 0%; d^2 = 58% for bicycling a^2 = 8%; c^2 = 31% for swimming
Koopmans et al. (1994)	1587 adolescent Dutch twin pairs (aged 13–22 years)	Do you participate in leisure-time exercise? (yes/no)	a^2 = 48%; c^2 = 38% for males and females
Heller et al. (1988)	200 twin pairs (aged 17–66 years)	Engaged in vigorous exercise in the past 2 weeks (yes/no)	a^2 = 39%

of the environmental barriers for exercise that are common in adult life, such as lack of time due to work or family responsibilities [43].

Recently, studies have appeared that not only investigate individual differences in exercise behavior but also focus on specific sedentary activities such as sitting behavior, watching television, time spent on the computer or the Internet, and gaming [e.g., 44,45]. Two studies investigated to what extent variation in these sedentary behaviors could be explained by genetic factors [46,47]. In a large sample of 5524 U.S. twins and siblings (mean age 16.5 years), the heritability of sedentary behavior, measured as hours per week engaged in TV/video watching and/or playing video/computer games, was 34%. Shared environmental effects accounted for 10% of the variance. At follow-up (mean age 22.4 years), the heritability of sedentary behavior was 28%, while the effects of shared environment had disappeared.

The second study in 5074 Dutch twins and siblings (mean age 15.9 years) found similar results [47]. The heritability of screen-viewing sedentary behaviors, measured as frequency of watching TV, gaming, and computer/Internet-use during leisure time, was 47% in boys and 30% in girls. The proportions of variance due to shared environment in boys and girls were 5% and 14%, respectively. They also investigated whether the heritability changed with age. They found that the effects of genetic factors became stronger in the age

period from 12 to 20 years. At age 12 years, heritability of sedentary behavior was 35% in boys and 19% in girls, while at age 20 years this was 48% in boys and 34% in girls. The effects of shared environmental factors diminished in this age period from 29%–48% at age 12 years to 0% at age 20 years. Although the genes affecting sedentary behavior need not to be the same as those for exercise behavior, it is striking that the heritability estimates and the observed age trends are very similar.

EXTENDED TWIN FAMILY STUDIES

The heritability estimates obtained from twin studies are only valid if the assumptions underlying the twin method hold. An important assumption is the equal environment assumption, which states that environmentally caused similarity in the trait or behavior of interest (i.e., exercise behavior) is the same in MZ and DZ twin pairs [48]. One twin study explicitly tested the equal environment assumption [36]. It was tested whether twin pairs with higher contact frequency were more similar in their total physical activity and physical activity at work or in leisure time separately and whether this effect depended on zygosity status. No evidence for violation of the equal environment assumption was found for any of the physical activity measures [36].

Other assumptions of the twin method include absence of assortative mating and the independence of genes and environment. If assortative mating is present, the genetic correlation in DZ twins or full siblings is underestimated in the twin model, which can cause underestimation of heritability and overestimation of the shared environmental effects. If assortative mating is present for exercise behavior, this could explain the finding for C in (young) adolescents. The previously mentioned assumptions can be tested by adding data from more types of relatives to the twin design, such as data from parents, grandparents, spouses, and siblings. Spouse correlations inform on the presence of assortative mating. Parent–offspring correlations enable to test for the effects of cultural transmission, i.e., the extent to which the shared environment found in adolescent twin studies on exercise behavior represents effects of the parent's exercise behavior on the exercise behavior of the children. Five studies employ extended family designs to report on the familial resemblance of exercise behavior among adolescent offspring (age range 13–20 years) and their parents, using different definitions such as TPA, leisure time exercise, and sports participation [16,23,49–51]. Two of these studies only included non-twin siblings and their parents [23,50]. One study included twins and their parents [16], while the other studies added to this data from either grandparents [49] or non-twin siblings and spouses of twins [51].

The spouse correlation for exercise behavior was significant in all these studies and ranged from 0.16 to 0.60 [16,23,49–51]. De Moor et al. [51] analyzed twin–spouse pairs to demonstrate that the significant spouse correlation for exercise was best explained by phenotypic assortment (i.e., that partners choose each other because they are similar in their exercise behavior) rather than by social homogamy (i.e., that partners similar in exercise behavior meet and marry because they come from similar social backgrounds) or social interaction processes (i.e., that partners resemble each other because they spend time together and mutually influence each other).

Parent–offspring correlations have ranged from 0.05 to 0.54 and are generally somewhat lower than the full sibling correlations [16,23,49–51]. De Moor et al. [51] estimated in a sample of 3525 adolescent twins and their siblings (13–18 years) and 3138 parents from 1736 families that variation in adolescent exercise behavior in boys could be explained for 42% by genetic factors and for 52% by shared environmental factors shared by family members of the same generation but not with the parents. In girls, 36% of the variance in exercise was explained by genetic factors and 41% by generation-specific environmental effects. Cultural transmission effects from parents to offspring were not significant. The effects of assortative mating on the heritability estimates were small. Thus, the results of extended twin family studies show that heritability estimates for exercise behavior obtained from studies using only twins are not overly biased.

GENE-FINDING STUDIES

The heritability of exercise behavior has been well established, but less is known about the genetic variants that are associated with this trait. So far, seven candidate gene association studies, three genome-wide linkage studies, and one genome-wide association (GWA) study have been conducted for exercise behavior or related physical activity phenotypes.

Seven studies tested for association of genetic variation in six candidate genes with exercise or physical activity phenotypes. In a study of adolescent girls [52], the calcium-sensing receptor (*CASR*) gene was associated ($p = 0.01$) with weekly hours spent on physical activities. In a study of Pima Indians [53], the leptin receptor (*LEPR*) gene was associated ($p = 0.007$) with 24 h energy expenditure and physical activity levels. In a study of 222 prepubertal boys [54], *LEPR* was also associated with physical activity energy expenditure ($p = 0.016$). In another study [55], the dopamine 2 receptor (*DRD2*) gene was associated ($p = 0.016$) with past year physical activity in women reporting European ancestry but not in subjects reporting African ancestry. In a sample of postmenopausal women [56], the aromatase (*CYP19*) gene was associated ($p = 0.04$) with physical activity. In a study of mild hypertensives [57], the angiotensin-converting enzyme (*ACE*) gene was associated ($p = 0.001$) with leisure-time physical activity. Finally, a study conducted in adults [58] showed that the melanocortin-4 receptor (*MC4R*) gene was associated ($p = 0.005$) with daily physical activity levels, independent of sex, age, and body mass index (BMI).

The first genome-wide linkage study for exercise behavior was conducted in 767 Caucasian adults from 207 families [59] (see also Table 115.4). Four physical activity phenotypes were measured, of which three reflected daily physical activity and one past year physical activity. For past year physical

[a] For linkage studies, chromosomal regions are reported for which suggestive or significant linkage was found. For the genome-wide association study, genes are reported for which genome-wide significant SNPs were found.

activity, suggestive linkage ($p < 0.01$) was found on chromosomes 11p15 and 15q13.3. For daily physical activity, a promising linkage ($p < 0.0023$) was found on chromosome 2p22-p16, and suggestive linkages were found for different loci on chromosomes 4q28.2, 7p11.2, 9q31.1, 13q22-q31, and 20q13.1. The second study consisted of 1030 children from 319 Hispanic American families [60]. Significant linkage was found on chromosome 18q12-q21 (logarithm of odds = 4.09) for daily physical activity. This region contains the *MC4R* gene, for which a significant association with adult physical activity had been found in a candidate gene study [58]. The third linkage study was conducted in 1432 adult Dutch sibling pairs from 622 families [61]. Suggestive linkage was found for regular exercise participation on chromosome 19p13.3 (LOD = 2.18).

The first GWA study tested 1,607,535 observed and imputed single nucleotide polymorphism (SNP) markers that passed stringent quality controls for their association with leisure-time exercise behavior in two independent samples comprising 1644 Dutch and 978 American subjects. Their most promising finding was in the *PAPSS2* gene (37 SNPs with pooled p values $< 1.0 \times 10^{-5}$) and in two intergenic regions on chromosomes 2q33.1 and 18p11.32. The *PAPSS2* gene encodes a protein that is involved in the sulfation of compounds such as lipids, carbohydrates, proteins, and exogenous drugs. The gene is widely expressed in skeletal and smooth muscles and the brain as well as in several other organs. The 10q23 region that harbors the *PAPSS2* gene has been linked to maximal exercise capacity in a genome-wide linkage study of 453 sib pairs [62]. This suggests that exercise ability may be an important determinant of leisure-time exercise behavior as has been suggested from a theoretical point of view [63].

There was no overlap in findings between this GWA study and previous candidate gene association and linkage studies, except for the suggestive evidence found for the *LEPR* gene (rs12405556: pooled p value 9.7×10^{-4}; American sample p value 9.8×10^{-5}) and in the *GABRG3* gene (rs8036270: pooled p value 4.6×10^{-5}) in the linkage region 15q12-13. The *LEPR* gene is expressed in the hypothalamus [64] and has frequently been linked to obesity and type 2 diabetes mellitus through its effect on positive energy balance and weight gain [64,65]. The genetic effects of SNPs in the *LEPR* gene found for exercise were independent of BMI [25]. This suggests that the *LEPR* gene may directly impact on the drive to exercise through the hypothalamic regulation of energy balance.

Replication of genes across the earlier summarized gene-finding studies for exercise behavior is modest. This is found to be a common problem for many of the complex traits we study in humans [66]. Clearly, more large-scale collaborative studies, combined with increased coverage of the genome using larger sets of genetic markers, refined phenotyping, and alternative methods are needed to solve part of this problem. This has already shown to be successful for other complex traits like height and BMI [67–69]. Nevertheless, the current findings for exercise already point to some (biological) pathways through which genetic variants may influence exercise behavior. These pathways may include genetic effects through exercise ability (i.e., the *CASR, PAPSS2*, and *ACE* genes), the hypothalamic drive to exercise and spend energy (i.e., *LEPR* and *MC4R*), and the rewarding or aversive experience of exercise (i.e., *DRD2* and *GABRG3*). These suggested pathways may also all to some extent explain the well-known phenotypic and genotypic links of exercise with other

lifestyle behaviors such as overeating and smoking, physical health problems like cardiovascular and metabolic disease [37,61,70], and mental health problems including depression [18,71]. Exercise training studies in twins (see, e.g., Bouchard et al. [72]) are needed to more fully understand the exact mechanisms though which genes, exercise, and different aspects of physical and mental health are related. Such studies have the great potential to inform on more "personalized" intervention programs.

CONCLUSIONS AND FUTURE RESEARCH

To summarize, it is shown that genetic influences play a role in exercise behavior at all ages. Although genetic influences are relatively stable across the life span, the heritability of exercise behavior seems largest in young adulthood. In (early) adolescence, shared environmental influences additionally explain family resemblance in exercise behavior. These influences appear to be largely generation specific and independent of the exercise behavior of the parents. The small number of GWA and linkage studies suggests that the heritability of regular exercise behavior may be explained by genes affecting exercise ability, the hypothalamic drive to spend energy, and the acute rewarding and aversive effects of exercise. An example is the independent involvement of the hypothalamus expressed *LEPR* gene in both exercise and obesity. Future progress is expected to come from the large-scale meta-analytic GWA studies that are being conducted for various exercise phenotypes.

INTRODUCTION AND ORGANIZATION OF THE CHAPTER

The purpose of this chapter is to highlight how physical activity (i.e., gross bodily movement) and exercise (i.e., engagement in purposeful physical activity to improve physiological capacity) improve cognitive function in the areas of thinking and memory. Just as physical activity benefits cardiovascular and musculoskeletal function, it also exerts remarkable effects on the brain resulting in the enhancement of cognitive function through the lifespan and the delay of cognitive decline with aging. Positive effects have been observed in the brains of animals and humans with benefits accruing in processing speed, working memory, learning, attention, executive and inhibitory control, as well as mental flexibility. Exercise has been shown to increase oxygen delivery to the brain and to expand blood vessels and mitochondria, resulting in improved metabolic capacity. Exercise also improves uptake of neurotransmitters and increases levels of neurotrophic factors, enabling more efficient brain communication, better maintenance and repair of neurons, and improved dendritic strength and connectivity. Evidence has even been provided in animal studies for the generation of new neurons in an area of the brain susceptible to deterioration with age, the hippocampal region that mediates the formation of new memories. All of these neurobiological effects contribute to a better working brain that is more efficient and can withstand insult from injury, stress, or aging, with greater integrity, ability to focus, networking between brain regions, and improved ability to adapt to change.

The chapter is organized around a three-part conceptual framework in which the first component considered is that of central nervous system (CNS) decline as related to both normal aging and pathological conditions such as Alzheimer's disease. A reasonable assumption is that the alterations in the anatomy and physiology of the brain with age and disease translate or present as cognitive decline in the form of memory loss and executive dysfunction. The second component considered is that related to the evidence for the benefits of physical activity and exercise to the brain, which has been revealed in both animal and human studies. In essence, these neurobiological benefits serve as a non-pharmacological prescription that can counteract the neural degeneration that is incurred over time. The third component considered is the promotion of resilience to age-related and pathological degeneration by building *biological reserve of the brain*. In essence, participation in physical activity serves to "vaccinate" the brain such that it can tolerate insult, injury, or cognitive decline to a greater degree as compared to the sedentary lifestyle. *This model of exercise-induced tolerance to age and diseases of the CNS applies to the entire brain and is the central concept offered in this chapter.* The principle provides a reasonable explanation of the benefits of exercise to cognitive function in older men and women. In addition, the masking of degenerative processes may be achieved through active compensatory strategies by which alternative brain networks are activated to respond to a given cognitive challenge when typical brain responses fail to meet the challenge. Interestingly, the foundation for this benefit during older age may well be laid during childhood and young and middle adulthood, as the benefits accruing to the brain may not reveal until significant decline has occurred such as experienced with advanced age and the presence of pathology. In this manner, *a physically active lifestyle at a younger age could be conceived as an "investment"* that provides apparent benefits to cognition and emotion in older age. Furthermore, genetic influence on the brain may yield different magnitudes of benefit from physical activity such that those who are at greater risk of age-related decline or accelerated aging, like carriers of the apolipoprotein E (APOE) ε4 allele who appear less resilient to neuropathology, have an apparent benefit relative to those who practice a sedentary lifestyle, thus underscoring the notion that exercise is *essential medicine for some!*

BRIEF HISTORY OF THE FIELD

A number of individuals have made outstanding contributions to the study of physical activity and neurocognitive processes, with some providing truly pioneering investigations. Seminal research on physical activity and cognitive function appeared in the 1970s with animal and human investigations into the role of dopamine (DA) and reaction time, with comparisons of young and older subjects [1]. More specifically, Waneen Spirduso [1] reported faster reactivity (i.e., shortened reaction times) in older men and women who engaged in regular physical activity and sport activities while advancing the notion that reaction time was an index of general integrity of the CNS. As such, Spirduso believed that an active lifestyle promoted the health of the brain. She provided biological plausibility for such a benefit in humans by the employment of animal models (rats) with demonstration of maintenance of central DA levels and increased receptor binding affinity with exercise across the lifespan. The research evolved beyond the consideration of reactivity with assessment of exercise-induced effects on perceptual and basic decision-making abilities in the first reported randomized clinical trial (RCT) with older men and women [2]. This classic work, reported by Robert Dustman et al. in 1984, provides the initial causal evidence of the benefit of physical activity on neurocognitive function in light of the rigorous experimental design. Subsequently, identification of specific cognitive tasks that benefitted most from exercise participation were identified by Chodko-Zajko and Moore [3], who described the difference between crystallized (i.e., vocabulary and accumulated knowledge) and fluid intelligence (i.e., effortful analyses and reasoning), with the former revealing little benefit from physical activity while, conversely, the latter revealed significant positive influence. This was the first time that specificity of the effect of exercise was reported, and determination that tasks that were more attentionally demanding, or more novel, were the most likely to benefit from physical fitness [3]. Kramer et al. advanced this concept further with the publication of a landmark study that further supported cognitive specificity in the response to exercise such that executive function tasks were particularly improved by engagement in physical activity [4].

Early in the 1990s, the psychophysiological approach to study in this area was introduced to the field, with use of event-related potentials (ERPs) derived from electroencephalography to determine workings of the brain in both young and older men who were characterized by low and high levels of cardiovascular fitness. Specifically, Dustman et al. examined the latencies and amplitudes of ERPs to determine the speed and engagement, respectively, of cerebral cortical responses to various stimuli as well as assessment of cortico-cortical communication between brain regions. They reported that high-fit older individuals exhibited relatively efficient neural responses and integrative processing when compared to low-fit older men [5]. In fact, the high-fit older men were more similar to younger men than they were to their age-matched counterparts—in essence, it appeared that physical fitness had arrested the aging of the human brain! The neurobiological basis of such effects in the human brain were provided by the first mechanistic studies on the neurogenic and neurotrophic effects of exercise that were observed in animal studies conducted under the leadership of Gage and Cotman, respectively [6,7]. These studies offered a robust and profound mechanism for the impact on cognition of a physically active lifestyle in children and men and women of all ages if such effects also occurred in the human brain. The first neuroimaging study, using structural magnetic resonance imaging (MRI), was reported by Colcombe et al. [8] and revealed a positive

relationship in brain tissue density and the integrity of white matter tracts with cardiovascular fitness in older men and women. These structural differences in the brains of individuals characterized by high and low fitness, suggested that a physically active lifestyle positively impacted the scaffolding of the human brain. This notion is based on the finding that older adults who were characterized by cardiovascular fitness exhibited resistance to atrophy of the brain with aging [8]. Further evidence that exercise causally influenced the brain in a positive manner was provided by Colcombe et al. [9] who reported the results of a RCT of the effects of cardiovascular conditioning on cortical and subcortical activation during executive challenge. In effect, the exercise training promoted an enhanced hemodynamic response during challenge via assessment of functional MRI (fMRI) blood-oxygen level dependent (BOLD) response, suggesting improved concentration and focus as a result of training [9]. These studies were the first to employ a measure of high spatial resolution in their studies of exercise and the brain (i.e., MRI), thus increasing our understanding and confidence in the biological underpinnings of the impact of exercise on the human brain.

The consideration of individual differences through the role of genetics was brought into the picture in 2001 with a landmark study that showed particularly strong cognitive benefits of physical activity for carriers of the APOE ε4 genotype, which has been associated with a higher risk of Alzheimer's dementia (AD) [10]. More recently, a RCT with employment of MRI in middle-aged men and women was reported by Erikson et al. [11]. They specifically examined the impact of exercise on the hippocampal region, which is the brain region primarily attacked by the pathology (i.e., plaques and tangles) that is responsible for AD [11]. The work holds profound implications for the prophylactic effect of exercise as a prescription for this terrible affliction. Research has continued to evolve in the aging literature, with neuroimaging studies investigating possible reversal of cognitive aging processes through exercise intervention with mid life and older adults [9,11], and detailed looks at the connectivity, or networking, of the brain, which appears to be more efficient with physical activity [12–14]. Investigations of the effects of physical activity in children have recently appeared in the literature as well, with consensus in the findings that aerobic fitness promotes superior executive functioning, improved academic performance, and increased brain volume of specific areas [15–18]. Collectively, both prospective and retrospective epidemiological studies, as well as the experimental studies with animal and human subjects cited earlier, strongly support the lifelong effects of a physically active lifestyle with promising results for "cognitive reserve." This suggests that an investment of physical activity and other healthy lifestyle factors throughout life may promote resilience to cognitive decline in old age [19,20].

It is truly amazing to consider the remarkable advances in our understanding of the influence of physical activity and exercise on the brain and cognition in a period spanning just 35 years from the seminal work of Spirduso in the mid-seventies to the present time with sophisticated molecular biology and advanced neuroimaging studies. In essence, modern science is providing confirmatory evidence for the ancient notion of mens sana in corpore sano—that is, a "sound/healthy mind within a sound/healthy body."

EXERCISE AND AGING: NORMAL VERSUS PATHOLOGIC

The beneficial influence of exercise on brain processes and cognition is pronounced when the opportunity for benefit is significant. Such is the case in older men and women (i.e., typically over the age of 60 years) who are likely to incur age-related decline of the CNS, promoted by such processes as inflammation, oxidative stress, and apoptosis [21] thus allowing "room for improvement" from physical activity participation compared to those who are characterized by relative integrity of brain processes as would be the case with young men and women. As such, investigations with older adults have been in the forefront of exercise and cognition research because this population appears to show some of the strongest benefits for physical activity in terms of a protective effect against both normal cognitive decline with aging as well as dementia-related pathology and deterioration.

It is helpful to understand the differences between "normal" or "demented" aging in order to understand the effects of physical activity more clearly. Individuals change over a lifetime, and as one ages, change in the brain can occur either as a normal process or, alternatively, as pathological aging manifested as various forms of dementia such as AD. The effects of normal aging, currently understood as a reduced ability for synaptic plasticity as opposed to a significant loss of neurons [22], reveal in the cognitive-behavioral domain as slower processing speed, less efficient working and episodic memory, as well as difficulties with executive function—a set of behaviors typically described as organizing, goal direction, and inhibition [23]. The loss of executive function can present in several ways such as perseveration or persistence in cognitive set as opposed to adaptive set shifting. This kind of age-related behavioral change can be revealed with challenge such as presentation of the Wisconsin Card Sort Test to older individuals, which requires mental flexibility. Typically, such individuals exhibit difficulty in recognition and adoption of a new rule to guide behavior relative to younger men and women, and this is likely due to frontally mediated executive decline, where such processes are largely mediated [24]. Interestingly, knowledge and expertise tend to be maintained in normal aging [23] and it is likely due to the relative independence of such processes in relation to the frontal lobes.

The cognitive decline associated with age is typically accompanied by structural changes in the brain. There is a decrease in brain volume in normal aging that occurs by the seventh decade [24] with major decreases found primarily in caudate, cerebellum, frontal gray matter, and hippocampal regions [23,25,26]. There are also changes in the characteristics of white matter, which is composed of the axonal

projections and tracts in the brain with the greatest loss of integrity concentrated in the frontal area [23]. Since white matter is associated with loss of myelin, this change may be correlated with the "slowing" of perceptual, cognitive, and motor processes typically observed in older adults [23]. White matter hyperintensities, revealed as abnormal alterations of healthy structure in structural magnetic resonance images, increase with aging [27,28]. Loss of dendritic complexity, with reduction in synapses, is another structural change with normal aging [24], as is reduction of blood vessel density and blood flow [29], both of which contribute to the alterations in memory, focus, and mental flexibility.

One common feature of non-pathological aging is a tendency toward reduced levels of regional specialization in neural processes when negotiating a cognitive challenge as compared to the neural activity seen in younger individuals. This difference is exemplified by bilateral cerebral hemispheric activation during problem solving (i.e., heightened activation of the brain when compared to younger adults who exhibit specificity of hemispheric activation) [23]. Such bilateral activation of the prefrontal cortex has been observed consistently in older adults, and suggests an adaptive compensatory mechanism, allowing for the requisite recruitment of neural resources to accomplish a task. While this adaptation, known as hemispheric asymmetry reduction in older men and women [30], has traditionally been considered indicative of diminished cognitive ability, current research suggests that it may be a positive and dynamic adaptation to a normally aging (i.e., changing) brain. Accordingly, individuals who are able to adjust to such changes are likely to maintain performance for a longer period through the aging process. In support of this notion, compensation has been shown to be associated with higher intellectual and physical activity [12,31] and retention of performance in attention- and memory-related functions. As a general proposition, it appears that normal aging is associated with accelerated frontal decline, relative to other brain regions, and that compensatory activation patterns are engaged as a coping strategy, particularly in the frontal region, in order to maintain executive function. Failure to maintain such an adaptive strategy can then reveal as a loss, to some degree, of executive function (focus, working memory, etc.).

The characterization of demented aging is less clear than that of normal cognitive aging. In terms of development toward dementia, there are questions as to whether AD is simply an exaggerated form of natural aging or whether it is a distinct disease process. Although there is no definitive anatomic or physiological landmark available that allows for a clinical diagnosis, there are data from neuroimaging investigations that appear to show distinct patterns of brain processes progressing toward dementia. Differences in brain activation and structural atrophy have been employed to successfully identify pathological aging. In this manner, Head et al. [26] examined brain volume in young compared to older adults who were classified as cognitively healthy or who were diagnosed with dementia. They reported an overall loss in frontal volume for all older adults regardless of status when compared to younger adults. However, the hippocampal structure of those with dementia revealed significant atrophy.

In another series of investigations, Sperling [32] employed a face-name recognition task during fMRI to assess the BOLD response, in order to compare young and older adults, the latter who were cognitively healthy versus those diagnosed with AD and mild cognitive impairment (MCI). MCI is characterized by memory dysfunction for which the magnitude does not impair the ability to maintain activities of independent daily living. MCI does not always convert to AD but is considered by some as a prodromal stage. The AD patients exhibited a pattern of hypoactivation in the hippocampal region that was not present in older healthy adults. Sperling's investigation with MCI patients revealed a period of hyperactivation of the hippocampus in early MCI, which changed to hypoactivation with late MCI. This dynamic evolution of brain activation could indicate a threshold whereby compensation described in normal aging is no longer able to work as deterioration of brain structure goes beyond the ability to function normally, rendering adaptation no longer possible [32]. The failure to maintain compensation can then reveal as memory impairment (see Figure 116.1).

The critical physical change in the brain associated with pathologic aging is the significant development of neurotoxic extracellular amyloid plaques and neurofibrillary tangles. Plaques are formed from amyloid peptides that are released from the amyloid precursor protein (APP), which is cleaved by beta and gamma secretases. In the most destructive form, APP is cleaved to a longer B42 form that has a greater tendency to aggregate destructively [33]. In addition, neurofibrillary tangles are formed from intracellular hyperphosphorylated tau protein. Tau protein is important to the cell, aiding in scaffolding of microtubules, but when the pathologic process occurs, it becomes hyperphosphorylated, forming tangles that disturb cell structure and function. The amyloid cascade theory postulates that these two processes are responsible for the beginning of the disease process of dementia, and that the destruction that follows is due to the degenerative properties of the plaques and tangles [34].

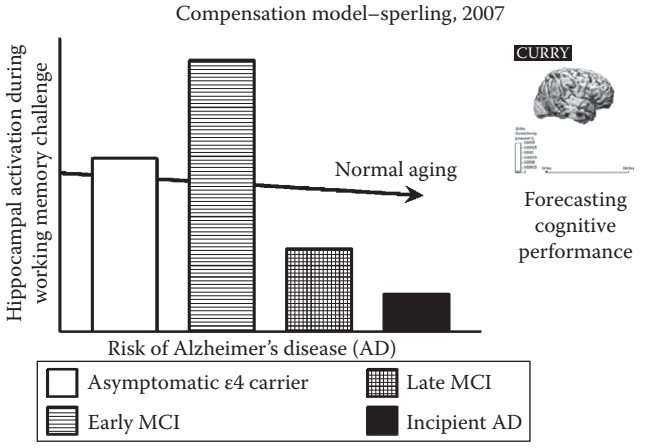

FIGURE 116.1 Compensation model. (From Sperling, R., *Ann. N. Y. Acad. Sci*., 1097, 146, 2007.)

As described in Figure 116.1, heightened activation of critical brain regions during challenge may provide for maintenance of cognitive function but may also serve as a "forecast" of cognitive decline to come. In the future, if the cost of such neuroimaging (e.g., fMRI) is reduced, routine examination of brain activation during medical exams over time may serve to predict forthcoming cognitive decline!

Although few studies have been conducted on the efficacy of exercise to influence neurocognitive processes in the elderly suffering from dementia, there is ample evidence of benefit in those who are normally aging, albeit somewhat more apparent for frontal regions and executive functions relative to other brain regions and nonexecutive tasks [35]. That is, cognition is maintained over time or even improved in several domains, but the magnitude of benefit is greatest with the frontally mediated executive tasks. A brief summary follows as to the biological plausibility of "exercise as good medicine for the mind."

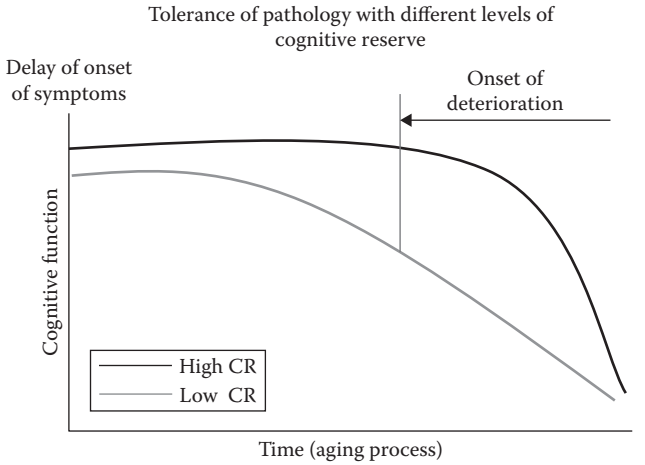

FIGURE 116.2 Tolerance of pathology with different levels of cognitive reserve. (Adapted from Hatfield and Kaplan, *NSCA's Essentials of Personal Training*, 2nd edition, 130, 2012.)

NEUROBIOLOGICAL BENEFITS OF EXERCISE ON BRAIN AND COGNITION

While there is robust evidence for the benefits of physical activity for cognition in humans, the mechanisms that determine these effects are not fully understood. However, animal studies have revealed several factors that appear to contribute positively to cognitive function. Examination of learning and memory in animals exposed to either an enriched environment (ladders, tubes, ropes, toys) or aerobic exercise regimens (running wheels or treadmill running) has consistently shown beneficial effects of exercise on cognitive function in young, adult, and aged animals.

In humans, it is challenging to determine specific effects of physical activity on brain function in light of ethical constraints, but noninvasive neuroimaging in tandem with cognitive-behavioral testing is informative of how exercise may impact the human brain. Overall, the use of animal studies to complement investigations involving human subjects suggests pathways and mechanisms for the beneficial effect of physical activity on the human brain. Neuroimaging studies, such as those described previously, have offered insight into brain mechanisms underlying cognition, such as compensatory activity, and these tools can be used to examine the effects of exercise on the brain. The benefits described later in this section are not likely to reverse any pathology (e.g., plaques and tangles in the brain), but they may help to build the reserve or resilience to both normal brain aging and pathology so that the individual may tolerate such degradation, be it largely concentrated in the frontal region as in normal aging or in the hippocampal region as in demented aging.

In this manner, we maintain that the primary role of physical activity and exercise on the human brain is to build reserve. Specifically, cognitive reserve is the hypothesized capacity of the mature adult brain to sustain the effects of disease or injury sufficient to cause clinical dementia in an individual possessing less cognitive reserve [21]. This important element of brain integrity can be classified as both active and passive reserve. The former refers to the efficiency and adaptability of neural circuits to respond to cognitive challenge exemplified by compensation, as described earlier, while the latter refers to brain tissue density, white matter integrity, and vascularity (see Figure 116.2). All of the neurobiological benefits of exercise likely contribute to a healthier cognitive reserve throughout life (note: most likely passive reserve) and are particularly beneficial in older adults to delay cognitive decline.

The following elements of the neurobiological response to exercise are likely contributors to cognitive reserve

Neurotransmitters

Physical activity elevates a number of neurotransmitters that enable communication between neurons underlying cognitive, motor, and affective processes. This is important as DA, for example, is reduced in the frontal regions of the brain with aging [36]. It exerts a significant effect on the quality of cognitive function, particularly on motor and executive processes in light of the relevant anatomical structures in these regions (i.e., basal ganglia and frontal lobes, respectively). Animal research has revealed that running can help reduce degeneration of DA both through the upregulation of brain-derived neurotrophic factor (BDNF), as observed in mice [37], as well as increased receptor binding affinity in aged rats [38]. In addition, acetylcholine (ACh), a neurotransmitter that is strongly associated with Alzheimer's disease (AD), with levels attenuated during the course of the disease [39], is affected by exercise. Importantly, long-term treadmill running in rats results in attenuation of the decline of muscarinic ACh receptor density that normally occurs with aging [40]. Based on another study using rats, Park et al. [41] reported that an enriched environment resulted in higher ACh synthesis in the cortex and hippocampus. The significance of such exercise-induced effects was revealed in a lesion study on cholinergic neural tracts in rats as the

lesions resulted in diminished neurogenesis in the dentate gyrus and increased cell death [42]. The importance of the finding rests on the fact that ACh is critical to memory and administration of ACh after its depletion results in reversal of memory deficits [43]. Serotonin (5HT) is also closely associated with BDNF and neurogenesis in the hippocampal region, which plays a key role in pathways related to memory and cognition. Of note, there is evidence that exercise results in increased 5HT levels in several areas of the brain, [44], and a study incorporating a $5HT_{1A}$ neurotoxin resulted in decreased cell proliferation in the dentate gyrus [45]. Collectively, these studies support a positive effect of exercise on neurotransmitter levels (i.e., DA, Ach, and 5HT) that mediate the critical neuronal communications that underlie executive, memory, and motor functions in the human brain thus contributing to cognitive reserve.

Neurotrophic Factors

Another way that physical activity likely benefits cognitive function in the human brain is through increased expression of neurotrophins. Neurotrophins are a family of growth factors that are responsible for the survival and maintenance of neurons and work toward growth and development of dendritic connections. The main neurotrophin that has shown a strong connection to exercise's role in cognitive function is BDNF, which supports neuronal maintenance and repair in many areas of the brain and is particularly active in the hippocampus and cerebral cortex [7]. It is associated with long-term potentiation (LTP) that is believed to underlie learning and memory [46] and facilitates synaptic plasticity. The blockage of BDNF uptake has been shown to reduce LTP and degrade learning and memory relative to animals not receiving BDNF blockade, which exhibit the typical exercise-induced improvements in cognition [44,47]. Conversely, increased brain BNDF levels are associated with dendritic complexity in the dentate gyrus, greater arborization, and increased dendritic length [48].

Studies reveal that BDNF upload is regulated both through activity such as exercise as well as an enriched environment [49,50]. Uptake of BDNF in the hippocampus has been shown to be greatly increased with physical activity in animals. In fact, BNDF mRNA has increased as high as 20% with running-wheel activity [7]. Tong et al. [51] showed, in a genetic study, that physical activity resulted in an elevation of numerous proteins related to BDNF and synaptogenesis, LTP, and synaptic plasticity, all providing additional support for findings of BDNF and downstream effects [51]. In addition, a recent clinical trial with human subjects examined memory performance on the Auditory Verbal Learning Test (AVLT) after a 6-month exercise period in older adults and revealed significant improvement in cognition as well as a positive effect for peripheral BDNF [52]. This finding reinforces the notion that the neurotrophic effects of exercise in animals likely occur in the human brain as well. There is a polymorphism of the BDNF gene ($val^{66}met$) that has been shown to have effects on cognitive function, with individuals having BDNF met revealing relatively impaired memory and hippocampal differences [53]. While there has been no published physical activity research to date in relation to cognition and this genetic relation, this may be important research in the future.

Other studies have revealed that different neurotrophic factors such as insulin-like growth factor-1 (IGF-1), a neurotrophin with structural similarities to insulin, may also be involved in the beneficial effects of exercise on cognition. Carro et al. observed that serum IGF-1 is upregulated from peripheral sources to several areas of the brain such as the cortex, hippocampus, striatum, cerebellum, thalamus, hypothalamus, and brain stem nuclei as a result of physical activity [54]. Ding et al. also reported that exercise elevated hippocampal IGF-1 and that blocking the uptake of IGF-1 reversed the exercise-induced elevation of hippocampal BDNF, eliminated the benefits of exercise on recall in the Morris Water Maze memory task, and abolished the effects of proteins downstream in the BDNF pathway related to synaptic function such as synapsin I [55]. IGF-1 is also known to promote both neurogenesis and angiogenesis in animals, with blockage of receptor uptake by IGF-1 completely eliminating exercise effects on neurogenesis [56] and blood vessel remodeling [57].

Vascular endothelial growth factor (VEGF) is a protein that also appears relevant to the benefit of exercise on cognition. VEGF is involved in angiogenesis and neurogenesis, suggesting an interaction between the two processes [58]. Experimental administration of VEGF has been shown to result in improvement in learning on a passive-avoidance task as well as memory processes during the performance of the Morris Water Maze in rats [58], while the blockade of peripheral VEGF results in elimination of exercise-related increased neurogenesis. Blockage also affects generation of new blood vessels in the brain, while not affecting the existing vasculature [59]. Overall, VEGF acts in concert with both IGF-1 and BDNF and appears to play an important modulatory role on the effects of physical activity on brain processes.

Synaptogenesis

There is evidence for synaptogenesis as a result of exposure to enriched environments, as animal studies have revealed that such exposure positively contributes to dendritic branching and synaptic density. Studies have demonstrated elevations in synapse number, with more synapses per neuron, as well as the strengthening of existing synaptic connections [60,61]. For example, synaptogenesis has been observed in mice exposed to complex obstacle courses requiring "acrobatic" activity, with specific adaptation in the motor and cerebellar cortices when compared to wheel running or sedentary controls [62]. The protein synapsin I, which acts to enhance neuronal communication through neurite outgrowth and synaptogenesis, is elevated with exercise and appears to be upregulated by the exercise-induced elevation of BDNF [63]. The relevance of this work to the exercise-cognition relationship in humans is

that engagement in exercise typically occurs in complex settings such as sport activities and outdoor settings that require navigation and memory of complex running routes. Thus, it seems reasonable that regular participation in physical activity would positively impact the vascular and neuronal architecture of the human brain, contributing to the resilience of active and fit individuals to age-related and disease-related degenerative processes.

Neurogenesis

Beyond the neurotrophic effects of exercise described earlier, neurogenesis, the growth of new neurons in the brain, as revealed in the dentate gyrus in animals, represents an exciting finding that holds great promise for medicine since the appearance of new neurons in the human hippocampus—the brain region most affected by AD dementia—would suggest resilience to the pathology (i.e., plaques and tangles) through participation in physical activity! In a classic study, van Praag et al. [6] reported that neurogenesis in adult mice occurred in response to wheel running activity. After controlling for the effects of environment, they determined that physical activity, alone, was responsible for the observed proliferation of neurons in the dentate gyrus [6]. In addition, van Praag et al. determined that the appearance of new hippocampal cells in adult mice housed with running wheels was associated with improved cognition, as shown in performance on the Morris Water Maze, and enhanced LTP, when compared to controls in standard housing [64]. Although neurogenesis is reduced in older adult animals [65], it has been shown that exercise can offer benefits for the creation of new neurons even during advanced age. van Praag et al. [66] extended the study of neurogenesis and enhanced learning in response to physical activity with aged mice who were sedentary until they were 19 months old. After a 1 month running-wheel intervention, they observed that aged mice exhibited improved water maze performance compared to age-matched controls, which coincided with a reversal of decline in neurogenic activity [66]. Comparison of the older exercisers to young adult mice revealed that the new neurons from enhanced neurogenesis in the older group were similar in quality to those of the younger mice. The investigators observed equivalent dendritic length and spine density, revealing that neurons in aged mice were functionally equivalent to those of younger animals. Such an effect in older humans would underscore the notion that it is never too late to accrue the benefits of a physically active lifestyle.

Neurogenesis cannot be determined directly in humans, although one study did confirm the process through postmortem examination [67]. However, a recent 12-month exercise intervention in older adults by Erikson et al. [11] revealed a specific increase in anterior hippocampal volume of 2% for an aerobic exercise group, while a decline in volume of 1.4% was seen over the course of the study in a comparison group that did stretching and toning activities. The change was accompanied by increases in circulating serum BDNF. Importantly, this increase in hippocampal volume was in the area where the dentate gyrus is located—the area where neurogenesis occurs. These researchers commented that normal hippocampal decline with aging averages 1%–2%/year, so this increase in volume in essence offered up to 2 years of reversal of deterioration for 1 year of exercise. While the study results cannot pinpoint that the hippocampal volume increases are indicative of neuronal cell proliferation and could alternatively be indicative of increases in dendritic branching or angiogenesis as well, the findings do show that the hippocampus is subject to positive change in aging individuals.

Angiogenesis

An additional manner by which physical activity may offer improvement in cognitive function in men and women is through improved vasculature and increased blood flow in the brain. Cerebral blood flow is normally decreased with age and in dementia [68,69], and exercise has been shown to improve both blood volume and the vasculature of the brain. Angiogenesis, the development of new blood vessels through sprouting of existing endothelial cells, results from an enriched environment and physical activity interventions in animals [62,70]. Angiogenesis takes place in several areas of the brain. Ding et al. observed increases in both angiogenesis and VEGF in the motor cortex and striatum of aged rats exercised on treadmills for 3 weeks [55]. These changes contributed to improved oxygen and nutrient delivery, as well as increased neurotrophin uptake, which provides for brain maintenance and repair [49,70].

More specific association of angiogenesis to improved cognitive function and interconnections with neurogenesis have been reported in several studies. Pereira et al. [71] investigated the relationship between angiogenesis and neurogenesis in the dentate gyrus in exercising mice and humans. A 2-week voluntary running-wheel intervention (compared to a non-exercising control group) was conducted with 7 week old mice. MRI was conducted at baseline, at cessation of the exercise period, and at 4 and 6 weeks after exercise to determine cerebral blood volume (CBV) in regions of the hippocampus. Thymidine analog BrdU marker was administered during the second week of exercise to examine for evidence of neurogenesis. The results revealed a selective increase in CBV in the dentate gyrus for the exercising group, and these findings also correlated with increased neurogenesis [71]. Pereira et al. also conducted a 3-month aerobic exercise intervention with men and women (mean age 33 years, range of 21–45 years), measuring CBV before and after training with MRI, changes in fitness via assessment of VO_2max, and memory function with the AVLT. As with the mice, there was increased CBV in the dentate gyrus post exercise, which correlated with increased VO_2max and improved learning in a short-term memory portion of the AVLT [71]. Additional animal studies support Pereira et al.'s findings. van De Borght et al. observed increases in blood vessel density after

3–10 days of wheel running in mice, which was correlated with cell proliferation in the dentate gyrus [72]. These findings were reversed upon cessation of the exercise regimen. Palmer et al. also observed that neurogenesis in mice was associated with clusters of capillaries and speculated that the angiogenic effects of exercise provide the critical adaptation that promotes neurogenesis [73].

The role of angiogenesis to improved cognitive function in older adults was revealed in a longitudinal study by Rogers et al. [74]. They examined the role of cerebral blood perfusion in cognitively healthy older adults. Lifestyle and work status were assessed, cerebrovascular function was obtained using positron emission tomography, and cognitive function was determined through a Cognitive Capacity Screening Examination annually over a period of 4 years. Rogers et al. observed that individuals who retired and lived sedentary lives exhibited reduced cerebral oxygen perfusion over time. This correlated with poorer cognitive function while older adults who continued to work or who retired, but maintained a physically active lifestyle, showed maintenance of cerebrovascular function and cognition [74]!

Mitochondrial Synthesis

Exercise training in mice also results in mitochondrial synthesis in many brain regions [75]. An enriched environment has been shown to improve mitochondrial function in the cerebral cortex and hippocampus in rats [76]. In addition, synaptogenesis may be dependent on mitochondrial adaptations in the hippocampus; a voluntary exercise intervention in mice that increased mitochondrial number was associated with increased synaptic density [77], and an in vitro experiment by Li et al. also revealed that mitochondria in the dendrites of hippocampal cells were associated with synaptic strengthening [78]. While there have not been direct findings in relation to mitochondria, exercise, and cognition, these findings illustrate additional links and interdependencies in the neurobiological effects that may contribute to improved cognitive function.

Attenuation of Glucocorticoids

Beyond the direct effects of exercise on the brain, exercise can mitigate the impact of chronic mental stress throughout life. Such stress contributes to cognitive dysfunction, possibly through degradative action on neurotrophins, such as BDNF, and through structural and functional deterioration in the hippocampus. Mental stress activates the hypothalamic-pituitary-adrenal axis, which results in elevation of corticosteroid hormones from the adrenal cortex. Elevated levels of adrenal steroid hormones in animals are known to decrease levels of BDNF [79], reduce neurogenesis [80], alter dendritic branching in the amygdala, hippocampus, and frontal cortex [81], and impair learning and memory tasks [82]. In fact, experiments with marmoset monkeys revealed decreased cell proliferation in the dentate gyrus after a single exposure to stress [83]. A study of 4-month-old rats found that social stress contributed to reduced reference and working memory [82]. Cameron and McKay observed that while a decline in neurogenesis in aged rats was associated with high corticosteroid levels, eliminating these steroid hormones through adrenalectomy returned dentate gyrus cell proliferation to that of younger animals [80].

Studies of older men and women have revealed a positive relationship between cortisol and hippocampal atrophy, memory deficits, and general cognitive decline. Lupien et al. reported that older adults with extended elevations of cortisol exhibited 14% lower hippocampal volumes than controls with normal cortisol levels, and that the reduced volumes correlated with diminished performance on hippocampal-dependent tasks of delayed memory recall and spatial memory (time to finding way through simple and complex maze) [84]. These relationships have been found to be of particular significance for individuals who are carriers of the APOE ε4 gene, which is a known risk factor for AD. In this manner, Lee et al. [85] tested midlife and older adults (ages 50–70 years) with or without the APOE ε4 genotype on several cognitive procedures and measured salivary cortisol levels. Poorer performance in all participants was correlated with elevated cortisol levels, and homozygous ε4 carriers who also exhibited high cortisol levels performed significantly worse than noncarriers in processing speed, executive function, and verbal memory [85]. As such, the impact of stress on some individuals is profound and it follows that exercise may be essential medicine for them.

Accordingly, exercise reverses some of the effects of elevated corticosterone in animals. Adlard and Cotman [86] studied four groups of adult mice—stressed or nonstressed, sedentary or exercising groups. After 3 weeks, during which half of the animals were given running wheels, restraint stress was applied to half of the sedentary and half of the exercising animals that were then sacrificed for testing. Sedentary stressed mice showed elevated corticosterone and decreased hippocampal BDNF compared to control groups. Exercised animals, on the other hand, exhibited increased corticosterone, but also showed increased hippocampal BDNF levels compared with controls, suggesting that exercise had countered the effect of stress exhibited in sedentary stressed mice. When animals were subjected to adrenalectomy in a second experiment, neither exercised or sedentary stressed mice showed a decrease in BDNF [79]. In related work, Nakajima et al. [87] examined cognitive function in mice subjected to restraint stress (12 h/day) for 8 weeks. An exercising group was allowed free running-wheel access during the hours not restrained. After 5 weeks of stress, the Morris water maze was administered, and the exercising group showed superior performance compared to control sedentary stressed group. This was accompanied by increased cell proliferation in dentate gyrus and increases in IGF-1 in the cerebral cortex [87]. Again, such findings, if also relevant to humans, suggest an additional mechanism by which exercise would build the reserve of the brain and the tolerance to stress, aging, and pathology.

HOW DOES PHYSICAL ACTIVITY COUNTERACT NORMAL AND PATHOLOGICAL COGNITIVE AGING?

It appears that building a biological reserve is one distinguishing effect of physical activity that appears to be a structural benefit, with evidence for a reduction in normal age-related atrophy and even reversal of structural decline. For example, MRI evaluation of older adults classified by cardiovascular fitness level found that higher fitness resulted in increased brain volume of white and gray matter [88]. Further investigations of physical activity interventions have confirmed that some structural deterioration may be reversed with exercise, with findings of significant increases in brain volume in both gray and white matter after a 6-month aerobic exercise intervention in older adults [89]. Another study revealed specific improvements in hippocampal volume after a 12-month intervention with an aerobic exercise intervention but not with a stretching and toning group [11].

The executive functions of inhibitory control, mental flexibility, and memory encoding have all shown benefit from physical activity. Aerobic exercise interventions with older adults have resulted in improvements in the frontally mediated executive functions of task switching and response inhibition [4,89]. Neuroimaging of older adult participants in a 6-month aerobic exercise intervention revealed greater post-intervention activation in prefrontal and parietal regions, with an accompanying decrease in activation of the anterior cingulate cortex (ACC), an area associated with conflict monitoring [9]. Collectively, the results of the study suggest improved function of the cortical attentional networks, thereby reducing the demand on the ACC. The finding is also significant in that the impact of exercise on the brain was regionally specific and not a generalized directional change—this illustrates the importance of examination of functional neural networks and not limited regions. Otherwise the results of various studies that examine different brain regions may appear contradictory in the effect of exercise!

Of essential importance to the basic theme of this chapter, it appears that physical activity may also delay the symptoms associated with dementia and the normal aging process. Importantly, the increase in hippocampal volume reported in the Erikson et al. study described earlier may offset the known hippocampal decline associated with progression to dementia [11]. More specifically, cardiovascular fitness in early-stage Alzheimer's patients was negatively related to brain atrophy and positively related to white matter [27]. In addition, biomarkers for amyloid plaque and tau protein tangles obtained through cerebrospinal fluid samples and amyloid imaging revealed that older adults engaging in higher levels of physical activity exhibited less accumulation of neurotoxic pathology [90].

In a recent study, Baker et al. [91] also observed a significant improvement in executive functioning as a result of a vigorous exercise intervention with individuals diagnosed with mild cognitive impairment (MCI), which is believed to be a prodromal stage for AD. Importantly, the observed improvement in cognitive function was more pronounced in women than in men. This gender-selective association was also related to improvement in insulin sensitivity and reduced cortisol levels in women [91]. The observed benefit to cognitive function in MCI patients suggests a reversal of neuropathological processes. However, the notion of a synchronous benefit (owing to neurobiological benefit of exercise that outweighs the presence of pathology) is equally tenable and even a more likely explanation as there is little evidence in humans of a reversal of brain pathology as a result of exercise participation. The notion of synchronous benefit is consistent with that of the building of cognitive reserve through regular participation in physical activity.

Cognitive Reserve: Epidemiological Evidence

The studies discussed earlier highlight some effects of physical activity interventions and provide a "window" on the state of brain and cognitive health through cross-sectional observation and intervention studies with humans as well as those with animals. Beyond such investigations, large-scale epidemiological studies offer a broader look at the exercise-cognition/brain health relationship across the lifespan and pose answers to the question of how choices made throughout life, including participation in physical activity, affect cognitive aging.

The theory of cognitive reserve suggests that an individual may be able to partially offset the effects of brain aging by nature of the resources he or she possesses or develops throughout life. It is believed that factors such as intellectual capacity, education, socioeconomic class, and intellectual, social, or physical lifestyle choices may affect how one is able to resist brain injury or insult. This theory is relevant, in particular, to the development of dementia, allowing one with superior reserve to operate cognitively at a more efficient level for many years of aging, or to function through use of alternative brain regions during early stages of pathology, possibly delaying decline into clinical dementia [31].

Cognitive reserve is classified as either passive or active. Passive reserve describes a model in which an individual is able to withstand disease by nature of superior brain "hardware"—such as greater brain volume, increased neural density, improved blood vessel organization, increased neurotransmitter uptake, or neurotrophin expression. These physical characteristics allow for the brain to sustain degenerative insult to a greater extent without revealing clinical symptoms, allowing for a greater threshold to be passed before exhibiting cognitive decline or dementia. An individual with passive reserve is also able to engage cognitive function with more efficiency. Alternatively, active cognitive reserve involves brain "software" and utilizes the concept of compensation, with which one who has compromised brain networks and processes may employ greater brain resources (neuronal recruitment) to solve a problem, using alternative brain networks for function when original regions or networks have been compromised through damage from aging

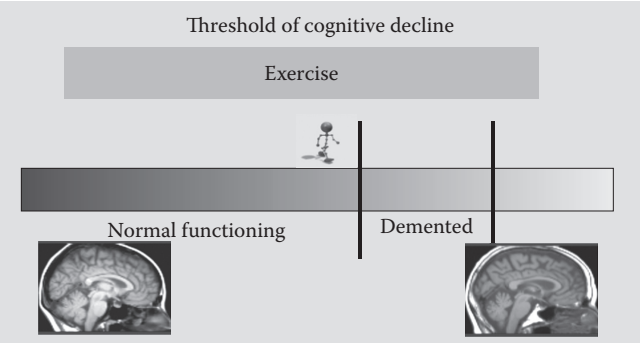

FIGURE 116.3 Threshold of cognitive decline, threshold moved to right-most vertical line.

or injury. Active reserve implies that deterioration in the brain can be tolerated, and that the symptoms of cognitive decline are not exhibiting clinically since the individual is able to compensate for the loss [31]. In this manner, the threshold for cognitive decline is elevated and the symptoms delayed (see Figure 116.3, threshold moved to right-most vertical line).

Cognitive reserve is examined most commonly through epidemiological investigations conducted prospectively or retrospectively to determine characteristics that may affect cognitive aging. Studies of early life factors have revealed that IQ or intellectual ability may correlate with later life cognitive ability. Researchers examining neuropathology postmortem in a study of Catholic nuns were able to correlate their dementia-related findings to the quality of writing exhibited by the young women upon entering the convent (i.e., at an early stage of life—approximately 20 years of age). Linguistic ability at a young age was positively associated with total brain volume and negatively related to clinical evidence of AD. Those with low idea density in early life showed significantly greater impairment in old age and pathology at postmortem [92]. Another study that examined IQ, educational level, and intellectual, social, and physical activities during early life found a strong positive correlation for IQ and education level to cognitive functioning in later life, but no long-lasting effects of social or physical activities [93]. Different researchers, however, have found a positive correlation for early life physical activity and processing speed in later life for men but not women [94]. These varied findings may indicate different mechanisms by which various reserve factors act, with some factors working from childhood and others being more responsive to adult manipulation. Limitations of retrospective studies may also affect outcomes for physical activity, since it is extremely difficult to obtain detailed and accurate information about lifestyle choices that occurred several decades in the past.

Examination of midlife activities has revealed more about the relation of physical activity to cognitive functioning in older adults. Scarmeas and Stern [19], in a review article examining midlife activities and education and their relation to later cognitive decline, revealed that there was a synergistic effect of high education and high levels of intellectual, social, and physical activities in helping older adults maintain cognitive function and resist cognitive decline or dementia. Physical activity performed in midlife has shown to be protective against dementia decades later [19]. Rovio et al. [20] examined 1449 survivors from a cohort study conducted with individuals at midlife (average interval to follow-up was 21 years). They discovered that those who engaged in leisure-time physical activity at least twice a week for 20–30 minutes that "made them breathless or caused them to sweat" exhibited 50% lower odds of developing dementia of any type, and were 60% less likely to experience AD, even after controlling for age, education, APOE genotype, vascular and other physical conditions, smoking, and alcohol [20]. Two other studies with follow-up times of 5 or 6 years showed similar findings [95,96]. While these findings do not indicate any "prevention" of AD and other forms of dementia, they do lead one to believe that physical activity can provide the means to delay onset of dementia by providing a reserve that enables a greater threshold to be passed before pathology is exhibited. The underlying basis of such an effect (i.e., building reserve) is likely due to the neurobiological mechanisms described in animals mentioned earlier.

Physical Activity and Brain Connectivity

Neuroimaging studies with humans provide more insight to the basis of cognitive reserve. Recent interventions examining connectivity between brain regions have allowed for investigation of how physical activity is related to both passive and active reserve, revealing that exercise can facilitate brain networks by working efficiently with elevated coherence between regions. This adaptation would likely promote resilience to aging or dementia, enabling one with good connectivity to achieve greater neuronal activation or strategically employ alternative networks as required by the age-related or pathology-related changes in the brain. Voss et al. [13] observed that 1 year of aerobic training resulted in greater functional connectivity in the brain's default mode network (DMN) and frontal executive networks. One year of stretching and toning (that involved learning of new routines) also resulted in greater connectivity, with increased DMN connectivity after 6 months and improved frontal-parietal network connectivity after 12 months. These neural changes were reflected in improved executive function in the participants and provide strong evidence of exercise-related brain plasticity in men and women [13]. Another study of networking by Burdette et al. [14] reported a comparison of brisk walking to a health education treatment and a "light stretching" control group (4 months duration for the interventions). The researchers observed that the ACC was better connected to the hippocampus in the walking group when compared to the sedentary control group and accompanied by improved cerebral blood flow [14]. These improvements show the power of physical activity to keep the brain operating efficiently and ready to meet cognitive challenges that could not be met if disconnectivity was occurring.

Genetic Influence on Cognition and the Mediating Role of Physical Activity

Although the study of genetic factors and cognition is in its infancy, there is evidence that genetics plays a role in the typical cognitive decline of older adults, both in terms of normal aging and in the development of AD. Autosomal dominant genes play a role in the small proportion of early-onset Alzheimer's (before age 65 years) accounting for about 5% of the disease [97,98]. The APOE gene is notable in its relation to development of late-onset AD, but it appears as a risk factor rather than showing direct causality. APOE is characterized by three variants or alleles—ε2, ε3, and ε4—with the ε4 allele present in about 15% of the population, but associated with about 40% of late-onset AD [33]. The risk for possession of one ε4 allele increases the risk of developing late-onset AD by three times, with two copies of the allele increasing risk to eight times compared to the general population [99]. However, about 50% of ε4 carriers at age 90 years will not have AD [100], so it is indeed a complex issue and raises the question about protective factors that enable cognitive reserve to occur in these genetically at-risk individuals, increasing the threshold to defend against dementia-related pathology.

The ε4 allele has a different orientation, with amino acid substitutions that contribute to a more unstable protein with higher likelihood of fragmentation of the protein [101]. As a result of these differences from ε2 or ε3, the ε4 genotype is associated with greater amyloid buildup, reduced amyloid clearance, increased neurofibrillary tangles, decreased glucose metabolism in some areas of the brain, reduced brain volume, lysosome leakage, translocation and damage to cytoskeleton, mitochondrial impairment, differences in brain activation, and cognitive impairment, particularly in regard to memory and executive function tasks in healthy adults [102]. In this manner, the ε4 carrier would garner greater neurobiological benefit from exercise owing to the lessened ability to maintain and repair aging and insult to the human brain!

Characteristic Differences in APOE ε4 Carriers

The characteristics of brain activity in ε4 carriers throughout life show some distinct differences from non-carriers. Hypometabolism at rest has been shown repeatedly to be a distinct aspect of ε4 carriers' brain function, even in healthy young adulthood, with reduced metabolism and lower oxygen delivery to the frontal, parietal, medial temporal lobes, and posterior cingulate cortex [103]. Differences in brain structure in APOE ε4 carriers compared to non-carriers also exist. For example, older adult ε4 carriers frequently show more brain atrophy compared to non-carriers even in cognitively healthy individuals [104], and this difference is pronounced in the hippocampal area [105]. With regard to brain activity, cognitively healthy APOE ε4 carriers show altered brain activation under memory challenge tasks [32,106]. Sperling reported that ε4 carriers displayed increased hippocampal activation that converted to hypoactivation as memory became more impaired, possibly forecasting a path toward dementia [32]. (Note: refer to Figure 1). Numerous studies have shown that older adults carrying the APOE ε4 allele exhibit lower cognitive function in areas of executive function, working memory, episodic memory, and perceptual processing and reveal cognitive deficits even in the absence of pathology [107–109]. Some recent findings in younger adults have shed some new light on possible effects of the ε4 allele. One study that examined postmortem gene transcripts from brain cortical samples of young adults who were either ε3 or ε4 revealed differences in mitochondrial function with ε4 carriers that was occurring before evidence of plaque or tangle formation [110]. Another study revealed mitochondrial damage postmortem in the posterior cingulate cortex in young adults, again found without plaque [111]. Both of these studies offer support for a theory of mitochondrial dysfunction mediating, at least in part, the role the APOE-ε4 allele in cognitive aging and development of AD. The mitochondrial synthetic effect of exercise reported earlier may mitigate this process.

Physical Activity and Cognition in Relation to APOE Genotype

With all of the findings showing differences in brain structure and function between APOE genotypes, as well as poorer cognitive performance in older adult ε4 carriers and a higher rate of development of AD, one may wonder about the benefit of physical activity for ε4 carriers in comparison to the general population. Few such studies are currently available, but findings from them suggest there may be particular benefit of physical activity for APOE ε4 carriers.

In light of the known risk of APOE genotype for AD, Schuit et al. [10] conducted a prospective study of the effects of physical activity participation on cognitive decline over a 3 year period in 347 older men aged 65–84 years. Participants were characterized for presence of APOE ε4, exercise behavior at baseline (less than or more than 1 h/day of walking, bicycling, gardening, odd jobs, and sport), and cognitive performance on the mini-Mental Status Exam (MMSE), both at study inception and follow-up. Incidence of cognitive decline, indicated by a drop of 3 or more points on the MMSE over the 3 year period, was related to activity level and genotype. Specifically, the risk of cognitive decline was 13.7 times higher in sedentary ε4 carriers relative to physically active non-carriers. Higher physical activity involvement was associated with remarkable attenuation of cognitive decline in the ε4 carriers [10].

Deeny et al. [112] investigated the effect of exercise on working memory in adults 50–70 years of age with regard to APOE genotype. Using both behavioral and magnetoencephalographic brain imaging evidence, these researchers examined cortical dynamics and cognitive performance on a behavioral Sternberg memory task, comparing carriers and non-carriers of the APOE ε4 allele. Highly active ε4 carriers showed faster reaction time in the memory task compared to

sedentary carriers. Seven sedentary ε4 carriers also showed a lower level of activation in the right medial temporal lobe compared to highly active ε4 carriers who were undifferentiated from non-carriers in activation [112]. This lower activation may be forecasting that a change to hypoactivation may be occurring even at midlife for sedentary ε4 carriers, while physical activity is providing cognitive protection. In addition, Etnier et al. [113] examined working and episodic memory in relation to aerobic capacity (VO_2max) in older women who were classified according to APOE e4 carrier or non-carrier groups. They reported that the cognitive-behavioral effects of ε4 showed evidence of a dose response, for sedentary ε4 carriers, with ε4 homozygotes of lower aerobic fitness exhibiting poorer response to a delayed memory task compared to ε4 heterozygotes or non-carriers [113].

Furthermore, Kayes et al. [114] examined the relation of both physical activity and cardiovascular fitness to cognitive function across a continuum of cognitive challenges consisting of inhibitory control, working memory, and mental flexibility (set shifting) in older adults considered with regard to APOE genotype. They reported that an inhibitory task (Erikson Flanker) revealed a benefit for cardiovascular fitness without regard to genotype, such that fitness was inversely related to interference (i.e., higher fitness was associated with reduced interference/distraction). However, when the cognitive challenge was more complex, as in the case of working memory or a combination of working memory and set shifting, the cognitive benefit from physical activity was observed only for ε4 carriers [114]. In essence, a pattern in the findings revealed that sedentary e4 carriers showed inferior performance to non-carriers, while participation in physical activity resulted in progressive improvement such that sufficiently active ε4 carriers exhibited similar cognitive performance to non-carriers.

In terms of the neurobiological mechanisms provided through physical activity, it appears reasonable why exercise would be particularly beneficial to carriers of the APOE ε4 allele. As previously described, physical activity increases angiogenesis in the brain and improves mitochondrial function, which could provide a direct benefit for the hypometabolism or mitochondrial dysfunction exhibited by ε4 carriers. The fact that physical activity increases uptake of BDNF may indicate possible repair to damage caused by the unstable conformation of ε4, and neurogenesis as reported in animal studies (and implied in at least one human study that showed improved hippocampal volume after an exercise intervention) could delay the destruction toward AD caused by this genotype if hippocampal regions show reversal of damage with aging due to the effects of physical activity. It should be noted that APOE-ε4 carriers are subject both to normal cognitive decline and pathological dementia-related decline, so there is a double insult to these individuals. Studies have revealed that even cognitively healthy ε4 carriers experience lower cognitive function in areas of working and episodic memory, processing speed, and executive function, and they may benefit from exercise in ways to improve frontal as well as hippocampal function [107–109]. Overall, exercise may offer benefits to APOE-ε4 carriers to extend cognitive reserve, preserving brain structure and function, offering ability to repair damage, and improving resilience to effects of aging and dementia pathology.

Benefits of Physical Activity in Children and Young Adults: An Investment Hypothesis

The notion that lifestyle choices in youth or young adulthood could affect cognitive aging decades later is intriguing, and studies in children have shown that physical activity may improve cognitive function. Some studies are revealing distinct effects of increased brain volume and improved executive function or working memory in children as young as 9 years of age. Greater relational memory in high-fit 9- and 10-year-olds compared to lower-fit children has been reported in one study, with the difference mediated by increases in hippocampal volume [17]. Another study revealed superior performance on an inhibitory control measure (Eriksen Flanker) in high-fit children compared to lower-fit children, with greater activation of the dorsal striatum that was positively related to inhibitory control [16]. Davis et al. [115] conducted a 3-month exercise intervention with 7- to 11-year-old children with two exercise groups (one 20-min three times per week; one 40-min) and observed improvement in executive function based on the Cognitive Assessment System and significant improvements in mathematics scores on the Woodcock-Johnson Test of Achievement. Both of these improvements showed a dose-response effect with the 40-min exercise group achieving significantly better than the 20-min exercise group. In addition, the exercise groups (combined) showed increased bilateral activation in the prefrontal cortex and decreased activation in bilateral posterior parietal cortex when compared to non-exercising controls [115]. Hillman further reported improved P300 amplitude and reduced latency in children who are "high fit," indicating that they exhibit enhanced attention resource allocation when challenged [15].

There is less research with young adults, but there are interesting results that add credence to the investment reserve theory. Woo et al. employed an oddball and go/no-go executive task in college-aged men with consideration of cardiovascular fitness and APOE genotype, and reported that fitness proved to be especially beneficial for APOE-ε4 carriers [116]. Further, a retrospective study of military records of young Swedish males born between 1950–1976, including comparisons in monozygotic twin pairs, found that cardiovascular fitness in adolescent years predicted intelligence in several areas (global, verbal, visuospatial, logical, and technical) [117]. A cohort study of adults revealed that physical activity at age 36 years was associated with verbal memory performance at age 43 years and was protective against memory decline from ages 43–53 years. This study reflects that effects of cognitive aging begin at surprisingly young ages for sedentary individuals and underscores the importance of physical activity in preserving memory [118]. The work

of Woo et al. suggests that the preservative effects of fitness on cognition in later life may be particularly important for APOE e4 carriers [116]. Even the prenatal environment may contribute to lifelong cognitive development. A study of guinea pigs in which nutrient and blood supply was reduced in utero showed a strong effect on hippocampal development, with lower volume and suboptimal dendritic outgrowth [119]. On a positive note, other studies have shown that when the mother is physically active during pregnancy, there is improved brain development [120]. While there is synaptic remodeling throughout life and evidence that enriched environment may offset prenatal insufficiencies, these findings do lead to questions about lifelong influences of cognitive reserve. This is an area in which additional research would be welcome!

ADDITIONAL CONSIDERATIONS: EXERCISE INTENSITY AND MODALITY VERSUS SKILLFUL MOVEMENT

One common question concerning the role of exercise in cognition is that of exercise prescription. Unfortunately, there is no definitive answer as to what type, intensity, frequency, or duration of physical activity extends the greatest benefit to cognitive function, but there are hints that can be gleaned from animal and human investigations that may provide a basis for future research in this area. Most of the research has involved aerobic exercise, and studies have consistently revealed associations between vigorous physical activity and improved executive function. However, animal research has shown that there are also important effects from enriched environment—i.e., social housing, tubes, toys, ladders, nesting material, and running wheel—that involves more learning or spatial activity when compared to running-wheel activity, alone. For example, Olsen et al. reported that elements of enriched environments offered more specific effects in memory improvement or in increasing synaptic strength [121]. In terms of neurogenesis, it appears that high-intensity running in animals is important for proliferation of progenitor cells in the dentate gyrus, but that an enriched environment is more related to survival of new cells [49,122]. A study that investigated running and enriched environment in tandem revealed that 10 days of wheel running followed by 35 days of enriched environment resulted in a 30% increase in neurogenesis compared to either alone. These authors suggested that aerobic exercise provides a "priming" mechanism for learning, with more complex physical activity from an enriched environment leading to more long-lasting benefits [123]. A study conducted with older rats revealed that an enriched environment preserved memory and synaptic plasticity in aging compared to sedentary controls [124]. Interestingly, a study that controlled for the social effects of enriched environment did not reveal the benefits for the socially enriched group that were shown when complex motor activities were present [49].

Translating to human research, several epidemiological studies have revealed that a variety of activities provides the most impressive cognitive benefit in older adults. Chan et al. reported on a cross-sectional study that mind-body exercises involving more cognitive processing (i.e., tai chi) and cardiovascular exercise performed together resulted in significantly improved memory scores for participants [125]. Another study revealed that overall physical activity, including leisure, household, and occupational activities, as measured by actigraphy predicted improved global cognition in older adults, whereas a self-report of physical activity that was more limited to exercise type activities did not [126]. Interestingly, these improvements were associated with increases in peripheral IGF-1. Even intervention studies that revealed impressive effects of aerobic exercise on improved hippocampal volume or improved networking also revealed positive effects on cognition from moderate physical activity relative to control groups whose intervention involved learning routines. Overall, it appears that both high-intensity aerobic activity and more moderate activity that involves cognitive challenge may be important for different aspects of cognition.

The issue of aerobic fitness versus motor fitness areas of strength, balance, or flexibility in humans is also of interest, and several studies of strength training have shown that these programs alone can provide cognitive effects. A moderate 6-month resistance and balance intervention predicted individual improvement in memory in older adults when compared to a wait-list control [127]. A 24-week intervention revealed that both moderate and high-intensity resistance training improved cognitive performance in older adults in attention and memory compared to a stretching control [128]. A recent fMRI study by Voelcker-Rehage et al. [129] examined motor fitness (strength, balance, flexibility, and fine motor control) as well as aerobic fitness and found distinct areas where each type of fitness was optimal for cognitive improvement. These researchers reported that inhibitory executive function accrued a selective benefit for aerobic fitness. Visuospatial tasks that required more attentional control were found to be more related to motor fitness [129]. These findings underscore that at this point in time, understanding of effects of different modalities and duration of exercise is in its infancy—the puzzle has only begun to be solved. Future kinesiology/cognitive neuroscience research with both animal and human research may be productive as it tries to elucidate the subtleties of movement and or aerobic fitness to find more specialized answers.

CHALLENGES FOR FUTURE RESEARCH

It appears that a reasonable role for physical activity participation and exercise is the building of cognitive reserve, both through active and passive mechanisms. In this manner the neurobiological benefits of exercise observed in animals, if also present in the human brain, would result in tolerance to age-related decline and pathology such as AD. The work on neurotrophic influence in animals and the observed benefit of exercise on hippocampal volume in humans suggest a powerful remediation effect that could reasonably delay the aging

and the symptoms associated with the pathology of dementia. In this manner the threshold for cognitive decline would be increased with a physically active lifestyle. In addition, it may be that physical activity early in life and during midlife exerts a profound benefit to cognitive function in later life. This type of an investment would underscore the importance of a physically active lifestyle throughout the entire developmental sequence. Finally, it appears that there are individual differences in genotype that may underscore a higher need for exercise in some individuals relative to others such as e4 carriers and non-carriers. In this manner, exercise may be essential medicine for some! The insight that has been accrued over the past 35 years in this area is remarkable and lends strong scientific support for the ancient notion of a sound mind with a sound body (mens sana in acorpore sano).

ANXIETY: DEFINITIONS AND DIAGNOSES

Anxiety generally is a normal and even essential human emotion as it secures survival. In preparing the organism for a fight or flight reaction, it signals (assumed) danger and may so protect the organism. It activates physiological changes (e.g., sweating, faster heartbeat), and, consequently, also has cognitive (e.g., dashing thoughts) and behavioral correlates (e.g., leaving the situation). Panic is differentiated from anxiety in the even faster changes and a very quick onset. So a panic reaction is a fast defensive reaction, which allows the organism to leave a possibly dangerous situation as fast as possible.

Anxiety will be considered as pathological if it emerges in situations not objectively dangerous, if it is excessively strong, and if anticipatory anxiety constrains life of the affected [1,2]. In this regard, anxiety disorders can be differentiated from "normal" and subclinical anxiety.

According to the International Classification of Diseases (ICD) of the World Health Organization (WHO), anxiety disorders are grouped within the neurotic, stress-related, and somatoform disorders (F4).

We will focus here on diagnoses relevant for the following chapter, i.e., anxiety disorders that have been studied in association with physical activity. For any other and for detailed diagnostic criteria, we recommit to ICD-10 [2].

Generally, the specific diagnoses can be classified by the nature of anxiety. In phobic anxiety disorders, anxiety is evoked only, or predominantly, by well-defined situations, which are not currently dangerous. As a result, these situations are avoided whenever possible or endured with dread. Furthermore, contemplating entering the phobic situation generates anticipatory anxiety.

Agoraphobia

- Anxiety in at least two of the following situations: public places, crowds, traveling far away from home, or traveling alone. Agoraphobia is further specified by existence of a history of panic disorder (PD).

Social anxiety disorders

- Are centered around the fear of scrutiny by other people.

Specific (isolated) phobias

- Anxiety is restricted to highly specific situations such as proximity to particular animals, heights, and thunder, and the phobic stimulus is avoided whenever possible.

In contrast, in the so labeled "other anxiety disorders," manifestation of anxiety is the major symptom and is not restricted to any particular situation or object.

Panic disorder

- Core feature are recurrent attacks of severe anxiety (panic). These are discrete periods of intensive fear accompanied by somatic or cognitive symptoms like sweating, trembling, breathlessness, dizziness, fear to lose control, or even mortal fear. Panic attacks are unpredictable as they are not restricted to any particular situation or circumstances. Although anticipatory anxiety (fear of further panic attacks) is common, people experience intervals without anxiety in between the attacks.

Generalized anxiety disorder

- Essential feature is anxiety, which is free-floating, i.e., which is generalized and persistent but, again, not restricted to any particular situations or circumstances.
- Furthermore, patients present worries (e.g., themselves or a relative will become ill), muscular tensions, vegetative hyper-irritability, and other physical symptoms.

Obsessive-compulsive disorder

Essential features are recurrent obsessional thoughts or compulsive acts, which are distressing, and the patient often tries to resist them. The acts are done to prevent objectively unlikely events, which the patient fears might otherwise occur. Anxiety is almost invariably present and gets worse if compulsive acts are resisted.

Posttraumatic stress disorder

Posttraumatic stress disorder (PTSD) differs from the others as to the existence of causative influences. It occurs as a response to a stressful event or situation of an exceptionally threatening or catastrophic nature, which is likely to cause distress in almost anyone. Typical features include episodes of reliving the trauma and feelings of emotional "numbness", detachment from other people, unresponsiveness to surroundings, anhedonia, and avoidance of activities or situations remembering the trauma. Usually, autonomic arousal with hypervigilance, an enhanced startle reaction, and insomnia are also present.

Anxiety disorders: incidence and impact

Within all mental disorders, anxiety disorders are among the most common and their prevalence and course are reasonably well documented. The overall prevalence of anxiety disorders is shown to be quite high. Kessler et al. [3,4] report a lifetime (12 month) prevalence of 28.8% (18.1%) for any anxiety disorder in the United States. There are considerable variations from the most (specific phobias, 12.5% [8.7%]) to the least prevalent (agoraphobia without a history of PD, 1.4% [0.8%]) disorders [3–5]. Statistics from six European countries reveal lower lifetime (and 12-month) prevalences (any anxiety disorder: 13.6% [6.4%], [6]) in these countries. The relative frequency is similar across countries [7].

Age of onset typically is in childhood or adolescence, course is often chronic-recurrent, and anxiety disorders are highly comorbid with each other and with other mental disorders [5]. Furthermore, women, with being twice as likely to suffer from anxiety disorders, are at a significantly higher risk [3,6,8].

The individual and social impact of anxiety disorders has been pointed out repeatedly. Among people with psychiatric disorders, those with anxiety disorders are high care utilizers who present to general practitioners more frequently than to psychiatric professionals [9], which places a high burden on the health care system. Their economic costs include psychiatric and nonpsychiatric care, emergency care, hospitalization, drug prescription, reduced productivity, absenteeism from work, and suicide [9].

TREATMENT: HOW CAN ANXIETY DISORDERS BE TREATED?

Psychotherapeutical Treatment of Anxiety Disorders

Cognitive behavioral therapy (CBT) is long known to be the gold standard in psychotherapy of anxiety disorders. Its positive effect is one of the best assured results in psychotherapy research in general. Numerous clinical trials have supported the efficacy of CBT for anxiety disorders. Several meta-analytic results of treatment outcome studies have supported this finding, showing strong effects of CBT for PD and agoraphobia, social phobia, obsessive-compulsive disorder (OCD), generalized anxiety disorder (GAD), and PTSD [10]. Cognitive therapy and exposure therapy alone, in combination or combined with relaxation training, could be shown to be effective across different anxiety disorders, with no differential efficacy for any treatment components for any specific diagnoses [10]. The authors reported that their meta-analytic findings showed superior effects for CBT in GAD and PTSD than for social anxiety disorders (SAD) as the only difference on the diagnostic level. In line with these earlier findings also is a more recent review of meta-analytic findings for the efficacy of CBT for the treatment of anxiety disorders by Olatunji et al. [11]. The authors reviewed contemporary meta-analytic studies and support the finding that CBT procedures and particularly exposure-based treatment approaches are highly efficacious. They could resume that CBT, in general, outperforms wait-list as well as placebo controls and achieves incremental efficacy above and beyond nonspecific factors. There now also are references that CBT is more efficacious than other psychosocial treatment modalities for some anxiety disorders [11]. While the efficacy of CBT for the treatment of anxiety disorders is one of the best empirically proven result in the field of research on psychotherapy, there are also relatively new sectors in the field to be looked at, e.g., the associated neuroanatomical changes coming along with the cognitive behavioral modification of psychotherapy. A recent systematic review [12] reported that CBT modified the neural

circuits involved in the regulation of negative emotions and fear extinction in treatment responders, which speaks in favor of CBT being able to change dysfunctions of the underlying neural basis. Neuroimaging also is considered to hold the opportunity to identify predictors of response to therapy, which will be one of the future challenges in the research of treatment efficacy. Until now, there is only evidence regarding OCD, where higher pretreatment regional metabolic activity in the left orbitofrontal cortex was associated with better outcome [12].

Recently, self-help efforts have also been taken into a closer look, playing a role as an initial minimal treatment in stepped-care models of treatment or as a strategy to prevent a disorder developing. Furthermore, it might be promising meeting the lack of professionals providing evidence-based therapy and the demand for treatment with minimal cost to health services. For a review on the outcomes of self-help efforts, see Morgan and Jorm [13].

Pharmacological Treatment of Anxiety Disorders

The pharmacological treatment of anxiety disorders has made great progress over the past few decades and has been intensively studied. Clinical trials showing the effectiveness of selective serotonin reuptake inhibitors (SSRIs) have been well replicated, while the effectiveness of other medication classes needs to be further validated [14]. When looking at PD, SAD, GAD, PTSD, and OCD, findings suggest that both SSRIs and serotonin-norepinephrine reuptake inhibitors are the first-line medications for most of the previously mentioned disorders [14,15]. Other antidepressants (tricyclic antidepressants or monoamino oxidase inhibitors) should rather be seen as second- and third-line choices, due to their tolerability issues. Other agents as anticonvulsants may have an adjunctive role. On the level of different diagnoses, azapirones have been used effectively for GAD, while in PD and GAD, there is empirical evidence for the use of benzodiazepines [14]. Benzodiazepines are very effective due to their rapid onset of action and ability to be used on an as-needed basis, although their long-term use is limited by the potential for abuse and dependence and their lack of antidepressant properties [16]. For detailed reviews of randomized, placebo-controlled trials and meta-analyses investigating the effects of different psychotropic medications used in the treatment of particular anxiety disorders, see Ravindran and Stein [14], Plag et al. [15], or Hoffman and Mathew [16].

In conclusion, though, when it comes to the pharmacological treatment of anxiety disorders, antidepressant treatment is the clinical standard for all types of anxiety disorders (excluding specific phobias) [15,17,18].

Is a Combination of Pharmacotherapy and Psychotherapy Even Better?

In order to increase the efficacy of either psychotherapy or pharmacological treatment, the combination of both has been discussed as an option toward faster and more sustained treatment. Although this approach may seem obvious, confirming empiric findings are not.

For patients with PD, Barlow et al. [19] could show that combining pharmacotherapy (Imipramine) and CBT was more effective than either therapy alone. In line, Blanco et al. [20] found combined therapy as being superior to either treatment alone and to placebo in patients with SAD.

Pull [21] resumed little benefit for a combination of psychotherapy and pharmacotherapy for the treatment of anxiety disorders versus monotherapies when taking randomized controlled trials, meta-analysis, and reviews into account. Zwanzger et al. [22] review that there might be some evidence for the superiority of combination therapy under some conditions, although the authors do not see evidence for beneficial effects of combined treatment for long-term outcome. Consistently, Hofmann et al. [23] report in their meta-analysis that pharmacotherapy may be a useful strategy for enhancing acute-phase CBT outcomes, while they do not see evidence for a benefit of combination therapy in the long-term CBT outcomes. Interestingly, the authors also report a significant publication bias in terms of smaller effects in more recent studies, which might be due to more rigorous assessment methods.

Following Bandelow et al. [17], the missing evidence for the combination of both strategies might, in part, be due to the number and quality of existing studies. Nevertheless, combined pharmacotherapy and psychotherapy is current clinical guideline for treating PD and agoraphobia, while for treatment of GAD, SAD, OCD, and PTSD, the benefit of a combined therapy up to date can neither be clearly supported nor rejected [17].

Complementary Treatment Methods

Psychotherapy and pharmacotherapy are the treatments of choice and recommended as the current treatment guidelines [17], although other complementary approaches might partly be useful in the amelioration of therapy. Although for most of them until now, only poor evidence base has been generated [24], complementary and alternative interventions used to treat anxiety are highly popular.

Due to methodological limitations of the underlying trials available up to date, empirically based recommendation cannot be given for the use of herbal and dietary supplements [17,25], homeopathy [26], acupuncture [27], therapeutic touch [28], tai chi, and qigong [29] in the treatment of anxiety. Conflicting results exist for meditation [29,30], while yoga has shown to be effective in a recent review [29]. All those approaches have to be further investigated.

Meta-analytic investigations could not support the effectiveness for repetitive transcranial magnetic stimulation [31], while the anxiolytic potential of relaxation trainings (e.g., applied relaxation, autogenic training, Jacobson's progressive relaxation) has been meta-analytically proven [30].

Exercise has been considered a promising therapeutical option for anxiety disorders, as in a wide range of research, it has been shown to have positive effects on major

depression [32]. A detailed illustration of evidence-based results for the link between anxiety disorders and physical activity will be given in the following passages.

WHAT LINKS ANXIETY (DISORDERS) AND PHYSICAL ACTIVITY?

Physical activity has been defined as bodily movements produced by skeletal muscles that result in energy expenditure [33]. It therefore includes either leisure activity (like jogging, cycling), which increases fitness such as labor, gardening, housework, or walking. Exercise is seen as a subset of physical activity, as it is defined as planned, structured, and repetitive physical activity that has improvement or maintenance of physical fitness as a final or intermediate goal [33]. Most research has focused on exercise [34], although in the last decade, there has been a shift in the public health recommendations, now also regarding everyday physical activity as beneficial [35]. In literature, though, both terms are not always differentiated. In the following, we will use physical activity, exercise (training), and sports equivalently.

Physical Activity, Exercise, and the Prevalence and Incidence of Anxiety Disorders

Physical activity is known to be associated with a range of health benefits and the absence can have harmful effects on health and well-being as it increases the risk for coronary heart disease, diabetes, certain cancers, obesity, hypertension, and all-cause mortality [36].

Compared with a wide range of research on the positive effects of physical activity in depression, anxiety disorders have been less frequently studied. Additionally, the diversity of anxiety disorders does not allow to generalize from studies in one specific anxiety disorder to other disorders. Furthermore, changes in the diagnostic criteria complicate the interpretation of early studies.

Cross-sectionally, the link between physical activity and anxiety has been intensively studied, and high self-reported levels of physical activity have mainly been found to be associated with better mental health.

When controlling for social class and status, e.g., Steptoe and Butler [37] could show that vigorous exercise participation was related to lower emotional distress in a large cohort (n = 5061). In line, Stephens [38] found in samples from the United States and Canada that self-reported levels of recreational physical activity were correlated with better mental health, which included fewer symptoms of anxiety as well. His results held after controlling for confounding variables such as sex, age, sociodemographic status, and physical illness, which speaks in favor of the robustness of the found relation.

The link between physical activity and (mental) health in the European Union was intensively studied by Abu-Omar et al. They were able to replicate earlier findings of associations between physical activity in everyday life with self-rated health in general [39] and also with self-rated mental health [40]. They used the relatively new developed International Physical Activity Questionnaire [41], which allows calculating of metabolic equivalents during the last week. This instrument had been developed following a shift in public health recommendations to allow standardized assessment of physical activity independent of the context.

Concerning different diagnoses in the field of anxiety disorders, Goodwin [42] analyzed the data of the U.S. National Comorbidity Survey and found significant associations of regular physical activity and a lower prevalence of specific phobia, social phobia, and agoraphobia in a representative sample of adults in the United States. These findings as well persisted after controlling for sociodemographic characteristics, self-reported physical disorders, and comorbid mental disorders.

Furthermore, a representative, cross-sectional study in Japan [43] including 4000 persons could show a positive relation between dislike of physical activity and higher odds ratios for panic attacks and PD, which was found to be especially true for women.

On the other hand, studies can be found, which do not underline the association between physical inactivity and symptoms of anxiety. For example, Thorsen et al. [44] could not replicate a positive association between (self-reported) physical activity and lower prevalence of anxiety in their study with long-time cancer survivors and in men of similar age from the general population after adjusting for background variables. In line with those findings is Backmand et al. [45], who could not find physical activity being associated with less symptoms of anxiety when examining former athletes.

Despite numerous studies on the topic, there are certain problems when it comes to their comparability as measurement of anxiety as well as measurement of physical activity has not been consistent. Furthermore, in most studies, fitness was not directly assessed, and measuring exercise habits and anxiety disorders in cross-sectional surveys generally is ambiguous about cause and effect. That is why prospective longitudinal studies are needed to further investigate the association of physical activity and mental disorders. Until now, these studies are very rare when it comes to anxiety disorders. At least, in part, though, prospective longitudinal studies support positive results driven from cross-sectional studies. In a sample of 2548 adolescents and young adults, Ströhle et al. [46] combined a cross-sectional and a prospective longitudinal design within their study. The cross-sectional results showed that regular physical activity was associated with decreased prevalence of any and comorbid mental disorder due to lower rates of substance use disorders, anxiety disorders, and dysthymia. Physical activity was assessed with four questions as part of the diagnostic interview, answers were grouped into three categories: regular (daily and several times a week), non-regular (one to four times a month), and no (less than once a month or no exercise at all) physical activity. Findings comparing people exercising non-regularly versus people with no physical activity were similar.

The prospective results showed that regular as well as non-regular physical activity was associated with a substantially reduced risk compared with people not exercising to experience any incident disorder and to develop comorbid conditions. These effects hold for control of educational status and body mass index, other mental disorders, and impairment days due to physical problems. Taking anxiety disorders into a closer focus, 5 year incidence of any anxiety disorder was lower for people exercising regularly and non-regularly compared to the group labeled as no physical activity at baseline. Comparing regularly exercising people with people not exercising, on the specific disorders level, the effect could only be shown for agoraphobia and specific phobia. Comparing non-regularly exercising people with people not exercising revealed an effect for agoraphobia as well as for PTSD.

Overall, the authors suggest a substantial protective effect of physical activity, especially if participating in sports daily or more frequent. The association of regular activity and mental health, however, is different by age, gender, and type of disorder. Regarding anxiety disorders, significant associations were found for agoraphobia, specific phobia, and PTSD. All revealed lower rates among those who exercised regularly, and the effects were less impressive for non-regular activity levels.

Limitations of the study, though, include the lack of objective indicators of physical activity and fitness.

Recently, Jonsdottir et al. [47] conducted a prospective study in 3114 Swedish health care workers and social insurance officers. On a cross-sectional approach, they could show that individuals reporting light or moderate-to-vigorous activity were less likely to report high levels of anxiety (as measured with the Hospital Anxiety and Depression scale (HAD) [48], while an activity level of at least moderate was needed to reduce the risk of symptoms of anxiety at follow-up 2 years later.

Although there are diverse and inconsistent results and cross-sectional trials are often difficult to compare due to diverse acquisition of both anxiety and physical activity, generally there is an association between physical activity and less symptoms of anxiety. Nevertheless, more consistently designed studies and, particularly, prospective trials are needed to further investigate the association and to learn more about the nature of effect of physical activity on anxiety. Furthermore, it is still unclear whether there really is a causal relationship between physical activity and (less) anxiety, as often is implicitly assumed in population-based studies. It is also conceivable that common genetic factors both influence exercise behavior and anxious symptoms, a possibility a recent Dutch study [49] showed some proof for.

Evidence of Therapeutical Impact of Physical Activity on Anxiety

Physical inactivity is, according to the WHO, one of the risk factors that most often contribute to an early death and is comparable in its harmfulness to cigarette smoke [50].

The positive influence of exercise on psychological well-being and mental health has been demonstrated several times.

Endurance training reduces anxiety, enhances mood, increases self-confidence, and improves stress management capacity in healthy people [51–54].

At the same time, a twin study demonstrated a relationship between physical activity and reduced mortality [55].

Anxiolytic Effect in the Healthy

The anxiolytic effect of aerobic physical exercise in healthy subjects has been investigated in numerous studies. Several meta-analyses suggest a fear-reducing effect in healthy people [56–58]. A training period of at least 10 weeks and a workout in the aerobic power range seem to be critical for the anxiolytic effect [58].

One-Time Physical Activity and Anxiety

The anxiolytic effect of a one-time physical activity was examined by Orwin [59]. Other case reports describe the anxiolytic effect of a one-time physical activity in patients with specific phobia [60,61]. Physical symptoms of anxiety in healthy patients, in which anxiety symptoms were experimentally induced by caffeine intake, cholecystokinin tetrapeptide (CCK-4), and CO_2 transfer, decreased after a single session of physical exercise on the bicycle ergometer or on treadmill [62–64].

Before a CO_2 challenge, 18 PD patients practiced either moderate exercise or very light exercise. Panic reactions were smaller in patients who performed moderate exercise compared with patients in the control condition (very-light exercise) [65].

In a crossover design, healthy subjects and patients with PD were studied by Ströhle et al. [66]. The effects of rest and 30 min aerobic treadmill exercise were compared with each other after CCK-4-induced panic attacks. It could be shown that panic attacks were less frequent in the exercise condition and that 30 min of physical activity caused an acute antipanic and anxiolytic activity.

Endurance Training and Anxiety

The effect of physical training in patients with manifest anxiety disorder has so far received little systematic study. Dratcu [67] could show an effect of aerobic endurance training for the treatment of patients with PD in his case series.

In a study of patients with anxiety neurosis, a 2 month endurance training led to a significant decline in anxiety scores [68]. Here, a 2 month training course was compared in terms of anxiolytic effect with 2 months of walking training (three to four times a week, 30 min). Both forms of training showed a significant effect in terms of anxiety reduction regardless of training status of subjects. In the follow-up after 6 months, however, the improvement of training correlated with the reduction of anxiety symptoms. Interestingly, patients who had completed the walking training increased their training frequency by their own initiative after the 2 month period. This suggests that walking exercise is sufficient to achieve an anxiolytic effect, which should also lead to higher compliance in the patients compared to running [68].

In a placebo-controlled study of Broocks et al. [69], the effect of a 10 week endurance training (5 km jogging three to four times a week) was compared to a proven drug therapy in patients with PD. Both endurance training and pharmacotherapy was superior to placebo for reduction of anxiety symptoms. However, the drug therapy was a bit faster and better. The delayed effect of endurance training can be attributed to some of the patients only being able to run the entire distance of 5 km after several weeks. Under treatment with the endurance training, there were no side effects in contrast to the pharmacotherapy [69]. In a more recent trial, Wedekind et al. [70] did not find exercise training to be superior to relaxation in patients with PD. However, the authors state that their similar results for exercise and relaxation were not due to in efficacy of exercise but to the large unspecific effects of the control group. Taking these two studies together, Wedekind et al. [70] resume that exercise seems to have an effect that exceeds pure placebo effect but seems to be less effective than drug treatment.

More recently, a meta-analysis by Wipfli et al. [71] concludes that exercise can reduce anxiety significantly better than other methods of anxiety reduction. Since that analysis is based on 49 randomized and controlled studies, the authors believe they can recommend the treatment of anxiety disorders through sport with high evidence (Level 1, Grade A). In general, it is found that sport and exercise can relieve so-called state anxiety by even a single exercise session. However, a significant improvement of "trait anxiety" requires more intensive and longer training.

A meta-analysis of Petruzzello et al. [58] came to the conclusion that a single training session needs to take at least 21 min and the overall treatment needs to last at least 10 weeks to establish significant effects on "trait anxiety."

There also exists evidence that patients with PTSD may benefit from exercise training [72,73], although adequately sized randomized controlled clinical trials are still needed to conclude that exercise training is effective. This is comparable to the situation up to date when it comes to patients with agoraphobia, social phobia, specific phobia, and GAD.

Also for OCD, promising but preliminary effects of exercise for acute symptom reduction have lately been reported [74].

In summary, it can be stated provisionally: next to a doubt-free "acute" anxiety-dissolving effect, physical exercise appears to have longer-term anxiety reduction effects when used in appropriate clinical pictures as an additional measure. To what extent exercise can also be used as the main intervention for anxiety disorders is still an unsettled question. Particularly, suitable sports cannot be named yet. It is, however, certain that athletes are consistently less anxious and depressed than physically inactive people [75]. On the other hand, it is not clear whether sport really sustains mental health or whether mental health is the basis for engaging in sports and being able to do so.

Mechanisms of the Activity of Exercise

Psychological Mechanisms

From a psychological point of view, there is some empirical evidence that the effect of exercise is based, in part, on the improvement of perceived coping skills and increased self-efficacy [76]. Anxiety disorders often go hand in hand with the most stressful experience of sitting in a trap, seeing no solution, and therefore helplessly being at the mercy of the symptoms. In such situations, the possibility to gain relief through exercise and sport opens a way out. Once a person sees a way out of a seemingly hopeless situation, and feels being able to exercise control over the events, the stress levels reduce and the associated symptoms improve. The awareness to have the means to self-regulate improves self-confidence and thereby promotes health [77].

Bahrke and Morgan [78] believe that the effect of physical activity lies in the deflection of negative thought content. If physical exercise is carried out in a group, social interaction could also contribute to the relieving of anxiety.

The anxiolytic effect of endurance training in patients with PD can also be explained by aspects of behavioral therapy. Panic patients often experience normal bodily sensations such as increased heart rate or a fast pulse as life threatening. If these sensations occur during a panic attack, they are inexplicable and uncontrollable for the patient. If these sensations, however, occur during exercise, they become natural for the patient. They are perceived as natural and not life-threatening reactions to the exercise. Physical exercise could be considered in this sense as a form of systematic desensitization [79].

Biological Mechanisms

Serotonin Metabolism

Animal experiments showed that acute physical stress leads to an increased turnover of serotonin, especially in the medial basal hypothalamus [80]. Endurance training appears to have the same effect. Broocks et al. [81,82] showed that endurance training leads to a normalization of serotonin receptors, which play a role in patients with PD. It is likely that endurance training leads to increased serotonin levels, as is also observed when serotonergic agents are administered (SSRIs). This belief is supported by a study of Dey et al. [83]. After a 4 week physical training, an increased serotonin synthesis and increased serotonin turnover was found in the cerebral cortex of rats.

Stress Hormone System

Among the physiological "stress systems," the so-called hypothalamic-pituitary-adrenal axis (HPA; see Figure 117.1) has a special position. The other subsystem is the autonomic nervous system, which consists of the sympathetic and parasympathetic nervous system. The HPA is a tripartite hormone axis, which consists of the hypothalamic peptide hormone corticotropin-releasing hormone (CRH), the pituitary peptide hormone adrenocorticotropic hormone (ACTH), and the adrenal steroid cortisol. The three hormones form several negative feedback loops to ensure optimal regulation of production and secretion of these messengers at all three levels. A dysfunction of the HPA axis is causally implicated in the development or pathogenesis of various diseases such as anxiety, depression, cancer, or eczema.

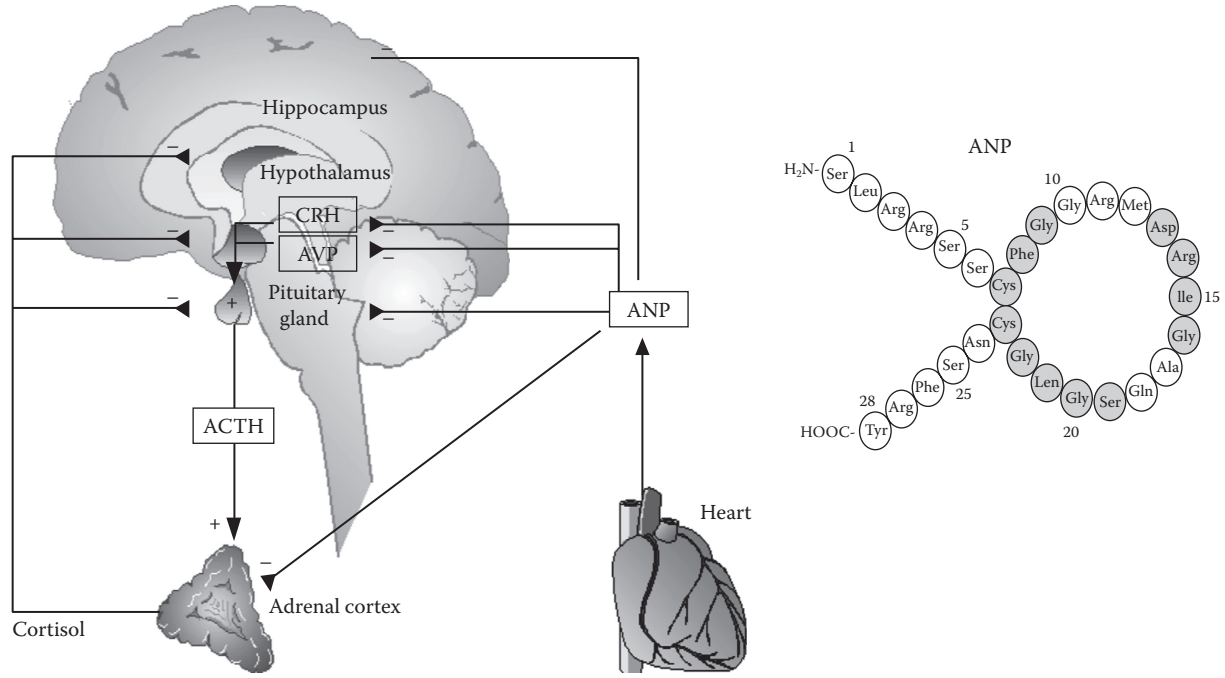

FIGURE 117.1 Inhibition of the HPA system by ANP. (From Ströhle, A., *Pharmacopsychiatry*, 36(3), 207, 2003.)

The end product of the HPA axis, cortisol, exerts lasting effects on nearly all organs of the body. In patients with anxiety disorders, an altered activity of the HPA system might be present [84]. The overactivity of the stress system in anxiety disorders is often associated with a permanently increased release of cortisol in the body. As the body immediately releases noradrenaline from the adrenal medulla in response to a threat, the release of cortisol represents a delayed onset of "supply response." A permanent increase in cortisol levels has many adverse consequences such as the loss of nerve cells in the hippocampus or the weakening of immune reactions [85,86]. Physical activity seems to be able to reduce cortisol levels in the body or prevent increases in cortisol [87].

In a study by Abelson and Curtis [88], the cortisol levels correlated with the severity of PD.

Ströhle et al. were able to show that induced panic attacks associated in patients with PD correlate with a strong activation of ACTH secretion without a simultaneous increase in cortisol secretion [89]. CRH stimulates the release of ACTH and appears to play an important role in the modulation of anxiety [90].

Various studies show that endurance training leads to decrease in cortisol concentration [91,92].

In a Swiss study, trained and untrained men were exposed to a stress test [93] in which various parameters such as cortisol response, heart rate, and psychological responses (mood, anxiety, and calmness) were measured before and after the test. In response to the stressor, cortisol levels and heart rate were significantly increased in both groups. However, trained men exhibited significantly lower cortisol and heart responses compared with untrained men. Furthermore, trained men showed better mood and lower state anxiety.

Through physical activity, the body learns to distribute less stress hormones under stress, to assimilate them better and to build protective factors against stress.

Persistent, regular physical training strengthens not only the physiological defenses but also the psychological resistance factors.

Atrial Natriuretic Peptide

Atrial natriuretic peptide (ANP; see Figure 117.1) is a powerful vasodilator and a protein (polypeptide) hormone secreted by heart muscle cells. It is involved in the homeostatic control of body water, sodium, potassium, and fat. It is released by muscle cells in the upper chambers of the heart, in response to high blood pressure. ANP acts to reduce the water, sodium, and adipose loads on the circulatory system, thereby reducing blood pressure. ANP was first described by de Bold et al. [94].

ANP is produced, stored, and released by cardiac myocytes of the atria of the heart. It is released in response to atrial stretch and a variety of other signals induced by hypervolemia, caloric restriction, or exercise. The hormone is constitutively expressed in the ventricle in response to stress induced by increased afterload (e.g., increased ventricular pressure from aortic stenosis) or injury (e.g., myocardial infarction) [95].

Acute physical exercise leads to an increase in ANP secretion, wherein the level of activity and quantity of the secreted ANP are proportional to each other [96,97]. This correlation, however, seems to affect only untrained persons. In a study by Rogers et al., they conducted a one-time maximum load in nine untrained volunteers to an increase in ANP concentration; at 10 trained subjects there was no change in plasma ANP levels to observe [98].

ANP and ANP-specific receptors were also detected in different brain regions, including the hypothalamus, the locus coeruleus, and central amygdala [99]. ANP inhibits the stress hormone system at several levels. Both the release of ACTH and CRH is reduced by ANP and thus inhibits the cortisol response induced by ACTH and CRH [100,101].

The effect of ANP on the stress hormone system and the impact on avoidance behavior in animals [102] points to a role of ANP in the modulation of anxiety. Ströhle et al. [103] showed that administration of ANP in the amygdala in rats showed an anxiolytic activity.

It has now been demonstrated that administration of ANP in humans shows anxiolytic effects. Pretreatment with ANP reduced the number of induced panic attacks and the severity of the symptoms compared to a placebo [104].

ANP appears to play an important role in the modulation of fear and panic and could be responsible for psychological adaptation processes during exercise. Moreover, it is possible that ANP is involved in the process of anxiolytic effects of chronic physical activity [105].

Endorphins

The influence of exercise on endorphins is another hypothesis to explain the anxiolytic activity of exercise.

Specially bred mice with a deficiency of endogenous opiates (enkephalins and endorphins) showed a significant increase in anxiety and solidified in even slightly threatening situations. They also only briefly tolerated to stay in the middle of a big box and preferred to hide themselves on to the edges of the box. Under light, these mice even avoided any activity and barely moved. A control population of normal mice behaved much more relaxed in these tests [106]. The body's own opiates, which also exist in humans, could therefore have the function to eliminate anxiety and fear.

Goldfarb and Jamurtas [107] showed in a study that physical activity with appropriate duration and intensity results in an increase of beta-endorphin plasma concentration. Furthermore, regular exercise leads to a potentiated release of beta-endorphins [108].

For a long time, the endorphin hypothesis was based entirely on findings of enhanced endorphin levels in the peripheral blood. Boecker et al. [109] were able to disclose the central mechanism and to identify a relationship to perceived euphoria during exercise by using a positron emission tomography study. The level of euphoria was significantly increased after running and was inversely correlated with opioid binding in several brain areas, such as the anterior cingulate cortex as well as temporoparietal regions. These findings indicate region-specific effects in frontolimbic brain areas that are involved in the processing of mood and affective states, such as anxiety. This has also been referred to as "runner's high."

Other Possible Mechanisms

In his case study, Dratcu [67] assumes that regular physical activity leads to a reduction of chronic hyperventilation in patients with PD, which may explain the antipanic effect.

A vegetative hyperarousal in patients with PD was demonstrated by Hoehn-Saric et al. [110]. These patients showed increased heart rates and elevated blood pressure even at rest. Endurance training may lead to compensation of the autonomic hyperarousal [110].

Physical activity is proven to lead to better sleep. Certain antidepressants are also based on a normalization of the sleep cycle [111]. Healthy sleep thus also appears to have anxiolytic effects.

Recent studies have shown that the body, under physical activity, releases a higher measure of so-called growth factors, which may lead to the formation of new nerve cells and a better "networking" (formation of synapses), particularly in the brain. At the center of the research and interest is brain-derived neurotrophic factor (BDNF) followed by insulin-like growth factor (IGF-1) [112,113]. BDNF can cause nerve regeneration particularly in the hippocampus, which is reduced in stress-affected patients. Since antidepressants produce the same effect, it is hypothesized that the antidepressant and anxiolytic effects of physical activity are mediated by an increased release of BDNF. It is based on neuroplasticity, the brain's ability to reorganize itself by forming new neural connections. Neuroplasticity allows the neurons (nerve cells) in the brain to compensate for disease and to adjust their activities in response to new situations or to changes in their environment. Physical activity can lead to a rapid transient increase of BDNF in the blood and the brain [114].

Another hypothesis is the hyperthermic model, which states that exercise leads to a rise in body temperature resulting in a relaxation of the muscles, an effect which has been compared to having a hot bath [115]. Relaxation and anxiety cannot simultaneously exist in the brain.

The most likely explanation is a multifactorial, psychobiological model, which combines several hypotheses.

CONCLUSION AND RECOMMENDATIONS

Although there are many studies underlining the association between (more) physical activity and (less) anxiety, many questions still remain. This especially concerns the empirical evidence of the causal mechanism underlying this association, as well as the further investigation of the therapeutic impact of physical activity. Further, methodically well-designed studies are needed in these fields.

Nevertheless, clear recommendations to integrate physical activity in our everyday life and to engage in exercise training can be given. Concerning the amount of physical activity people should engage in to achieve health benefits, the guidelines of the WHO and the Centers for Disease Control and Prevention of the U.S. Department of Health and Human Services can be followed (unless specific medical conditions indicate to the contrary): adults aged 18–64 years should at least do 150 min of moderate-intensity aerobic activity (e.g., brisk walking, general gardening) or 75 min of vigorous-intensity aerobic activity (e.g., jogging) or an equivalent mix of moderate- and vigorous-intensity aerobic activity each week, all performed in bouts of at least

10 min [116,117]. Additionally, strengthening exercises of all major muscle groups should be performed on at least 2 days a week, with exercises repeated 8–12 times a set [116,117]. Adapted recommendations are given for older adults and for children and adolescents.

At the end, it should especially be pointed out that, as referred, many trials have shown beneficial effects of physical activity in people not fulfilling any anxiety disorder diagnosis, so it should be considered if physical activity should not only be therapeutically used to treat anxiety disorders, but should be considered by healthy people as well as a way to encounter any states and conditions of (subclinical) anxiety.

PREVALENCE AND BURDEN OF DEPRESSION

Depressive disorders annually affect approximately 10% of the population in the United States with a lifetime prevalence of 10% in men and 15% in women. Along with the high prevalence, costs associated with depressive disorders have also grown, as the annual economic burden of depressive disorders is estimated at $83 billion [1]. Furthermore, even in individuals who do not meet diagnostic criteria for major depressive disorder (MDD), depressive symptoms have negative influences on health. Elevated depressive symptoms are associated with an increased risk of MDD [2], functional impairment [3–5], higher rates of disability [6], and increased social dysfunction [3,7].

Further increasing the burden of depressive disorders is the limited accessibility and effectiveness of treatments. Only 55% of people afflicted with a depressive disorder are receiving treatment, while alleviation of depressive symptoms is seen in only 32% of those receiving treatment [8]. Randomized controlled trials (RCTs) have shown the efficacy of three classes of treatment to be effective in reducing depressive symptoms: antidepressants, psychotherapy, and neurostimulation (electroconvulsive therapy [ECT], repetitive transmagnetic stimulation [rTMS]) [9]. Despite the empirical evidence demonstrating the efficacy of these treatments, response rates for antidepressants [10,11], psychotherapy [12], rTMS [13], and ECT [14] indicate that a significant portion of individuals do not respond to these treatments. These statistics indicate the need for more cost-effective, accessible, and alternative treatments for depressive disorders. Exercise is one potential treatment that has been supported through research.

Cross-Sectional and Longitudinal Studies of Exercise

The relationship between physical activity and depressive disorders was first identified in epidemiological work. Farmer et al. [15] examined the associations between depressive symptoms and physical activity in the National Health and Nutrition Examination Study I. In this nationally

representative sample, there were significant correlations with lower physical activity levels associated with higher levels of depressive symptoms. Additionally, low levels of physical activity in this sample were also associated with twofold increased risk of MDD at follow-up 8 years later. Similar results have been reported in other epidemiological studies. Results from the Harvard Alumni Study indicate that higher levels of physical activity were associated with lower incidence of MDD during a 5 year follow-up [16]. Using the Alameda County Study Data, Camacho et al. [17] found that individuals who reported low levels of physical activity were at greater risk for developing MDD at the 9 year follow-up. This study also included a second follow-up period that allowed for the examination of the relationship between changes in physical activity and future MDD. Participants who reported decreased physical activity from baseline to follow-up were at greater risk for MDD at a second follow-up 18 years after baseline, while participants who increased activity were not at a higher risk for MDD at the 18 year follow-up compared to those who remained physically active. Finally, Galper et al. [18] examined the relationship between physical fitness (assessed by maximal exercise test) and depressive symptoms in the Aerobics Center Longitudinal Study. Results of this analysis indicate a significant inverse relationship between physical fitness and depressive symptoms.

Randomized Controlled Trials of Exercise

Efficacy of Aerobic Exercise in Reducing Depressive Symptoms

Building on the findings from epidemiological studies, a number of RCTs have examined the treatment effects of aerobic exercise on depressive symptoms in individuals with MDD (Table 118.1). Dunn et al. [19] randomized 80 adults, aged 20–45 years, to either high dose aerobic exercise (17.5 kilocalories per kilogram of weight (KKW) at a self-selected intensity), low dose aerobic exercise (7 KKW at a self-selected intensity), or an exercise placebo group (i.e., stretching). In this sample, participants in the high dose group demonstrated significantly greater reductions in depressive symptoms following 12 weeks compared to both the low dose and placebo groups. The mean Hamilton Rating Scale for Depression (HRSD) score was reduced by 47% in the high exercise group, which was significantly greater than the reductions in HRSD score observed in the low dose exercise (30%) and placebo groups (29%). The individuals in the high dose exercise group were also more likely than those in the control group to elicit a treatment response (defined as a 50% reduction in HRSD score) and achieve remission (defined as an HRSD score of 7 or lower).

Similarly, Blumenthal et al. [20] randomized adults, aged 40 years and older, with MDD to one of four treatment groups: home-based aerobic exercise, supervised aerobic exercise, selective serotonin reuptake inhibitor (SSRI) (sertraline), or placebo pill. Following 16 weeks of treatment, greater remission rates were observed in the home-based (45%) and supervised exercise (40%) compared to a placebo pill (31%). The remission rates for the supervised exercise group and home-based exercise group were similar to those observed by Dunn et al. [19]. In another trial, Nabkasorn et al. [21] randomized females, aged 18–20 years, with MDD to either aerobic exercise or a wait-list control. They report greater decreases in depressive symptoms, measured by the Center for Epidemiologic Studies Depression scale, in the exercise group compared to a wait-list control.

Efficacy of Resistance Training Exercise in Reducing Depressive Symptoms

Another group of studies have examined the effect of resistance training exercise on depressive symptoms. One study examined the effects of a 10 week supervised resistance training program with an attentional-control group in 32 adults, aged 60 years and older. Following the intervention, the resistance training group had significantly reduced depressive symptoms compared to the attentional-control group. Furthermore, 59% of the resistance training group had achieved a clinically meaningful response (defined as 50% reduction in HRSD score) compared to only 26% in the control group [22]. After the 10 week assessments, participants in the resistance training group were instructed to continue engaging in twice-weekly, unsupervised resistance training sessions for another 10 weeks. Depressive symptoms, measured by the Beck Depression Inventory (BDI), remained significantly lower in the resistance training group after this phase, and the percentage of participants classified as "nondepressed" (defined as a BDI score of less than 9) was 73% compared to 36% in the control group. The difference in depressive symptoms between the groups remained at a 26 month follow-up [23].

In another trial of older adults, participants were randomized to one of three conditions: high dose resistance training, low dose resistance training, or standard care. At the end of 8 weeks, the high dose resistance training group had significantly greater reductions in depressive symptoms compared to the other two groups, and there was no significant difference between the low dose and standard care groups. Participants in the high dose group were also more likely to achieve a clinical response (defined as a 50% reduction in HRSD), as 61% of the high dose participants achieved a clinical response compared to 29% of the low dose group and 21% of the standard care group [24].

Meta-Analyses Examining the Efficacy of Exercise in Reducing Depressive Symptoms

In addition to the studies referenced earlier, several other trials have examined the effect of exercise interventions in patients with depressive disorders. The results of these studies have been summarized in a number of meta-analyses [25–28]. These meta-analyses report significant effect sizes for the reduction of depressive symptoms following an exercise intervention. The effect sizes reported in these meta-analyses range from 0.83 to 1.39, indicating a large treatment effect [29].

TABLE 118.1
Trials Examining Efficacy of Exercise in the Treatment of MDD

Study	Comparison Group(s)	*N*	Intervention Length (Weeks)	Exercise Frequency (per Week)	Bout Duration (min)	Intensity	Outcome
Blumenthal et al. [30]	1. Aerobic exercise 2. SSRI 3. SSRI + aerobic exercise	156	16	3	30	70%–85% HRmax	No significant differences in depressive symptoms among the three groups following treatment
Blumenthal et al. [20]	1. Home-based aerobic exercise 2. Supervised aerobic exercise 3. SSRI 4. Placebo pill	202	16	3	30	70%–85% HRmax	Remission rates were greater for three active treatment groups compared to placebo pill
Dunn et al. [19]	1. High dose aerobic exercise 2. Low dose aerobic exercise 3. Exercise placebo	80	12	3	NA	NA	Reduction in HRSD score and remission rates were significantly greater in the HD exercise group compared to the LD exercise and placebo groups
Martinsen et al. [117]	1. Aerobic exercise 2. Control (occupational therapy)	43	9	3	60	50–70% HRmax	Reduction in depressive symptoms was greater in exercise group
Martinsen et al. [37]	1. Aerobic exercise 2. Resistance training	99					
Mather [34]	1. Aerobic exercise 2. Control (health education)	86	10	2	45	NA	Exercise group had a significantly higher response rate compared to the health education group
McCann and Holmes [118]	1. Aerobic exercise 2. Exercise placebo (Stretching) 3. No-treatment control	43	10	2	60	NA	Greater reductions in depressive symptoms were observed in the exercise group
McNeil et al. [119]	1. Aerobic exercise 2. Social contact control 3. Wait-list control	30	6	3	40	NA	Exercise and social contact groups had significant decreases in depressive symptoms. Only exercise resulted in decreased somatic symptoms
Nabkasorn et al. [21]	1. Aerobic exercise 2. No-treatment control	49	8	5	50	<50% HRR	Decreases in depressive symptoms were greater in the exercise group compared to a wait-list control
Pinchasov et al. [120]	1. Aerobic exercise 2. Bright light 3. No-treatment control	63	1 week	7	60	75% HRmax	Exercise and bright light groups demonstrated significant reductions in depressive symptoms
Singh et al. [22]	1. Resistance training 2. Control (health education)	32	10	3	45	80% 1-RM	Exercise group had significantly reduced depressive symptoms and higher rates of treatment response compared to the control group
Singh et al. [23]	1. Resistance training 2. Control (health education)	32	20	3	45	80% 1-RM	Depressive symptoms were significantly lower in the resistance training group. The difference in depressive symptoms between the groups remained at a 26 month follow-up
Singh et al. [24]	1. High dose resistance training 2. Low dose resistance training	60	8	3	60	80% 1-RM	HD resistance training group had significantly greater reductions in depressive symptoms compared to the other two groups. No significant difference between the low dose and standard care groups. Participants in the high dose group were also more likely to achieve a clinical response

TABLE 118.1 (continued)
Trials Examining Efficacy of Exercise in the Treatment of MDD

Study	Comparison Group(s)	*N*	Intervention Length (Weeks)	Exercise Frequency (per Week)	Bout Duration (min)	Intensity	Outcome
Trivedi et al. [35]	1. High dose aerobic exercise 2. Low dose aerobic exercise	126	16	NA	NA	NA	No significant difference in remission rates between HD and LD exercise
Veale et al. [121]	1. Aerobic exercise 2. No-treatment control	83	12	3	NA	NA	Augmenting treatment with exercise did not result in significantly greater reductions in depressive symptoms

Exercise versus Established Treatments

The studies described earlier compare exercise to some version of control group. Further studies have been conducted comparing exercise to established treatments for MDD. Blumenthal et al. [30] conducted an RCT in which participants were randomized to one of three conditions: aerobic exercise, an SSRI (sertraline), or a combination of exercise and medication. There were no significant differences in depressive symptoms among the three groups following 16 weeks of treatments. However, the SSRI group showed a more rapid response compared to the exercise and combination groups. At a 6 month follow-up, the exercise group demonstrated lower rates of MDD and engaging in exercise significantly predicted presence of MDD, while continued use of SSRI did not significantly predict presence of MDD [31].

Blumenthal et al. [20] randomized participants to one of four groups: two supervised aerobic exercise, home-based aerobic exercise, SSRI (sertraline), and placebo. The three active treatments resulted in higher remission rates compared to the placebo group, yet there were no differences in remission rates among the three active treatment groups. Similarly, one published trial has compared an exercise intervention to psychotherapy. Klein [32] found no significant difference in changes in depressive symptoms between exercise and group psychotherapy. These findings are further supported by the Rethorst et al. [27] meta-analysis, which also included the results of unpublished studies and reported no difference in effect size in studies comparing exercise to SSRI or psychotherapy.

Exercise as an Adjunctive/Augmentative Therapy

In addition to trials that have examined the efficacy of exercise as a monotherapy, trials have also examined the efficacy of exercise as an adjunctive or augmentative therapy. As previously mentioned, Blumenthal et al. [30] examined exercise as an adjunctive treatment by including a group that received both SSRI and aerobic exercise. While this group demonstrated significant reductions in depressive symptoms, this decline in depressive symptoms was not significantly different from those who received only SSRIs or aerobic exercise.

In an open label trial, augmentation with an aerobic exercise intervention resulted in reductions in depressive symptoms [33]. Additionally, two RCTs to date have examined exercise as an augmentative treatment for non-remitted MDD. Mather [34] randomized older adults who had received at least 6 weeks of antidepressant medications without a sustained response to either aerobic exercise or health education classes. Following a 10 week intervention, the exercise group had a significantly higher response rate (defined as a decrease of 30% or more on the Hamilton Ratings Scale for Depression) compared to the health education group. Trivedi et al. [35] compared the efficacy of two doses of aerobic exercise as augmentation for non-remitted MDD. In this study, non-remission was defined as residual depressive symptomatology following 2–6 months of SSRI treatment. Following the 12 week intervention, both groups had significant increases in remission rates, and there was a trend toward higher remission rates in the high dose exercise group, though the difference between the two groups was not significant.

Exercise Prescription

While there is substantial evidence supporting the use of exercise in the treatment of MDD, research has not provided a clear indication of the proper dose of exercise needed to elicit an antidepressant effect. Complicating the matter is the fact that several aspects of the exercise intervention could potentially influence the efficacy of the intervention including session frequency, session duration, exercise intensity, intervention duration, and exercise modality (Table 118.2).

Session Frequency and Duration

Exercise intervention trials in participants with MDD have varied in frequency of exercise sessions (i.e., the number of sessions per week). While most interventions have consisted of three exercise sessions per week, others have included session frequencies ranging from two sessions per week to five sessions per week. Dunn et al. [19] found no difference in effect between groups exercising three times per week versus five times per week. This finding is supported by meta-analytic results demonstrating no difference in effect sizes across trials with different session frequency [27].

Typically, exercise has been prescribed in terms of session duration, in which participants exercise for a set amount during each session. The session duration used in trials for

TABLE 118.2
Summary of Exercise Dosing Recommendations for Patients with MDD

Exercise modality
- Aerobic exercise or resistance training

Exercise session frequency
- 3–5 sessions per week. No evidence to support differential efficacy within that range

Exercise session duration
- 30–60 min. Meta-analytic support for sessions lasting 45–60 min
- Session duration can also be determined by energy expenditure. Weekly doses of 12–16 KKW can be equally divided over the weekly sessions

Exercise intensity
- Aerobic exercise: 50%–85% of HRmax. No evidence to support differential efficacy within that range
- Resistance training: 80% 1-RM results in greater reductions in depressive symptoms than 20% 1-RM
- Intervention duration
- At least 10 weeks. Greater reductions in depressive symptoms are observed in intervention lasting 10 weeks or more

MDD has usually ranged between 30 and 60 min. To date, no trial has directly compared interventions of differing session duration. However, examination of moderating variables in the Rethorst et al. [27] meta-analysis suggest that sessions lasting 45–59 min are most effective.

Another approach to prescribing exercise has been through calculation of caloric expenditure. For example, Trivedi et al. [35] and Dunn et al. [19] prescribed exercise dose based on KKW. Dunn et al. compared low dose (7 KKW) to high dose (17.5 KKW). In this trial, the high dose exercise resulted in greater reductions in depressive symptoms, suggesting that there is a minimum dose of exercise needed to elicit an antidepressant response. The Dunn et al. [19] trial suggests that the total amount of exercise completed may be more important in determining the optimal exercise dose than session frequency or session duration.

Exercise Intensity

Exercise intensity for aerobic exercise is typically quantified as a percentage of an individual's maximum heart rate (HRmax). One shortcoming in previous research in this area is the lack of adequate monitoring of exercise intensity. Some trials have not monitored exercise intensity or have allowed participants to "self-select" exercise intensity. Among those trials that did monitor exercise intensity, the prescribed exercise intensity ranged from 50% to 85% of HRmax. No trial has compared the efficacy of various exercise intensities in reducing depressive symptoms, though the Rethorst et al. meta-analysis found no difference in effect size across trials based on exercise intensity.

Exercise intensity for resistance training is typically quantified by percent of one-repetition maximum (1-RM; i.e., the maximum weight that can be lifted one time). Both trials conducted by Singh et al. [22,24] prescribed resistance training at 80% of 1-RM, though Singh et al. [24] compared this intensity of resistance training to a group of lower intensity resistance training at 20% of 1-RM. The results of this trial suggest a dose-response relationship between resistance training intensity and changes in depressive symptoms as the high dose group (80% 1-RM) had significantly greater reductions in depressive symptoms, while the low dose group (20% 1-RM) did not differ significantly from a usual care control group.

Intervention Duration

Transient reductions in depressive symptoms are observed immediately following an acute bout of aerobic exercise [36]. However, sustained reductions in depressive symptoms require intervention durations of several weeks or months. Previous trials have reported significant reductions in depressive symptoms in as little as 4 weeks, though most trials have treatment periods of several months. Meta-analytical results suggest that longer intervention durations may be more efficacious in reducing depressive symptoms in patients with MDD. Rethorst et al. [27] report larger effect sizes in trials of 10 weeks or longer compared to those trials with intervention durations of 4–9 weeks.

Exercise Modality

The majority of trials examining the antidepressant effects of exercise have used aerobic exercise activities (i.e., walking, running, cycling, or a combination of these activities). Though as previously noted, other trials have shown the efficacy of resistance training in reducing depressive symptoms [22,24]. However, there are no indications currently that one modality of exercise is more efficacious in treating MDD. One trial has directly compared differing modalities, finding no difference between an aerobic exercise group and a resistance training group [37], while meta-analytic results have revealed no difference in effect size between the two modalities [27].

Adherence to Exercise Interventions

Ultimately, the aim of prescription of exercise as a treatment for MDD is to individualize treatments to optimize patient outcomes. This requires identification of factors that may influence response to treatment. One of the largest influences on treatment efficacy is treatment adherence. It has been postulated that exercise may be unsuccessful as a treatment for MDD due to the belief that patients with MDD will not adhere to an exercise program. However, in studies that have compared exercise interventions to SSRIs, there are no statistical differences in treatment adherence between the two treatments [20,30]. Furthermore, the Rethorst et al. [27] meta-analysis calculated the adherence rates of trials included and found a dropout rate of 14.6%. This rate is comparable to dropout rates observed in groups receiving SSRIs and psychotherapy [38,39].

Additional strategies can be used in conjunction with an exercise intervention to improve adherence. First, the

intervention itself can be modified to improve adherence. For example, Blumenthal et al. [20] found better adherence to a home-based exercise compared to laboratory-based exercise. In another study, Dunn et al. [19] found altering session frequency (3/week vs. 5/week) resulted in no difference in adherence. Additionally, psychosocial strategies may be effective in increasing adherence to an exercise intervention. While there is strong evidence for the use of psychosocial interventions to increase physical activity [40–42], none have examined this in a depressed population. However, Trivedi et al. [35] did implement a web-based approach to monitor adherence and provide psychosocial support.

Reduction of Depressive Symptoms in Diseased Populations

In addition to trials examining the effect of exercise in individuals with MDD, another group of trials have examined the effect of exercise on depressive symptoms in diseased populations. Comorbid depressive disorders are commonly observed among individuals with chronic diseases. In addition to the burden associated with a MDD, the comorbidity of MDD is often associated with poorer disease outcomes due to a reduction in treatment adherence associated with the presence of a depressive disorder.

Cardiovascular Disease

Given the role of exercise in the prevention and treatment of cardiovascular disease, there have been several trials that have examined the effects of an exercise program on depressive symptoms in cardiovascular disease patients. Blumenthal et al. [43] found that participants with ischemic heart disease randomized to a 16 week aerobic exercise intervention had significantly lower BDI scores compared to participants receiving usual care. In another trial, participants with chronic heart failure randomized to an aerobic exercise intervention had significantly lower BDI scores compared to the treatment as usual (TAU) group [44]. Similarly, Kulcu et al. [45] found a significant decrease in BDI scores following 8 weeks of aerobic exercise in patients with congestive heart failure compared to TAU.

Other Diseases

While the number of trials in other diseased populations is not as large as in cardiovascular disease, research has examined the effects of exercise on depressive symptoms in patient populations with fibromyalgia, cancer, and chronic obstructive pulmonary disease (COPD). Patients with fibromyalgia display lower levels of depressive symptoms following exercise interventions [46,47]. Similarly, patients with COPD have reductions in depressive symptoms following an exercise intervention [48,49]. In patients with cancer, trials have examined the effects of exercise both during and following treatment. The outcomes of these trials are not always focused on depressive symptoms, and the results of those trials that did assess depressive symptoms are equivocal [50]. However, there are clear psychological benefits from exercise in cancer patients including decreased fatigue, increases in positive mood, and improved quality of life [44,51].

Mechanisms of the Antidepressant Action of Exercise

Several mechanisms have been proposed to explain the antidepressant action of exercise. These mechanisms typically fall into one of two categories: neurobiological markers and psychosocial factors.

Serotonin

Serotonin is the neurobiological marker most commonly associated with MDD. Low levels of plasma serotonin have been widely observed in patients with MDD [52]. Furthermore, SSRI medications target the release and reuptake of serotonin. SSRIs act on the serotonergic system by inhibiting 5-HTT and thus decreasing the reuptake of 5-HT from the synaptic cleft [53]. SSRI treatment has been associated with decreases in platelet, plasma, serum, and whole-blood serotonin levels [54–58].

Exercise has been found to alter function of the serotonergic system. Similar to SSRIs, exercise results in a decrease in serum 5-HT [59] and decreases in 5-HT_{2A} receptor densities [60,61]. Exercise also results in increases in tryptophan hydroxylase [62], which is necessary for serotonin synthesis. Furthermore, results of animal studies indicate that physical activity can increase the neural discharge of serotonin [52,62], increases in tryptophan levels in the raphe nucleus [63–65] and hippocampus [62], and increased serotonin metabolism [66–68].

Brain-Derived Neurotrophic Factor

Research indicates that brain-derived neurotrophic factor (BDNF) is thought to play a role in the development and treatment of MDD. Serum BDNF is lower in untreated MDD patients and inversely correlated with symptom severity [69]. In response to treatment, BDNF levels are increased following treatment with antidepressant medication [70] and ECT [71]. Similarly, an acute bout of aerobic exercise results in an increase in serum BDNF in patients with MDD [72,73]. In healthy subjects, chronic aerobic exercise results in an increased release of BDNF [74].

Hypothalamic-Pituitary-Adrenal Axis

Hyperactivity of the hypothalamic-pituitary-adrenal (HPA) axis has been associated with MDD. Patients with MDD demonstrate elevated levels of cortisol in plasma and urine [75–77], increased corticotropin-releasing factor (CRF) in cerebral spinal fluid [78,79], and increased size and activity of the pituitary and adrenal glands [80]. Patients with MDD also demonstrate increased HPA reactivity to psychological stress [81] and dexamethasone (DEX) [82]. Finally, there are indications that normalizing regulation of the HPA-axis indicates treatment response for MDD, as normalized response to DEX following SSRI treatment initiation can predict future remission [83,84].

Evidence also suggests alterations in the HPA-axis in response to exercise. Bouts of acute aerobic exercise result in

increased cortisol excretion, while chronic aerobic exercise is associated with reduced cortisol excretion [21]. Furthermore, physical fitness is associated with reduced cortisol response to stress in the form of exercise [85] and psychological stress [86]. These findings are supported by a wealth of animal research demonstrating altered HPA-axis response to stressors following chronic exercise training [87–89].

Endocannabinoids

Recent research has implicated endocannabinoids in the etiology and treatment of MDD [90]. Patients with MDD demonstrate lower levels of endocannabinoid ligands serum 2-arachidonylglycerol (2-AG) and anandamide [91,92], while the level of 2-AG is negatively correlated with the duration of the current depressive episode [92]. Studies in rats indicate that endocannabinoid receptor CB_1 antagonists produce antidepressant effects [93,94], while administration of fluoxetine results in a decrease in CB_1 gene expression [95].

A single bout of aerobic exercise in humans results in an increase in anandamide, suggesting that exercise activates the endocannabinoid system [96]. In an animal model, CB_1 gene expression is reduced with chronic aerobic exercise [97], mirroring the effect of fluoxetine of CB_1 gene expression. Exercise also alters CB_1 receptor sensitivity [98]. Furthermore, this altered sensitivity following exercise associated with a protective effect against exposure to stress [98]. Chronic exercise also increases CB_1 receptor density, resulting in increased proliferation of progenitor cells in the hippocampus. This increase in progenitor cell proliferation was attenuated through administration of a CB_1 receptor antagonist, thus highlighting the role of the endocannabinoid system in exercise-induced neurogenesis [99].

Psychosocial Factors

In addition to the neurobiological mechanisms described earlier, psychosocial factors may also play a role in the antidepressant effects of exercise. Low self-efficacy is often associated with depressive symptoms [100]. It has been proposed that self-efficacy can be improved through physical activity [101,102]. Trials in patients with MDD consistently report an increase in self-efficacy following chronic exercise [103–105], and these increases in self-efficacy are associated with a decrease in depressive symptoms [104]. Another construct proposed as a mechanism for the antidepressant action of exercise is distraction. It has been postulated that exercise can serve as a distraction from stress and therefore reduce depressive symptoms [106,107]. However, Craft [104] found no significant difference in distraction following an aerobic exercise intervention in women with MDD.

Future Directions

Research to date supports the efficacy of exercise interventions in the treatment of MDD. However, the quality of some of this research has been scrutinized [25,108]. These criticisms include the absence of clinical interviews to confirm MDD diagnosis, the lack of proper treatment allocation concealment, and a paucity of studies using intent-to-treat analysis. Therefore, it is vital that future research in the area adheres to strict scientific methodology.

In addition, several other areas for research will further clarify and define the role of exercise in the treatment of MDD. First, while there is evidence for a dose-response relationship, the combination of time, frequency, and intensity of exercise required for the optimal reduction of depressive symptoms has not been identified. Not only will this maximize the treatment effect, but identifying the appropriate dose of exercise is also important to allow physicians to provide a clear exercise prescription to patients. In addition, further work should continue to explore the role of exercise as an adjunctive or augmentation treatment. Integrating exercise with established treatments has the potential to maximize treatment in a population that typically has modest response to treatment. Results from previous trials suggest that exercise may be especially effective in maintaining treatment effects [23,31] and as a treatment for individuals who do not fully respond to initial SSRI treatment [34,35]. Finally, despite epidemiological evidence suggesting the protective effect of physical activity on future MDD, no trial has prospectively examined the preventive effects of exercise.

Considering the relatively low rates of treatment response in MDD, recent research has focused on identifying moderators of treatment efficacy. Identified moderators of antidepressant treatments range from demographic and psychosocial factors to candidate genes. In the STAR*D study, gender, race, employment status, income, and comorbid psychiatric disorders all moderated treatment efficacy [11]. Additionally, candidate genes such as the serotonin transporter gene, 5-HTTLPR, have been proposed to have a role in the etiology and treatment of depression [109–111]. Several studies have shown the *s* allele of 5-HTTLPR to be associated with lower remission rates following SSRI treatment as well as higher negative side effects associated with SSRI treatment [112].

Similarly, these factors are likely to moderate the changes in depressive symptoms following exercise. Trivedi et al. [35] report gender and family history of depression to moderate response to exercise in patients with non-remitted MDD. In this study, men and women with a family history of MDD had higher remission rates to high dose exercise, while women without a family history of MDD had higher remission rates with low dose exercise. There is also evidence for genetic moderation of treatment response to exercise. Given the potential role of the serotonergic system and BDNF in the antidepressant effects of exercise, it is plausible that these two candidate genes impact the treatment effect of exercise on MDD. In fact, one trial examined the moderating effect of 5-HTTLPR in a healthy sample, finding that the *s* allele was associated with a blunted antidepressant response to exercise [113]. Further evidence for genetic moderation of the antidepressant effect of exercise is seen in cross-sectional data. Mata et al. [114] report that the relationship between physical activity and depressive symptoms in a sample of adolescent

females is moderated by the BDNF gene. In this sample, physical activity was associated with lower levels of depressive symptoms in individuals with at least one *met* allele of the BDNF gene, while there was no association between physical activity and depressive symptoms in individuals with the *val/val* BDNF genotype.

Finally, the role of exercise in the treatment of MDD will ultimately depend on treatment professionals being willing and properly educated to prescribe exercise to their patients. Recent data indicate that only 5% of general practitioners include exercise as one of their most recommended treatments for MDD, compared to 92% for antidepressant medications. This disparity is likely due to the fact that only 41% of general practitioners believe exercise to be "very effective" or "quite effective" in treating MDD [115]. However, in the American Psychiatric Association's updated Guidelines for Treatment of MDD [116], exercise is now included as a treatment recommendation. Along with the growing evidence supporting the antidepressant effects of exercise, this recognition by an influential professional association will hopefully encourage more treatment professionals to consider the use of exercise in the treatment of MDD.

119 Redrawing the Model of the Exercising Human in Exercise Prescriptions

From Headless Manikin to a Creature with Feelings

Panteleimon Ekkekakis, PhD, FACSM

CONTENTS

Spectacular Triumphs....1421
Epic Failures....1423
Exercise Is Medicine but What Should Be in the Prescription?....1424
Exercise Prescriptions as a Motivational (and Demotivational) Force....1425
If the Product Is So Good, Why Are We Still Failing in Marketing It?....1425
Pleasure as the Missing Essential Ingredient....1428
An Illustrative Example: The Boom–Bust Hypothesis of Exercise Behavior in Obesity....1430
References....1431

Please answer this simple pop-quiz question. Exercise and physical activity should be (a) effective in promoting health, (b) as safe as possible, (c) pleasant and enjoyable, (d) a and b, or (e) a, b, and c. If you answered (e), you might be surprised to learn that, according to the logic behind most of the contemporary exercise prescription guidelines and physical activity recommendations, your answer would be incorrect; the "correct" answer is (d). At least in the United States, such guidelines and recommendations have traditionally been developed based on a biomedical model, focusing strictly on effectiveness and safety and incorporating little or no evidence from psychology, behavioral economics, marketing, or the behavioral sciences in general.

The history of exercise science over the second half of the twentieth century is filled with spectacular triumphs but also some epic failures. The successes consist in discovering a wealth of scientific evidence supporting the beneficial effects of physical activity on health and raising the awareness not only of the medical community but also of the public at large. The failures are the result of the inability to raise the rates of physical activity participation, which remain discouragingly low in most industrialized countries. This chapter will specifically focus on the possible role played by exercise prescription guidelines and physical activity recommendations in these failures. These documents are criticized for lacking an overarching philosophy, containing numerous inconsistencies and conflicting messages, and having persistently neglected the importance of how exercise is experienced. Finally, a proposal is put forth for considering pleasure as a fundamental criterion when exercise is prescribed or physical activity is recommended. Ensuring that exercise and physical activity are not just effective and safe but also pleasurable can increase the chances that these behaviors will become lifelong habits. In turn, this may help the field of exercise science succeed in its central mission of promoting human health by increasing the number of people who have permanently integrated exercise and physical activity into their lives.

SPECTACULAR TRIUMPHS

A perusal of the medical literature over the past 60 years offers some perspective on the colossal attitudinal shift that has occurred in the biomedical community with respect to the public health value of exercise. The first substantial scientific evidence supporting a role of physical activity in health came from a series of studies conducted by the epidemiologist Jeremy Morris with British civil servants. Perhaps cognizant that they were addressing a skeptical readership, Morris et al.[1] were extremely circumspect in their analyses and interpretations, emphasizing that "we are dealing with what is still hypothesis rather than established fact" (p. 1120). They showed that "bus conductors (on double-decker vehicles) were found to have less coronary heart-disease than bus drivers, and postmen less than telephonists, executive officers, and clerks"; and on the basis of these findings, they proposed that "men in physically active jobs have a lower incidence of coronary heart disease in middle age than have men in physically inactive jobs" (p. 1120). In the following years, despite additional data, the hypothesis that physical activity may have a cardioprotective effect was viewed as a marginal and odd idea. Its impact on research was minimal and, on medical practice, practically nonexistent. Following another

publication by Morris' group in the early 1970s, the famous mile-runner and neurologist Roger Bannister[2] wrote a letter to *The Lancet* expressing his frustration: "Perhaps instead of reaching for the prescription pad we should help to swing our patients over to a more positive view of health so that they change their life style to include sufficient exercise" (p. 613).

In the United States, a landmark report published in 1970 by the Inter-Society Commission for Heart Disease Resources, entitled *Primary Prevention of the Atherosclerotic Diseases*,[3] included "sedentary living" among a list of possible secondary risk factors but stressed that the evidence linking it to coronary heart disease was "not entirely consistent" and that "the apparent impact… observed in some studies is less than that for the major risk factors" (p. A-71). Along the same lines, an additional statement that "exercise … may have a role to play in the prevention of atherosclerotic diseases" was immediately juxtaposed with the warning that "exercise is not free of danger both to the musculoskeletal and the cardiovascular systems" (p. A-89). This view remained prominent during the 1970s. Discussing data from the Framingham study, for example, Kannel and Sorlie[4] commented: "It has not yet been convincingly or consistently established that physical activity is an important determinant of the degree to which the major risk factors exist in the general population. Nor has it been conclusively shown that the protective role of physical activity found by some is the result of a favorable influence on the established major cardiovascular risk factors" (p. 860). Furthermore: "It does not seem likely that exercise programs can make as great an impact on incidence of cardiovascular disease as can control of blood pressure, the cigarette habit, obesity, or hyperlipemia" (p. 860). Echoing an argument that was commonly expressed at the time, Kannel and Sorlie[4] alerted physicians to the fact that "data from eastern Finland, where physical activity levels are high, record an incidence of ischemic heart disease that is the highest observed anywhere" (p. 860).

Reading these passages today, one cannot but be amazed by how parochial or even shortsighted they seem. In 1992, a committee of the American Heart Association[5] first declared that "inactivity is recognized as a risk factor for coronary artery disease" (p. 340). This was followed in 1995 by the first physical activity recommendations specifically developed for health promotion, published jointly by the Centers for Disease Control and Prevention and the American College of Sports Medicine (ACSM).[6] In 1996, the U.S. Department of Health and Human Services published a landmark Surgeon General's report[7] on the relationship between physical activity and health. Conducted by a panel of internationally recognized experts, this thorough analysis of the epidemiologic and experimental evidence led to the conclusion that "physical activity of the type that improves cardiorespiratory endurance reduces the risk of developing or dying from cardiovascular disease (coronary heart disease in particular), hypertension, colon cancer, and non-insulin-dependent diabetes mellitus and improves mental health" (p. 149). Furthermore, according to the report, the "findings are highly suggestive that endurance-type physical activity may reduce the risk of developing obesity, osteoporosis, and depression and may improve psychological well-being and quality of life" (p. 149).

In 2003, a report[8] developed by a committee of the American Health Association, entitled *Exercise and Physical Activity in the Prevention and Treatment of Atherosclerotic Cardiovascular Disease*, stated, in no uncertain terms, that habitual physical activity "prevents the development of coronary artery disease (CAD) and reduces symptoms in patients with established cardiovascular disease. There is also evidence that exercise reduces the risk of other chronic diseases, including type 2 diabetes, osteoporosis, obesity, depression, and cancer of the breast and colon" (p. 3109). Referring specifically to atherosclerosis, the committee declared:

> The data satisfy the criteria required to infer a causal relationship from epidemiological evidence. The results are strong, with the most physically active subjects generally demonstrating CAD rates half those of the most sedentary group. The data demonstrate a graded relationship of decreasing CAD rates with increasing levels of activity… Physical activity both prevents and helps treat many established atherosclerotic risk factors, including elevated blood pressure, insulin resistance and glucose intolerance, elevated triglyceride concentrations, low high-density lipoprotein cholesterol concentrations, and obesity (p. 3110).

Interestingly, the committee also encouraged physicians to "personally engage in an active lifestyle to… set a positive example for patients and the public" and recommended that information about the importance of physical activity for health "be incorporated into the education of physicians and other medical professionals" (p. 3114). In 2007, for the first time, the American Heart Association published physical activity guidelines[9] jointly with the ACSM, emphasizing that "frequent physical activity is an important behavior for individual and population health" (p. 1431). The culmination of more than five decades of research came with the publication of the first *Physical Activity Guidelines for Americans* by the U.S. Department of Health and Human Services in 2008.[10]

Besides these undeniable triumphs on the scientific front, there have also been some notable advances in communicating the message about the healthful effects of physical activity to the public. Of the 2002 U.S. adults surveyed by Morrow et al.,[11] representing the 48 contiguous states and the District of Columbia, 84% knew that physical inactivity was related to the development of heart disease. Furthermore, 97% identified physical inactivity as a health risk factor, with 52% rating it as "very important," 37% as "important," and 8% as "somewhat important."[12] Analyses of media coverage of stories about the effects of physical activity on health in western countries have shown that the topic receives some prominence, even if the journalistic quality of the articles is less than optimal[13] or if physical activity is allotted less space than other lifestyle factors, such as obesity or smoking.[14]

EPIC FAILURES

One might have expected that the staggering accumulation of scientific evidence over the past 60 years and the heightened awareness of the health benefits of physical activity among health care providers and the public would have begun to influence the rates of participation in physical activity. Unfortunately, this has not happened. Discovering and disseminating information, which is an intervention strategy credited with success in promoting other health behaviors (e.g., greatly reducing the rates of cigarette smoking or containing the HIV/AIDS epidemic), appears to have been largely ineffective in the case of physical activity.

A few years ago, an analysis of data from the Behavioral Risk Factor Surveillance System (BRFSS), which is a nationwide survey conducted by telephone, gave the impression that there might be some cause for optimism, showing that "from 2001 to 2005, the prevalence of regular physical activity increased by 8.6% (from 43.0% to 46.7%) among women overall and by 3.5% (from 48.0% to 49.7%) among men" (p. 1210).[15] The exuberance, however, was short lived. The final progress review of the Healthy People 2010 program,[16] which was based on data from the National Health Interview Survey (NHIS), collected from in-home (face-to-face) interviews, stated that "individual physical activity behaviors for adolescents and adults are essentially unchanged since baselines were established" (p. 2). Specifically, the percentage of adults who reported no participation in any leisure-time physical activity was 40% in 1997 and 39% in 2006.

As sobering as these statistics might seem, the problem of physical inactivity in the United States was shown to be significantly more severe when data from the 2003–2004 National Health and Nutritional Examination Survey (NHANES), in which physical activity was measured objectively by accelerometry ($N = 6329$), were analyzed.[17] Among adults between the ages of 20 and 59 years, only 3.5% (3.8% of men, 3.2% of women) participated in bouts of at least moderate-intensity physical activity totaling at least 30 min/day on at least 5 days/week. For those over the age of 60 years, the percentage was even lower, at 2.4% (2.5% of men, 2.3% of women). A latent class analysis[18] of the same data set showed that, when every minute of activity was considered, 78.7% of the population was included in two least active classes (33.6% averaging 5.3 min and 45.1% averaging 21.0 min of moderate-to-vigorous physical activity per day). When only activity performed in bouts of at least 10 min was considered (during which at least 70% of the counts were above the threshold for moderate-to-vigorous activity), 93.5% of the population was included in the two least active classes (56.1% averaging nearly zero and 37.4% averaging 10.3 min of moderate-to-vigorous physical activity per day). The data for vigorous activity were even more disconcerting. In 91.1% of all days, participants accumulated less than 1 min of vigorous physical activity. Of 3462 participants who provided valid data for at least 3 days, only 23 registered 20 min of vigorous physical activity on at least 3 days/week.

Although there is still no systematic study of objectively assessed rates of physical activity within special populations, data derived from self-reports suggest that individuals who face physical or psychological challenges tend to be even less active than the general population. A case in point is obesity, a condition for which regular physical activity would be of great benefit. According to data[19] from the 2000 BRFSS, 59.9% of overweight women and 35.9% of overweight men (i.e., with a body mass index (BMI) ≥ 25 kg/m^2) as well as 70.0% of obese women and 62.8% of obese men (i.e., with a BMI ≥ 30 kg/m^2) reported trying to lose weight. Approximately two-thirds of them reported using physical activity as part of their weight-loss efforts. However, only 19.8% of the overweight women and 22.8% of the overweight men reported combining a reduction in caloric intake and at least 150 min/week of physical activity (approximately five 30 min sessions/week). The numbers were even lower for obese individuals, with 15.9% of women and 21.3% of men reaching at least 150 min/week. Similarly, according to data[20] from the 1999–2002 NHANES, 44.7% of the overweight respondents and 61.8% of those who were obese reported trying to lose weight. However, only 30.0% of those who were overweight and 21.6% of those who were obese reported that their physical activity participation reached 600 min and 20 sessions/month or approximately five 30 min sessions/week.

Importantly, however, current recommendations for weight management set the minimum duration of daily physical activity at 60 min, twice the duration recommended for health promotion in the general population. According to data[19] from the 2000 BRFSS, only 4.1% of overweight women, 3.0% of obese women, 6.9% of overweight men, and 6.4% of obese men trying to lose weight reported reaching 420 min of activity weekly (or 60 min daily) besides restricting their caloric intake. Even in a study[21] in which participants knew that their activity was being monitored since they volunteered to wear accelerometers for 7 days, only 13% of the overweight or obese individuals accumulated 60 min of daily activity.

It is crucial to point out that the problem of physical inactivity is not merely the result of people's unwillingness to become physically active. To a large extent, it is also the result of discontinuation or "dropout." The exact magnitude of this problem is unknown. A statistic frequently reported in the literature is that 50% of those who start an activity program drop out within the first 6 months.[22] However, this number is somewhat deceptive for two reasons. First, this estimate is derived from published clinical trials, most of which include some intervention component designed to improve adherence and retention (e.g., anything from one-on-one counseling, goal-setting, social support, or efficacy-building approaches to provision of monetary incentives, free transportation, or childcare). Clearly, such benefits are absent outside the context of well-funded clinical trials. Second, the 50% figure is merely an average, which conceals the great variation that exists between studies. Dropout rates from individual published studies have ranged from a low of 9% to a high of 87%.[23]

It could be argued that the problem of dropout represents an even greater failure for exercise science and practice compared to the low rates of initial engagement. Although the responsibility for disseminating the message of physical activity is arguably shared among many stakeholders (including the media, national and state health agencies, health educators, and health care providers), the responsibility of designing and delivering exercise or activity programs that people want to incorporate into their lives on a permanent basis is primarily the responsibility of exercise scientists and practitioners.

Overall, the physical activity participation data paint a very disconcerting picture, one that stands in stark contrast to the remarkable successes on the scientific front. Exercise science has managed to uncover a wealth of evidence supporting the beneficial effects of exercise on human health and has, to a large extent, succeeded in publicizing, and even popularizing, these discoveries. On the other hand, no progress has been made in capitalizing on these remarkable scientific findings by changing behavior at the population level. For the most part, this is not due to an unwillingness to undertake policy initiatives or a lack of funds channeled into research and community outreach programs (although most researchers and practitioners would probably argue that more funds would be desirable). The culprit for the massive failure should probably be sought in an unsuccessful communication strategy and an inability to adequately prepare practitioners for their challenging mission. Addressing the problem of physical inactivity represents one of the greatest challenges in public health. Based on substantial epidemiologic evidence from the Aerobics Center Longitudinal Study that low cardiorespiratory fitness is a stronger predictor of mortality than "traditional" risk factors like hypertension, cholesterol, obesity, or smoking, Blair[24] proclaimed that physical inactivity should be recognized as "the biggest public health problem of the 21st century" (p. 1).

EXERCISE IS MEDICINE BUT WHAT SHOULD BE IN THE PRESCRIPTION?

Exercise prescription guidelines were first developed by the ACSM in the 1970s. From the beginning, the development of guidelines was driven by two main considerations: (a) maximizing the training effect, defined primarily as an increase in cardiorespiratory fitness (VO_2max) and (b) reducing the risk of adverse cardiac, skeletal, or muscular events, especially among individuals exercising in clinical or rehabilitation settings (e.g., pre- or postinfarct cardiac patients). Issue (a) pertains to cardiac, respiratory, and muscular (energy-system) adaptations and, thus, falls within the area of expertise of exercise physiologists, many of whom have backgrounds in sport and human performance. Issue (b) pertains to pathology and is, thus, within the purview of physicians. Four decades after the development of the first guidelines, the panel of experts convened by the ACSM to update the guidelines reportedly took into account the same two considerations: (a) "the dose that induces the greatest health benefit" and (b) "the potential risk in a particular population" (p. 133).[25]

As the aforementioned participation and dropout data illustrate, however, a program that is effective and safe may not necessarily be one that people want to follow. This brings up the crucial, yet seldom discussed, issue of the philosophy undergirding exercise prescriptions and physical activity recommendations. What should be the prime objective of such prescriptions or recommendations? What the public or each individual client is advised might differ, perhaps considerably so, if the prime objective, for example, is to stimulate the largest possible gain in cardiorespiratory fitness (or any other beneficial physiological adaptation) in the shortest amount of time compared to instilling a lifelong habit of physical activity. In the former case, developing a prescription based on the traditional bipartite rationale of effectiveness and safety could be sufficient. However, in the latter case, incorporating some additional considerations, beyond just effectiveness and safety, would probably be necessary. Although it is becoming increasingly clear that views on this subject within the field of exercise science diverge, an open debate has yet to take place.

The absence of a consistent guiding philosophy is evident in the guidelines issued by most scientific and professional organizations. It is interesting, for example, that a statement favoring behavior change as the prime objective of exercise prescriptions in the seventh edition of the ACSM guidelines[25] ("the most appropriate exercise prescription … is the one that is most helpful in achieving… behavioral change" [p. 136]) was edited out in the eighth edition.[26] Although a clear statement of philosophy is also missing from the guidelines[27] issued by the British Association of Sport and Exercise Sciences, it is reassuring to note that this document at least acknowledges some of the challenges faced by beginner exercisers, including the fact that the exercise may be too "demanding" (p. 585). Along the same lines, it is striking that, although activity guidelines for overweight and obese participants calling for at least 60–90 min of daily activity had been criticized as "too daunting" (p. 769)[28] and "too ambitious" (p. 2264),[21] the latest ACSM[29] and European College of Sport Science[30] position stands contain no mention of this challenge or the shockingly low participation rates among overweight and obese individuals. Likewise, several scientific groups have concluded that "adherence is lower with higher-intensity exercise programs" (p. 142)[25] and that "moderate-intensity physical activities are more likely to be continued than are high-intensity activities" (p. 243).[31] Nevertheless, in recent years, several authors have advocated higher intensities for cardiac adaptations,[32] weight management,[33] and health in general,[34,35] without addressing the implications of their suggestions for long-term motivation and adherence.

Presumably, guideline documents are revised following extensive debate among experts. So, an inspection of historical trends may be a good basis for deciphering the changing conceptual and philosophical undercurrents in this field. An analysis of the eighth edition of the ACSM guidelines[26] would suggest a resistance to the idea that exercise prescriptions may have to involve creative combinations of art and science. Furthermore, the notion that the ultimate goal of the

guidelines is to facilitate the instillation of a lifelong activity habit, a goal that necessitates input from psychology, is apparently viewed with ambivalence. It would be wonderful if the maximization of effectiveness, the ascertainment of safety, and the promotion of lifelong activity could all be accomplished within the same prescription. However, in many cases, this might not be feasible. This is why a clear philosophical stance on what the prime objective should be is of such fundamental importance. If we cannot accomplish all three objectives simultaneously, then having a crystalized consensus on a prime, overarching objective is the only way to develop a workable solution. Dishman[36] recognized this challenge approximately 30 years ago, when he wrote that "although exercise prescriptions based strictly on objective thresholds of energy demand or heart rate may optimize physiological adaptations, they may also minimize the chances that certain individuals will adhere to that prescription" (p. 174). He urged exercise scientists and practitioners to seek "some compromise between the ideal physiological prescription and a manageable behavioral prescription … to allow adherence to be sufficient for desired biological changes to occur" (p. 248).[37] Decades later, very limited progress appears to have been made on this front.

EXERCISE PRESCRIPTIONS AS A MOTIVATIONAL (AND DEMOTIVATIONAL) FORCE

In an exceptionally insightful review of the history of exercise prescriptions and physical activity recommendations in the United States, Blair et al.[38] offer a rare glimpse into the "battle of paradigms" that has taken place within the field. They identify the early 1990s as a turning point, at which the first realization was made that guidelines, besides serving as a technical aid to practitioners worldwide, also function as a communication and marketing apparatus whose echoes can influence public behavior. By specifying the minimum recommended dose of activity, the guidelines let the public make important judgments that have direct impact on behavioral decision making. These include, for example, whether the recommended dose is attainable or unrealistic, or whether exercising for a given amount of time or up to a given intensity is "worth doing."

According to Blair et al.,[38] a sense began to develop that the ACSM guidelines "led to somewhat regimented thinking about how much exercise should be recommended, … [causing] most persons to think that exercise not meeting these specific criteria would be of limited or no value" (p. 915S). In particular, exercise intensity emerged as a possible culprit, responsible for intimidating large segments of the sedentary public. This was first expressed in the 1990 ACSM position stand[39] on *The Recommended Quantity and Quality of Exercise for Developing and Maintaining Cardiorespiratory and Muscular Fitness in Healthy Adults*, which stated that the "ACSM recognizes the potential health benefits of regular exercise performed more frequently and for a longer duration, but *at lower intensities* than prescribed in this position statement" (p. 266, emphasis added).

Along similar lines, the fifth edition of the ACSM guidelines[40] was prefaced with the statement: "It is increasingly clear that less regimented approaches are needed in community health and activity promotion efforts. The vast majority of physically active adults are not involved in structured, formal exercise programs, nor do they need to be" (p. 3). The 1995 physical activity recommendations[6] by the Centers for Disease Control and Prevention and the ACSM, the first that introduced the idea that "moderate-intensity," ordinary lifestyle activities like fishing, home care, or lawn mowing can be beneficial for health, were explicitly aimed "to encourage increased participation in physical activity" (p. 402). The preface to the seventh edition of the ACSM guidelines[25] included the following acknowledgment: "Because Americans are highly sedentary … persuading sedentary individuals to become physically active is more likely to be successful when the target level of physical activity is moderate, rather than the traditional higher-intensity level" (pp. 5–6). These statements illustrate that, over time, the leaders in the field of exercise science became sensitized to the fact that exercise prescription guidelines and physical activity recommendations were not just that; they also played a central role in the ongoing social marketing campaign to promote physical activity to larger segments of the public. In the mid-1990s, with the advent of the simpler and less intimidating message[6] of "30 minutes or more of moderate-intensity physical activity on most, preferably all, days of the week," most exercise professionals were anticipating a significant shift in physical activity behavior. However, more than a decade and a half later, it is clear that, contrary to expectations, the new approach has not been any more successful than the previous approaches in increasing the number of people who are active enough to benefit their health.

IF THE PRODUCT IS SO GOOD, WHY ARE WE STILL FAILING IN MARKETING IT?

It seems that, more than 35 years after the first exercise prescription guidelines and with no visible improvement in the rates of physical activity participation in industrialized countries, it is time for reflection and a reconsideration of the operational plan. Clearly, there are failures in the system that must be identified and corrected. The list of systemic failures is probably long and impossible to cover in a comprehensive manner. So, emphasis here is placed on just one: confusion. There is hardly a greater impediment to the success of a marketing campaign than message confusion, and there is hardly a more potent cause of confusion than inconsistency. On this issue, the failure is pervasive, persistent, and absolute. One would be hard pressed to find another health behavior for which more sets of guidelines and recommendations have been issued, by a larger array of scientific and professional bodies, or with so many revisions and updates. Marketing experts warn that social marketing campaigns have reduced chances of success if they are subject to "contradictory counter-marketing" or the concurrent exposure

of the target market to conflicting or inconsistent messages. The social marketing of exercise and physical activity faces contradictory counter-marketing from both external and internal sources.

Examples of contradictory counter-marketing messages from sources outside of exercise science abound. Following the recommendations by the ACSM and the Centers for Disease Control and Prevention,[6] as well as the Surgeon General's report[7] extolling the virtues of moderate-intensity physical activity, a best-selling book[41] by a well-known trainer to the stars asserted that people should exercise "at the highest intensity that is safe" (p. 108). According to the same source, the appropriate intensity is one that induces "a definite feeling of fatigue" (p. 113) and takes people "past [their] level of comfort" (p. 115). Presumably, this book was read by a much larger number of people than those who turned to credible scientific sources.

One illustrative example of a contradictory message from within the domain of public health was the call by the Institute of Medicine[42] in 2002 for 60, as opposed to 30, min of daily physical activity. In a draft report that received extensive media attention, the Institute of Medicine noted that "30 minutes per day of regular activity is insufficient to maintain body weight … and achieve all the identified health benefits fully." Thus, the institute recommended that "to prevent weight gain as well as to accrue additional, weight-independent health benefits of physical activity, 60 minutes of daily moderate intensity physical activity" should be performed. In the days that followed the release of the report, news articles were as critical of the 60 min figure, which was portrayed as exorbitant, as they were of the inconsistency. A search of the news archives for September 2002 shows that, in several of the articles, the focus was not on the contents of the report as much as it was on the fact that researchers cannot agree ("How much time does it take to stay healthy? Even the experts don't agree" read one headline). An article in a major newspaper on September 30 opened with the sentence "Millions of Americans are thrown into a tizzy of confusion" and proceeded with statements from an exerciser who said that the report was "confusing" and she was "unclear about what constituted 'moderately intense' exercise." In another major newspaper, on October 7, a journalist wrote that "the recent call for 60 minutes of daily exercise has sparked plenty of confusion among consumers and heated debate among fitness experts." In an interview, a member of the public said that she "[did] not know what to think anymore… It's confusing because you hear different schools of thought all the time … You don't know what to believe."

In August 2007, the joint recommendation[9] by the ACSM and the American Heart Association specified that each American adult should "perform moderate-intensity aerobic (endurance) physical activity for a minimum of 30 min on five days each week or vigorous-intensity aerobic activity for a minimum of 20 min on three days each week" (p. 1431). Thus the minimum recommended duration per week amounted to 150 min of moderate or 60 min of vigorous activity. Only 14 months later, in early October 2008, the Department of Health and Human Services published the first *Physical Activity Guidelines for Americans*.[10] Although the minimum recommended duration of moderate activity per week was also 150 min (2 h and 30 min), the minimum recommended duration for vigorous activity was not 60 but 75 min/week (1 h and 15 min).

Confusion can even be generated within the same document, by statements that do not appear to be entirely consistent. For example, in the physical activity recommendations[10] for adults issued by the ACSM and the American Heart Association, the purpose of which reportedly was to clarify some of the inconsistencies and confusing aspects of previous recommendations, some points seem hard to reconcile. On the one hand, the document advises the public that "individuals should start at the lower end of this range when beginning an activity program" (p. 1428) and warns that, by exceeding the minimal recommendations, the "musculoskeletal health risks are increased as well, possibly negating some of the added benefit" (p. 1430). On the other hand, the public is also advised that adults who "wish to improve their personal fitness or further reduce their risk for premature chronic health conditions and mortality related to physical inactivity *should* exceed the minimum recommended amounts of physical activity" (p. 1426, emphasis added). It is also noteworthy that issues of adherence and dropout are not addressed anywhere in this document, which is strictly based on a consideration of effectiveness and risk.

Moreover, confusion can be generated by a lack of specificity. For example, in exercise prescription guidelines, the standard approach since the 1970s has been to recommend a broad range of frequencies, durations, and intensities. These ranges are reportedly "intentionally broad" (p. 141)[25] in order to accommodate the widest possible array of individual capabilities and preferences. However, finding the level that is appropriate for each individual is left on the individual and his or her advisors (health care provider, exercise leader, or rehabilitation specialist). The guidelines do not (and perhaps could not) provide specific guidance. So, an interesting question to ponder is whether recommending such broad ranges ultimately serves to exacerbate the confusion and uncertainty that the guidelines were developed to alleviate in the first place. The current ACSM guidelines,[26] for instance, specify that the range of effective and safe intensity extends from a low of 40% of oxygen uptake reserve or heart rate reserve (or 64% of maximal heart rate) to a high of 85% of oxygen uptake reserve or heart rate reserve (or 94% of maximal heart rate). For most individuals, these intensities encompass a very broad range of activity modalities, from a slow to moderately paced walk to a fairly hard run. Similarly, the descriptors "moderate" (i.e., 3–6 metabolic equivalent units or 10.5–21.0 $mL \cdot kg^{-1} \cdot min^{-1}$) and "vigorous" (i.e., more than 6 metabolic equivalent units or 21.0 $mL \cdot kg^{-1} \cdot min^{-1}$), which are used in current physical activity recommendations,[10] are also essentially all-encompassing. According to a widely used compendium, examples of activities that correspond to 3.0 metabolic equivalent units include putting away household items, washing the car or windows, fishing while

standing, and dressing a child. On the other hand, activities that correspond to 9.0 metabolic equivalent units include cross-country running or skiing, playing football competitively, and climbing hills with a 42+ pound load. For adults returning to physical activity after decades of sedentary living, with no experience of how a severely deconditioned body responds to physical challenges, this array of options, all sanctioned as effective and safe, may be bewildering. It is also important to point out that, within these recommended ranges, there are intensities that will leave some individuals unchallenged or bored, as well as intensities that may cause overexertion, discomfort, exhaustion, pain, and even fear or embarrassment. All of these intensities might have been judged by experts to be effective and safe, but whether they are truly appropriate for a given individual is not always easy for a novice to decide.

Confusion can also be the unintended consequence of a seemingly mundane process, such as the periodic update and revision of guidelines. For example, the ACSM has revised the recommended ranges of intensity and duration for the development and maintenance of cardiorespiratory fitness several times since 1975 and has also varied these ranges for special populations, such as people with heart disease, hypertension, diabetes, or obesity (see Figure 119.1). Experts in physiology or medicine might argue that frequent updates are a necessity and a direct consequence of a rapidly evolving literature. On the other hand, a marketing or communications expert would probably claim that, if one considers the promotion of physical activity as a prime objective, then maintaining a consistent message should be seen as of overriding importance. From this point of view, a 5% upward or downward adjustment in the guidelines probably does more harm than good. One reason is that, in the eyes of the public and even of professionals in a wide range of health care-related fields, constant changes are more likely to be interpreted as a sign of an immature and unreliable knowledge base than a sign of a field striving to bring the latest scientific information to the forefront. Furthermore, the changes are so many that, outside of a dedicated core of specialists, keeping up with the new sets of numbers becomes a nearly impossible task. The challenge becomes even more difficult due to the fact that, in some cases, the changes may have more to do with transient trends than a clearly identifiable scientific rationale. As one example, the term "moderate intensity" was defined as extending from 60% to 79% of maximal heart rate in the fifth edition of the ACSM guidelines, from 55% to 69% in the sixth edition, and from 64% to 76% in the seventh and eighth editions.

The result of this stream of inconsistent messages over many years, not surprisingly, has been widespread confusion, not only among the public but also among health care providers, as documented in a growing number of studies. One of the goals set in the precursor to the Healthy People program in 1980 was that, by 1990, the proportion of adults who would be able to accurately identify the dose of exercise thought to promote cardiovascular fitness most effectively would be higher than 70%. At that time, this "most effective"

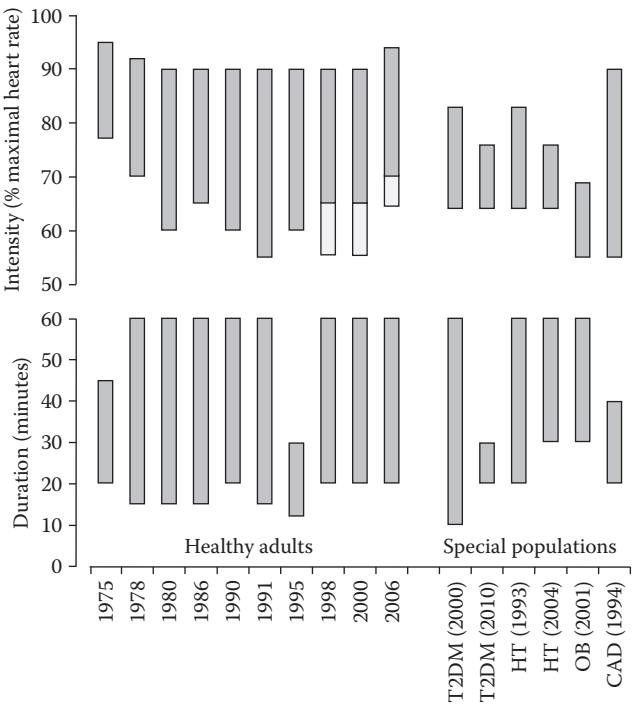

FIGURE 119.1 Changes in the lower and upper limits of the recommended range of exercise intensity (top panel) and daily duration (bottom panel), according to the American College of Sports Medicine. The figures for healthy adults are drawn from *ACSM's Guidelines for Exercise Testing and Prescription* and Position Stands on the *Recommended Quantity and Quality of Exercise for Developing and Maintaining Cardiorespiratory and Muscular Fitness in Healthy Adults*. The lighter gray part of the bars refers to recommendations in which the lower limit of intensity was specified as a range, as opposed to a single level (e.g., 64%–70% of maximal heart rate). T2DM, type 2 diabetes mellitus; HT, hypertension; OB, obesity; CAD, coronary artery disease.

dose was believed to be at least 20 min, on ≥3 days/week, and an intensity of at least 60% of an individual's cardiorespiratory capacity. Caspersen et al.[43] analyzed the responses of more than 170,000 adults from the 1985 NHIS. They reported that 37.9% of respondents could not choose the correct answer from a list of options for any of the three questions (pertaining to frequency, duration, and intensity, respectively). Another 33.6% selected one correct answer and 23.5% selected two. However, only 5.1% of respondents selected all three answers correctly. Even when more relaxed criteria were used (considering any answer above the minimum recommended threshold as correct), the percentage of respondents answering all three questions "correctly" was 63.7%.

Morrow et al.[44] surveyed a random nationwide sample of 2002 individuals. Most respondents answered correctly that it is "true" that "Everyone should get 30 minutes of moderate physical activity most days of the week" (87.7%), that it is "false" that "Moderate levels physical activity do NOT provide any health benefits" (86.7%), and that it is "false" that "Vigorous levels of physical activity are necessary to provide a health benefit" (64.2%). On the other hand, more than

half (57.1%) of the respondents answered (incorrectly) that it is "false" that "Ten minutes physical activity three times per day provide the same health benefits as a single session of 30 minutes." Similarly, when asked in an open-ended fashion to specify "What is the minimum length of time (in minutes) one needs to be physically active throughout a typical day in order to achieve a health benefit," more than half (52.9%) gave answers other than "30 minutes."

Bennett et al.[45] analyzed data from 2381 participants in the 2005 Health Information National Trends Survey. When asked in an open-ended fashion, most participants responded correctly that the frequency of physical activity should be at least 5 days/week (57%) and the duration should be at least 30 min (86%), although any number over 5 days and 30 min was considered correct. However, only 33% of respondents gave correct answers to both questions. Importantly, 74.5% of respondents agreed (either "somewhat" or "strongly") that "there are so many different recommendations about physical activity or exercise that it's hard to know which ones to follow."

One might argue that the uncertainty and confusion reflected in public surveys might be due not to the flaws of the marketing message itself (i.e., inconsistencies and contradictions) but rather due to deficiencies in the preparation of the public to process the subtleties of the message (e.g., lack of specialized training and exposure to original research, lack of comprehension of important distinctions, such as between "exercise" and "physical activity"). The data, however, indicate that the confusion also extends to physicians and other health care professionals, to whom these limitations presumably do not apply.

Petrella et al.[46] surveyed 27,980 primary care physicians in Canada. Only 15.8% of them reported providing their patients with written exercise prescriptions, a finding that the authors attributed to "inadequate knowledge, skills, and tools needed to write exercise prescriptions" (p. 1779).

Allen et al.[47] surveyed 175 family physicians and 31 cardiologists in Canada. On a scale ranging from 1 (no knowledge) to 5 (strong knowledge), the family physicians rated their knowledge for prescribing exercise for two hypothetical cases (a patient with stable angina and a patient 2 weeks after discharge for an uncomplicated myocardial infarction) as 2.5 on average, with the cardiologists scoring just one point higher. To put these figures in perspective, the family physicians rated the knowledge needed in order to provide appropriate exercise prescriptions as 1.7 points higher than their perceived current level of knowledge. For family physicians, inadequate knowledge of safe levels of exercise was by far the most frequently reported barrier to prescribing exercise. In focus groups, physicians indicated that, although they are capable of providing general advice (i.e., that one should undertake physical activity), they did not know how to provide specific advice (i.e., cite specific figures for frequency, duration, intensity, and progression).

Essentially, the same finding was reported by Bull et al.[48] based on survey data from 789 family practitioners in Australia. Although nearly all (91.3%) physicians reported that they felt capable of providing general advice on physical activity, fewer than half felt capable of providing specific advice (45.5%; 51.4% of men, 31.7% of women).

Douglas et al.[49] studied 757 general practitioners, nurses, and health visitors in Scotland. The majority reported that they felt they had "sufficient knowledge to advise patients about physical activity" (66% of general practitioners, 71% of nurses, and 80% of health visitors either "agreed" or "strongly agreed"). However, when asked, only 13% of general practitioners, 7% of nurses, and 9% of health visitors correctly described the current recommendations (i.e., accumulation of at least 30 min of moderate activity, 5 days/week). The numbers of those who thought that the current recommendations call for 20 min, three times per week were larger (18% of general practitioners, 10% of nurses, and 12% of health visitors).

Daley et al.[50] surveyed 138 general practitioners in England. Almost two-thirds (64.5%) knew the "minimum amount of moderate-intensity physical activity that adults should aim to achieve each day for health benefits." On the other hand, only about a third (32.6%) knew the recommended minimum number of days per week and one-tenth (10.9%) knew how many minutes of moderate physical activity is recommended for the prevention of obesity.

One factor that may explain the relatively low level of knowledge of physicians and other health care professionals regarding exercise prescriptions is that such information is typically not offered as part of their formal education. According to a questionnaire survey[51] of 72 deans of medical schools and directors of medical education from the United States, even though almost half of them (47.2%) felt that being able to design an exercise prescription is "highly important," only 10.0% believed that students graduating from their programs were "highly competent" in doing so. Therefore, it seems that physicians, like the rest of the public, have to track down, read, and decode this information on their own. The fact that many, if not most, fail to do so effectively, despite their background, is an indication of the difficulty of this task.

PLEASURE AS THE MISSING ESSENTIAL INGREDIENT

At present, an exercise prescription or physical activity recommendation is considered successful if, within a relatively short period of time (i.e., usually that employed in experimental studies, such as 2–4 months), the exercise or physical activity is shown to produce statistically significant beneficial changes in the outcome variables without causing adverse events. This, however, is a dubious criterion of success since all short-term exercise- or activity-induced adaptations are reversible once the exercise or activity is discontinued. Therefore, although effectiveness and safety are obviously essential considerations, they may become meaningless unless participation is continued over the long haul, ideally for a lifetime. This fundamental principle implies that, ultimately, the prime objective of exercise prescriptions and

physical activity recommendations must be the instillation of a sustainable activity habit. If this principle is endorsed by exercise scientists and practitioners, it has the potential to act as a catalyst in reshaping the entire field. The development of instructions about what one *should* do without taking into account what one *can* do or *is willing* to do must become a thing of the past. Furthermore, shifting the focus to long-term maintenance as the prime objective could potentially unburden guidelines and recommendations from the massive confusion and marketing failures that have plagued them over the past four decades.

Certainly, instilling a lifelong activity habit is more easily said than done. The contributing variables are probably numerous, they may interact in complex ways, they are likely to vary from one individual to the next, and they remain mostly beyond the reach of our current understanding. Thus, the development of a comprehensive model that can serve as the basis of interventions that can be delivered by practitioners in the field is still a long way from becoming a reality. So, the position advanced here focuses specifically on one variable, namely pleasure.

This variable is selected for the following important reasons. First, the strong link between pleasure and human motivation for action has been known since antiquity. An emerging literature now suggests that the pleasure experienced during bouts of physical activity predicts subsequent physical activity participation. For example, Williams et al.,[52] using a single-item rating scale, measured pleasure at a "moderate" level of intensity (64% of age-predicted maximal heart rate) from a sample of formerly sedentary adults. These ratings were found to be significantly correlated with self-reported levels of physical activity 6 and 12 months later. Each one-unit increase on the 11-point rating scale of pleasure that was used was associated with 38 additional minutes of at least moderate-intensity physical activity per week at 6 months and 41 min/week at 12 months. Similarly, Schneider et al.[53] collected pleasure ratings from 124 adolescents as they cycled on an ergometer for 30 min at a moderate intensity (80% of the workload corresponding to their ventilatory threshold). After controlling for aerobic capacity and gender, each one-unit increase on the 11-point rating scale of pleasure was associated with 4.18 min of additional daily moderate-to-vigorous physical activity, assessed by accelerometer. For many exercise practitioners, the link between pleasure and subsequent exercise behavior is something they have learned from experience. Cardiac rehabilitation specialists have noted that "[managing] anxieties from the fear of overexertion causing an event, and attaining enjoyment from the exercise" are crucial contributors to adherence. Unless these are addressed, "the required longer-term changes of behavior for maintaining physical activity at appropriate levels are less likely" (p. 48).[54] Likewise, physical therapists working with individuals with chronic pain or fatigue use the construct of "kinesiophobia" to describe the fear that some of their patients have that exercise may exacerbate their symptoms. Once this fear develops, it tends to predict reduced physical activity participation.[55,56]

Second, when individuals who manage to remain active are asked in an open-ended fashion about the reasons behind their adherence; variants of pleasure (such as enjoyment, energy, relaxation, or pride) are among the most commonly reported factors. Conversely, variants of displeasure (such as exhaustion, pain, disappointment, or embarrassment) are ubiquitous in the reports of those who have dropped out. For example, Hendry et al.[57] interviewed patients with osteoarthritis about their exercise habits. Among the themes that most strongly distinguished those who were consistently active from those who had given up on exercise were statements related to pleasure versus displeasure or enjoyment versus aversion. Those in the former category used statements such as "I really do enjoy the gym; I look forward to going." Those in the latter category used statements such as "I can't enjoy exercise because it's so painful." According to a review of this literature,[58] constructs such as fun and enjoyment (or lack thereof) "were reported more often as predictors of participation and non-participation than perceived health benefits" (p. 832).

Third, several studies, particularly during the last decade, have examined the relationship between the dose characteristics of physical activity and the degree of pleasure that participants report. This research has shown that relative intensity, in particular, seems to exert a strong influence on pleasure. To illustrate this close linkage, Lind et al.[59] designed a study to simulate a scenario in which an exercise professional prescribed a level of intensity that was just 10% higher than that which participants would have selected if given this option. A sample of middle-aged women who were exercising for the first time in at least a year (but, in many cases, much longer) reached 84.17% ± 12.86% of their peak heart rate at the end of a 20 min treadmill bout, with the range recommended by the ACSM[26] extending from 64% to 94%. In contrast, imposing a treadmill speed that was just 10% faster than the self-selected caused the women to reach 91.14% ± 13.83% of their peak heart rate. Although both intensities were within the ACSM-recommended range, ratings of pleasure remained positive and stable during the bout at self-selected intensity but declined continuously and significantly when the speed was raised by just 10%. In this study, the women spontaneously selected an intensity that did not differ significantly from their ventilatory threshold (reached 98.07% ± 24.79% at the 20th min). In contrast, when the speed was raised by 10%, the women significantly exceeded their ventilatory threshold (115.40% ± 31.04%). In general, when adults are allowed to self-select their intensity, in most cases, they choose levels well within the range recommended by the ACSM for the development and maintenance of cardiorespiratory fitness. Furthermore, ratings of pleasure tend to remain stable and positive.[60]

Such findings support a reconceptualization of the constructs of "exercise prescription" and "physical activity recommendation." Instead of constantly revising the boundaries of the recommended heart rate range and risking massive confusion, it might be more effective to prescribe or recommend activity based on a constant and easy-to-understand reference

criterion: the intensity should be such that it does not cause a significant decrease in pleasure. Although this may sound simplistic, it represents an evidence-based approach to reaching the "compromise between the ideal physiological prescription and a manageable behavioral prescription" that was envisioned decades ago by Dishman[37] (p. 248). An intensity that does not induce a decrease in pleasure is, in most cases, close to the ventilatory threshold.[60] Such an intensity allows the maintenance of a physiological steady-state and can thus be continued over a prolonged period of time. Furthermore, since the ventilatory threshold typically occurs at approximately 50%–60% of maximal aerobic capacity in healthy nonathletic adults,[61,62] this intensity is within the range currently recommended by the ACSM.[26] Therefore, maintaining a steady level of pleasure during exercise can benefit motivation without compromising effectiveness or safety.

Calling for the maintenance of pleasure as a central consideration does not mean that monitoring intensity by objective means should be eliminated. The relationship between intensity and pleasure varies between, and even within, populations of exercisers with different physiological and psychological characteristics. It is also subject to situational influences, such as the perceived features of the social environment in which the exercise or physical activity takes place (e.g., whether the individual appraises the context as threatening by emphasizing competition or evaluation).

The presence of interpopulation and interindividual variability presents challenges and necessitates some radical changes in the way that exercise practitioners are trained (e.g., educational curricula will have to place at least as much emphasis on the psychology of exercise and physical activity as they do on the physiology). Furthermore, there is a need to direct resources toward a broad research agenda. The range of research topics that will have to be investigated in the years ahead includes (a) population-specific variations in the relationship between intensity and pleasure-displeasure responses (e.g., among individuals who are overweight or obese, patients with various exercise-limiting conditions), (b) physiological and psychological bases of interindividual differences in pleasure–displeasure responses, (c) the link between pleasure and exercise behavior (e.g., what aspects of pleasure–displeasure experiences may be more strongly predictive of subsequent behavior), (d) the mechanisms underlying pleasure–displeasure responses during exercise, and (e) the effectiveness and limitations of interventions aimed at increasing pleasure or decreasing displeasure during exercise.

AN ILLUSTRATIVE EXAMPLE: THE BOOM–BUST HYPOTHESIS OF EXERCISE BEHAVIOR IN OBESITY

Although the majority of the population in many industrialized countries is presently overweight or obese, how overweight or obese individuals feel when they exercise remains largely unexplored. Perhaps not coincidentally, the failure to increase physical activity among obese individuals has been nearly absolute. As noted earlier, according to data from the 2000 BRFSS, only 3.0% of obese women and 6.4% of obese men trying to lose weight report averaging 60 min of physical activity daily,[19] which is the minimum amount recommended by most agencies for effective weight management. As was also mentioned earlier, position statements by European and American scientific societies address how much exercise people should be doing for weight management but make no mention of the fact that the vast majority of people cannot or do not follow these guidelines.[29,30]

The ACSM[26] recommends that, initially, training intensity for obese individuals should be "moderate," defined as 40%–60% of oxygen uptake or heart rate reserve, with eventual progression to 50%–75%. This intensity should be maintained initially for 30–60 min and eventually for at least 60 min, with the option of performing the activity intermittently, as long as each period is at least 10 min long. If weight loss is desired (which is the case for the majority of obese women and men), then 60–90 min/day is deemed necessary.

To put these figures into perspective, a group of obese and sedentary, but otherwise healthy, middle-aged women reached 61% of their maximal oxygen uptake after walking at a relatively slow speed (2.50 miles/h, corresponding to approximately 3.0 metabolic equivalent units) for only 2 min.[63] A group of more active and fit obese women reached 56.0% of their maximal oxygen uptake after walking at a similar speed (2.65 miles/h) for only 4 min.[64] These figures illustrate that, at least when walking is chosen as the mode of physical activity, it may be impossible to maintain intensity within the recommended range of 40%–60% of maximal oxygen uptake for more than a few minutes. The challenge of accumulating 60–90 min of activity daily under these circumstances should become evident.

Studies have also shown that, unlike normal-weight individuals who typically show significant declines in pleasure at intensities that exceed the ventilatory threshold, obese individuals feel worse across most of the range of intensity.[63] Furthermore, obese participants may exhibit an attenuated "rebound" in pleasure (typically experienced as an increased sense of energy and reinvigoration) after exercise is stopped.[63]

Taken together, these data compose a likely scenario that could shed some light on the reasons behind the low levels of physical activity participation among obese individuals. It appears that many obese individuals, because of low cardiorespiratory fitness relative to body mass, need to raise intensity to fairly high percentages of maximal capacity in order to perform activities that may appear to be fairly "manageable" on paper (such as walking at 2.50 miles/h). This entails that most activities, at least after the first few minutes, would require effort that exceeds the ventilatory threshold. Because of the inability to maintain a physiological steady-state, these activities cannot be continued over extended periods of time, making the accumulation of 60–90 min on a daily basis a very challenging undertaking. Because initial attempts are likely to produce decreases in pleasure that are essentially unavoidable, giving up after a few trials is a phenomenon that should be considered predictable. This pattern can be

described as a series of "boom–bust" cycles that eventually serve to associate the idea of physical activity with displeasure. Because it is inherent in human nature to gravitate toward pleasant options and avoid unpleasant ones, activities associated with displeasure are avoided.

While this "boom–bust" hypothesis certainly requires considerable empirical testing and theoretical elaboration, it is interesting to use it as a possible frame of reference in evaluating recent calls for high-intensity exercise not only for weight management[33] but also for health promotion in general.[34,35] The main argument in support of these proposals is that, by using high intensity, the same fitness and health benefits can be accomplished within a shorter period of time compared to exercise of lower intensity. Although this argument may seem reasonable, it ignores some important empirical observations. First, with weekly energy expenditure fixed, given a choice between higher intensity or longer duration as a method of facilitating adherence, more obese individuals chose a reduction in intensity and a prolongation of duration.[65] Second, with daily duration fixed at 30 min, higher intensity was negatively associated with adherence (proportion of prescribed activity that was completed), whereas higher frequency (and, therefore, additional overall time investment) was not.[66] Third, higher intensity (specifically, intensity above the ventilatory threshold) produced a significant reduction in pleasure, whereas longer duration did not.[67]

Considering the persistent failure to promote physical activity to a larger segment of the public, it seems reasonable to suggest that prescriptions or recommendations for a given dose of exercise or physical activity should be accompanied by careful consideration of the possible impact on pleasure and adherence. The model of the exercising human without a head and without feelings is a relic of the dualistic past of biomedicine. The pressure to solve the problem of physical inactivity should accelerate its long-overdue decline into obsolescence.

With this in mind, the latest *Quantity and Quality of Exercise for Developing and Maintaining Cardiorespiratory, Musculoskeletal, and Neuromotor Fitness in Apparently Healthy Adults*,[68] issued by ACSM, should be considered a development of historical significance. According to this position stand, "moderate-intensity exercise and exercise that is enjoyable can enhance the affective responses to exercise, and may improve exercise adherence" (p. 1335). Moreover, "limited evidence suggests that pleasant affective responses to exercise (i.e., how enjoyable or pleasant is the exercise) may enhance future exercise behavior and vice versa" (p. 1347).

Despite the numerous benefits associated with moderate to vigorous physical activity (PA), more than half of U.S. adults are not meeting participation recommendations (i.e., 30 min of moderate PA per day, 5 or more days of the week, or vigorous PA at least 20 min/day, 3 or more days a week) [1]. Approximately 25% report that they engage in no PA for exercise in their leisure time [2]. Although physical inactivity is common among Americans, rates are higher among women, minorities, and those having little or no social capital [3]. Individuals who lead sedentary lifestyles as they age considerably increase their risks of developing psychological problems, cardiovascular disease, diabetes, obesity, some types of cancer, and premature death ([4]; see also other chapters in this book). It is therefore imperative to better understand variables or determinants that explain variation in PA in efforts to design effective interventions that increase the adoption and maintenance of PA [5].

To understand, promote, and maintain PA, we need to look at a comprehensive approach. The list of PA determinants is long and includes age, sex, education, income, ethnicity, body weight, climate, smoking status, health status, previous PA behavior, attitudes, perceived control, self-efficacy, intentions, motivation, commitment, enjoyment, perceived benefits and barriers, knowledge, skills, distance from a fitness facility, aesthetics, having home exercise equipment, amount of park space, time spent outdoors, spousal and peer support, number of children at home, extraversion, neuroticism, cohesion, group norms, class size, muscle fiber type, and genetic predispositions [6–9]. However, in this chapter, the focus is on modifiable psychological, social, environmental, and policy determinants. The rationale of this focus on modifiable determinants is a practical consideration—so that programs and practitioners know what they can change. The summary of these determinants provides the tools for application, enables plotting trends of generalized beliefs, and generates ideas for creative intervention approaches and research directions.

The social ecological framework [10] provides the framework to present the PA determinants. This ecological perspective highlights people's interactions with their physical and social/interpersonal environments, with the individual shaping their environments, as well as being shaped by their environments [11] (Figure 120.1).

INDIVIDUAL/PSYCHOLOGICAL DETERMINANTS

Many psychological determinants of PA have been documented, and the ones with the best evidence or the most practical promise are highlighted here. There are several

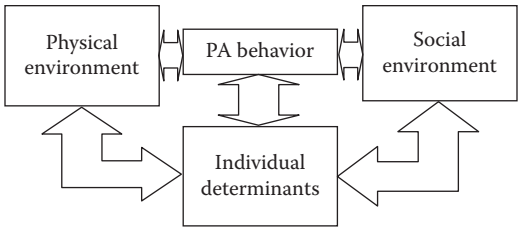

FIGURE 120.1 A conceptualization of the social ecological framework for physical activity (PA).

resources that present more comprehensive summaries and the reader is encouraged to explore these more in depth [12–15].

ATTITUDE

Attitude is the overall appraisal or evaluation concerning a behavior [16]. A recent meta-analysis confirmed the effect that PA attitude has on PA intention (d = 1.07) [17]. In particular, attitude was conceived as having affective (pleasure, enjoyment) and instrumental (utility, benefit) qualities [18,19] and this theoretical separation has been empirically supported [20], and subsequent meta-analyses show that affective attitude is clearly the largest predictor of intention [21]. Thus, the affective qualities of PA are the driving factor of PA intentions, which appears distinct from several other behaviors in health and social behavior [22].

Changing PA Attitude in Practice

Health care practitioners have opportunities to influence affective attitudes about PA by specifically building positive attitudes toward PA. One way to do this is to focus on physical activities that bring out positive (or less negative) attitudes. Have the individual/client list sedentary activities for which they have negative attitudes. Then encourage them to reward themselves (or their children) with active activities for which they have positive feelings. Concern should be given to the time, context, and amount and feeling of the PA. The PA should also be clearly defined in terms of moderate to vigorous activity (Table 120.1).

For example, an individual reports they enjoy working in their garden. For this to be a usable reward, it is important to specifically define the metrics: work on and harvest the garden for 1 h, in the afternoon to relax and make something fresh and healthy for dinner. Using the General Physical Activities Defined by Level of Intensity worksheet [23], define with the patient both moderate to vigorous gardening activities and describe their examples in detail:

> Gardening and Yard Work: raking the lawn, bagging grass or leaves, digging, hoeing, light shoveling (less than 10 lbs per minutes), or weeding while standing or bending. Planting trees, trimming shrubs and trees, hauling branches, stacking wood, pushing a power lawn mower or tiller.

In this manner, PA takes on a positive value (i.e., becomes a reward) and therefore facilitates positive affective attitudes about PA. People enjoy achieving or receiving awards. For children, a teacher might reward her/his entire class's academic achievements with 1 free day/hour of outdoor games, which is acknowledged by a certificate to be displayed in the classroom (Figure 120.2).

Likewise, parents may reward completion of chores with a trip to the park with friends. By clearly defining and changing the value of moderate to vigorous PA, affective attitudes will lead to increased intention and motivation for PA.

TABLE 120.1
Examples of Active Rewards for Completing Sedentary Activities to Build Positive Attitudes

Sedentary Things I Must Do	Active Rewards for Completion
1. Format the reference section	1. Go for a brisk walk at sunset
2. Do my homework	2. Bike to the park with a friend
3. Pay bills	3. Harvest the garden

FIGURE 120.2 Physical activity award certificate for a class.

DECISIONAL BALANCE (PROS AND CONS)

Decisional balance captures how individuals' weigh the consequences of a specific behavior in terms of gains and losses [24]. The importance of decisional balance has been documented in a recent meta-analysis, individuals who adopt health behaviors (including PA) increase their pros and decrease their cons in this process [25]. The decisional balance sheet (DBS) is the practical application of this concept, asking participants to record the anticipated pros and cons associated with the adoption of a preventive health behavior. As a health promotional tool, the DBS provides basic health knowledge and introduces personal control over one's own health. This approach has been supported within the PA domain [26,27].

TABLE 120.2
Decisional Balance Sheet

	Self	Others
Gains		
Losses		
Approval		
Disapproval		

Changing Decisional Balance for PA in Practice

The DBS is a simple method to get people to think about the pros and cons of engaging in PA [28]. Individuals list the pros in terms of gains and approval to self and to others incorporating instrumental and affective components at the individual and social levels. The mechanism at work here is to convince oneself. Similarly, by listing the cons for these same categories, it prepares the individual for these negative outcomes, and by being prepared, one can deal with them. This mechanism can be seen as an inoculation. The DBS technique is very useful for helping individuals start to exercise regularly, and for maintaining regular exercise may have to be redone with a specific focus on the pros and cons of maintaining PA (Table 120.2).

SELF-EFFICACY

Self-efficacy can be viewed as, and has been found to be, both a determinant and consequence of PA participation [29,30]. As a determinant, self-efficacy has shown an overall correlation of $r = 0.35$ with PA behavior in a recent meta-analysis [31]; this represents a medium effect size [32] and one of the largest overall correlates of PA [33].

In PA, two types of self-efficacy commonly used are barrier/coping efficacy and task efficacy [34]. Barrier efficacy is the confidence to overcome and navigate the possible barriers that interfere with performing PA, while task efficacy is the confidence to perform the specific PA act itself. In general, it appears that barrier efficacy is the critical predictor of PA participation, with the exception of clinical or physically compromised populations [34,35]. In these cases, it appears that task self-efficacy is the best predictor. This makes theoretical sense, as confidence in performing the task itself would seem necessary before one concerns themselves with confidence to regulate their daily barriers in order to act. Several other self-efficacy measures have emerged in the PA literature to define the specific barriers or behaviors that contribute to regular PA participation (proxy, scheduling, planning, etc.). Because self-efficacy is situation and behavior specific, multiple efficacies are theoretically valid and could all aid in promoting PA.

A similar concept to self-efficacy is perceived behavioral control (PBC), which refers to an individual's perception of the ability that they have to perform a behavior. This can include barriers or facilitators, such as resources, skills, and opportunities (i.e., time, fatigue, weather, access to facilities, money, etc.) needed to perform a behavior. It is thought to predict behavior directly because intention is less likely to be translated into an actual behavior under conditions of low PBC, and PBC acts as a proxy measure of actual behavioral control [16]. A meta-analysis reported a large effect size between intention and PBC ($d = 0.90$) [17].

TABLE 120.3
How to Build PA Self-Efficacy

Self-Efficacy Determinant	How to
Mastery experience	Enabling the person to succeed in attainable but increasingly challenging performances of desired behaviors For example, start out with 5 min walks once a week, then each week add another day, then after the 7th week at 2 min per day for each 2 weeks gradually progressing to 30 min of walking per day
Social modeling	Showing the person that others like themselves can do it. For example, providing examples of active coworkers
Improving physical and emotional states	Making sure people are well rested before attempting a new behavior. For example, reduce stress/depression, increase positive emotions
Verbal persuasion	Telling the person she or he can do it. For example, "Yes you can work out for 10 minutes"

Changing Self-Efficacy for PA in Practice

There are four determinants of self-efficacy: mastery experiences, social modeling, improving physical and emotional states, and verbal persuasion. Experiencing performance mastery has the strongest influence on self-efficacy beliefs. How to build self-efficacy through these four concepts is shown in Table 120.3.

Attitudes, decisional balance, PBC, and self-efficacy also influence intention to be PA. This is important to be aware of as changes in PA were positively predicted by changes in intentions [36], which is supported by a recent meta-analysis reporting a large effect size between intention and PA ($d = 1.01$) [17].

SOCIAL/INTERPERSONAL DETERMINANTS

Our interactions with others are central to our health and well-being [37]. Clearly, the social environment helps shape our behaviors, yet the concepts that comprise our social environment are complex and not widely agreed upon. McNeil et al. [38] summarized social concepts into three basic categories for use with PA: interpersonal relationships, social inequities, and neighborhood and community characteristics. From this categorization, it is clear that the scope of social determinants spans from the individual to

policy-level considerations. In the following section, we highlight social support and subjective norm, the two most prevalent constructs in PA research within the categorization of interpersonal relationships. The categorizations of social inequalities and community characteristics are discussed in the individual and environmental sections, respectively.

SOCIAL SUPPORT AND SUBJECTIVE NORM

Social support is a term that has seen great use in lay conversations and research literature over the last 20 years, but it was seldom used prior to the latter part of the twentieth century. There is no singular or formal definition of the construct, but many researchers can agree that social support involves multiple dimensions that encompass attachment to others, a sense of integration, and assistance or aid [39,40]. By contrast, subjective norm involves the perceived sense of pressure from others, either in the form of injunctive (psychological perception of others) or descriptive (behavioral acts of others) means [16,41].

The two constructs have seen considerable research attention with PA [7,33,42], and much of this work has resided from their application within psychological theories. Specifically, social support features prominently in social cognitive theory [43] and to a lesser extent in the transtheoretical model of behavior change (under the term helping relationships; [44]) and self-determination theory (under the term relatedness; [45]), while subjective norm resides within the theories of planned behavior [46] and reasoned action [47]. Of the two, social support has had superior validation as a determinant of PA. In prior reviews, Trost et al. identified social support as a reliable correlate of PA among adults [33], and similar conclusions were found with children [7]. By contrast, subjective norm has repeatedly been found as a small or trivial correlate of PA [17,48]. This has also been identified in direct comparison of the two constructs [49] when predicting PA.

Courneya et al. [50] suggest that subjective norm may be relevant for behaviors that are under complete volitional control because for such behaviors a person only needs to know whether important others approve of the behavior. By definition, they do not need any help. For behaviors that are not entirely volitional, however (e.g., regular PA), it is likely that assistance from others for performing the behavior (i.e., social support) in lieu of other time demands [51] would be helpful beyond knowing that they approve of the behavior.

Another potential way to view interpersonal determinants of PA involves the assessment of support or norms for specific referents [16,51]. In this case, specific people such as family members, friends/peers, and health professionals may have different influences upon one's PA behavior. In the subsequent sections, we highlight these three types of referents and the state of the evidence for their effect as PA determinants.

Peers

When one considers the constructs of subjective norm and social support generally, peers are the most likely candidates for these judgments. Indeed, peers followed by family members are the central consideration for subjective norm and social support as highlighted in focus groups [16,51]. Thus, it should not be surprising that peer influence, young children notwithstanding, is the critical interpersonal referent in PA. In terms of norms, peers show a larger correlation with PA than other social referents [52–54]. A similar result has also been identified with social support [7,33,55]. The likely reason for this powerful influence is due to the proximity and similarities of peers in day-to-day lifestyle. First, peers are in a position to interact, and thus influence, our behaviors daily. For repeated behaviors like regular PA, this offers the constant presence for both norms and support to take place. Second, peers, whether in the form of friends, partners, or coworkers are often selected for their similarities or values; thus, social influence to PA is a relatively natural extension of the social arrangement one has with their peers. The positive results in the PA domain appear to support this logic [16,33,56].

Parents

For children and adolescents, their parents and/or guardians represent pivotal social influences on behavioral, moral, and personal development. Indeed, parents are considered the primary gate control to exposure of almost all behaviors, and certainly health behaviors like PA. A review by Gustafson and Rhodes [57] of 34 studies pairing children and their parents highlighted the relative contribution of parental social influence. This review demonstrated that social norms, in the form of symmetry between the PA patterns of parents and their children, had mixed evidence. The results thus suggest that descriptive norms are not particularly powerful indicators of the parent–child PA relationship. By contrast, all but one study supported the importance of parental support on child PA behavior. The evidence suggested that the key factors for social support included encouragement (e.g., verbal), involvement (e.g., coaching of kids teams), and facilitation (e.g., driving children to events). These factors lend strong evidence for the notion of gate control of parents and youth PA and demonstrate that while parents may not need to be active themselves to influence their children's PA, they do need to foster active support.

Changing Social Support for PA in Practice

An example of a tool that encourages obtaining social support along with the individual/psychological determinants is provided (Figure 120.3).

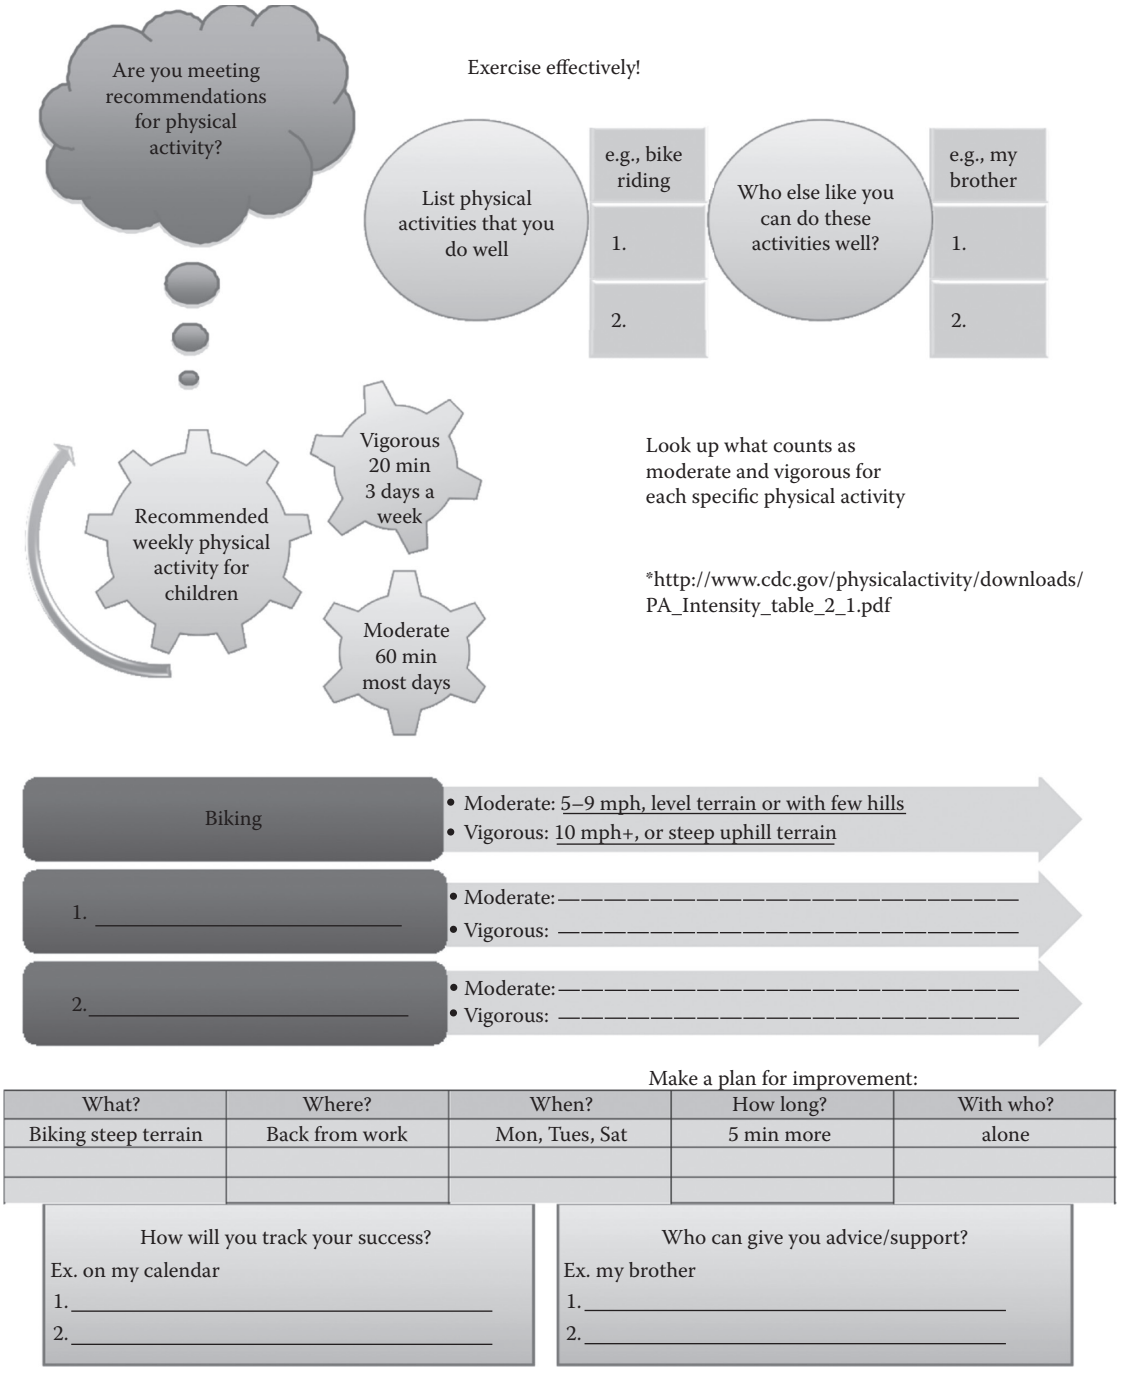

FIGURE 120.3 A tool to promote individual/psychological and interpersonal/social determinants.

Professional Support

It would seem like physicians and other health providers/practitioners are placed in a pivotal position for influencing PA. First, these individuals are considered credible in terms of health outcomes, and health behaviors could also act as a natural extension of this credibility. Second, people visit health professionals with the primary purpose of seeking information to health conditions; thus it would seem that they have an aperture for influencing health behavior. Still, there are limitations to the potential influence of health professionals. The most obvious is the low frequency of this visit; unlike peers and family, physician interactions are often extremely brief. Further, physician and health care models are often diagnostic and include passive recommendations to treat conditions (e.g., use of medications, surgery) that complement the brevity of these visits and the interpersonal distance between a patient and health care provider. These factors do not provide a strong climate for behavior change. To examine the effectiveness

of health care professionals on influencing PA, Williams et al. [58] conducted a systematic review and meta-analysis of 18 studies in this domain. The results showed modest evidence (OR = 1.2 times more likely than control participants) that physician/health care providers can influence PA among their patients. The complicated issue of exercise adherence, far exceeding what can be achieved in a short medical visit, was the main reason for these modest findings. Overall, it seems that health care professionals, while in a natural position to affect PA change, are not always able to do so within the context of the current health care structure due to the complications of sustained behavior change.

ENVIRONMENTAL DETERMINANTS

Environments contain a range of behavior settings that are seen to provide, in different degrees, "opportunities" or "affordances" for desired behaviors; the extent and the ways that those behaviors occur are further dependent on factors

TABLE 120.4
How to Change the PA Environment

Environmental Context	How to Change It
Policies	• Involve local communities and experts at all stages of policy development to maximize PA potential • Advance assessment of impact (intended and unintended) of the proposals on PA levels • New developments always prioritize PA • Local facilities and services be easily accessible on foot, bicycle, and other modes of transport involving PA • Ensure children can participate in PA play
Transport	• Reallocate road space to support physically active modes of transport (e.g., widen pavements and introduce bicycle lanes) • Restrict motor vehicle access (e.g., close or narrow roads to reduce capacity) • Implement road-user charging schemes • Introduce traffic-calming schemes (using signage and changes to highway design) • Develop safe routes to schools (e.g., traffic-calming measures by schools and create/improve walking and cycle routes to schools) • Plan and provide a comprehensive routes network for walking, cycling, and using other modes of transport involving PA, which should be convenient, safe, and attractive • Access workplaces, homes, schools, and other public facilities—shops, play and green areas, and social destinations be built and maintained to a high standard
Public open spaces	• Ensure public open spaces and public paths can be reached on foot, by bicycle, public transport, and other modes of transport involving PA • Should be safe, attractive, welcoming to everyone, and maintained to a high standard
Buildings	• Campus sites (two or more related buildings set together—e.g., hospitals and universities) should be linked by walking and cycling routes • Link new workplaces to walking and cycling networks improving the existing walking and cycling infrastructure by creating new, through routes (and not just links to the new facility) • Staircases should be designed and positioned to encourage use • Clearly signpost staircases and make staircases attractive (e.g., well lit and well decorated)
Schools	• Ensure that school playground designs encourage varied, PA play • Schools should create areas to promote individual and group PA such as hopscotch and other games (e.g., use different colors)

that are conceptualized as "filters" (e.g., perception, cognition, motivation) and "antecedent conditions" (e.g., opening hours, income, physical ability) [59,60]. Regular walking can be predicted by the proximity to retail and shopping [61], and dog ownership [62]. An environment that is not aesthetically appealing and is inaccessible to walking has been shown to be a barrier to engaging in PA [63]. Similarly, Brownson et al. [64] also listed adequate neighborhood characteristics as a motivator for PA, in addition to lacking energy, motivation, and time.

Proximity or nearness to PA resources from one's residence is a primary characteristic of environmental resources that support active transport [65], demonstrating a strong positive association with PA and walking across numerous examinations [66]. Density, which is commonly operationalized as the number of PA resources within a certain area or distance from residence was documented as a significant contributor to increased PA among adults in six of six review articles [66].

Environments exert, therefore, probabilistic influences, making behavior more or less likely. Thus, they vary in the support they provide for activities, enabling or promoting some, while preventing or discouraging others [67].

Changing the Environment for PA in Practice

To facilitate changing the environment to promote PA, key stakeholders need to be involved in addition to the health professional including planning and transport agencies (regional and local authorities), architects, designers, developers, employers, facility managers of public buildings, children's services, school governing bodies, principals, and PA coalitions. Practical suggestions are provided in Table 120.4.

What is important to consider when beginning the journey of changing the PA environment is to also be aware of the perceptions that the people have of the environment. To illustrate, families may feel very unsafe in a neighborhood due to a perception of high crime rates, whereas the police already implemented a frequent surveillance schedule, and the crime rate has been minimized. The perception in this case is the barrier, not the environment itself.

CONCLUSION

Research also suggests that environmental modifications will have greater effects when combined with strategies that target individual and social factors to foster participation in PA [69]. Social and environmental factors like an unsupportive partner and a lack of access to PA opportunities predict a return to previous PA levels after an intervention is completed [70,71]. A recent review of 22 interventions suggests a synergistic approach considering physical and social environmental and individual factors may be an effective strategy for initiation *and* maintenance [72]. Therefore, interventions aimed at simultaneously impacting individual and environmental PA determinants are likely to have the strongest and sustained effects.

INTRODUCTION

Today, chronic diseases and injuries have replaced infectious diseases as the leading causes of death in America, but no vaccines are available for these maladies. Injuries, which include both unintentional injuries and violence (e.g., homicide and suicide), are a major public health problem that affect patients, families, and the communities in which they live. This chapter will focus on unintentional injuries, which account for two-thirds of the public health injury burden.

The Centers for Disease Control and Prevention (CDC) and the Lifestyle Medicine Association share a common goal: to increase awareness of lifestyle-based causes of disease and injury in the general public and to assist in the integration of health professionals working in lifestyle-related disease and injury management and prevention. In addition to the many preventable diseases that are seen in medicine, there is one health threat that the public still accepts as a *fait accompli*: injuries. We have not yet fully integrated injury prevention into preventive medicine, and patients are not as educated on how to lower the risks of injury as they are on how to lower the risks of cancer or heart disease. Perhaps this is in part due to the belief that injuries are "accidents," acts of fate, random events, or acts of God.

The science of injury prevention teaches us that injuries are not accidents, they are predictable and they are preventable.[1,2] Lifestyle Medicine can be an important source to dispel the myth of "accidents" and help patients and the public recognize that injuries are preventable if only certain steps were taken to reduce the risks at home, on the road, at work, and in the community.

The ways we drive, walk, use alcohol and drugs, play sports, organize our home environment, select a car, use playground equipment, take prescription and over-the-counter medications, and supervise our children at play all affect the likelihood of injury. Effective interventions may include education and behavior change but also environmental supports such as legislation/enforcement and technology, engineering, and the environment. Interventions that support prevention include using individual protective devices; reducing risky driving behaviors; purchasing and using safety equipment; promoting regulations and legislation; supporting enhanced enforcement; and improving practices of physicians, providers, and other health care workers. A growing body of scientific evidence has demonstrated that lifestyle interventions for injury can and do work to lower risks.[1,2]

BURDEN OF INJURIES

Injuries are a large, predictable, and preventable national and international problem affecting individuals, families, and communities. In the United States, unintentional injuries are the fifth leading cause of death for people of all ages and the leading cause of years of potential life lost before age 65 years.[3] The consequences of injuries can be extensive and wide ranging. The effects are physical, emotional, and financial; and in the case of disabling injuries, the

* Disclaimer: The opinions expressed in this chapter are those of the authors, and do not necessarily represent any official position of the Centers for Disease Prevention Control and Prevention.

consequences are enduring. In 2007, nearly 123,706 people died from unintentional injuries in the United States; and in 2009, approximately 1 in 10 people or 27,632,781 experienced a nonfatal injury serious enough to require a visit to the emergency department.[3] Approximately one-third of all emergency department visits[4] and 6% of all hospital stays[5] are due to injuries. Today, millions of people in the United States suffer from chronic disability that was caused by injury.

The costs of all injuries are staggering.[6] In 2005 alone, injuries (unintentional and violence) cost $355 billion. This includes estimates of $77 billion in medical care costs and $278 billion in work loss costs.[3] In 2007, 9 of 10 deaths and more than two-thirds of disabling injuries suffered by workers occurred off the job, while 75 million days were lost to work injuries.[7] Moreover, costs associated with treatment of injuries and their long-term effects account for 12% of the total U.S. medical spending.[8]

The impacts to communities are equally enormous and multidimensional. Not only do communities suffer the emotional and psychological impacts of injury-related deaths (consider the death of a young teen driver) but also the economic and social strain injuries can cause. Loss of a job, care for the injured person, costs of rehabilitation, family disruption, medical care visits, insurance claims, marital difficulties, etc., all have enormous economic and social costs.

Injuries are also an international problem, especially among children and in developing countries. According to the 2008 WHO/UNICEF *World Report on Child Injury Prevention*,[9] the lives of more than 2000 families are torn apart every day around the world by the loss of a child to an unintentional injury or what is sometimes referred to as an "accident" that could have been prevented. Once children reach 5 years of age, unintentional injuries are the biggest threat to their survival. The pattern for children is similar in the United States. According to a 2008 CDC report,[10] about 33 children die every day from an unintentional injury and an estimated 9.2 million are rushed to the emergency department every year to be treated for an unintentional injury.

TRENDS AND VARIATIONS

Incident rates for injuries, like those for diseases, demonstrate long-term trends and geographic, socioeconomic, and seasonal variations. Injury rates also vary according to characteristics among individuals (e.g., age, sex, income) and environments (e.g., neighborhood, workplace, home). Injury epidemiology helps us understand and explain these variations, identify groups at higher risk for injury, and target specific interventions.

Table 121.1 compares the 10 leading causes of death in 2007 by age group. In the United States, injuries are among the top 10 causes of death in each age group throughout the lifespan. Unintentional injuries are the leading cause of death for people of ages 1–44 years. Within the 15 to 24-year-old age group, the top three leading causes of death (unintentional injuries, homicide, and suicide) accounted for 25,588 deaths. The total number of deaths from the remaining seven leading causes of death for this age group total only 3825. Unintentional injuries dominate the picture across all age groups, and violence from homicide and suicide occupies the second position as the major cause of death for those between the ages of 15 and 34.[3]

Among persons aged 1–44 years, unintentional injuries claim more lives than any other cause. In 2007, 42,031 motor vehicle traffic fatalities accounted for 3% of unintentional injury deaths (Table 121.2). Poisoning 29,846 (24%), falls 22,631 (18%), suffocation 5997 (5%), drowning 3443 (3%), and fire/burns 3375 (3%) together accounted for approximately 53% of deaths.[3]

Deaths are only a part of the devastating effect of injury on society (Table 121.3). Falls are the leading cause of injury-related emergency department visits for people of all ages, accounting for an estimated 8.8 million visits in 2009 or 32% of all injury visits. Another 4.4 million visits are for being struck by or against and 4.2 million are transportation related.[3]

An estimated 1.4 million people in the United States sustain a traumatic brain injury (TBI) annually. Falls and motor vehicle traffic crashes are leading causes of TBI. Fifty thousand die, 235,000 are hospitalized, and 1.1 million are treated and released from emergency departments.[11] CDC estimates that at least 5.3 million Americans currently have long-term or lifelong need for help to perform activities of daily living as a result of a TBI.[12] Additionally, it is estimated that 11,000 people are hospitalized with spinal cord injuries each year, and currently, nearly 200,000 people in the United States are living with these injury-related disabilities.[13] Out of the more than 50 million Americans with disabilities, about 10 million require personal assistance to carry out everyday activities; over 80% of the people who take on the role of primary helper are relatives.[14]

DISPROPORTIONATE IMPACT

As with many public health problems, injury disproportionately affects those who can least afford to suffer from it. In the United States, Native Americans 19 years and younger are at greater risk of preventable injury-related deaths than other populations in the same age group. Compared with blacks and whites, this group had the highest injury-related death rates for motor vehicle crashes, pedestrian events, and suicide. Rates for these causes were two to three times greater than rates for whites of the same age. During 1989–1998, injuries and violence caused the deaths of 3314 Native American children living in Indian Health Service areas.[15] In 2007, American Indians/Alaska Natives (AI/AN) have the highest age-adjusted rate of all injury deaths in the United States at 76.1. Blacks have the second highest rate at 65.1, while whites have an age-adjusted rate of 59.6.[3] According to the U.S. Census Bureau, the 3 year average poverty rate (2003–2005) for people who reported

American Indian and Alaska Native was 25.3%; the poverty rate for blacks was 24.9% between 2004 and 2005; and for Hispanics was 21.8%, non-Hispanic whites had a poverty rate of 8.3%.[16] The combination of high injury rates, high poverty rates, and high rates of uninsured people among AI/ANs created a demand for action, which has led to the development of targeted interventions and implementation of capacity building programs for tribes and communities to reduce and prevent injuries.

INJURY OR ACCIDENT?

An injury is distinct from an accident. Accidents are not usually considered predictable or preventable. In fact, The Oxford English Dictionary defines the term *accident* as "an unusual event, which proceeds from some unknown cause … unexpected … happening by chance or fortune."[17]

The word *injury* has its root in the Latin term *injuris*, which literally means "not right." The dictionary defines injury as "harm of any kind, done or sustained." Injury in public health is defined as unintentional or intentional damage to the body resulting from acute exposure to thermal, mechanical, electrical or chemical energy, or from the absence of such essentials as heat or oxygen.[18] These exposures are affected by lifestyle.

Most injuries can be prevented through changes to products, behaviors, and environments.[2] Using terms such as *injury prevention* rather than *accident prevention* helps make clear that injuries are controllable and can be prevented. Former U.S. Surgeon General C. Everett Koop underscored this distinction when he said: "We must accept that the injuries associated with motor vehicles are not 'accidents' and that much can be done to reduce them. We must realize that violence in the forms of abuse, assault or suicide is within the purview of the health system. An informed and aroused public can change the behavior of each of us, but more importantly it must lead to community outrage and action in regard to unsafe playgrounds, automobiles, highways, work places, toys, homes and use of handguns."[18]

TABLE 121.2
Unintentional Injury Deaths, All Ages, All Race/Ethnicities, Both Sexes—United States, 2007

Cause of Death	*N*	Percentage
Motor vehicle traffic	42,031	34.0
Poisoning	29,846	24.1
Falls	22,631	18.3
Suffocation	5,997	4.8
Drownings	3,443	2.8
Fire and burns	3,375	2.7

[c] Injuries inflicted by law enforcement personnel during the course of official duties.

CAUSES OF INJURY

The terms *injury* and *trauma* are often used interchangeably. Although there are many kinds and causes of injury, two main categories prevail;

1. *Acute exposure to energy* refers to injuries resulting from falls, motor vehicle crashes, and sports injury (kinetic energy); fires and burns (thermal energy); poisonings (chemical energy); electrocution (electrical energy); and from radiation
2. *Absence of essentials* includes lack of oxygen (as in asphyxiation, strangulation, or drowning) and lack of heat (as in hypothermia or frostbite)

PUBLIC HEALTH RESPONSE

According to the National Academy of Sciences, injury is the most under-recognized public health problem facing the nation today.[19] The science of injury control demonstrates that using the public health approaches can be effective in injury prevention. Injuries, like diseases, result from interactions between persons (host factors), agents or vectors (e.g., energy exchange), and the environment (physical and social environmental factors).[20] This approach is the foundation for understanding injury prevention.[21–23]

In response to the public health burden of injuries, the National Center for Injury Prevention and Control (Injury Center) was established at the CDC to prevent premature death and disability and to reduce the human suffering and medical costs caused by injuries.[8] To do this, the Injury Center uses the public health approach (Figure 121.1)—a systematic process to (1) define the injury problem, (2) identify risk and protective factors, (3) develop and test prevention interventions and strategies, and (4) translate and disseminate effective interventions to assure widespread adoption.

The mission of the Injury Center at CDC is to prevent injuries and violence and reduce the consequences so that people can live to their full potential.[24] The CDC Injury Center

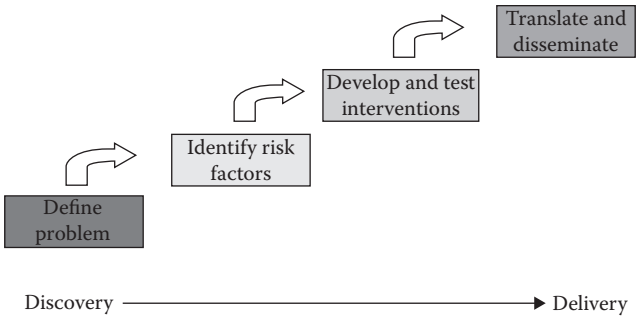

FIGURE 121.1 Steps in the public health approach to injury prevention.

is the only organization in the federal government with the responsibility to address all phases of the injury problem from foundational research to implementation of interventions and widespread adoption of effective strategies.

Control of injuries requires preventing the occurrence or reducing the severity of the injury event. In the case of an injury to an older adult falling, damage to the host (the person harmed) is brought about through a rapid transfer of kinetic energy. Changing this pattern of energy transfer can be modified in many ways, for instance, by making the host more resistant to it (by increasing injury tolerance through exercise and diet), by reducing the amount of energy transferred to the host (by landing on a softer surface or wearing hip protectors), or by creating a safer home environment (by removing trip hazards and installing proper lightening on stairs or installing grab bars in the bathroom). These are lifestyle changes within reach of most patients, manufacturers, homebuilders, governments, and parents.

The practice of successful injury prevention requires the application of lifestyle change and health promotion strategies that modify individual and population behavioral risks, reduce exposure to hazardous environment, and remove or modifying harmful products in the marketplace.[1,21] Individual and community actions are required for these strategies to succeed, and they are fostered by education, stimulated by social and organizational change, and encouraged through public policy, legislation, and enforcement activities. These actions, by their diversity alone, require the involvement of many professionals including physicians, nurses, coaches, designers, product engineers, and many others.

AXIOMS IN INJURY PREVENTION

Several axioms for injury prevention can help guide efforts in controlling injuries.[21,25,26]

1. *Injury results from interactions between people and the environment*: There are both human and environmental determinants of injury. The agent of injury will cause relatively little damage if the amount reaching tissues is within the limits of human tolerance. Tap water can scald in seconds or not at all depending on its temperature. The importance of this interaction is recognized in approaches that control the environment by reducing hot water temperatures at the tap and approaches that simultaneously target parents of small children and the elderly about hot water scald risks (including the need for reduced tap water temperatures).
2. *Injury-producing interactions can be modified through changing behavior, products, or environments*: Injuries can be reduced by modifying the weakest or most adaptable link in the chain of causation. Unsanctioned swimming in a home swimming pool is more easily reduced by placing an isolation fence or barrier between the child and the pool than by supervising the child's behavior at all times. During sanctioned swimming, while in the pool, close supervision is the most important strategy. Changing the environment, the laws, the person, or the product can all lead to reductions in injuries.
3. *Environmental changes have the potential to protect the greatest number of people*: Changes to the environment that automatically provide protection to every person have the potential to prevent the most injuries. This includes automatic protection built into roads (such as barriers), into buildings (such as fire sprinkler systems), into automobiles (such as shatter-proof glass), into homes (such as fuses), and into products (such as child-resistant packaging on medicines). Few "passive" interventions succeed without an active behavioral component (such as replacing lids on medicines) and succeed better when the public is informed and convinced of their need and benefit.
4. *Effective injury prevention requires a mixture of strategies and methods*: Three primary strategies—education/behavior change, technology/engineering, and legislation/enforcement—are widely recognized as effective in preventing injuries. Individual behavior change, product engineering, public education, legal requirements, law enforcement, and changes in the physical and social environment work together to reduce injuries. The challenge in intervention planning is to select the most effective combination of strategies to produce the desired result.
5. *Public participation is essential for community action*: Effective public policy requires the support and participation of people. Local problems and resource availability often determine the direction of injury prevention programs. Factors influencing success in injury prevention are best identified by public feedback and participation

in the process. Without public support, effective laws designed to protect the public (such as mandatory motorcycle helmet use laws) may be ignored, or worse, repealed.

6. *Intersectoral collaboration is necessary*: Injury prevention requires coordinated action by many groups. Participation by community leaders (in addition to health officers, hospital administrators, and others) is necessary in planning and implementing injury prevention programs. Different sectors can play different roles—ranging from identifying problems to mobilizing community action, evaluating intervention effectiveness, and advocating for change. Identifying and building a constituency and shifting or sharing resources require collaboration across many different sectors.

An illustration of these axioms can be seen in the following case study involving burn prevention and modifications to cigarette lighters to make them child-resistant.

PUBLIC HEALTH, PREVENTIVE MEDICINE, AND INJURY CONTROL

Injury prevention has received less than its share of coverage in the public health and preventive medicine literature.[25] As injury prevention and lifestyle medicine become more closely aligned, the potential benefits of comprehensive injury prevention strategies, including behavioral and environmental change, will become clearer and more widely accepted.[22] Health promotion approaches using a combination of approaches including educational, behavioral, engineering and technology change, and legislation, policy, and enforcement provide the greatest chance of success.[1,21,25]

There are many examples[1,2] of successful strategies to reduce risky behaviors, change policies to promote safer practices, support stronger enforcement efforts, and change products to make them safer (as in the case study). Working with community leaders and advocates and implementing low-cost but effective interventions to reduce preventable injuries is also a common theme in injury prevention.[1,2] Translating successful strategies for use in primary care settings is more challenging (even in traditional prevention arenas such as

CASE STUDY: BURN PREVENTION AND CHILD-RESISTANT CIGARETTE LIGHTERS

After seeing many children suffering from burns, Diane Denton, an emergency room nurse in Louisville, Kentucky, began asking parents how these tragic burns occurred. She learned that a large number of cases were the result of children playing with disposable cigarette lighters. The lighters are small enough to fit in the palm of the child's hand, are brightly colored, and become "sparking toys" when moved rapidly along a carpet or mattress. Ms. Denton documented these case findings within her own community and then, armed with the data, petitioned the U.S. Consumer Product Safety Commission (CPSC) to investigate more widely the risks posed by disposable cigarette lighters. Others in the burn prevention community nationally joined her plea for action to either ban the lighters or modify them to make them child-resistant.

Impressed with the data Ms. Denton provided, the CPSC-funded research to examine cases nationwide in which children had been badly burned while playing with disposable cigarette lighters. It found that children playing with lighters ignited 5900 residential fires that resulted in an average of 150 deaths and 1100 injuries annually. Average annual property damage from such fires totaled almost $70 million. As many as 190 burn-related deaths among children younger than 3 years could be prevented, they estimated, by a simple and inexpensive childproof device costing less than nine cents.

Ten years after Denton's efforts, with CPSC prompting, the major cigarette lighter manufacturers complied with a request to make disposable lighters childproof, reengineered them so that small children could not operate them, and marketed them to the public as safer for the protection of children. CPSC finally set a standard (effective in 1994) requiring disposable and novelty lighters to be child-resistant. Since the standard took effect, there has been a 58% reduction in fires caused by children under 5 years of age, representing the prevention of hundreds of deaths and injuries and thousands of fires. However, in a recent year, there were still 2400 fires resulting in 70 deaths and 480 injuries because of children under age 5 years playing with lighters. Back as far as 2004 to the present, CPSC was still recalling novelty lighters (digital wristwatch lighters, lighters made into shapes of toy cars) that are sold in the United States but do not meet the current child-resistant standard (see http://www.nonoveltylighters.com for a website dedicated to these activities in Arkansas).

Manufacturers and marketers who disable or tamper with the childproof feature in lighters, or import nonstandard lighters have been jailed and fined. In this example, the actions of one emergency care nurse and a small community of injury prevention advocates from the medical community changed an entire industry, saving hundreds of lives and preventing thousands of children from being seriously burned.

cancer prevention and women's health,[27,28]) but it is critical in injury control where using known and effective interventions can save lives almost immediately. The challenge now is to stimulate primary care physicians and family practitioners to become more engaged in using and adapting the evidence with patients and families to save lives and prevent injuries.

One additional benefit to preventing unintentional injury is that it not only saves lives but also saves dollars. Many low-cost safe practices that protect children and adults will help reduce economic costs to society.[29] For example,

- A child safety seat can save $100 in direct medical costs and an additional $1360 in other costs.
- A bicycle helmet can save $440 in direct medical costs and other costs.
- A smoke alarm can save $15 in direct medical costs and an additional $710 in other costs.
- Every dollar spent on poison control centers can save $6.70 in medical costs.

Among the most urgent priorities is the area of motor vehicle injury prevention where more than 35% of the injury deaths occur (Table 121.2). Examples of evidence-based strategies to prevent motor vehicle occupant injuries can be found in the Guide to Community Preventive Services (Community Guide) and recent reviews.[30–33] The guide summarizes what is known about the effectiveness, economic efficiency, and feasibility of interventions to promote community health and prevent disease, and it makes recommendations for the use of various interventions based on the evidence gathered in the rigorous and systematic scientific reviews of published studies.

HOW LIFESTYLE MEDICINE PRACTITIONERS CAN HELP PREVENT INJURIES

Lifestyle medicine physicians often see patients and their families after an injury has occurred, or meet practitioners responsible for managing, implementing, or evaluating injury prevention programs. These are opportunities to share effective strategies and build traffic injury prevention opportunities into clinical care. Physicians can also influence decision makers to enact or strengthen legislation or to set health care and reimbursement policies that promote prevention. Health care professionals who serve on medical school or nursing faculty and teach courses on trauma prevention or public health can also help prepare their students with material related to injury prevention.

Reducing injuries will also require a shift in how society thinks about hazards, the environment they live in, their personal risk behaviors, and the value of prevention. Lifestyle medicine can contribute to this shift by a variety of actions:

1. At the individual level
   a. Include injury prevention in all your health promotion and disease prevention activities with patients
   b. Expand your record keeping to collect and monitor patient risk factors for injuries (e.g., chart reminder about teens counseling about driving or unintentional poisoning among middle-aged adults).
   c. Assess the safety practices of patients and their families (e.g., helmet use, texting while driving, use of life jackets).
   d. Set goals for your patients to change risky lifestyles that predispose to injuries.
   e. Collect data on the clinical and health care costs and consequences of the injuries you treat.
   f. Have information available on how patients can access resources in the community for injury prevention (e.g., local safety council, MADD, bicycle helmet programs).
   g. Screen for alcohol misuse, using existing tools such as brief intervention and motivational interviewing.
   h. Screen for use of age-appropriate child safety seats and booster seat use.
   i. Support improvements in prehospital and hospital care for injured victims and support comprehensive trauma care systems in your community.
   j. Talk to parents of teenage drivers about the importance of graduated driver licensing.
2. At the community level
   a. Support efforts to strengthen policies in your state that prevent injuries such as primary seat belt laws, stronger teen driving policies, smoke alarm policies, and motor cycle safety.
   b. Discourage efforts to repeal legislation that has had a positive safety benefit.
   c. Strengthen collaboration with local coalitions, such as Safe Kids, a local drowning prevention coalition, the National Safety Council, or State Offices of Highway Safety.
   d. Support efforts to build injury prevention into initiatives into health care reform.
   e. Testify at hearings and town meetings about evidence-based strategies that work.
   f. Support research on risk and protective factors and interventions to reduce all forms of injury and trauma, including injury prevention on and off the job.

FUTURE CHALLENGES

The National Academy of Sciences Institute of Medicine Report, Reducing the Burden of Injury[8] reemphasized the importance of using a scientific approach to injury prevention and called on CDC and others to work with medical care organizations, health care providers, states and communities, businesses, and other federal agencies to pursue

alliances that would help reduce injuries. Lifestyle medicine practitioners and the Lifestyle Medicine Association can be important partners in this prevention solution. It's time to add *injuries* to the broad range of conditions resulting from lifestyle choices and engage the primary caregivers and other gatekeeper health care professionals in advocating for lifestyle choices that reduce injuries from all causes.

CONCLUSIONS

Although injuries have plagued societies since the beginning of time, preventive and lifestyle medicine have only recently recognized these events as important public health problems that are both predictable and preventable. Injuries are seldom distributed randomly—they are concentrated in physical space and time, and they affect definable populations at risk. Using ecological public health approaches that are based on sound epidemiology,[34] human factors research[35] and behavioral and social science theories[1] stand the best chance of succeeding. Targeting the host, agent, and environmental factors, including hazardous products that contribute to injury, will help reduce overall injury rates. Approaches will need to be adapted to different populations, lifestyles, and life stages. Because there are so many different injuries with varied causes, tailored strategies are necessary.

Reductions in injury and their costs to patients and their families are possible, but will need support, collaboration, and partnering from policy makers, clinicians, and health care practitioners. Lifestyle medicine and primary care family practitioners are important allies in encouraging lifestyle choices that reduce injuries and in advocating for medical and public health policies related to injury prevention. Primary caregivers and other health care professionals can help reduce injuries from all causes using clinical-based prevention skills[36] and advocating in the community for changes that reduce injury potential.

Who Gets IPC? 1457
Does It Work? 1458
Barriers to IPC 1459
The Injury Prevention Program 1459
Guidelines for Adolescent Preventive Services 1461
Conclusion 1461
References 1462

Unintentional injuries are a leading cause of morbidity and mortality in the United States. In 2007, unintentional injury accounted for over 123,000 deaths and over 27 million emergency department visits. Unintentional injury is the leading cause of death for individuals who are 1–44 years of age, the fourth leading cause of death for all ages combined, and the leading cause of years of potential life lost before 65 years [1].

The most common causes of injury death are motor vehicle traffic crashes, poisoning, fall, suffocation, drowning, and fire and burns, while the most common causes of nonfatal injury are fall, struck by/against, overexertion, motor vehicle crashes, and cut/pierce [1]. The toll on the health care system is dramatic, with injuries in a single year resulting in $406 billion in lifetime medical expenses and lost productivity [2].

Many injuries are preventable through the application of proven effective interventions. These interventions include policy changes, environmental modification, and personal protective behaviors. For example, graduated driver licensing policies, the presence of home smoke alarms, and the use of car seats, seat belts, and bike helmets have all demonstrated their risk-reducing potential [3]. How to communicate risk-reduction messages and get proven effective safety products into the hands of those who need them remains a challenge for injury prevention [4,5].

The purpose of this chapter is to explore one solution to this challenge, injury prevention counseling (IPC) by health care providers. This is one strategy to reduce risk by encouraging people to modify their environment or their personal behaviors to protect themselves or their loved ones.

Physicians and other health care providers are trusted sources of health information [6] and can play an important role in injury prevention. This is particularly true of pediatricians who often see infants and their parents multiple times in the first years of life [7]. IPC is included in the American Academy of Pediatrics (AAP) recommendations for well-child visits [8] and in the U.S. Preventive Services Task Force *Guide to Clinical Preventive Services* [9]. The aims of this chapter are to describe the prevalence and effectiveness of IPC and to suggest which elements of an IPC program are associated with greater success. The results can be used to inform future efforts to strengthen this injury prevention strategy.

WHO GETS IPC?

Despite the professional endorsements of IPC, recent national surveys have found that few patients are receiving IPC. Only 1 in 5 adults who visit a health care provider reported receiving counseling on any injury topic and only 1 in 10 was counseled on seat belt safety and 1 in 17 was counseled on home smoke alarms. Other than seat belt use, there has been little change in these percentages over the past 10 years. Prevalence of IPC differed by age, sex, race/ethnicity, household poverty status, education level, health insurance status, and presence of children in the household [10].

Pediatricians have been more successful. Over 40% of children with a medical visit reported receiving IPC delivered either to themselves or their parents; however, this percentage decreased with increasing patient age (0–1 year: 62.8%; 2–6 years: 44.6%; 7–12 years: 39.0%; 13–14 years: 27.3%). Overall, the percentage of U.S. children with reported IPC for any injury topic has not changed over time, but there have been modest increases in IPC on home smoke alarms, bicycle helmets, and car seats for children 6 years of age or younger [11].

* Disclaimer: The findings and conclusions in this report are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention.

DOES IT WORK?

The evidence of IPC being effective at increasing safety practices comes mostly from the pediatric literature and is inconsistent. A review of studies from 1964 to 1991 by Bass et al. found that IPC taking place in pediatric primary care settings can change parents' knowledge, attitudes, and behavior related to motor vehicle, household, and environmental injuries [12]. The studies in this review included various methodologies including randomized controlled trials, non-randomized studies, multiple time series (before and after), and descriptive approaches. The Centers for Disease Control and Prevention's Second Injury Control and Risk Survey examined IPC through a nationally representative random-digit-dial telephone survey, which asked respondents if they or their children had received any IPC during visits to health care providers. Additionally, specific safety practices and behaviors related to children were also assessed. This study found that IPC improved safety behaviors for posting the poison control center number and always using a bicycle helmet; there was no association between IPC and having a working smoke alarm in the home or always using a seat belt [11]. However, another review looking exclusively at 22 randomized controlled trials of IPC delivered in a variety of settings such as physician offices, clinics, emergency departments, and hospitals. They found that safety practices, which may have been self-reported or observed, improved for motor vehicle restraint use, smoke alarm ownership, and maintenance of a safe hot tap water temperature; but there was not added protection for general injury prevention at home or bicycle helmet use [13].

There are several possible reasons why some IPC efforts have been shown to be effective while others have not. Choices in study designs and outcomes examined (i.e., change in knowledge, change in behavior, and occurrence of an injury) may limit the ability of individual studies to demonstrate an effect. In some instances, IPC may have a true benefit, but that benefit may not be clear in the short term or measureable. Furthermore, counseling recommendations for some injury issues may involve more effort, cost, or inconvenience by the patient or parent compared with other injury issues. For example, a recommendation to check the temperature of the hot water heater and turn it down if it is over 120°F is a one-time action versus the recommendation to always wear a bicycle helmet, which must be demonstrated each time one cycles. Additionally, perceived risk and consequences also vary by injury issue and can affect the impact of counseling. Counseling to prevent drowning or a motor vehicle injury may be perceived as more serious than counseling to prevent a sports injury. A person's beliefs about their susceptibility to an injury, the severity of the injury should it occur, the effectiveness of the recommended action, and the benefits versus the costs of the action (as described by *the Health Belief Model*) all affect behavior change and thus the receptivity to the counseling efforts [14].

Counseling that is based on behavior change theories used in health education, health promotion, and health communication is likely to be the most effective [15]. DiGuiseppi and Roberts [13], using the theoretical planning framework of the PRECEDE-PROCEED model [16], suggest addressing three types of factors that health education can modify, based on (1) *predisposing factors* (these include knowledge, beliefs, values, attitudes, and confidence; use these to motivate the patient to change behavior), (2) *enabling factors* (allow the motivation to be realized; these factors include skills mastery, accessibility of resources, and product design and legislation), and (3) *reinforcing factors* (reinforce and reward implementation and maintenance of safety behaviors—e.g., follow-up visits or calls, incentives, reminders, media messages, and legislative enforcement). IPC effectiveness can be improved by combining these strategies, or by combining education with demonstrations, the provision of subsidized safety devices, and reinforcement.

Consideration of other theories of behavior change could also improve counseling approaches and effectiveness. For example, the *Protection Motivation Theory* addresses protection motivation through individual appraisals of threat and coping (e.g., parents must be convinced that teen driving poses a personal and serious threat and that actions they could take would protect against this threat) [14]. The *Theory of Reasoned Action* and the related *Theory of Planned Behavior* examine factors related to behavioral intention (which predicts behavior). Intention can be influenced by attitudes toward behavior (e.g., my child would be safer in a car seat), subjective norms (e.g., my spouse would approve of using a car seat), and perceived behavioral control (e.g., I can put my child in a car seat successfully) [14].

The effectiveness of patient counseling that addresses other health issues varies by topic area. Data exist that patient counseling to prevent sexually transmitted infections [17], promote healthy diet [18], reduce risky or harmful alcohol use [19], and promote smoking cessation can be effective [20]. Evidence is inconclusive about the effectiveness of counseling to increase physical activity [21].

Reviews of studies on these topic areas suggest other factors for why some counseling is effective. Counseling done in truly low-risk populations show minimal benefit, so physicians should consider concentrating their counseling efforts on patients at higher risk. This may involve screening patients to understand this level of risk. Identification of high-risk patients can be done through the appropriate use of validated screening instruments (e.g., CAGE to detect alcoholism [22]) in conjunction with clinical assessment and judgment. It is important to note that counseling interventions differ from screening interventions in that counseling may address complex behaviors and be influenced by multiple contexts (i.e., family, peers, school, work, and community) [23].

Intervention intensity also seems to be an important factor in effectiveness. Higher intensity interventions take more time, and may involve more patient contacts (such as follow-up visits) and individual risk-based counseling, which could include tailored risk-reduction plans.

The evidence for effectiveness of counseling for these other health areas is based on systematic reviews of individual studies. Some of these studies used specifically trained professionals, such as nutritionists or dieticians in counseling interventions that addressed dietary changes, and study protocols often involved the use of study-specific clinics and staff to provide screening and assessment services. In practice, access to these resources may not be available, so translating effective interventions done in a research context may be challenging.

BARRIERS TO IPC

Health care providers who want to include IPC in the care of their patients also face a number of additional barriers. The most obvious barrier is a lack of time. The health care provider may be seeing a patient for a health maintenance visit, to treat an injury, or to treat another medical problem in an inpatient or outpatient setting. It can be difficult for a provider to balance the time needed to manage the reason for the visit with the time needed for IPC or counseling for other health issues. Additional barriers include the feeling that they have more important things to do, fear of patients' or parents' reactions to discussion of some aspects of injury prevention, and a sense that this problem is too big to be solved by a provider working one-on-one with a patient or family [24,25]. In fact, injury prevention often is perceived as more outside the physician's role compared to other clinical preventive services, and therefore, many physicians are unprepared to deliver IPC [26].

These gaps and challenges can be addressed with more emphasis during medical education on the importance of injuries as a health issue and how to conduct IPC. A broader effort is needed to improve the attitudes of providers, parents, and patients that it is within the purview of individual health care providers to discuss the prevention of injuries from motor vehicle travel, in sports and recreation, at work, in the home, and in the community.

There may be a unique opportunity at this time to increase IPC because of health care reform efforts, which have raised the visibility and importance of preventive services. While insurance programs typically cover preventive services such as vaccines, they do not cover IPC or safety products. It's estimated that Medicaid could save $1 million per 100,000 children by supporting child safety seat distribution and education [27].

Gielen found that coupling pediatric counseling with convenient access to low-cost safety supplies and personalized information can improve home safety practices among low-income urban families [28]. The IPC utilized here was developed specifically for this project and involved the SAFE Communication Framework, which was found to increase physician counseling and improve parent satisfaction with the medical visit [29]. This framework involved four steps: (1) *solicit information* (i.e., ask what patient or parent knows, does, and is concerned about regarding specific injury issues), (2) *advise* (i.e., explain safety practice and provide information on how to do it), (3) *focus on risks and barriers* (i.e., help patient or parent understand the injury risk, acknowledge barriers to safety practice, and help problem solve), and (4) *encourage compliance* (i.e., reinforce intentions and efforts and plan to follow up). Pediatric residents received specific instruction on SAFE that included practice in role playing as well as demonstration skill stations. Part of this comprehensive approach was a standard 1 h seminar on the problem of injuries and an overview of the AAP's The Injury Prevention Program (TIPP).

THE INJURY PREVENTION PROGRAM

TIPP is an educational program for parents of children from newborns through 12 years of age [30,31]. It addresses the prevention of common injuries from motor vehicles, drownings, burns, firearms, poisoning, falls, bicycle crashes, choking, and pedestrian hazards. TIPP is designed to assist pediatricians with a systematic method to counsel parents and children about adopting behaviors to prevent injuries. There are three major elements in TIPP: (1) a policy statement on injury prevention approved by the APP [32], (2) Childhood Safety Counseling Schedules for early and middle childhood, and (3) a package of materials consisting of Safety Surveys and age-specific, color-coded Safety Sheets for use in providing anticipatory guidelines to parents and children (Table 122.1).

TIPP can be integrated into a physician's practice through the following steps:

1. Have a parent answer a Safety Survey in the reception room. The child can complete the survey at 10 years of age.
2. Have the completed survey placed in the child's medical chart for review by the physician.
3. Note "at-risk" answers on surveys that have been completed.
4. Counsel the parent or child on specific injury prevention behaviors using the Safety Sheets and the counseling guidelines prompted by the "at-risk" answers obtained from surveys.
5. Reinforce the counseling by giving the parent or child an age-appropriate Safety Sheet emphasizing the targeted safety messages of the counseling schedule.
6. Document the counseling in the child's medical record.

There is some evidence that TIPP is also a cost-effective method of preventing childhood injuries. Miller and Galbraith estimated that pediatric IPC for parents of children younger than 5 years can achieve an estimated savings of $880 per child or $80 per visit. Each dollar spent of TIPP targeting this age group returns nearly $13 [33].

TABLE 122.1
TIPP Counseling Guidelines

The first year of life

Household hazards

- Keep crib sides raised
- If you leave, even for a moment, place your baby in a playpen or crib with the sides up
- Provide constant supervision
- Keep plastic bags and balloons away from your children
- Do not put anything around a baby's neck—objects around the neck may strangle the baby
- Do not allow your child to play with small objects
- Select an experienced babysitter
- Check heating systems and fireplaces at least once a year
- Place operable window guards on all windows in your home
- Do not place your child in a walker

Burns

- About one-third of home fires involving fatalities are caused by smoking
- Develop an escape plan in the event of a fire in the home
- Buy a fire extinguisher for the home
- Install smoke alarms in your home
- Do not drink or carry hot liquids when holding your child or when children are nearby
- Erect barriers around space heaters

Water safety

- Never leave a child alone in or near a tub, pail, toilet, or pool of water
- Fence in your pool or hot tub on all four sides

Auto safety

- Your child should ride in a car safety seat during every trip, even if you will be traveling a short distance
- Never place an infant in front of an air bag
- Seat a child in the rear seat of the car

Bicycle safety

- Do not carry children younger than 12 months on bicycles

Firearms hazards

- Remove all guns from places children live and play

From 1 to 4 years

Household hazards

- Never leave small children alone in the home
- Select an experienced babysitter
- Keep plastic bags and balloons out of reach
- Small objects and solid foods such as hot dogs, peanuts, grapes, carrots, or popcorn may block your child's airway
- Mechanical garage doors may crush a child
- Place operable window guards on all windows in your home
- Keep small children out of the yard while the lawn mower is in use
- Use gates on stairways
- Place your baby's crib away from windows
- Check for hazards in homes your child may visit
- Report any history of injuries to the pediatrician

Firearm hazards

- Remove all guns from places children live and play

TABLE 122.1 (continued)
TIPP Counseling Guidelines

Poisonings

- Keep medicines and hazardous products out of the sight and reach of children
- Dispose of old medicines
- Purchase medicines with child-resistant safety caps
- Inspect walls for peeling paint
- Learn first aid for poisoning
- Heating ventilation systems and fireplaces should be checked at least once a year

Burns

- Do not leave electrical appliances within the reach of a child in the bathroom
- Keep electrical cords out of a child's reach
- Keep matches and lighters out of the reach of children
- Most deaths due to home fires are caused by smoking
- Develop an escape plan in the event of a fire in the home
- Buy a fire extinguisher for your home
- Install smoke alarms in your home
- Check hot water temperature
- Keep hot pots and pans out of the reach of children

Water safety

- Do not leave your child alone in a tub, even for a moment
- Always wear a Coast Guard-approved life jacket
- Fence in your pool or hot tub on all four sides
- Do not let children swim without supervision

Bicycle safety

- Use an approved child carrier

Auto safety

- Children of this age should always be properly restrained in a car safety seat. Select a car safety seat that fits your child's size and weight and that can be installed properly in your car
- Never leave a child alone in a car
- Seat a child in the rear seat of the car
- Never put children in front of passenger air bags
- Buckle up and lock up!
- Young children should not play in driveways or near busy streets

Toy safety

- Inspect toys for safety hazards

From 5 to 9 years

Firearm hazards

- Do not keep guns in your home

Household hazards

- Never let children this age operate a lawn mower or ride with you on one
- Report any history of injuries to the pediatrician
- Heating ventilation systems and fireplaces should be checked at least once a year

Burns

- Develop an escape plan in the event of a fire in the home
- A third of deaths due to home fires are caused by smoking
- Do not let children play with fire
- Buy a fire extinguisher for your home
- Do not let children play with fireworks
- Install smoke alarms in your home

TABLE 122.1 (continued)
TIPP Counseling Guidelines

Water safety
- Teach children how to swim
- Teach and enforce the rules of swimming and diving safety
- Be sure your child wears a life jacket when on a boat

Auto safety
- A booster seat should be used on every trip by all children who have outgrown their car safety seats with harnesses (usually around 40 lb) until the seat belt fits correctly (usually around 4 ft 9 in. tall or between 8 and 12 years old)
- Never seat a child in front of a passenger air bag

Pedestrian safety
- Teach your child pedestrian safety skills

Bicycle safety
- Teach and enforce bicycle safety rules
- Wear a bicycle helmet

Recreational safety
- Wear protective gear during sports
- All children should wear an approved equestrian helmet when riding a horse

From 10 to 12 years

Firearm hazards

Do not play with guns!

Burns
- Check to see that your home has smoke alarms

Bicycle safety
- Never ride with passengers on your bike
- Always wear a helmet when riding a bike

Auto safety
- Buckle up
- Do not sit in front of a passenger air bag
- The safest place for you to ride is in the back seat, buckled up

Pedestrian safety
- Follow safety rules when crossing the street

Water safety
- Never play near water without an adult nearby

Farm safety
- Farm equipment is very dangerous to children

Source: AAP, The Injury Prevention Program (TIPP): A Guide to Safety Counseling in Office Practice, American Academy of Pediatrics, Elk Grove Village, IL, 1994.

GUIDELINES FOR ADOLESCENT PREVENTIVE SERVICES

The Guidelines for Adolescent Preventive Services (GAPS) is a comprehensive set of recommendations developed by the American Medical Association's Department of Adolescent Health that are intended to be applied to 11- to 21-year-old patients. The rationale for GAPS is that at an early age, high-risk behaviors and negative lifestyle patterns can be identified and interventions can reduce premature morbidity and mortality [34].

GAPS is organized into four types of service that address 14 separate topics or health conditions, including injury prevention. GAPS consists of 24 recommendations that encompass health care delivery, health guidance, screening, and immunizations.

GAPS recommendation 6 states, "All adolescents should receive health guidance annually to promote their *reduction of injuries*" [35]. The GAPS health guidance for injury prevention includes counseling to

- Avoid the use of alcohol or other substances while using motor or recreational vehicles or where impaired judgment may lead to injury
- Use safety devices, including seat belts, motorcycle and bicycle helmets, and appropriate athletic protective devices
- Resolve interpersonal conflicts without violence
- Avoid the use of weapons and/or promote weapon safety
- Promote appropriate physical conditioning before exercise

While the physician is responsible for making decisions on how to apply GAPS during interactions with adolescents in their offices, GAPS provide the framework for the organization and content of these preventive health services. The use of the GAPS model can increase clinicians' detection and discussion of risk behaviors [36].

CONCLUSION

Physician counseling can play a critical role in efforts to prevent unintentional injuries. IPC is a promising, but underutilized, prevention strategy. Evidence suggests that it is most effective if based on behavior change theory and used in conjunction with other strategies such as providing access to affordable low-cost safety resources and equipment. The research base is limited relative to the broad array of IPC opportunities, which span the lifecourse from car seats for infants for which much work has been done to falls prevention strategies for older adults where little is known about the role of IPC. There is a particular need to understand if IPC is effective for adult patient populations. Barriers for delivering IPC can be overcome by improving physician medical education to include injury prevention and counseling skills and by providing incentives, such as reimbursement for IPC and safety products distribution as part of covered preventive services. Materials and recommendations from TIPP and GAPS can be used to guide clinicians who wish to incorporate IPC into their practices.

Traffic-related injuries have only recently been recognized as a fundamental part of public health practice. With an eye toward the health of populations, but clinical practice at the individual level, primary care providers can have a positive influence on their patients' behavior and help prevent one of the leading causes of death in America. There are many effective strategies to address these preventable deaths and injuries that are closely related to lifestyle factors and can be incorporated into clinical assessments. For example, clinicians can support primary prevention by screening for alcohol dependency and counseling patients about drinking and driving or support secondary prevention by counseling patients about the need for seat belts for themselves and child safety seats (CSS) for their young children. This chapter will describe the current traffic environment, the epidemiology of traffic-related deaths and injury, and review what is known about effective prevention strategies with an emphasis on strategies that are most applicable to lifestyle medicine.

TRAFFIC INJURY AND LIFESTYLE

Traffic-related injury and lifestyle are inextricably linked. Our culture values independence, and for many, independence comes with the ability to drive. The motor vehicle dominates all other modes of travel in the United States. In the span of 100+ years, the number of registered automobiles grew from 8000 in 1900 to 259 million in 2009 [1]. In 2009, 20% of households reported three or more vehicles and

only 9% reported zero vehicles [2]. A high degree of mobility is integral to our lifestyle. There are more than 200 million licensed drivers in the United States and they drive an average of 14,000 miles/year on 4 million miles of roads [3].

Figure 123.1 indicates that while exposure to the road environment has increased, there has been a long-term decline in the rate of traffic-related deaths, over 90% since 1925 [1], primarily due to advances in the safety of vehicles, roads, and improvements in driver behavior [4], which have mitigated the negative effects of increased motorization. In spite of these declines, traffic crashes remain the leading cause of death among children, adolescents, and young adults and fall within the top 10 causes of death among all age groups combined [5].

EPIDEMIOLOGY

Traffic crashes result in about 33,000 deaths and more than 3 million nonfatal injuries treated in hospital emergency departments each year [5,6]. The risk of death or injury varies by many factors including sex, age, race/ethnicity, type of road user (e.g., occupant, pedestrian, motorcyclist, cyclist (nonmotorized)), and state. There is a significant risk difference by sex. Males have death rates at least twice that of females overall; for vehicle occupants, motorcyclists, pedestrians, and cyclists; and for all age groups after the age of licensure (age groups 15–19 years and older). The difference is especially high for motorcyclists (death rate 10.7 times higher among males) and cyclists (8 times higher among males). For nonfatal injuries, males have higher injury rates than females except in the case of motor vehicle occupants where the injury rate among females is 1.27 times that among males [5].

Death rates vary widely by age with the lowest rates among children aged 0–14 years and the highest rates among those aged 15–24 years and 80 years and older [5]. Young drivers represent 6% of all licensed drivers but are involved in 11% of all fatal crashes [7]. Young drivers have higher crash involvement rates than any other age group; this holds true for fatal crashes, injury crashes, and property damage only crashes [6]. Novice teen drivers have especially high death rates given their lack of experience driving and risk-taking behaviors. Defined later in this chapter, graduated driver licensing (GDL) systems are an effective crash prevention strategy for teen drivers and are the likely reason fewer teens are currently licensed. In 2000, 37% of 16 year olds were licensed drivers compared with 31% in 2009, among 17 year olds, the decline was from 57% to 49%, and among 18 year olds, the decline was from 70% to 64% [8,9].

Older drivers, aged 65 years and older, represent a fast growing segment of the driving population. In just 10 years time, from 2000 to 2009, the number of older licensed drivers grew 20% to 33 million, nearly 16% of the driving population in the country. The proportion of the population who are licensed drivers has also increased in this age group: in 2000, 88% of 65–69 year olds were licensed drivers; in 2009, this had increased to 94%. Similar increases were seen in all older age groups, including those aged 85 years and older, who increased from 48% to 58% [8,9].

Per mile traveled, fatal crash rates increase starting at age 75 years and increase notably after age 80 years. This is largely due to an increased susceptibility to injury and medical complications among older drivers rather than an increase in crash involvement [10]. However, age-related declines in vision and cognitive functioning, as well as physical changes, may affect some older adults' driving abilities. The American Medical Association has resources for physicians to assess and counsel their patients [11].

There are also racial and ethnic differences in crash-related deaths. Generally, American Indian and Alaska

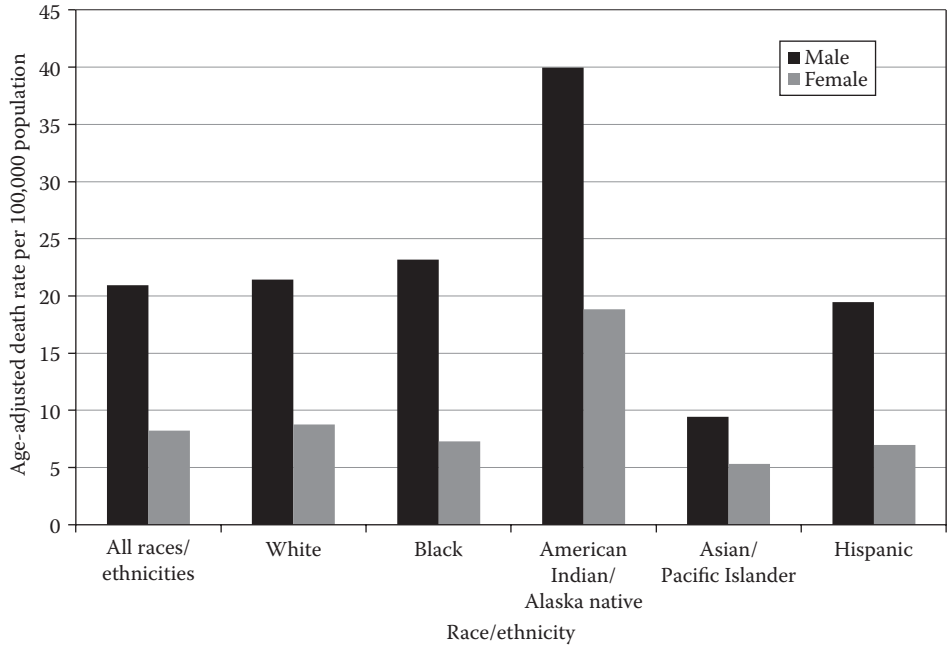

FIGURE 123.2 Motor vehicle-related death rates by race/ethnicity and sex, 2007. (From Centers for Disease Control and Prevention, Web-based Injury Statistics Query and Reporting System [WISQARS].)

Native populations have the highest death rates, while Asian and Pacific Islander populations have the lowest; African American and white populations have similar death rates [5]. However, when adjusting for time on the road, or vehicle miles traveled, vehicle occupants who are African American and Hispanic have higher death rates than whites [12]. Racial and ethnic minorities are disproportionately affected by motor vehicle crashes; approximately 7% of all deaths among American Indian and Alaska Native populations are due to crashes, 5% of all deaths among Hispanics are due to crashes, while less than 2% of all deaths among African American and white populations are crash-related [13]. Figure 123.2 shows age-adjusted motor vehicle-related deaths rates by race/ethnicity and sex. For all racial/ethnic groups, males have higher death rates than females; American Indian and Alaska Native males have higher deaths rates than all other groups [5].

Death rates vary by road user type. Motor vehicle occupants (drivers and passengers) represent the majority of crash deaths, 72%, motorcyclists represent 13%, pedestrians 12%, cyclists 2%, and others 1% [14]. However, these unadjusted statistics do not incorporate exposure to the road environment into their calculation. For example, motorcyclists represent 13% of the crash deaths but only 3% of all registered vehicles and 0.4% of all vehicle miles traveled. Per vehicle mile traveled, motorcyclists are 37 times more likely than a passenger car occupant to die in a crash [15]. Alcohol is prevalent in crashes among motorcyclists; the percentage of drivers with a blood alcohol concentration (BAC) of 0.08 g/dL in fatal crashes was highest for motorcyclists at 29% [16]. For nondrivers, the prevalence of alcohol impairment in fatal crashes was also considerable. Among cyclists killed in crashes, 24% had a BAC of 0.08 g/dL or higher [17]. Among pedestrians killed in crashes, 35% had a BAC of 0.08 g/dL or higher [18].

States vary in the number and rate of traffic crash deaths, the use of seat belts, the incidence of self-reported drinking and driving, the proportion of urban versus rural area, the coverage of level one trauma care centers, safety legislation, and many other factors related to the risk of a crash and the risk of death or injury given a crash has occurred. Consequently, as shown in Figure 123.3, there is nearly a fivefold difference in death rates [5].

EFFECTIVE INTERVENTIONS

While this chapter focuses primarily on strategies designed to modify personal behaviors, it also includes some information on vehicle safety devices and public policies (such as legislation and enforcement) that address other countermeasures. Most strategies, however, are ultimately designed to change the behavior of drivers, passengers, or pedestrians. The intent is to provide a practical review of interventions designed to reduce traffic crash deaths and injuries that can be supported by clinicians, whether through patient education in clinical settings or by advocacy to support effective public policy.

Alcohol-Impaired Driving

In 2009, 32% of all traffic deaths (around 11,000) involved a driver with a BAC of 0.08 g/dL or higher, a level illegal in every state [16]. Each year, millions of adults admit to an estimated 147 million episodes of alcohol-impaired driving [19], yet only a small proportion, 1.4 million, are arrested for this offense [20]. Progress has stalled in this area; while the

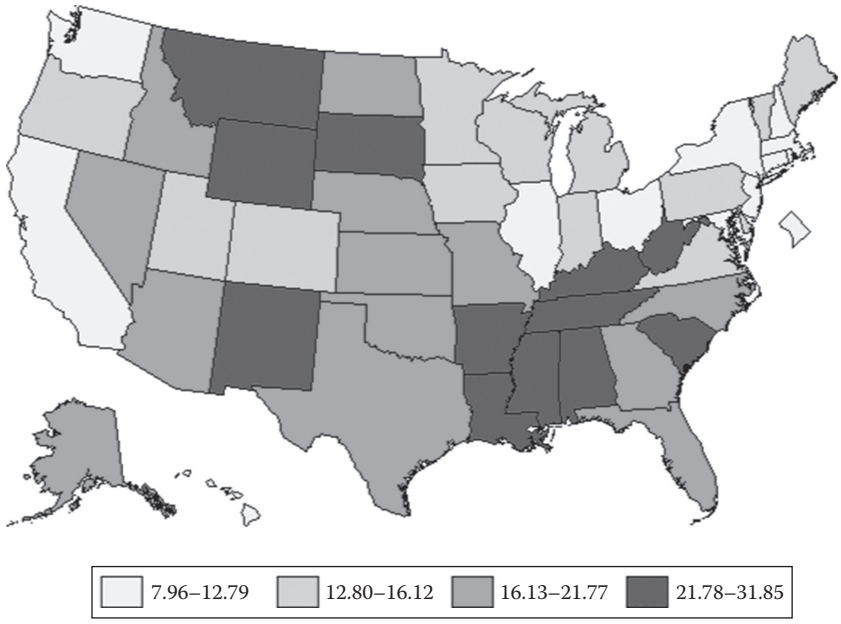

FIGURE 123.3 Age-adjusted death rates per 100,000 population by state. (From Centers for Disease Control and Prevention, Web-based Injury Statistics Query and Reporting System [WISQARS].)

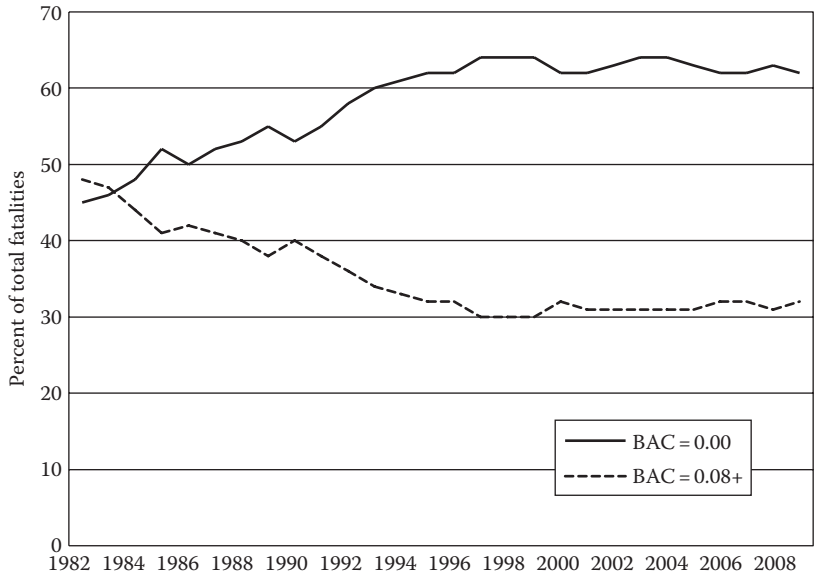

FIGURE 123.4 Proportion of persons killed, by highest driver blood alcohol concentration (BAC) in the crash, 1982–2009. (From National Highway Traffic Safety Administration, Traffic Safety Facts 2009, Early Edition.)

number of alcohol-related traffic deaths has declined with the overall decline in all traffic deaths, the proportion of traffic deaths that are alcohol-related has stabilized. Figure 123.4 shows that since the late 1990s, this proportion has hovered around 30% [21].

Interventions to reduce alcohol-impaired driving include the following:

Zero Tolerance Laws

These laws make it illegal for persons younger than 21 years to drive after any drinking, but the threshold is usually set at 0.02 g/dL BAC. These laws have been associated with declines in alcohol-related deaths [22,23]. Voas et al. found declines from 19% to 24% in underage drinking drivers in fatal crashes [24]. All states have passed zero tolerance laws for young drivers.

Minimum Legal Drinking Age Laws

Minimum legal drinking age (MLDA) laws are effective in reducing alcohol-related crashes and injuries [23,25]. This type of law is especially important given the high crash and death rates of young drivers [24,26–28]. At the same blood alcohol level, crash risk is higher for young drivers than older drivers [29]. All states have increased their MLDA to 21 years, the National Highway Traffic Safety Administration (NHTSA) estimates more than 600 lives saved in 2009 due

to MLDA laws [30]. Lowering the MLDA so that younger people can legally purchase alcohol can increase alcohol-impaired crashes by a median of 10% [23].

Sobriety Checkpoints

Alcohol roadside checkpoints, whether randomly or selectively implemented, are an effective law enforcement intervention. Sobriety checkpoints are generally paired with media efforts to publicize the effort, which helps to increase the perceived risk of arrest. Sobriety checkpoints have been shown to decrease fatal and nonfatal injury crashes [31].

Lower BAC

BAC laws make it illegal "per se" to operate a motor vehicle at or above a specified BAC. Originally set at 0.10 or 0.15, these laws have had their limits lowered over time; 0.08 g/dL BAC laws have been found effective in reducing alcohol-impaired driving [22,23,28]. All 50 states have passed 0.08 g/dL BAC laws that place the legal "per se" limit for driving after drinking (for adults) below 0.08 g/dL. The United States lags behind many other countries that have reduced their legal BAC limit for drivers to under 0.05 g/dL [32].

Ignition Interlocks

These devices prevent a drinking driver from starting the vehicle by requiring the driver to provide a breath sample before starting the vehicle. If the breath sample exceeds a specified blood alcohol content, the ignition is locked, and the vehicle will not start. Reports that have combined data from multiple studies estimate that interlocks account for 65% reductions in driving while impaired (DWI) recidivism, a beneficial effect that is usually limited to the period of installment [33–35]. Because drivers with a prior (DWI) violation are seven times more likely to have a subsequent violation than drivers without a history of DWI [36], ignition interlocks should be considered for all convicted DWI offenders—even first-time offenders.

Server Intervention Training

Server intervention and training programs are designed to prevent patron intoxication and alcohol-impaired driving by offering food with drinks, delaying service to rapid drinkers, and refusing service to intoxicated patrons. Evidence for effectiveness comes from studies of establishments that volunteered to participate in training servers; therefore, management support was well established, and server training was intensive, high quality, and face-to-face (not video training) [23].

Screening and Brief Intervention

Screening for heavy alcohol use and subsequent brief intervention has been found effective in emergency departments [37], trauma centers [38], and primary care settings [39]. A study by Fleming et al. found that two 15 min sessions with a physician followed by two 5 min telephone calls from an office nurse resulted in sustained effects. The treatment group had significant reductions in 7-day alcohol use, number of binge drinking episodes, and frequency of excessive drinking compared to controls. In addition, the treatment group had fewer days of hospitalization and fewer emergency department visits. The largest cost benefit was due to fewer motor vehicle-related events [39]. These results indicate that a modest investment in time and resources can have a clinically important effect that is maintained over several years.

Increasing Alcohol Taxes

Alcohol excise taxes affect the price of alcohol and are intended to reduce alcohol-related harms, raise revenue, or both. Alcohol taxes are implemented at the state and federal level and are beverage specific (i.e., they differ for beer, wine, and spirits). A systematic review of 73 studies looking the relationship between either tax rates or total price on measures related to excessive alcohol consumption and its harms found consistent evidence that higher alcohol prices were associated with less youth drinking. The bulk of the studies showed higher prices were related to fewer traffic crashes and deaths, less alcohol-impaired driving, less mortality from liver cirrhosis, and less all-cause mortality. Effects were also demonstrated for outcomes of violence, sexually transmitted diseases, and alcohol dependence [40].

Occupant Protection

Occupant restraints, including lap and shoulder belts, CSS, and booster seats, are among the most effective injury prevention interventions available. Seat belts reduce the risk of death and serious injury in a crash by about half [41]. CSS are 71% effective in reducing fatalities among infants and 54% effective among toddlers. An estimated 284 children younger than 5 years were saved in 2009 by CSS [42]. Booster seats are 59% more effective than adult belts alone in reducing injury in age- and size-appropriate children [43].

Interventions to increase occupant protection include the following:

Seat Belts

Seat belts provide the greatest protection available to drivers and occupants. The National Occupant Protection Use Survey conducted in 2010 found belt use to be 85% nationwide [41]. To date, 49 states, the District of Columbia, Puerto Rico, and all U.S. territories have adult seat belt use laws in place. Primary enforcement laws allow a law enforcement officer to stop a motorist based on a belt violation alone, while secondary enforcement laws require another reason to stop a motorist other than a seat belt infraction. Both primary and secondary enforcement laws are effective in increasing belt use and reducing fatal and nonfatal injury, with primary laws showing the greatest effectiveness [44–46]. As of January 2011, 19 states do not have primary enforcement laws [47]. Enhanced enforcement programs of seat belt laws, through more officers on patrol, or by increasing the number of citations issued, are also effective in reducing fatal and nonfatal injuries and increasing belt use [44].

Child Safety Seats

All states require children to be restrained, although the specifics of coverage vary [48]. CSS use laws require children to be restrained in federally approved safety seats appropriate for the child's age and size. CSS use laws decrease fatal and nonfatal injury and increase CSS use. Distribution of safety seats, plus CSS education programs, in combination, have been found to decrease fatal and nonfatal injury, increase CSS use, and increase possession of CSSs. Community-wide information plus enhanced enforcement campaigns have also been found to increase CSS use. Finally, incentive plus education programs (including rewards for either parents or children for correctly using CSS) have been shown to increase CSS use [49,50].

Booster Seats

Booster seats are designed to raise a child so that the vehicle lap and shoulder belts fit properly. They are recommended for children until they reach 4 ft 9 in. tall, usually between ages 8–12 years [51]. A systematic review of the impact of various legislative, educational, and promotional interventions among children aged 4–8 years found that interventions that combined education with distribution of booster seats or incentives such as discounted coupons had the greatest positive impact [52]. Moreover, booster seat legislation has been shown to reduce injury and save costs [53,54].

Rear Seating Position

The number of children sitting in the front seat is declining. Although the catalyst for moving children to the rear seat was the danger from passenger-side air bags, rear seating position is still the safest place for children whether or not there is a passenger-side air bag present [55–57]. A recent study found that children in the rear row(s) of the vehicle were one-half to two-thirds as likely to sustain injury than those in the front [58].

Motorcycle Helmets

Motorcycle helmets are estimated to be 37% effective in preventing fatal injury to motorcyclists [59], and 72% effective in reducing head injury [60]. Helmet use is especially important since, per vehicle mile traveled, motorcyclists are about 37 times more likely to die in a crash than passenger car occupants. Motorcycle helmet use laws are effective. In states with mandatory or universal (covers riders of all ages) helmet use laws, 76% of motorcyclists wear them—without a law, use is 40%. In 2010, 20 states plus the District of Columbia required helmet use by all operators and passengers. An estimated 71% of motorcyclists wore helmets in 2000, compared with only 54% in 2010 [61].

Bicycle Helmets

Bicycle helmets are effective in preventing head injury, brain injury, facial injury, and death [62–64]. However, only about half of children aged 5–14 years always wear their helmets when riding, and less than half the states in the United States have statewide helmet laws in place [65]. Interventions designed to increase bicycle helmet use generally target children and adolescents, as does legislation requiring helmet use. Legislation with supporting helmet promotional activities has successfully increased observed helmet use and reduced injury and death in the United States and abroad [66–69]. Community-based interventions that included free helmets and an educational component had the strongest evidence of effectiveness, along with school-based interventions and those that subsidized helmets [70].

Graduated Driver Licensing Systems

Motor vehicle crashes are the leading cause of death among teenagers in the United States. GDL systems address the high risks faced by new drivers by requiring an apprenticeship of planned and supervised practice (learners permit stage) followed by a provisional license that places temporary restrictions on unsupervised driving [71]. Two commonly imposed restrictions are limits on nighttime driving and passenger limits. These restrictions are lifted as new drivers gain experience and teenage drivers mature (full licensure). Although the specific requirements for advancing through the three stages of GDL vary across jurisdictions, they provide a protective environment, while new drivers become more experienced. GDL has proven effective in reducing new driver crash risk, and the stronger the policy the stronger the effect [72–76]. The most restrictive GDL policies were associated with a 38% reduction in fatal crashes among 16 year old drivers [77]. Figure 123.5 shows the number of states with GDL plotted by the fatal crash rate involving 16 or 17 year old drivers and indicates that the more states with GDL systems, the better the outlook for young novice drivers [21,78].

An issue related to GDL and teen driver safety is driver education resulting in early licensure. Early licensure can lead to increased exposure of inexperienced drivers and to

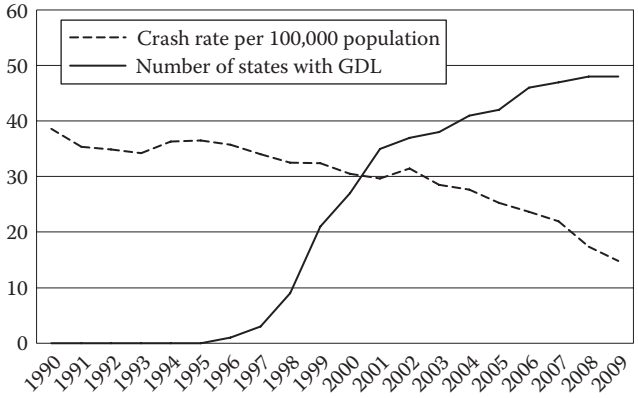

FIGURE 123.5 Fatal traffic crashes involving 16 or 17 year old drivers, United States, 1990–2009 and number of states with a graduated driver licensing (GDL) system. **GDL is defined as a graduated driver licensing law that includes an intermediate stage (From National Highway Traffic Safety Administration Traffic Safety Facts 2009; Insurance Institute for Highway Safety, Highway Loss Data Institute.)

more crashes. School-based driver education training can often lead to earlier licensure, which can be harmful. Studies by Levy, Vernick et al., and Roberts and Kwan [79–81] have consistently indicated that young drivers who take driver education tend to get their licenses earlier than young drivers who do not. Any potential safety benefit from the driver training may be offset by the increase in exposure of teens to unsupervised driving.

Parental Monitoring of Young Drivers

Although not definitive, there are studies of the effect of parental monitoring on young driver safety. Results have varied from indicating no effect to modest effects on risky driving behaviors [82]. However, parents are in a strong position to delay licensure and to restrict driving under higher risk conditions, such as nighttime driving and driving with teenage passengers [83,84], whether or not these restrictions are part of their states' GDL law. Research has shown that teens whose parents set and maintain strict limits are less likely to engage in risky driving behaviors, have traffic violations, or to crash during the first year of licensure [84]. Clinicians are in a unique position to counsel parents about their responsibility and effectiveness in keeping their teens safe on the road.

Automated Enforcement: Speed Cameras

Speed affects both the likelihood of a crash and the severity of a crash. Crashes at higher speeds are more severe and, therefore, the risk of injury is greater. For vulnerable road users, such as pedestrians and cyclists, this is especially problematic. Automated enforcement is one way to obviate conventional enforcement, which requires law enforcement officers to stop drivers and issue citations and the likelihood of being caught speeding is relatively low. Automated speed enforcement has been shown to reduce speeds and speeding violations [85]. Reviews of the effectiveness of speed cameras have found decreases in both crashes and injuries [62,86,87].

INTERVENTIONS WITH LIMITED EVIDENCE OF EFFECTIVENESS

Legislation to Restrict Cell Phone Use While Driving

Research has shown that drivers using cell phones are four times more likely to be involved in a serious crash [88]. Research by the AAA Foundation found that 69% of drivers reported that they had talked on a cell phone while driving in the past 30 days [89]. Cell phone legislation varies with some states or localities banning handheld devices, some banning use among young drivers or bus drivers, and some state bans including texting while driving. Although most people agree that using a cell phone while driving is unsafe, the effectiveness of legislation to address this problem has yielded inconsistent results [82]. A paradox for safety researchers is the increasing use of cell phones during a time of declining crashes.

Designated Driver Programs

A designated driver is a person who agrees to either abstain or limit alcoholic consumption and drive others home. Designated driver promotion programs set in restaurants or drinking establishments encourage individuals to act as designated drivers by offering incentives such as free nonalcoholic drinks, food, or free admission. Despite their widespread use in the United States, relatively few programs have been thoroughly evaluated. A systematic review of designated driver programs in drinking establishments found insufficient evidence of their effectiveness in reducing alcohol-impaired driving or alcohol-related crashes [90]. A more recent review by Nielson and Watson found that while awareness and use of designated drivers may increase, evidence of a reduction in drinking and driving or alcohol-related crashes has not been well documented [91].

IMPLICATIONS FOR PRIMARY CARE PRACTICE

Despite the great success in reducing motor vehicle-related death rates in the past 50 years, motor vehicle crashes remain the leading cause of injury-related deaths in the United States. Primary care practitioners have the opportunity to reduce death and injury using a variety of strategies, including screening and counseling [92–94]. Practitioners also can help patients understand the importance of reducing their exposure to risk on the road and the importance of safety behaviors. In clinical practice, traffic injury prevention can become a regular part of the practice of lifestyle medicine and integrated into care and preventive services. Science tells us that traffic injuries are not "accidents"—they are predictable and preventable. Through efforts to educate and change behaviors, promote stronger traffic safety legislation and enforcement, and encourage more effective use of technology and engineering, lifestyle medicine can contribute to reducing traffic injuries and help promote a culture of safety [95].

Unintentional injury poses a significant health threat for children. In most industrialized nations,[1] including the United States, unintentional injuries are the leading cause of death for children older than 1 year of age.[2,3] In fact, the number of injury-related child deaths in the United States exceeds that of the next nine causes combined.[2] Approximately 12,000 Americans of 0–19 years die annually from an unintentional injury, about 33 children per day.[4] The financial burden is staggering. For example, in 2000, injuries to American children cost an estimated $24 billion in lifetime medical expenses and $82 billion in present and future work losses, including the caregiver's income loss.[5] Of course, these costs do not even account for the burden of suffering and reduced quality of life that can result from injury. There is a pressing need to identify the key factors that influence the risk of injury to children so that interventions can be developed to address these issues.[6–8]

Caregivers can substantially influence children's risk of injury,[9] particularly for toddlers and preschool-aged children whose injuries often occur in the home when they are presumably being supervised by a caregiver.[10–12] Because many of these injuries have been judged to be preventable,[13] there has been considerable interest aimed at understanding what caregivers do, why they make the choices they do about safety practices, and how to motivate them to make better choices in order to reduce children's risk of injury at home. Historically, this research has focused primarily on environmental modifications by caregivers (e.g., use of safety devices, hazard removal practices)[14–18]; however, recognition that not all risks can be addressed by environmental modifications has fueled interest in studying supervision as a risk management strategy.

WHAT IS "SUPERVISION"?

For the most part, past research on "supervision" did not specify a definition of the term. And those definitions that have been published are often vague and not based on any conceptual framework about supervision. Moreover, often in past research, the *act of supervising* (i.e., directly observing and attending to the child) and *monitoring* from a distance based on prior knowledge of the child (i.e., the child is not in view but the supervisor has sufficient prior experiences to surmise where the child is likely to be and what she or he is probably doing) have been used interchangeably as indicators of "supervision" even though it has never been confirmed that a supervisor's past knowledge about a child's behavior is an adequate substitute for directly observing and attending to that child's actual behavior. Given that studies of childhood injuries have highlighted how unpredictable young children's behavior can be,[19] Morrongiello has argued that direct "attention" to confirm what the child is doing is an essential aspect to defining "supervision" if one is interested in relating the construct to injury risk.[20] Monitoring from a distance, therefore, may be more developmentally appropriate and commonplace than direct observation for older school-age children, but this is not likely to yield as many protective benefits as direct observation in which one frequently confirms the child's location and activity.[21] Consistent with this view, low levels of monitoring (i.e., awareness of a child's activities and location) have been associated with high levels of problem and risk-taking behaviors,[22] as well as with more frequent injuries.[23]

Drawing on this developmental literature, Morrongiello recently proposed a definition of supervision to guide

research on children's risk of injury.[20] Three dimensions of behavior are considered in the definition: *attention* (extent of watching and listening, which is relevant for determining when to intervene), *proximity* (within versus beyond arm's reach, which is relevant to readiness to physically intervene with a child who may not comply with a verbal directive[24]), and *continuity* of attention and proximity (coded as constant, intermittent, not at all). Maximum supervision and lowest risk of injury occur when a supervisor is attentively watching and listening to the child, is in the closest proximity possible (i.e., touching), and these behaviors are sustained and constant over time. Any change in one or more of the three dimensions (e.g., being farther from the child, lack of constant attention) would result in lower levels of supervision and, therefore, increase injury risk. The usefulness of this definition has been confirmed in studies that have found that distinct patterns of supervision systematically relate to children's frequency of injury (see the following literature).

WHAT IS "ADEQUATE" SUPERVISION?

A number of factors influence the level of supervision needed to ensure a child's safety, making it difficult to determine what constitutes "adequate" supervision. A child's developmental level, often indexed by age, is one such factor. Not surprisingly, young children require continuous, close supervision to ensure their safety in most situations, and the need for continuous, direct supervision declines with increasing age during childhood.[23,25] There are no guidelines or minimal standards for supervising children at different ages, however, and professionals do not agree about possible guidelines.[25] The most common approach, therefore, is to set a minimum legal age at which children can remain at home unsupervised. It should be emphasized, however, that these cutoff ages are not based on any scientific evidence, which is probably why they vary so much across jurisdictions (e.g., some states set this cutoff as young as 8 years and others as old as 13 years).

Situational context is another variable that impacts what constitutes "adequate" supervision. When environmental risk is high, it is generally accepted that time unsupervised should be minimal to ensure a child's safety,[25,26] and evidence based on studies of pediatric farm injuries confirms this.[27] Furthermore, Morrongiello and her colleagues examined supervision at the time of farm injuries[19] and found that one-third of the children who were injured were receiving what would typically be considered "adequate" supervision (i.e., acceptable levels of attention, proximity, and continuity). This increased injury risk under presumably adequate supervision reflects the fact that when children are on a farm, being in *close proximity* to an adult often means *greater* exposure to hazards (e.g., machinery, animals) because the adult is working. Findings such as these highlight the challenge of determining what constitutes "adequate" supervision. Simply stated, if both child age and situational context interact to influence the risk, it may be unrealistic to create one set of guidelines that aims to protect all children in all circumstances.

HOW SHOULD SUPERVISION BE MEASURED?

A variety of approaches to measuring supervision have been used in research, including questionnaires, naturalistic observations, and self-report diary measures. When questionnaires are used, parents are often asked to describe how they supervise their own children[24,28–36] or how they would supervise a child in particular situations.[25,26,37,38] Sometimes parents have listened to story vignettes or watched videos about children engaging in risky behaviors and then reported on how they would react if they were supervising the child shown.[39] A handful of studies have used participant event-monitoring, in which parents have been asked to keep track of their actual supervision over a 24 h period and over days.[26,35,40–44] Supervision at times when children happened to be injured can then be compared to times when the child was not injured, providing insight into patterns of supervision that are associated with injury. Although a potential limitation of self-report measures is the possibility of response bias in that parents may be reluctant to report information if they feel it could reflect poor parenting skills, the fact that parents readily report leaving their child unsupervised (see next section) suggests that this concern may not apply in these research studies.

Morrongiello has suggested an alternative approach to self-reports about supervisory practices, namely, to focus on measuring parent attributes (e.g., attitudes toward supervising closely, beliefs about children's need for close supervision, parenting values related to safety, personality traits that impact parent practices such as conscientiousness) that provide a foundation for parenting decisions and supervisory "styles" (i.e., consistent behavioral patterns or approaches to supervising). Applying this approach, she developed the Parent Supervision Attributes Profile Questionnaire (PSAPQ[29]), which measures parental attributes that have been shown to influence supervision decisions. Psychometric evaluations have shown that the measure is both reliable and valid.[30] High scores on the PSAPQ have been shown to predict closer supervision and low scores to predict poorer supervision in naturalistic observation situations, and these scores positively relate to children's frequency of both risk taking and injuries. Recently, this approach was extended to develop a similar measure (Supervision and Risk Taking Questionnaire) that applies to the supervision of elementary school children[45]; preliminary testing of the measure shows good validity and that scores relate as one would expect to measures of actual parental supervision and children's frequency of injuries.

Observational studies are also an excellent approach to measuring supervision as they provide insights into how caregivers supervise in typical situation.[46–50] For example, Harrell conducted a series of naturalistic observations of children and their supervisors in the grocery store and found reliable variations in child risk behaviors depending on supervision patterns.[51–55] Although observational studies are high on ecological validity, they are very time and labor intensive and not applicable to all settings (e.g., home). An alternative

approach that has been developed is to conduct naturalistic observations in a laboratory setting that contains "contrived" hazards, that is, hazards that appear real but that have been modified to pose no real risk of injury (e.g., blue water in a Windex bottle, glue-shut sharp scissors).[24,56] This approach creates a "simulated" risk situation, and if supervisors' reactions are unobtrusively video recorded, then one can obtain a highly accurate index of "typical" supervision practices in situations that pose some risk of injury. Although not all injury risks are amenable to being recreated in a contrived situation, this is an excellent approach to measuring supervision under seemingly natural conditions for those hazards that can be so represented.

Supervision and Injury: A Complex Process

It has long been assumed in the child injury literature that supervision must serve a protective role and prevent injury, particularly for preschool children who have limited capacity to keep themselves safe.[9,57,58] Some have gone so far as to argue that if an injury can be attributable to inadequate supervision, then this should be reported as child abuse/neglect.[59] Most of this speculation about supervision, however, is fueled by "indirect" evidence, such as the fact that there is increased frequency of injuries for children living in families with only a single parent[69] or with multiple siblings at home.[70] Although insufficient caregiver attention has been mentioned as a contributing factor for a variety of types of childhood injuries (drowning,[60] pedestrian injuries,[61,62] poisoning,[63] choking,[32] playground injuries,[64] dog bites,[65] escalator injuries,[66] falls,[51] and injuries from handling dangerous substances in grocery stores[54] or at home[67]), this is based on logical arguments rather than evidence.[68] Studies aimed at directly examining links between supervision and child injury risk have only recently been conducted, and the findings suggest a more complex interrelation than previously thought.

SUPERVISOR PRESENCE INFLUENCES CHILDREN'S RISK TAKING

Not surprisingly, individuals behave differently depending on whether or not a supervisor is present. School-age children have been shown to behave more cautiously when a supervisor is nearby.[71,72] Similarly, young children have been shown to engage in more risky play activities at supermarkets and playgrounds when supervisors are more distant physically.[29,51] Even adult and child swimmers have been shown to violate more rules in public pools when there are fewer lifeguards present.[55]

Sex differences in how boys and girls behave when a supervisor is present also have been noted. For example, in a prospective study of home injuries and caregiver supervision patterns, the intermittent appearance of a parent supervisor was sufficient to reduce girls' risk taking to the low level observed when the supervisor was continuously present. In contrast, boys' risk taking was as high in frequency as when they were completely unsupervised for an extended period of time.[35] Similarly, unobtrusive observations of parent–child dyads in injury-risk situations revealed that boys do more ignoring of supervisors than girls, resulting in caregivers needing to enact increasingly more effortful supervision strategies (e.g., when verbal redirections are ignored, they then need to physically redirect the child) to ensure that boys do not interact with hazards.[24]

In summary, the presence of a supervisor often reduces children's risk taking, and for girls even the intermittent appearance of a supervisor achieves this outcome. Generally, even if the supervisor is continuously present, boys require more effortful supervision efforts than do girls to keep them safe.

SUPERVISORY BEHAVIORS AND CHILD INJURY

Ideally, parents should engage in the highest level of supervision possible (i.e., continuous watching, close proximity); however, this is not often the case. Consistent with social-cognitive models of health behavior,[73] research indicates that parents are "strategic" in allocating effort. Hence, the safety strategies they implement vary with their injury-risk appraisals (likely occurrence of the injury, beliefs about their child's personal vulnerability, the potential injury severity, and the extent to which they attribute injuries to bad luck), as well as parent characteristics (e.g., personality characteristics such as conscientiousness, parenting style such as permissiveness), environmental context (e.g., presence of hazards), and perceived child attributes (e.g., age, personality).[35,44,74–79] For example, parents engage in more child safety practices if they believe that resulting injuries are likely to be severe and their child is particularly vulnerable (e.g., due to age or personality); the level of inconvenience to the parent is low in terms of time, cost, or effort; and they feel they have the potential to lower risk and actually prevent injury. In fact, drawing on research on the determinants of parents' safety practices, Morrongiello developed an evidence-based conceptual model (see Figure 124.1) that illustrates the multi-determined nature of childhood injury risk and how factors often interact to influence parent safety decisions and determine injury risk.[20] Similarly, complex interactions among risk factors are emerging in research relating caregiver supervisory behaviors to children's risk of injury.

Evidence that supervision relates to frequency of children's injuries has been reported in a number of studies. For example, in a prospective study of children's minor injuries in the home, examining the patterns of supervision provided by parents to 2–3 year-olds at the time of injury revealed five levels of supervision, and as supervision level decreased, there was an increase in the frequency of children's injuries.[35,79] Similarly, research relating reports of supervision on a questionnaire measure (PSAPQ[29,30]) to children's injury histories revealed that mothers who more strongly endorsed statements indicative of supervision (e.g., "I keep a close watch on my child") had children with a history of fewer injuries. Most recently, applying a case–control design, the supervision

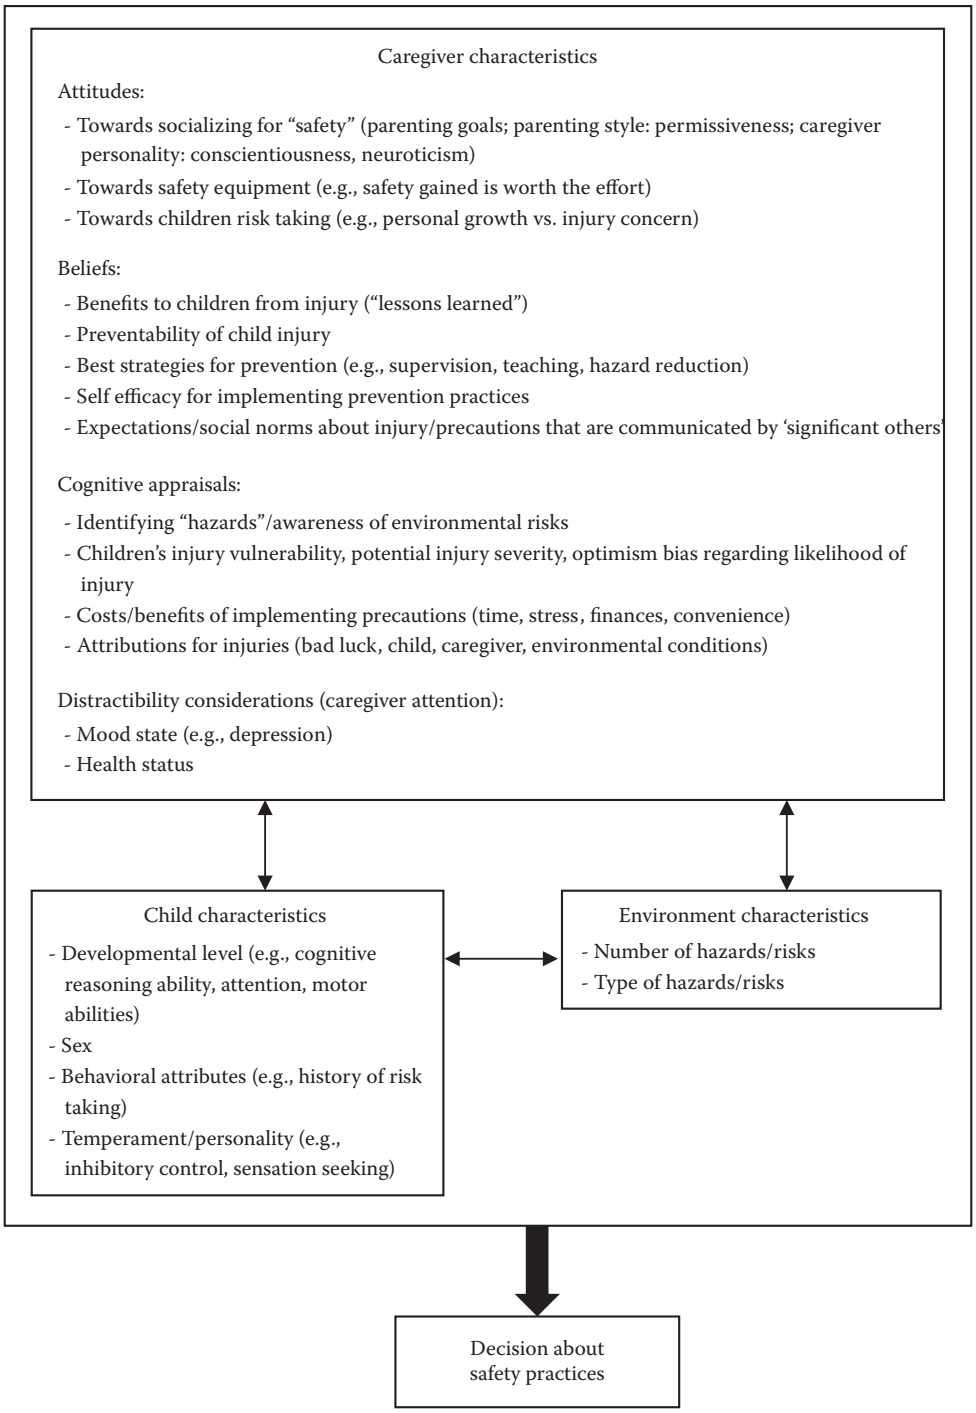

FIGURE 124.1 Empirically derived conceptual model representing the dynamic interplay of factors that affect caregivers' decisions about whether or not to implement safety precautions to prevent injury to young children. (Adapted from Morrongiello, B.A. and Corbett, M., *Health Psychol. Rev.*, 2, 191, 2008.)

provided "injured children" (cases) at the time of injury was compared with that experienced by same age/sex-matched "uninjured ill children" (controls) the last time they did the activity that resulted in injury to their matched case, with all children recruited at the same hospital emergency department to match for demographic characteristics.[80] Results revealed significantly lower levels of supervision for injured than uninjured children, and this pattern emerged across several measures of supervision. Thus, a number of studies have now confirmed that at the time of injury (minor or medically attended), there is often a reduced level of supervision relative to noninjury times.

Complexity in the relation between supervision and injury risk emerges, however, when one considers the more general question of "how caregivers *routinely* supervise" on a day-to-day basis. This research reveals that young children are

unsupervised (i.e., parent does not know where the child is or what the child is doing) for up to 8% of their awake time when at home with a parent and they are completely out of view of supervisors an additional 20% of their awake time.[44] The fact that not all children incur injuries under reduced supervision conditions, however, raises questions about why reduced supervision poses injury risk for some children more so than for others.

Exploring the possibility that child behavioral attributes *interact* with supervision to increase injury risk for some children, Morrongiello and her colleagues found mothers altered their level of supervision according to their beliefs about their child's behavioral attributes.[35,78] Moreover, supervision statistically moderated the relation between several of children's behavioral attributes and injury outcomes, confirming that injury risk arises from an *interaction* between child behavioral attributes and caregiver supervision level.[81] Children who scored high in behavioral intensity had a history of more medically attended injuries when their parents reported reduced supervision but not when their parents reported close supervision. Thus, more intense supervision counteracted the elevated risk of injury typically found for temperamentally difficult children.[82,83] On the other hand, the child attribute of inhibitory control (e.g., child can exercise self-control and resist doing things prohibited by a caregiver) always served a protective function; thus it predicted fewer medically attended injuries even under conditions of *reduced* supervision. Children high in sensation seeking (i.e., the tendency to seek novel and excitement-eliciting risky activities),[84] experienced increased risk of medically attended injury *regardless* of the level of supervision, whereas for children low in sensation seeking, less supervision was associated with more frequent injuries. Figure 124.1 illustrates the dynamic interplay of these various risk factors.

Overall, the pattern of these findings suggests that high levels of supervision can counteract the potential negative effect on injury risk of some child attributes, thereby serving a protective or risk-reducing function. However, there are some attributes (sensation seeking) for which this is less likely to occur and there are other attributes (inhibitory control) for which supervision is less relevant for children's injury risk. Thus, relations between supervision and injury are complex, and it is not always the case that more supervision is necessary or sufficient to reduce children's risk of injury. This type of complexity mitigates against formalizing guidelines about "adequate" supervision that can apply broadly to all children in all circumstances.

Additional evidence that supervision interacts with child behavioral attributes to influence injury risk can be found in the limited research examining siblings as supervisors. Younger siblings are one-third more likely to be injured when supervised by an older sibling, particularly when the supervisee is less than 2 years of age and there is less than a 2 year interval between children.[85] Although few studies have explored how often siblings act as primary supervisors in North America, one study in the United States found that this occurred 8% of the time after school[86] and another in Canada reported 11% of the time when sibs were awake and at home together.[87] The general assumption in the literature has been that the risk arises because older children who supervise younger siblings lack the judgment[85] and cognitive skills[88] to effectively deal with young children and they are, therefore, poorer supervisors than adults. Recent evidence, however, reveals a more complex process than this and suggests that both supervisee *and* supervisor behaviors elevate the risk of injury to the supervisee.

Research examining injury history scores of supervisees and relating these to the extent of sibling supervision has shown that the more often siblings (approximately 6 years of age) supervised, the more frequently younger children (approximately 2 years of age) experienced minor and moderately severe injuries.[87] When parents were asked to comment on this finding, they believed that older siblings supervised in similar ways to parents but that younger children were less compliant with sibling supervisors. And, in fact, parents' ratings of their younger child's compliance when the older sibling was supervising predicted the younger child's frequency of injury better than how often the older sibling supervised. Consistent with this finding, recent evidence comparing how young children behave with sibling versus parent supervisors reveals greater noncompliance by supervisees in response to sibling than parent supervisors.[89] In fact, negative cyclical interactions between younger and older siblings occurred often when siblings supervised, fueled by both noncompliance from the supervisee and a high frequency of prohibitions from the supervisor, and this often then detracted attention from the actual safety issue.

Direct comparisons of the supervisory practices of sibling and parents when looking after a younger child in the family have shown, in contrast to what parents believe (see earlier text), that older siblings are *poorer* supervisors than parents. Specifically, parents engaged in more proactive safety behaviors by removing hazards, whereas older siblings more often modeled injury-risk behaviors by interacting with interesting hazards and this then led supervisees to interact with these same hazards. Although supervisees displayed more injury-risk behaviors when supervised by a sibling, sibling supervisors were less attentive to supervisee risk behaviors than parents,[90] sibling supervisors reacted to only one-third of risk behaviors by supervisees, whereas parents were more vigilant and reacted to stop most of these risk behaviors. And sibling supervisors reacted to risk behaviors with more forceful prohibitions, whereas mothers adopted a teaching orientation and gave more explanations and directions in response to risk behaviors by the supervised.[90] This was fueled, sibling supervisors were generally mostly concerned with controlling the immediate behavior by the supervisee rather than with promoting understanding about any underlying safety- or rule-based issue. In contrast, mothers' reactions to risk and rule violation behaviors balanced prohibitions

with teaching, and they emphasized explaining about risk and rules to reinforce the supervisee's understanding for the prohibition. From a learning perspective, the reactions of maternal supervisors are more likely to promote understanding by the supervisee and, therefore, to increase the likelihood a young child might avoid the behavior in the future. Moreover, research relating childrearing practices to compliance reports that children who receive more directives and prohibitions by caregivers react with more defiance and noncompliance.[91–94] Thus, frequent forceful prohibitions by sibling supervisors, even when these are appropriately delivered in response to a risk or rule violation by the supervisee, are likely to result in greater noncompliance by the supervisee that then fuels the delivery of further prohibitions and leads to an escalating cycle of negative interactions that increases risk of injury to the supervisee. In summary, the process leading to elevated injury risk among young children when supervised by older siblings is a fairly complex one that involves interactions of behaviors by both the supervisor (poorer supervision) and the supervisee (noncompliance).

ENVIRONMENTAL RISKS

In addition to supervision interacting with child attributes to influence the risk of injury, level of environmental risk is another factor to be considered. Generally, proximity to a supervisor enhances readiness to intervene and, therefore, reflects a high level of supervision that is associated with reduced risk of injury to children. Exceptions to this finding, however, illustrate that the extent of environmental risk matters too.[19]

Based on a retrospective review of the circumstances of 334 pediatric farm injuries that resulted in death or hospitalization, patterns of supervision were coded according to attention, proximity, and continuity. Surprisingly, approximately one-third of injuries occurred under what traditionally would be interpreted as "adequate" supervision, namely, supervision was available, proximal, and continuous. Further analyses revealed that such injuries occurred because, on farms, children who are proximal to adults are typically in the vicinity of environmental hazards (e.g., machinery, animals) because supervising adults are also engaged in farmwork. Hence, while proximity to a supervisor usually increases readiness to intervene and improves supervision, in farm contexts, it often increases exposure to environmental hazards. Coupled with normative unpredictability in how young children behave, this creates risk of injury by increasing the likelihood they will interact with hazards, particularly preschoolers.[27] Thus, defining "adequate" supervision is more complex than assuming greater attention, proximity, and continuity will necessarily translate into a reduction in children's risk of injury. What constitutes "adequate" supervision will likely need to reflect a consideration of the interactions between the environment and child characteristics, and different definitions of "adequate" are likely to be needed for different types of children in different risk environments.[25]

Interestingly, for certain activities and contexts, such as in organized sports, there is debate about not only what constitutes "adequate" supervision but whose responsibility it is to provide this supervision. Should an older child be expected to consistently follow safety rules that have been stated by a coach, making close supervision not essential? Should parents who are present assume responsibility for supervising their children during organized/team sports activities? Are coaches substituting for parents and responsible for supervising every child at all times?[95] Many of these issues remain to be resolved, but there is increasing interest in them given the frequency of children injured when participating in organized sports activities.

Strategies to Promote Supervision

Surprisingly, despite how often supervision is mentioned as a risk factor for injury in the pediatric literature and the relevance it has for parenting neglect,[96,97] there are no published prevention programs that aim to improve supervision. Much is known about strategies to increase caregivers' safety knowledge and/or their use of safety devices for hazard reduction in the home.[14–16,18,98,99] However, supervision probably matters at least as much as household hazards for preventing childhood injury because not all hazards can be removed from the environment.[100] Interestingly, parents do not seem to realize this. For example, in a study of caregiver perceptions of factors that led to child injury in/around the home, poor supervision was not even mentioned as a contributing factor. Instead parents focused on hazards in the physical environment, citing passive prevention approaches as primary ways to improve a child's safety at home.[101] Thus, despite the fact that caregivers recognize that close supervision can promote children's safety,[37] they do not seem to recognize (or are unwilling to admit) that supervisors are implicated when young children are injured. These opinions probably arise out of a need to preserve self-esteem and a positive parental identity[102] and to reduce guilt after a child is injured.[103] It is particularly important, therefore, that messaging aimed at improving caregiver supervision does not evoke defensiveness or challenge parenting identity. In fact, several recent advances have been achieved with regard to identifying messaging that is effective to motivate parents to more closely supervise.

A recent study explored parental reactions to different types of messages about supervision and identified several that were effective to elicit caregivers' commitment to supervising children more closely. Because parents prefer parenting information in a video format[104,105] and this has the added benefit of standardizing message delivery across individuals, the investigators used this approach to present the different types of messages to parents.[106] The 20 min video comprised three phases and incorporated different messaging strategies that were aimed at eliciting distinct cognitive and emotional reactions that would promote a readiness to change and culminate in parents' commitment to changing their supervisory patterns and more closely attending to their child when at home. Focus group testing of the video with

TABLE 124.1
Summary of Key Messages That Parents Endorsed as Promoting a Commitment to More Actively Supervise Their Child

Aim of Message	Messaging Approach
1. Educate about unintentional injuries (i.e., falls, drowning, burns, and poisonings) and evoke interest in knowing more	• Injury statistics • Injury images • Long-term consequences of injury • Mood-inducing sound effects • Discuss unique hazards • Parent testimonials • Questions posed to viewer
2. Empower parent	Reinforce that: • Children depend on their caregivers to keep them safe • Do not ignore "doubts" about leaving child alone • Parents have many positive characteristics, but no one is perfect • Most parents are capable of making even better choices about supervising their children
3. Acknowledge potential barriers to behavior change and suggest strategies to address these and encourage viewers to problem-solve too	• Suggest solutions to common barriers • Normalize parental concern about injuries and emphasize each parent's need to problem-solve to more actively supervise

TABLE 124.2
Mean Ratings (SD) for Each Cognition (Ratings Scale: 1–8) Given by Intervention (n = 40) and Matched Control (n = 40) Parents before and after the Intervention

	Pre-Intervention		Post-Intervention	
Cognition	Intervention	Control	Intervention	Control
Injury severity	7.41 (0.82)	7.33 (0.78)	7.96 (0.50)	7.03 (0.91)
Injury vulnerability	7.05 (0.78)	6.90 (0.93)	7.73 (0.42)	6.76 (0.83)
Injury preventability	5.12 (0.83)	5.14 (0.86)	5.96 (0.96)	4.93 (0.83)
Value of supervision	4.78 (0.68)	4.89 (0.72)	5.35 (0.72)	4.56 (0.86)
Self-efficacy to supervise	5.86 (1.00)	5.62 (0.91)	6.53 (0.75)	5.73 (0.98)

TABLE 124.3
Average Percent of Time (SD) Child Was in View and Out of View of Intervention (n = 40) and Matched Control (n = 40) Parents before and after the Intervention

	Pre-Intervention		Post-Intervention	
Group	In View	Out of View	In View	Out of View
Intervention	80.65 (15.66)	19.35 (15.66)	88.03 (15.55)	11.97 (15.55)
Control	80.86 (14.62)	19.14 (14.62)	79.53 (15.78)	20.47 (15.78)

ethnically diverse parents of children 2–5 years provided a number of insights into what messaging was most effective and what should be avoided. A summary of these key messages appears in Table 124.1.

These findings were then used to finalize the videotape for inclusion as part of the *Supervising for Home Safety Program* in a randomized control trial.[107] Preliminary analyses (based on over half the sample) from this ongoing intervention study reveal a number of positive findings and confirm no differences in demographic characteristics between intervention and control parents at baseline. First, pre- and post-measures of parental cognitions relevant to child injury (vulnerability, severity, and preventability) and supervision (self-efficacy, value of close supervision) were taken. As shown in Table 124.2, parents in the intervention group, but not the control group, showed significant ($p < 0.05$) changes in their beliefs about injuries and supervision in reaction to viewing the videotape. Thus, the video produced the desired changes in beliefs and attitudes related to childhood injury and caregiver supervision.

Most importantly, analyses of the actual supervision shown by parents revealed significant ($p < 0.05$) improvement in supervision (greater watching and keeping the child in view) during the post-intervention phase for the intervention but not the control group; there were no group differences in the extent of supervision scores obtained during the pre-intervention or baseline phase. Thus, the intervention is having a positive impact on parents' beliefs about supervision and their actual supervisory practices. Assuming that these preliminary findings are replicated when the full sample is completed, the *Supervising for Home Safety Program* will be the first intervention that has proven to positively impact caregiver supervision (Table 124.3).

CONCLUSION AND FUTURE DIRECTIONS IN RESEARCH

There is now clear evidence to confirm what has long been assumed in the child injury literature, namely, that the nature and extent of caregiver supervision influence children's risk of injury.[108] Research reveals too that this influence is not just relevant to very young children but operates across a broad age range throughout childhood. While it is generally true that increased supervision is associated with decreased risk of injury, evidence also indicates that other factors can interact to influence this process, including child behavioral attributes, parent characteristics, and level of environmental risk. The complexity of factors that can influence how supervision relates to child injury makes it difficult to prescribe a fixed set of guidelines for what constitutes "adequate" supervision. It may be, for example, that any definition of "adequate" supervision may need to vary for high- versus low-risk environments.[27]

With regard to future research, additional work is needed comparing mothers' and fathers' appraisals of injury risk and their supervisory practices. The few studies that have been

conducted have found no differences between mothers and fathers in their beliefs about the need for supervision of their young children[109] and reactions to their toddlers' risk-taking behaviors.[110] However, school-age children believe that fathers are more likely than mothers to tolerate risks when supervising children.[111] It may be, therefore, that differences in supervision styles between mothers and fathers emerge as children develop and become increasingly independent or in reaction to children behaving differently with mothers and fathers (e.g., differences in compliance, play activities, disclosure about risk taking). Longitudinal research examining bidirectional parent–child interactions is needed to address this issue because the findings could have important implications for developing programs that aim to improve the supervisory practices of parents; possibly, programs would need to target different determinants of supervisory decisions for mothers compared with fathers.

An additional direction for future research is in the area of sibling supervision, which is a very common occurrence in families. It is important that we now know both supervisor and supervisee behaviors contribute to elevate injury risk when siblings supervise. There now needs to be research aimed at identifying ways to modify the behaviors of both the supervisor and the supervisee so that injury risk is reduced. Interventions that achieve this goal might be as simple as having the parent make explicit to both children that the older child is to watch the younger one and the younger one is to comply with directives from the older one.[112] More extensive interventions might involve online training programs for older children that aim to improve supervisory skills and behavior management skills.[113] Thus, research is needed to determine the nature and scope of interventions that are effective to reduce injury risk when siblings supervise younger children in their family.

To conclude, as outlined in this article, there have been many recent advances to our understanding of how supervision influences children's risk of injury. These findings have important implications for clinical practice and anticipatory guidance. The development of effective programs and appropriate counseling strategies to improve supervision of children is critical, especially because most caregivers do not provide continuous, proximal, and focused attention to their children at all times. The recent identification of effective messaging approaches and the positive outcomes noted of an intervention based on these messaging approaches could serve as the first evidence-based approach to improving supervision as a means of reducing childhood injuries.

EPIDEMIOLOGY AND BURDEN OF HOME INJURIES

The burden and cost of home injuries are substantial. There are approximately 18,000 injury-related deaths at home each year,[1] and there are an average of 21 million medical visits made each year due to home injuries.[2] The home is the second most common location for deaths from injuries in the United States following motor vehicle injuries.[1] There are approximately 49 home injury deaths every day (Figure 125.1) and the leading causes of these deaths include falls (33%), poisonings (26.8%), fire/burns (18.8%), choking/suffocations (6.1%), and drownings (4.6%). Together, these comprise 90% of all home injury deaths.[1] Children younger than 15 years and adults older than 70 years are at high risk for injuries in the home. Among children ages 0–14 years, the leading causes of home injury deaths are fire/burns, choking/suffocations, drownings, firearms, and poisonings. Among older adults, the leading causes of home injury deaths are falls, fire/burns, poisonings, natural/environmental exposures (primarily exposures to excessive heat or cold), and choking/suffocations.[2]

Home injuries are not equally distributed across population groups or geographic regions. Individuals with disabilities are at higher risk for home injuries.[3,4] Males experience many more home injury deaths than females.[1] Home injuries death rates are greatest in New Mexico followed by Mississippi and Arizona.[2] Southeastern states have high death rates due to residential fires, whereas drownings are highest in Florida, Arizona, Nevada, and California.

Home injuries pose a substantial cost burden to society. In 1998, these injuries cost at least $217 billion[5]: $34 billion for deaths from injuries and $183 for nonfatal injuries. The proportion attributed to medical costs totaled $22 billion. This chapter provides practitioners with an overview of the epidemiology and burden of home injuries (focusing on the leading causes of injury death), evidence for prevention by life stage, and conclusions about best practices. For the purpose of this chapter, home is broadly defined as a structure and includes the garage and yard.

LEADING CAUSES OF HOME INJURY

Falls

Falls alone account for 53.7% of all home injury deaths,[1] 36%–45% of all nonfatal home injuries, and almost 4 million emergency department (ED) visits annually.[6] Falls are the most common cause of injury death among adults aged 65 years and older.[7,8] More than one-third of all adults 65 years of age and older fall each year—with women 67% more likely to have a nonfatal fall than men.[7–9] As a result of falls, many older adults experience devastating consequences such as fractures and head trauma.[10,11] Important fall-related hazards for older adults in the home include poor lighting on stairs, lack of handrails on stairs, lack of grab bars in bathroom areas, use of throw rugs, and individual conditions such as impaired balance and vision.[7]

Falls also are a major cause of nonfatal injury in children and resulted in an estimated 2.5 million emergency room visits in 2007 for children ages 0–18 years.[9] Fall rates

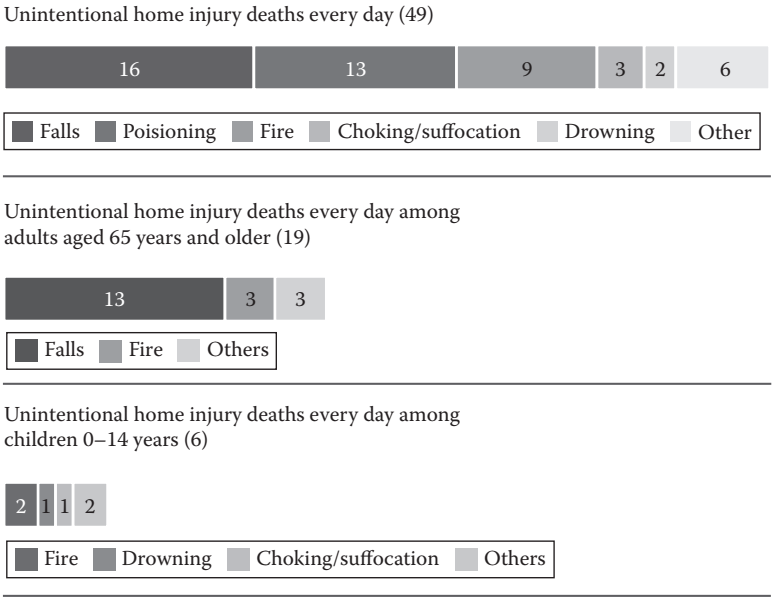

FIGURE 125.1 Unintentional injury deaths at home by cause.

among children younger than age 5 years are second only to those observed among adults aged 65 years of age and older.[12] Young age (children 0–6 years), male gender, and low socioeconomic status have been shown to be risk factors for fall injuries.[13] Important fall-related hazards for children in the home include baby walkers, stairs, windows above ground level, bathrooms, and furniture.[14,15] Beds have been identified as the leading product involved in injuries in infants and as the leading product in the percentage of nonfatal home injury costs for children younger than 5 years of age.[5,16] In particular, an estimated 23,000 children ages 0–9 years are treated in EDs annually for bunk bed-related injuries.[17] Outside play equipment, including play sets and trampolines, can also be dangerous for children. Most injuries occur when a child falls from the equipment onto the ground.[18]

Poisonings

Poisoning deaths and injuries continue to rise.[19] More than two-thirds of all home poisoning deaths occur among adults aged 30–49 years, and males have higher rates of poisoning death than females across all age groups.[1] Data from the American Association of Poison Control Centers show that in 2008, there were 2,491,049 human exposures to substances reported.[20] Almost all exposures (94%) occurred in the home. For children aged 5 or younger, the leading substances were

- Cosmetics and personal care products (13.5%)
- Analgesics (9.7%)
- Cleaning substances (9.7%)
- Foreign bodies (7.5%)
- Topical preparations (6.9%)

The leading substances involved in exposures across all age groups were

- Analgesics (13.3%)
- Cosmetics/personal care products (9.0%)
- Household cleaning substances (8.6%)
- Sedatives/hypnotics/antipsychotics (6.6%)
- Foreign bodies (5.2%)[20]

Poisonings led to 732,316 ED visits in 2008, and approximately 25% of the ED visits resulted in hospitalization or transfer.[9] In 2000, poisonings led to $26 billion in medical expenses and made up 6% of the economic costs of all injuries in the United States.[19]

Fire/Burns/Carbon Monoxide Poisoning

In 2009, house fires were responsible for approximately 2565 deaths and injuries to approximately another 12,650 persons (not including firefighters).[21] Most fire victims do not die from burns but from smoke or toxic gases.[22] Those at high risk of death because of fire or heightened difficulty in benefiting from smoke alarms include children 4 years and younger; older adults (65 years and older); those living in poverty; people with hearing, vision, or other physical or mental limitations or disabilities; and smokers.[23–26] Households with income below the poverty level, with lower levels of education attainment, or with older or no children were less likely to have a smoke alarm.[27] Additional groups at high risk for dying in a house fire include African Americans and people who live in substandard homes where emergency egress is often compromised.[28] Approximately $7 billion in property loss occurred in residential properties in 2009.[21]

A primary risk factor for death and injury in residential fires is absent or nonworking smoke alarms.[24,29,30] Studies show that even though over 90% of homes in the United States have smoke alarms, only about three-quarters of the alarms are functioning.[30,31] When a fire occurs in a home with a functioning smoke alarm, the death rate is decreased by 51%.[30]

Scalds and thermal and electrical burns also contribute to home injuries. Between 1997 and 2002, 78,000 infants and toddlers were treated annually in ambulatory care settings for injuries due to contact with a hot object or substance.[32] Exposure in an adult for 2 s to water at a temperature of 150°F can result in a third-degree burn and for children, it can happen even more quickly.[33,34]

Carbon monoxide (CO) is found in combustion fumes, such as those produced by stoves, lanterns, burning charcoal and wood, gas ranges, and heating systems. Each year, more than 400 Americans die from CO poisoning, more than 20,000 visit the emergency room, and more than 4000 are hospitalized.[35,36] Death rates are highest among older Americans.

Choking/Suffocation

More than 1000 suffocation/choking deaths occur in the home each year.[1] In 1998, costs from deaths and nonfatal choking/suffocation injuries totaled 3.2 billion.[5] Young children and older adults have the highest death rates from choking and suffocation. More than half (60%) of infant suffocation occurs in the sleeping environment.[15] Cribs and playpens are responsible for half of all nursery product-related deaths among children ages 5 years and younger.[15] Strangulation deaths from window cords happen in places such as in a crib or a bedroom. From 1991 to 2000, the U.S. Consumer Product Safety Commission received reports of 160 strangulations involving cords on window blinds.[37]

For older adults, predisposing factors for asphyxia of food include poor dentition, insufficiently chewing food, semisolid diet, alcohol use, sedative drug use, reduced motor coordination, dementia, and various neurological or other diseases.[38] Positional asphyxia is also a cause of suffocation-related death in older adults. Body position in these cases causes airway obstruction or impaired respiration. People who live alone may be at higher risk for choking because they may be less likely to enlist help when they are choking.

Drowning

Approximately 820 deaths occur in home settings each year due to drowning.[1] In 1998, costs from deaths and nonfatal drowning injuries totaled 2.1 billion.[5] The majority of residential pool drownings (61%) occur at the victims' home; however, 22% take place at the homes of neighbors, friends, and relatives.[39]

Drowning is the second leading cause of home injury death among children aged 1–9 years.[1] Among infants, 71% of drownings occur in bathtubs and 16% in buckets.[40] Among children ages 1–4 years, 56% of drownings are in pools, and among children ages 5–9 years, 31% are in pools.[40]

Males are 3.7 times more likely than females to die from drownings in the United States.[9] Between 2000 and 2007, the drowning death rate for African Americans across all ages was 1.2 times that of whites and for American Indians and Alaskan Natives, this rate was 1.7 times that of whites.[9] In the summer, between May and August, drowning deaths among children increased to 89% compared with the rest of the year.[41]

Excessive Heat–Cold Exposure

Extreme hot and cold temperatures (or environmental injury) are a leading cause of home injury death among older adults.[2] This may include illnesses, as well as injuries and conditions, related to excessive heat (e.g., heat cramps, heat exhaustion, heat syncope, heatstroke, or hyperthermia) or excessive cold (e.g., central nervous system depression, arrhythmias, and renal failure). In 1998, costs for natural and environmental exposures totaled approximately 1.5 billion,[5] and roughly 420 deaths occur in homes each year due to natural and environmental exposures.[1] Among all heat exposure deaths (inside and outside the home), males accounted for 66% of deaths.[42] Seven percent of the deaths were among those aged younger than 15 years, 53% were aged 15–64 years, and 40% were aged older than 65 years. The states with the highest average annual hyperthermia-related death rate were Arizona, Nevada, and Missouri.[42] Among all cold exposure deaths (inside and outside the home), males accounted for 67% of deaths.[43] Among those who died from hypothermia, 49% were aged 65 years or older. States with the highest average annual rates were Alaska, Montana, Wyoming, and New Mexico.[43]

Animal and Insect Bites

Although not a leading cause of injury death, bites and stings are the third leading cause of ED visits for young children, and many of these events occur at home. Dogs bite more than 4.7 million people/year in the United States with more than 800,000 Americans seeking medical attention.[44] The rate of dog bite-related injury is highest for children ages 5–9 and decreases as children age. Non-canine bites and stings (e.g., cats, bees, snakes) result in more than 900,000 ED visits annually, with nearly 90% of the injuries occurring in and around the home.[45] These numbers do not include deaths from bites or stings or the multitude of bite and sting injuries that are treated outside the ED by other health care providers or treated at home. Risk is typically greatest in the summer months, and injuries mostly occur to extremities of the body. According to the American Veterinary Medical Association, there were nearly 81.7 million pet cats, 72 million pet dogs, 11.2 million pet birds, 6 million pet rabbits, 1.2 million pet hamsters, and 586,000 pet snakes in the U.S. households in 2006.[46] As the practice of exotic pet

trade activity increases, practitioners are more likely to be treating injuries from these species.[46]

Mammalian bites are of particular concern for public health because they can lead to rabies exposure, rat-bite fever, and other zoonotic infectious diseases. The U.S. animal species that carry rabies include raccoons, skunks, bats, foxes, cats, dogs, and cattle. Distribution of hamsters and other pet rodents from centralized breeding facilities to pet stores located in various states and the distribution of imported, exotic pets have resulted in the diffusion of potential infectious exposures that may be infrequently seen by local physicians.

PREVENTION OF HOME INJURIES: PRACTICE CONSIDERATIONS

Health care professionals should be aware that educating about home safety in a clinical setting can be effective in increasing a range of safety practices, especially when partnered with the provision of home safety equipment.[47,48] Patient counseling can be a promising injury prevention strategy, especially if it is based on established behavioral and communication theories.[49] The following practice recommendations are arranged by three life stages: children, adults, and older adults. The recommendations for preventing injuries in children are meant to be provided to parents or caregivers. The topics covered were selected based upon contribution to the leading causes of injury deaths in the age group and practice recommendations established in the literature.

Children

Preparing and practicing a fire escape plan, especially teaching fire escape skills to children, can minimize injuries and death from fires.[15,50] Parents and caregivers should store all matches and lighters away from children up high in a locked cabinet and institute a "kid-free zone" of at least 3 ft around the stove and areas where hot food or drink is prepared or carried. Scald injuries can be prevented as well. Home safety education can be effective in increasing the proportion of families that have a safe hot tap water temperature.[47,51] Successful strategies to decrease scalds include reducing the temperature in water heaters to 120°F, installing hot water temperature limiters at the faucet, using roll-up cords for electric coffee pots, and using pots, pans, and kettles designed to be less likely to tip and spill hot liquids.[52] Five years after a 1983 Washington state law required new water heaters to be preset at 120°F at the factory, 77% of homes tested had safe tap water temperatures accompanied by a reduction in the frequency, morbidity, and mortality of tap water burn injuries in children.[53]

Parents and caregivers should be advised on the types of objects that pose a strangulation or suffocation risk for children and familiarized with methods to reduce this risk. For example, children younger than 4 years should not be fed round, firm foods (e.g., hot dogs, nuts and seeds, grapes, hard candy, raw vegetables) unless they are chopped completely. Dangerous household items include balloons, coins, magnets, marbles, and toys with small parts. Parents should be advised to learn and practice cardiopulmonary resuscitation (CPR) and basic first aid in case of emergencies at home.

Infants should be placed on their back on a firm sleep surface, such as a safety approved crib mattress, and soft objects or loose bedding should not be placed in a crib. Loop window blind and drapery cords should be tied up out of reach or the ends should be cut and retrofitted with safety tassels. The inner cords of blinds should be fitted with cord stops.[37]

Recent research suggests that formal swim lessons can reduce the risk of drowning in 1 to 4 year old children.[54] To help prevent drowning, parents might consider enrolling children in formal swim lessons, but they also need to be within arm's length of children who are bathing or playing around water.[55] Children should never swim alone or without adult supervision.[56] When combined with self-closing and self-latching gates, four-sided fencing provides a passive intervention that prevents unintended access to pools by residents and visitors.[57]

To protect children from poisonings, it is recommended that the poison control number, 1-800-222-1222, be kept on or near each home phone and saved on cell phones. Drugs and medicine should be kept in locked cabinets, and patients should be advised to follow all label instructions. Child-resistant packaging significantly reduces the morbidity and mortality of childhood poisonings. Studies show clear declines in poisonings after passage of the Poison Prevention Packaging Act (PPPA) in 1970.[58,59] One study revealed that a substantial number of the post-PPPA poisonings (as high as 40%) were due to either improperly secured safety caps or products that were not required to be packaged in a child-resistant container.[60] Clinicians should urge patients to keep medicines in original bottles and containers and to turn on a light at night when using medications. Adults should never leave children alone around medicines. Homes with pools should store pool chemicals away from children and animals as well as store them as recommended by the manufacturer.[61] Chemicals should be protected from mixing or getting wet.

While not a leading cause of injury death among children, falls are a leading cause of injuries and there has been substantial work on the topic. Residential hazards associated with falls among children include a lack of safety devices such as properly installed and used safety gates or window guards, use of bicycle helmets, and structural defects (e.g., uneven floors, insufficient surfacing under play equipment). Although few child fall prevention interventions have been rigorously evaluated, individual studies have suggested positive results. Interventions to increase stair gate use and reduce baby walker use have been shown to be effective.[62] Other interventions that may help to prevent childhood fall injuries include window guards,[63] balcony railings less than 4 inches apart, and window locks for windows above ground level.[15] The evidence that window guards reduce childhood morbidity and mortality from falls comes primarily from dramatic results following a community-wide program to

provide window guards in high-risk apartments where falls declined 50% in the 2 years after the program's inception.[64] Building codes that require window guards, safe stair and balcony design, and other modifications are likely to be effective for fall prevention because they remove the need for home dwellers to modify their home for safety.

Playground equipment should be properly sited within the yard, have appropriate surfacing beneath the equipment, and be age appropriate and well maintained.[65] Children should be adequately supervised when playing on the equipment. Children should use bike helmets when riding bicycles; indeed, many states and localities have laws requiring their use.[66]

Injuries to children from common household equipment can be extremely damaging. Recent reviews of injuries from equipment such as lawn mowers[67] and treadmills[68] demonstrate the potential harm. Although equipment redesigns to enhance passive safety measures might be the most effective way to prevent these injuries, clinicians can advise parents to keep children away from this equipment, especially when adult supervision is not present. Other measures, such as keeping keys for these devices out of reach of children, is also prudent. Furniture can also be a source of injury for children. Televisions were the most common item of furniture associated with injury among children aged 9 years or younger, whereas other items, such as desks, cabinets, and bookshelves, were the most common source of injury among children aged 10–17 years.[69] Clinicians can encourage parents to secure large furniture to a stable stand or a wall.

The American Academy of Pediatrics has anticipatory guidance available in The Injury Prevention Program. It is designed to provide a systematic method for clinicians to counsel parents and children about adopting safe behaviors during various child development stages to prevent injuries.[70] It targets the parents of children, newborn through 12 years of age, to help prevent common injuries from motor vehicles, firearms, bicycle crashes, drowning, poisoning, choking, burns, falls, and pedestrian hazards.

Adults

To prevent residential fire and burn deaths, smokers should be advised to quit since smoking is the leading cause of residential fire deaths. The U.S. Department of Health and Human Services, National Institutes of Health, and National Cancer Institute provide a free helpline (1–800-Quit Now) for smokers who want to quit and need help doing so. In addition, families should be counseled about fire and burn prevention. Home safety education has been effective in increasing the proportion of families with a functional smoke alarm.[47] Homes should have properly placed smoke alarms, and the batteries should be checked and replaced when appropriate. Patient reminders for new batteries can be timed to coincide with when clocks are reset to daylight standard time. In addition, residential sprinklers are a promising strategy to prevent deaths and injuries due to fires and are gaining greater acceptance as a feature of new home construction.[71–73] Only 23% of homes in the United States have a fire escape plan and practice it, and yet residents should be prepared to exit a home when a smoke alarm sounds.[27] The fire escape plan should include at least two different ways of escape for each household resident (and that egress routes are not blocked), and a safe place should be designated outside of the home to meet after escaping the fire.

Cooking is the leading cause of home fires and home fire injuries.[74] Food that is cooking should not be left unattended, and caution should be used when frying foods. The stove should be turned off if leaving the kitchen for even a short period of time. While cooking, it is prudent practice to roll up sleeves and use oven mitts. Grilling outdoors can cause house fires as well.[75] Grills should be placed well away from the house. Generators, camp stoves, and propane or charcoal grills should only be used outdoors to avoid fire and or CO hazards. Before using gas grills and propane tanks, the fuel lines should be examined to be sure they are working properly and not leaking.[76] To prevent CO poisoning, the heating system, water heater, and any other gas, oil, or coal burning appliances should be serviced by a qualified technician every year. Homes should have properly placed CO detectors, and the batteries should be checked and replaced when appropriate.[77]

Falls from ladders can result in serious injuries.[78,79] Prevention strategies for ladder safety include ensuring the ladder is on secure and level ground before climbing, spacing the base of the ladder 1 ft away from the wall for every 4 ft it extends up, and staying centered between the rails of the ladder.[80] Patients should be advised not to overreach or stand on the top two rungs of the ladder. To reach a roof, the ladder should be extended at least 3 ft beyond the edge of the roof. A folding step ladder should never be used when it is closed.

Older Adults

Older adult falls in the home can be prevented, in part, by taking note of home hazards and safety features. Structural residential hazards associated with falls among older adults include lack of handrails on stairs, lack of grab bars and nonslip surfaces in the bathroom, tripping or slipping hazards (e.g., throw rugs, waxed flooring), outdoor steps, inadequate lighting, and the presence of electrical or telephone cords in the walkway.[81] Individual behaviors and physical ability levels also are important factors contributing to falls in older adults.[82,83] Homes can be designed and constructed to protect older adults from fall-related injuries through installation of grab bars in bathtubs and showers and adding handrails and good lighting in stairwells. Many homes currently do not have these simple safety features. The evidence that structural modifications, such as installation of handrails, grab bars, and improved lighting, are promising interventions for reducing risk of falls among older adults comes from two systematic reviews.[84,85]

Similar to recommendations for children, preparing and practicing a fire escape plan can be beneficial for older adults.

Increased risk for death in fires for older adults may arise, in part, from decreased mobility, hearing loss, and confusion. Smoke alarms may be less effective at waking older adults who suffer hearing loss.[23] Older adults may want to consider alarms with flashing lights or vibration alerts. Clinicians should recommend that older adults stay in the kitchen when food is cooking on the stove and not wear loose clothing while cooking.

Periods of extreme heat or cold are potentially dangerous for older adults. During periods of extreme heat or cold, having a system in place for checking in with relatives or neighbors can be helpful. Air-conditioning is a key protective factor against heat-related illness and death.[42] If a home is not air-conditioned, older adults might consider spending time in public facilities that are air-conditioned. Clinicians can recommend the following during hot weather: staying cool indoors, drinking plenty of fluids, replacing salt and minerals, wearing appropriate clothing and sunscreen, and using a buddy system. The ability to feel a change in temperature decreases with age.[43] Also, older people are more susceptible to health problems caused by cold. Two practical measures to recommend for older adults include placing an easy-to-read thermometer in an indoor location where they can see it frequently and checking the temperature of the home often during the winter months.

CONCLUSIONS

All patients are entitled to a healthy and safe home. Clinicians can help patients and families take actions to change lifestyle behaviors and create safer home environments. The principles of healthy and safe homes have been previously explained,[86,87] but examples of the more important "best practices" to be encouraged by health professionals include the following:

1. Recommend installation, maintenance, and consistent use of safety devices (Figure 125.2):
   a. Smoke alarms
   b. Stair gates in homes where young children live or visit
   c. Grab bars in bathrooms
   d. Adequate lighting outside and on stairs
   e. Proper storage areas for medicines, cleaning solutions, automotive supplies, pool chemicals, and pesticides
   f. Four-sided isolation fencing with self-closing, self-latching doors around pools
   g. CO detectors
2. Recommend parents dispose of baby walkers—they are inherently dangerous
3. Have patients in homes where older adults live or visit complete a home fall prevention checklist (see http://www.cdc.gov/HomeandRecreationalSafety/Falls/pubs.html)
4. Encourage patients to prepare and practice an emergency fire escape plan (see http://www.usfa.fema.gov/campaigns/smokealarms/escapeplans/index.shtm)
5. Encourage homeowners and renters to set their water heater temperature at (or below) 120°F to prevent scalding
6. To reduce home fires, encourage patients to not smoke and provide active support for quitting (http://www.smokefree.gov)
7. Have patients complete a playground safety checklist if they have playground equipment in their yard (see http://www.cpsc.gov/cpscpub/pubs/pg1.pdf)
8. Have patients choose poison prevention packaging for all toxic products in the home
9. Provide advice to patients regarding basic first aid and recommend CPR and first aid classes to parents
10. Recommend that infants sleep on their backs on firm sleeping surfaces
11. Advise adults aged 65 years and older to exercise caution in extreme hot or cold weather (http://emergency.cdc.gov/disasters)

Homes injuries are not accidents. Most are predictable and, more important, preventable. Clinicians can help patients choose lifestyles that prevent home injuries by promoting safe behaviors and changing hazardous home environments.[88] Clinicians, however, cannot do this alone.

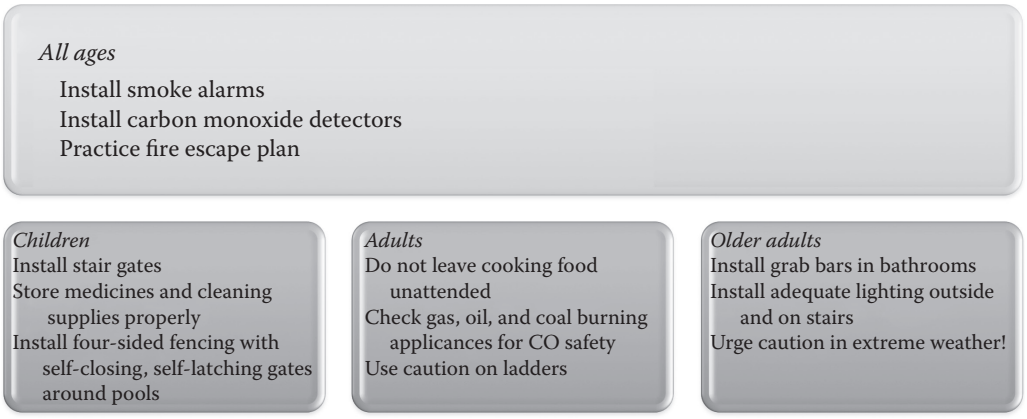

FIGURE 125.2 Help patients take actions to create safer home environments through safety devices.

It is important for home injury prevention messages to be embraced and advocated by teachers, schools, media, local health departments, advocacy groups, business, law enforcement, and policy makers.[89] Home injuries are related to many factors that span individual, interpersonal, organizational, community, and societal determinants. The costs and consequences of home injuries can be significant, both to families and society as a whole. Home injury prevention should be considered right alongside disease prevention as both predictable and preventable through changes in behavior, public policy, enforcement, environment, and product/engineering.[89,90] Although injury statistics guide our practice and research, a more powerful force are the people behind the statistics whose lives can be spared and disabilities prevented through the application of effective injury prevention strategies at home.

INTRODUCTION

The U.S. population is aging rapidly. At present, 35 million people—one-eighth of the U.S. population—are 65 years of age or older, and by 2020, this number is expected to reach 77 million. The aging process typically involves cognitive and physical changes to the body's brain and nervous, cardiovascular, and sensory systems. These changes, in turn, may cause a reduction in functional abilities including decreased muscle strength and endurance, slower recovery times after exertion or stress, and delayed reaction times to different types of stimuli. Such physiological changes can make older adults (those aged 65 years and older) particularly susceptible to falling [1].

Falls among people who are 65 years or older are a major public health concern. More than a third of older adults fall annually [2] and those who fall are two to three times more likely to fall again within a year [3]. Although most falls do not result in injury, about 20% cause serious injuries such as head trauma, lacerations, and fractures [4]—injuries that can limit mobility, diminish quality of life, and increase the risk of premature death [5,6]. Although both men and women are susceptible to falls and fall injuries, women are disproportionately affected because they outnumber men in the older age groups and because they are more vulnerable to sustaining fall injuries such as hip fractures.

This chapter describes the magnitude of this health issue and highlights how falls and fall injuries are influenced by biological, environmental, and behavioral factors. It summarizes the epidemiology of older adult falls and describes our current knowledge about interventions that can reduce these injuries.

PUBLIC HEALTH BURDEN

Falls are the leading cause of both fatal and nonfatal injuries among people aged 65 years and older [7]. In 2007, there were 38,300 unintentional injury deaths among older adults, of which 48% were caused by falls. But fatal falls represent only the "tip of the iceberg." In the same year, 3.1 million nonfatal unintentional injuries among older adults were treated in emergency departments, of which 1.9 million (62%) were due to fall injuries. Sixty-nine percent of these fall injuries were sustained by women (Figure 126.1).

One of the most serious fall outcomes is hip fracture, an injury that often results in long-term functional impairment, nursing home admission, and increased mortality [9]. More than 90% of all hip fractures in older adults are caused by falls [10]. In 2006, there were 309,000 hospital admissions for hip fractures, and about three-quarters of these injuries were sustained by women [11].

In addition to physical injuries, falls can have significant psychological and social consequences. Many people who fall, whether or not they sustain injuries, develop a fear of falling. Studies show that 12%–39% of older adults report they are afraid of falling [12]. This fear can cause them to restrict their activities, leading to reduced mobility, muscle weakness, and subsequent increased fall risk [13]. Fear of falling is strongly associated with future falls and has been found to lead to deteriorating health, a decline in physical and social functioning, and nursing home admission [14].

The financial burden of falls is substantial. In 2000, the direct medical costs of fall injuries among adults 65 years and older totaled $19.2 billion [15] or $30.0 billion in 2010 dollars. About two-thirds of these costs were for people who were hospitalized.

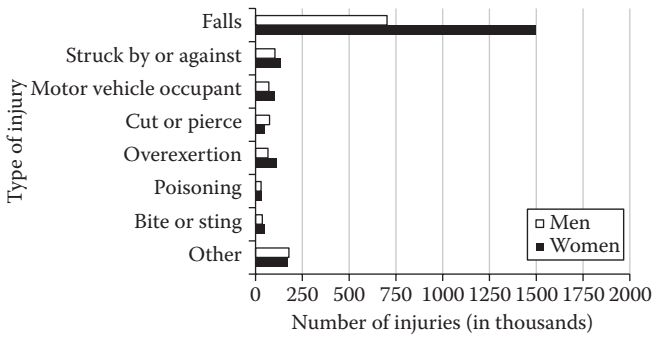

FIGURE 126.1 Leading causes of unintentional nonfatal injuries among men and women aged 65 years or older, United States, 2009. (Data source from NEISS-AIP, 2009.)

Community Settings

Although older adults reside in a variety of settings, including assisted living facilities and nursing homes, approximately 96% of the 35 million adults aged 65 years and older live independently in the community. In a 2006 national survey, about 5.8 million (15.9%) community-dwelling adults aged 65 years and older reported falling at least once during the preceding 3 months [16]. Of those who said they had fallen, 23.1% reported falling three or more times. People who fall repeatedly are at greatly increased risk of sustaining a serious injury [17].

Many older adults living in the community spend much of their time at home, so it is not surprising that between one-half and two-thirds of all falls, and about half of fatal falls, happen in or around the home [18,19]. Studies show that most people fall from a standing height (e.g., by slipping or tripping while walking) [20], and most falls happen on the same level rather than from heights (e.g., down stairs or off ladders) [21]. Berg et al. found that the majority of falls (82%) occurred during the day; 14% happened in the evening and only 4% happened at night [18].

Nursing Homes

In 2004, there were 1.3 million persons aged 65 years and older living in nursing homes; half were 85 years and older and three-quarters were women [22]. The median length of stay for residents was 511 days for women and 355 days for men. By 2030, the number of nursing home residents is projected to double [23].

Nursing home residents are particularly vulnerable to falls and fall-related injuries. At least half of nursing home residents fall annually and the proportion is higher among certain high-risk populations, such as people with dementia, where the incidence is 70%–80% [24]. Compared to seniors living in the community, people in nursing homes are older, frailer, and have a higher prevalence of cognitive impairment. Nursing home residents also tend to have a greater number and more severe chronic conditions; greater limitations in their basic activities of daily living; and a higher prevalence of gait problems [25]; all factors that are associated with falling [26].

The fall rate among nursing home residents is two to three times the rate for older adults living in the community, with the average incidence 1.5 falls per bed per year [27]. A typical 100-bed nursing home reports between 100 and 200 falls annually, and many falls probably go unreported [28]. Nursing home residents tend to fall repeatedly, which increases their chances of sustaining injuries. In this population, approximately 12% of falls cause severe injuries such as head trauma and serious lacerations and an additional 4% result in fractures. About 35% of fall-related injuries occur among non-ambulatory residents [29].

Hospitals

Fall rates among hospital patients vary by patient population, type of hospital, and reasons for hospitalization. The highest

rates are seen among the oldest patients and, within the geriatric population, rates of 8.9–17.1 falls per 1,000 patient days have been reported for neuroscience, rehabilitation, and psychiatry departments [30,31]. Methods for calculating hospital fall rates differ. The most accurate approach is to report the number of falls per 1,000 patient bed-days, but many studies calculate the fall rate as the number of falls per 100 hospital admissions. These differences make it difficult to compare fall rates among and across institutions.

EPIDEMIOLOGY

Fatal Falls

In 2007, 18,300 older adults died from fall injuries, an average of one death every 35 min [8]. Rates differ by both sex and race. Whites have the highest fall death rates followed by the rates for Asians and blacks [32]. Men are much more likely than women to die from a fall. In 2010, the age-adjusted fall death rate for men (63.1 per 100,000 population) was 55% higher than the rate for women (44.9 per 100,000) [7]. For both men and women, rates increased sharply with age with the greatest rate increase occurring after 80 years of age [7] (Figure 126.2).

It is unclear why men are more likely than women to die from a fall. This disparity may be due to gender differences in the prevalence of underlying chronic conditions at similar ages, such as cardiovascular disease, or it may reflect greater risk-taking behaviors, such as climbing on ladders, among men.

National data show that fall death rates are increasing [7]. From 2000 to 2007, age-adjusted rates increased 45% in men and 55% in women (Figure 126.3). Reasons for this increase are unclear. The number and rate of fatal fall injuries are calculated using vital records data that are compiled by the National Center for Health Statistics. Although comprehensive, the quality of these data depends on the training and/or experience of the physician or medical examiner filling out the death certificate. The number of deaths attributable to falls may be undercounted if a fall did not occur close to the time of death.

Few studies have examined the specific causes of fall-related deaths, although there is evidence that up to half are due to traumatic brain injuries [33]. Complications following fractures, especially hip fractures, also contribute significantly to fall deaths [19].

Nonfatal Falls

In 2009, 2.2 million nonfatal falls among people aged 65 years and older were treated in hospital emergency departments [7]. The majority of fall injuries were mild to moderate; about three-quarters of patients were treated and released, while one quarter were hospitalized. Like fatal fall rates, nonfatal rates have increased, although to a lesser extent. From 2001 to 2009, age-adjusted fall injury rates increased 21.4% in men and 16.4% in women [7].

A recent analysis of the 2006 Current Medicare Beneficiary Survey data found that nearly 7 million community-dwelling Medicare beneficiaries aged 65 years and older reported having fallen in the past year [8], and over 2 million beneficiaries sought medical attention following a fall. Women were significantly more likely than men to seek medical treatment for a fall (37.5% vs. 24.3%) and to talk with a health care provider about preventing future falls (31.2% vs. 24.3%). This is consistent with other studies that have noted women's higher incidence of fall injuries [34,35].

Women are disproportionately affected by nonfatal fall injuries (Figure 126.4). In 2009, after adjusting for age, the fall injury rate for women was 40% higher than for men [8]. In a population-based study, Stevens and Sogolow found that nonfatal fall-related injury rates for women were 40%–60% higher than for men of comparable age [34].

Women also were more likely to sustain serious injuries such as fractures and head injuries that required hospitalization. The most prevalent nonfatal fall injuries were fractures, contusions or abrasions, and lacerations. Compared to men, injury rates for women were 2.2 times higher for fractures, 70% higher for contusions or abrasions, and 10% higher for lacerations [34].

Not surprisingly, the hospitalization rate for women was 1.8 times that for men, and women's hospital admission rates for fractures and lower trunk injuries were more than twice as

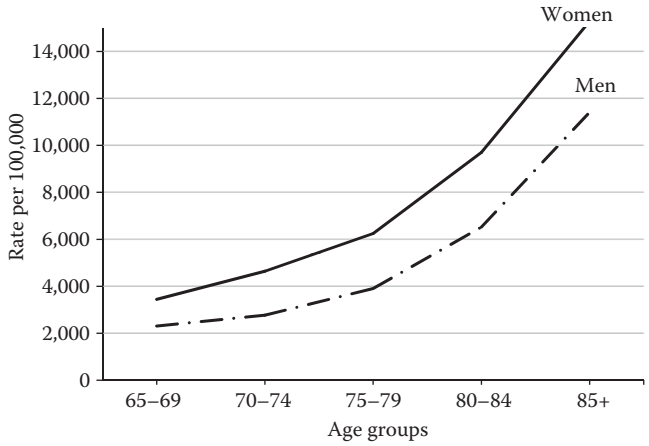

FIGURE 126.4 Nonfatal fall injury rates for men and women aged 65 years or older by age-group, United States, 2009. (Data source from NEISS-AIP, 2010.)

high as men's rates. Similarly, in an analysis of Washington State hospital discharge data, researchers found that fall-related hospitalization rate for women was twice that for men [36]. About 46.7% of all patients who were hospitalized for a fall injury were subsequently transferred to a skilled nursing facility [36].

Much of the gender disparity is due to women's greater susceptibility to hip fracture, an extremely serious fall injury that can result in disability, nursing home admission, and increased mortality [37–39]. White women are much more likely to sustain hip fractures than are African American or Asian women [20]. Treatment typically includes surgery and hospitalization, frequently followed by admission to a nursing home and extensive rehabilitation [40].

Falls are the strongest risk factor for hip fracture [41]. However, a significant contributing factor is osteoporosis, a metabolic disease that affects postmenopausal women and men over 80 years of age. It is characterized by low bone mineral density (BMD) and deterioration of bone structure that make bones porous and susceptible to fracture. The National Osteoporosis Foundation estimates that more than 10 million people over age 50 years in the United States have osteoporosis and 80% of those affected are women. An additional 34 million people have low BMD and are at risk for the disease [42].

FALL RISK FACTORS

Epidemiologic studies have identified numerous fall risk factors and the prevalence of many of these increases with age. Risk factors frequently are classified as either intrinsic (i.e., originating within the body, such as age, female gender, leg weakness, balance disorders, and poor vision) or extrinsic (i.e., originating outside the body, such as environmental hazards). Some researchers have further refined this classification to include biological, behavioral, environmental, and socioeconomic risk factors [43]. The following table lists selected risk factors in each category (Table 126.1).

TABLE 126.1
Selected Fall Risk Factors

Biological	Behavioral	Environmental	Socioeconomic
Advanced age	Multiple medications	Lack of stair handrails	Low income
Previous falls	Psychoactive medications	Poor stair design	Lack of education
Female gender	Inactivity	Lack of bathroom grab bars	Poor living conditions
Muscle weakness	Risk-taking behaviors	Dim lighting or glare	Lack of social support
Poor balance and coordination	Fear of falling	Obstacles and tripping hazards	Living alone
Gait disorders	Improper or inappropriate use of mobility aids	Slippery or uneven surfaces	Illiteracy and/or language barriers
Chronic conditions: Arthritis, diabetes, stroke, Parkinson's disease, incontinence, dementia	Inappropriate footwear	Poor building design and/or maintenance Poorly designed or maintained public spaces	
Poor vision			
Functional limitations			
Acute illness			

Source: Data adapted from Scott, V., *Prevention of Falls and Injuries among the Elderly*, British Columbia-Office of the Provincial Health Officer, Vancouver, British Columbia, Canada, 2004; Rubenstein, L.Z. and Josephson, K.R., *Med. Clin. North Am.*, 90(5), 807, 2006.

Biological Factors

Some biological risk factors are important but cannot be modified, such as older age, being female, and being cognitively impaired. Having certain chronic conditions also increase fall risk through various mechanisms. Conditions such as stroke and Parkinson's disease adversely affect balance, gait, and muscular coordination [44,45]; diabetes can cause loss of vision and peripheral neuropathy leading to decreased sensation in the feet [46]; and arthritis affects flexibility [47] and also may cause chronic pain [48].

Behavioral Factors

Behavioral factors are the focus of public health efforts because they are generally considered modifiable. Risky behaviors include climbing on ladders or chairs [17]; being inactive, which leads to poor physical conditioning and muscle weakness [49]; taking four or more medications; and taking medications that affect the central nervous system.

Psychoactive medications such as tranquilizers, sedatives, and antidepressants have been most strongly associated with falls [50], but diuretics, antihypertensive medications, and narcotic analgesics also increase fall risk [51].

Although all these factors are potentially modifiable through science-based interventions, it is well documented that human behavior is very difficult to change, especially for sustained periods of time. Changing older adults' behaviors to prevent falls is no exception [52].

Environmental Factors

Some environmental factors, such as uneven pavement and poorly designed public spaces, such as street crossings and parking lots, are difficult or impossible to change. Fortunately, there are environmental risk factors in the home that can be modified. Examples include clutter in walkways, tripping hazards, dim lighting, and lack of stair railings or grab bars in the bathroom [53].

Socioeconomic Factors

Although evidence is limited, some research suggests that a number of risk and protective factors are related to socioeconomic conditions. For example, low income is highly associated with poor health status and disability that, in turn, are associated with increased fall risk [54,55]. Some psychosocial conditions such as depression also increase the risk of falls and fall-related injuries [56–58]. Conversely, social integration, as measured by the size and quality of family and friendship networks, has been shown to protect against falls [59] and fall-related fractures [56]. Fear of falling has been identified as a fall risk factor, particularly when it causes a reduction in physical activity, which may be protective [60].

Risk Factor Interactions

Most falls are the result of interactions among multiple risk factors [44]. In an early study of community-dwelling older adults, Tinetti et al. found that the likelihood of falling increased with the number of risk factors present [61]. The proportion of people who fell increased from 27% for those with up to one risk factor to 78% for those with four or more risk factors.

Fall prevention efforts have focused on a number of potentially modifiable risk factors. These include muscle weakness in the legs, gait and balance problems, poor vision, and environmental hazards [5]. In addition, identifying and treating the symptoms of chronic conditions may reduce fall risk [62].

FALL INTERVENTIONS

The frequency of falls among older adults, combined with a high susceptibility to injury due to age-related physiological changes (e.g., decreased muscle strength and endurance, delayed reaction times) and a high prevalence of chronic conditions, makes all fall outcomes potentially serious. Unfortunately, many older people are not aware of their risk of falling or avoid discussing these issues with their health care providers [52]. Consequently, opportunities to implement prevention strategies are often missed.

Clinical Assessment and Risk Factor Reduction

In a meta-analysis of randomized controlled trials (RCTs) of fall interventions, Gillespie et al. concluded that the most effective multifactorial fall intervention was a clinical assessment by a health care provider combined with individualized fall risk factor reduction, referral, and patient follow-up [63].

The American Geriatrics Society (AGS) published clinical fall assessment guideline in 2001 [64] and updated them in 2010 [62]. The AGS recommends that a health care provider ask all older adults if they have fallen in the past year. People who have fallen two or more times, or who are experiencing difficulties with walking or balance, should receive a multifactorial fall risk assessment followed by individualized interventions including treatment and/or referrals.

A multifactorial fall risk assessment includes taking a fall history; reviewing all medications; testing gait, balance, neurological function, lower extremity muscle strength, cardiovascular status, and visual acuity; assessing activities of daily living including the use of mobility aids and fear of falling; and evaluating the condition of the feet and usual footwear. Intervention strategies would include medical management tailored to the identified risk factors, including referrals to specialists, such as neurologists and ophthalmologists, coupled with an appropriate exercise program [62].

Primary care physicians have been slow to put the AGS recommendations into clinical practice because many feel they do not have adequate knowledge about methods of risk assessment and/or fall prevention [65–67].

Exercise

After clinical assessment with targeted risk factor reduction, the most effective single intervention is exercise, which can reduce fall risk by 24% on average [68]. However, recruiting participants and maintaining long-term compliance with an exercise program can be problematic.

The Cochrane group conducted a meta-analysis of 43 RCTs of fall interventions that included exercise [63]. They concluded that multiple component exercise interventions were effective in reducing the rate and risk of falling. The evidence supported three different approaches: multiple component group exercise programs, individually prescribed multiple component exercise carried out at home, and Tai chi as a group exercise.

In an RCT of a Tai chi intervention, Li et al. found the risk of falling was decreased 55% among participants in the Tai chi group compared to the control group [69]. In another RCT, Voukelatos et al. studied the effectiveness of a community-based Tai chi program and found that the fall rate in the Tai chi group was 28% lower than in the control group after 16 weeks and 33% lower after 24 weeks [70].

Sherrington et al. carried out a meta-analysis of 44 fall intervention studies that devoted at least 25% of the time to exercise [71]. They found that challenging balance, making exercises progressively more difficult, and having at least 50 h of exercise were the key factors associated with program effectiveness. Including a walking program did not contribute to reducing fall rates, possibly because the time spent walking took the place of time spent improving balance [71]. However, walking programs have other health benefits including improved fitness, weight loss, and lowered blood pressure [72]. Research is needed to better understanding the effect of walking programs on fall risk.

Medication Management

Studies have demonstrated clearly that psychoactive medications—specifically benzodiazepines, antidepressants, and sedatives/hypnotics—increase fall risk [50,73–75]. Medication management involves a doctor or pharmacist first reviewing all prescription and the over-the-counter medications an older adult is taking and then reducing the number of medications, finding alternative drugs, and/or adjusting dosages so as to reduce side effects and interactions that may lead to falls [50,73]. A relatively small study by Campbell et al. found that eliminating psychoactive medication use among community-dwelling older adults reduced fall rates by 66% [76]. However, 6 months after the study ended, almost half the participants had resumed taking psychoactive medications.

Vision Enhancement

Impaired vision, which encompasses poor visual acuity, reduced contrast sensitivity and depth perception, and visual field loss, increases the risk of falling [77,78]. Eye examinations and vision correction would be expected to help reduce this risk. However, fall interventions employing vision correction have been disappointing [79]. Evidence that cataract surgery reduces falls has been inconclusive [80–82].

Many older adults use glasses with multifocal lenses that can reduce edge contrast and depth perception, creating a fall hazard [83]; single vision lenses may be a better choice for activities, such as walking, that require good depth perception. A recent Australian study concluded that providing glasses with single vision lenses to older adults who usually wear multifocal glasses is an effective fall prevention strategy, but only for those people who are fairly active and take part in regular outdoor activities [84].

Home Modification

More than half of falls in community-dwelling older adults occur in or around the home [18,21], so modifying the home environment is a popular fall prevention strategy. However, simply reducing household environmental risks, such as improving lighting and removing tripping hazards, has not been shown to reduce falls among the older community population [85,86]. Day et al. conducted a factorial trial of three fall interventions: exercise, vision enhancement, and home hazard reduction [53]. Individually, only the exercise program was effective; this intervention reduced falls by 18%. However, when home hazard reduction was combined with the exercise program, falls were reduced by 24%, and when the intervention included all three components, falls were reduced by 33%.

Three randomized controlled intervention studies for community-dwelling older adults that focused on home modification were effective in reducing falls [87–89]. These individualized interventions involved home visits by occupational therapists who discussed behavioral changes with each client, tailored environmental changes to the client's specific needs, and facilitated recommended home modifications.

Results of interventions to reduce falls among nursing home residents have been inconsistent. Some multifactorial interventions that included environmental modification, staff education and training, and other factors (e.g., exercise programs, hip protectors, medication modification), have been effective in reducing falls [90–92]. However, other interventions for this population have been ineffective [93,94].

Vitamin D

Vitamin D has a direct effect on muscle strength, calcium absorption, and bone growth, and vitamin D with calcium may help decrease the risks of falls and fractures in older adults [95]. Sources of vitamin D include food (such as fish, eggs, and fortified milk), sun exposure, and dietary supplements.

After conducting a meta-analysis of eight randomized clinical trials, Bischoff-Ferrari et al. concluded that vitamin D supplementation in a dose of 700–1000 IU a day reduced the risk of falls among older adults by 19% [96], while a Cochrane review reported that vitamin D supplements reduced falls only in community-dwelling older adults with initially low 25-hydroxyvitamin D levels [97]. A systematic review by the Agency for Healthcare Research and Quality concluded that the evidence that vitamin D reduced falls and fractures was inconclusive [98], while a recent report by the U.S. Preventive Services Task Force concluded that vitamin D with or without calcium was associated with a 17% reduced risk of falling during 6–36 months of follow-up [99].

Vitamin D as a fall prevention strategy is appealing because it is inexpensive and would be acceptable to high-risk older adults [100].

Multifactorial Interventions

Falls often are caused by a complex interaction between the individual and their environment. In 1994, Tinetti et al. published the results of a landmark fall intervention study that focused on a number of risk factors: balance, gait, impaired arm or leg strength or range of motion, use of sedatives, use of four or more prescription medications, postural hypotension, and ability to transfer safely (i.e., move from the bed to a chair) [101]. This study demonstrated that an intervention

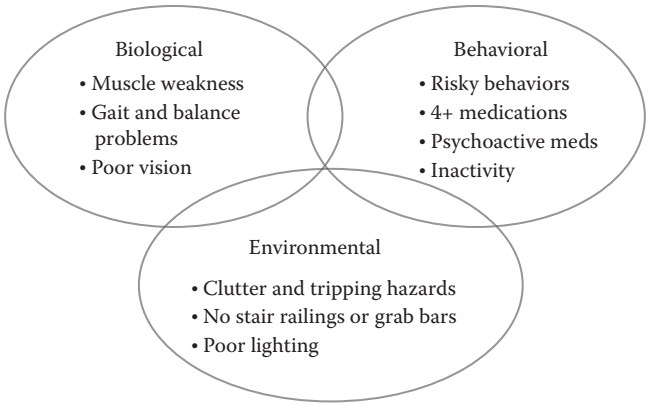

FIGURE 126.5 Risk factors addressed by multifactorial fall interventions.

that addressed multiple risk factors could significantly reduce falls among community-dwelling older adults.

The majority of effective interventions include multiple components that address a variety of risk factors (Figure 126.5). These may incorporate risk factor screening and treatment or referrals to specialists to reduce fall risk; exercise programs or physical therapy to improve gait, balance, and strength; medication management; environmental modification; and other elements such as education about fall risk factors and vision assessment and correction [53,102–104].

PERCEPTIONS OF RISK

Many older people are not aware of their fall risk or avoid discussing these issues with their health care providers [52]. Consequently, opportunities to implement prevention strategies are often missed. Effective fall prevention approaches require older adults to adopt new behaviors and such changes are unlikely if older adults do not perceive fall prevention advice to be relevant or personally meaningful.

Some people believe falls are an inevitable part of aging and cannot be prevented; others do recognize preventable fall risks in the general older population or among their peers but do not see themselves as personally vulnerable. Others attribute falls simply to unavoidable bad luck [105,106].

Because many older adults reject the idea that they are at risk of falling, messages promoting fall prevention programs should focus on the positive health and social benefits, such as improving balance and maintaining independence, rather than emphasizing negative information about falls and fall injuries [52,106]. Formative research with target audiences will increase the likelihood that messages will be well received.

The Centers for Disease Control and Prevention Injury Center has developed educational materials about falls for older adults, caregivers, and health care providers. Links to selected resources are provided in Table 126.2.

RESEARCH GAPS

Research has identified effective interventions for community-dwelling older adults [107], but fall interventions for nursing home residents and hospital patients are more limited. There is evidence that multifactorial interventions including risk assessment, staff education, and supervised exercise can reduce falls and fall risk in hospital patients and that vitamin D supplementation can reduce fall in nursing home residents [108].

Further research is needed now to study the effectiveness of walking programs to reduce fall risk; to tailor interventions for subgroups with differing characteristics and risk factors, such as people with chronic conditions or differing levels of functional impairment; to determine the relative contribution of selected risk factors to fall events; to determine the underlying causes and/or circumstances of falls; and to understand how these factors differ for men and women. Clarifying these differences as well as collecting information about the location and events preceding a fall or fall-related injury is vital to identifying high-risk behaviors and situations, and for developing and implementing targeted fall prevention strategies.

Future Directions

Much is known about effective fall prevention strategies [107]. We now need to refine these proven interventions to broaden their use across diverse populations; create an infrastructure to train implementers how to use proven strategies; disseminate effective fall prevention programs; and support widespread adoption at the local level. We also must enhance provider training to incorporate fall risk assessment and interventions into clinical settings, as well as linking clinicians to community-based interventions. Such a multifaceted approach would support broad implementation of effective fall interventions and would reduce the personal and societal burden associated with older adult falls.

CONCLUSION

Falls and fall-related injuries are age-related problems, and the U.S. population is aging rapidly. People older than 85 years are the fastest growing segment of the older population [109] and have the highest fall injury rate [8]. In future, a greater number of older adults will be affected by fall injuries unless we take preventive action—including educating older adults, health care providers, and senior services providers about fall risk factors and effective prevention strategies, incorporating fall prevention into clinical care, and disseminating and implementing effective fall prevention programs in our communities. Such a comprehensive approach will reduce the societal burden of fall injuries and will improve the health and quality of life of older adults.

INTRODUCTION

Over the past 25 years, intimate partner violence (IPV) has gained increased recognition in the medical and public health fields as a significant problem affecting women in the United States and globally. IPV is perpetrated by one partner in a relationship (either current or former spouses or dating partners) against the other and can include physical violence, sexual violence, threats of violence, or emotional abuse [1]. The consequences of IPV are broad, ranging from physical injuries, chronic conditions, mental health outcomes, and death and costing billions of dollars a year in medical expenditures and lost productivity. Therefore, preventing repeat IPV should be a priority for medical and public health practitioners.

This chapter provides the necessary background to facilitate action by health care and public health practitioners. Following an overview of the epidemiology and health consequences of IPV in the United States, the chapter will discuss the current state of the science on screening for IPV in the clinical setting and present existing interventions to address IPV. Finally, this chapter will summarize the role of the health care and public health practitioner in addressing IPV in order to prevent repeat violence among women.

IPV IN THE UNITED STATES

Epidemiology of IPV

One of five women experience physical assault by an intimate partner in their lifetime, and an estimated 1.3 million women are victimized by 4.5 million physical assaults in their intimate relationships annually [2]. Among clinical samples, the prevalence rates range from 4% to 44% of women experiencing IPV in the past year [3–6]. Both men and women are victims as well as perpetrators of violence in their intimate relationships. However, women are more often the victims of IPV, are more likely to sustain more severe physical injury, and are more likely to be killed by an intimate partner as compared to men [7–10].

While women of all ages, race/ethnicities, and sociodemographic statuses experience violence in their intimate

relationships, the prevalence of IPV varies between different groups. Findings from the National Violence Against Women Survey indicated that American Indian/Alaska Native women experience higher rates of IPV compared to women of other racial backgrounds, while Asian/Pacific Islander women report lower rates of IPV [9]. The National Violence Against Women (NVAW) survey and other research indicates that African American women report experiencing significantly higher rates of lifetime abuse and intimate partner homicide compared to women overall, and higher rates of severe violence than white women [2,11–13]. For example, in one large sample of African American women in Baltimore, 62% of women reported past year abuse from an intimate partner, a rate that is significantly higher than most estimates of IPV in the general population [14]. Women of mid-level socioeconomic status and those with higher levels of education have a lower prevalence of IPV than their low-income counterparts [15]. Low-income women, regardless of race and ethnicity, may be doubly disadvantaged because they not only have fewer resources for leaving an abusive relationship but their health status may already be compromised due to their impoverished circumstances. These factors make IPV and its associated health consequences a central concern as a health disparities problem in need of attention.

Health Consequences of IPV

IPV is the largest cause of injury for women who are treated in emergency departments (EDs) as well as the most prevalent cause of homicides in women [15]. Approximately 42% of women who are physically assaulted by their partner sustain injuries, [1,9] and between 40% and 60% of murders of women are committed by their intimate partners [15]. Women who have experienced IPV are more likely than women who are injured through other causes to sustain injuries to their face, neck, throat, breast, and abdomen and often experience chronic pain and gastrointestinal (GI) disorders. The chronic pain and GI disorders can result not only from the injuries themselves but from the fear and stress associated with experiencing abuse as well. Moreover, psychological IPV itself has been associated with several physical health outcomes such as arthritis, chronic pain, migraine, stomach ulcers, and chronic pelvic pain [16].

Numerous reproductive health consequences can result from IPV. Women who experience IPV are more likely to have gynecological health issues, such as sexually transmitted infection (including HIV), vaginal bleeding or infection, fibroids, pelvic pain, and urinary tract infections, and other reproductive health outcomes such as unintended pregnancy [15]. IPV experienced during pregnancy can have additional health impacts such as delayed entry into prenatal care, premature labor, poor weight gain, anemia, first or second trimester bleeding, as well as negative health consequences for the infant, such as low birthweight or fetal trauma resulting in miscarriage or spontaneous abortion [17].

In addition to experiencing physical and reproductive health consequences, abused women also suffer from numerous mental health sequelae of IPV. Depression, anxiety, and posttraumatic stress disorder (PTSD) are the most common mental health outcomes associated with IPV, and suicidality has also been associated with the experience of violence in intimate relationships [18]. Several studies have described the increased risk of depressive and PTSD symptoms associated with living with IPV [18–29]. A meta-analysis of 11 studies indicated that between 31% and 84.4% of women who had experienced IPV subsequently met the criteria for PTSD [30]. Furthermore, qualitative inquiries into the lives of women who have experienced IPV have indicated that these women describe violence, substance use, and depression as intricately related and overlapping problems [31].

Need for Interventions

Given the significant impact of IPV on women's physical, reproductive, and mental health, it is not surprising that women who experience IPV consume more medical care than their non-abused counterparts. Not only do they seek more medical care for their injuries associated with the violence they experience but they also use more of other types of health care services and more prescriptions [15,32]. Evaluations of women's health care utilization and costs indicate that women who experience IPV use more health care services, including increased hospitalization, more use of general clinics and mental health services, and more out-of-plan referrals, which result in increased costs as compared to their non-abused counterparts [33]. A study of female Health Maintenance Organization (HMO) enrollees indicated that the average health care cost of women who experienced IPV was $1700 more over a 3 year span than matched women who were never abused [34].

Thus, the medical care setting provides an ideal, albeit usually missed, opportunity to address this important women's health issue. Addressing IPV in the health care setting could help to prevent injury and numerous other health-related sequelae. However, in order to provide treatment or intervene to prevent repeat IPV, it is necessary to first identify the women who are experiencing it. Screening for IPV is the obvious choice as a means to accomplish this in the health care setting.

UNIVERSAL SCREENING FOR IPV

A feasible low-cost, high impact policy to address IPV is the universal screening of women for IPV in the medical care setting. Universal screening has been defined as "universal routine inquiry" [35] or "a standardized assessment of patients, regardless of their reasons for seeking medical attention" [36]. Therefore, a policy of universal screening would require that every woman would be asked questions, regardless of the nature of her visit to the health care setting, that could identify her as being exposed to violence in her intimate relationship. Universal screening could identify women who are experiencing IPV, but do not present with outward clinical signs such as injury, and assist with

the primary prevention of serious health-related outcomes of IPV. Screening for IPV would also allow for the identification of women who are at high risk of serious or fatal violence. By identifying women who are experiencing IPV, especially those who are particularly vulnerable or at risk for severe abuse, clinical providers can provide counseling and referral to existing social services, such as shelters, legal services, or mental health services and thus reduce women's risk of repeat victimization.

Several issues arise in determining whether universal screening for IPV is an appropriate policy to implement to begin to prevent future IPV. First, are there validated screening tools that can correctly identify women who are experiencing IPV? Second, is universally screening all women who present in health care settings an acceptable practice for patients as well as providers? And lastly, can a policy of universal screening effectively lead to the prevention of subsequent IPV? Each of these questions is addressed in the following sections.

Validated Screening Tools

Several screening tools have been tested and validated as useful in identifying women experiencing IPV or at risk for severe physical harm as a result of IPV. These tools can be used to quickly identify women who present in primary care for regular check-ups or in the ED and are currently experiencing violence, alert clinicians to this issue, and create an opportunity to refer women to existing IPV services in the community such as legal aid, shelters, or specialty health care. The utilization of these tools in a systematic and universal way could identify many at-risk or abused women who would have otherwise gone without intervention.

A few systematic reviews have evaluated IPV screening tools that have been tested in health care settings, and the Centers for Disease Control has published a compilation of more than 30 tools available to clinicians to screen for violence among their patients [37,38]. While the reviewers found that further testing and validation of these scales in more diverse populations is warranted, their work also synthesizes the utility of several scales in the clinical setting. The systematic review focuses on the most studied tools in clinical settings, which include Abuse Assessment Screen (AAS), the Hurt, Insult, Threaten, and Scream (HITS), the Partner Violence Screen (PVS), and the Woman Abuse Screening Tool (WAST), which are summarized in Table 127.1 [37]. The AAS has been tested mostly among low-income and uninsured women and in countries outside the United States and was found to have high sensitivity and positive predictive values but varying specificity. The HITS has been tested among varying populations, including Hispanic and African American women, as well as in Spanish, and was found to have adequate internal consistency (alpha = 0.80) and good validity compared to the Conflict Tactics Scale, which is a previously validated instrument to measure IPV. The PVS has a wide range of sensitivities and specificities when tested among a population with a range of race/ethnicities and socioeconomic status (SES), but all were adequate. The WAST was tested among white, African American and Latina, and Spanish women and was also found to have varying sensitivities and specificities but good internal reliability and discriminant validity in differentiating between abused and non-abused women.

Despite the need for additional testing of some of these tools, they are viable options for clinicians to identify women who are experiencing or at risk for IPV. Women can be screened using very few items that take a small amount of time to administer, making these tools appropriate for a clinical setting where the lack of time with patients might be an issue.

Acceptability of Screening to Patients and Providers

Because IPV is historically not an issue that is dealt with in the health care setting, or typically considered appropriate to mention, discuss, or intervene with, clinicians do not often or routinely screen for IPV. In fact, the rates of IPV screening by health providers are surprisingly low and vary by setting [43]. Women who present to emergency rooms with certain types of injuries are more likely to be screened for IPV than women who present with no visible signs or symptoms of IPV-related health outcomes or women who visit clinicians for other medical issues [44]. Among a nationally representative sample of women, only 7% reported having ever been asked about experiencing violence by a health care professional [45].

In studies of the acceptability of IPV screening, the majority of women have reported that IPV screening in clinical setting is acceptable [46]. The systematic review by Ramsay et al. determined that women's acceptability of IPV screening in a clinical setting ranged from 49% to 75% [46–48]. In one study of 442 abused and non-abused women, high proportions of both groups believed that screening would make it easier for abused women to get help (86%) and that they would be glad someone took interest (96%); moreover, 88% of the non-abused women reported that they would not be insulted if asked about IPV [47].

However, in studies of provider acceptability of screening, two-thirds of physicians and one-half of ED nurses were *not* in favor of screening [48,49]. Some of the barriers to screening for IPV that were cited include a lack of skills or education in screening, a fear of offending or harming women, a lack of known effective interventions, and limited time. Other studies indicate that the acceptability of screening can vary based on provider characteristics. For example, providers who are females, obstetricians/gynecologists, trained within the past 5–10 years, and who work in clinics or hospitals perceive fewer barriers to screening [50].

The limited data that are available suggest that patients would be supportive of universal screening and that more recently trained health care providers would be as well. Thus, the next question concerns whether such screening is effective. The systematic review by Ramsay et al. found that, in general, screening programs resulted in increased rates of identifying women experiencing IPV in various clinical

TABLE 127.1
IPV Screening Tools

Screening Tool	Administration Method	Items	Scoring
Abuse Assessment Screen (AAS) [39]	Clinician administered	1. Have you ever been emotionally or physically abused by your partner or someone important to you? 2. Within the last year, have you been hit, slapped, kicked, or otherwise physically hurt by someone? If yes, by whom? How many times? 3. Have you been hit, slapped, kicked, or otherwise physically hurt by someone? If yes, by whom? How many times and where? 4. In the last year, has anyone forced you to have sexual activities? If so, whom? How many times? 5. Are you afraid of your partner or anyone you listed above?	Abuse indicated by positive response to one or more items
Hurt, Insult, Threaten, and Scream (HITS) [40]	Clinician administered or self-report	How often does your partner: 1. Physically hurt you? 2. Insult you or talk down to you? 3. Threaten you with harm? 4. Scream or curse at you? (Response options on five-point Likert scale: 1 = never, 2 = rarely, 3 = sometimes, 4 = fairly often, and 5 = frequently)	Abuse indicated by score of ≥10.5
Partner Violence Screen (PVS) [41]	Clinician administered	1. Have you ever been hit, kicked, punched, or otherwise hurt by someone in the past year? If so, by whom? 2. Do you feel safe in your current relationship? 3. Is there a partner from a previous relationship who is making you feel unsafe now?	Abuse indicated by positive response to items 1 or 3, or negative response to item 2
Woman Abuse Screening Tool (WAST) [42]	Self-report	1. In general, how would you describe your relationship—a lot of tension, some tension, or no tension? 2. Do you and your partner work out arguments with great difficulty, some difficulty, or no difficulty? 3. Do arguments ever result in you feeling down or bad about yourself? 4. Do arguments ever result in hitting, kicking, or punching? 5. Do you ever feel frightened by what your partner says or does? 6. Has your partner ever abused you physically? 7. Has your partner ever abused you emotionally? 8. Has your partner ever abused you sexually? (Response options for #3–#8: often, sometimes, never)	Cut off for abuse not available

settings, including primary care clinics and EDs [46]. Because the first step toward intervention for IPV is identification of women who are experiencing IPV, universal screening offers a feasible and acceptable means to that end.

Effectiveness of Screening for IPV

There are two related questions that address the effectiveness of screening for IPV. First, does *screening increase identification of IPV* and if so, does *identification reduce repeat victimization?* Several studies have indicated that instituting screening protocols for IPV in health care settings results in a significant increase in identification of IPV with acceptable accuracy [51–54]. Evidence addressing the question as to whether identification of IPV in the health care setting reduces repeat victimization is discussed in the following section.

The U.S. Preventative Services Task Force Evaluation of IPV Screening

In order to assess the effectiveness of IPV screening, the U.S. Preventative Services Task Force (USPSTF) conducted

a systematic review of the existing literature on IPV screening and IPV interventions. A total of 14 studies that met the USPSTF inclusion criteria for screening studies were examined. These studies compared various screening instruments against each other [39–41,55–57], compared screening instruments with a directed interview [54,58], measured inter-rater reliability or internal consistency of screening tools [59–61], and compared methods of administration of screening tools [62–64]. Of these, only four were ranked as having good internal and external validity (the HITS, PVS, AAS, and WAST summarized in "Validated Screening Tools" Section).

A systematic review specifically examining interventions for violence against women was conducted, which included interventions for batterers and couples, and interventions for women outside of the clinical setting, in addition to interventions for women in health care settings. This review found that screening instruments for IPV are available to identify women experiencing abuse but concurred with other reviews and studies that the effectiveness of screening for explicitly reducing violence or improving health outcomes has not been evaluated [65].

However, some critical evidence concerning IPV screening was excluded from the collection of studies in the USPSTF's systematic review, as was identified in a response by the Family Violence Prevention Fund [66]. First, the USPSTF used an analytic framework for screening tools that examines its use only among asymptomatic patients. Many IPV experts believe that a behavioral assessment and counseling tool using a different analytic framework would be more appropriate for a problem like IPV. This distinction is based on the observation that IPV is more of a chronic problem that can escalate over time, making it difficult if not impossible to distinguish "asymptomatic" from "symptomatic" women. Therefore, screening can be beneficial even for women who are already "symptomatic"—i.e., women who present with physical or mental trauma as a result of IPV that they may have been experiencing for years. Even such women have shown improvements in health outcomes and reduced risk for repeat violence after screening. A study by McFarlane et al. was excluded from the review because it was designed to asses an intervention for reducing repeat IPV but found that all women who were assessed using the AAS and subsequently offered a resource card or counseling sessions showed a decrease in threats of abuse, assaults, and danger risk for homicide over time [67]. Therefore, the USPSTF's decision to consider IPV screening as a way to identify asymptomatic patients, as opposed to a way to "diagnose" women with IPV who might have presented with some symptoms, they systematically excluded all research involving patients presenting with any signs of prior trauma or IPV. Given the nature of IPV, this was potentially an inappropriate distinction and could explain the USPSTF's inclusion of only 14 screening studies of 886 identified in the literature search.

Additionally, IPV experts and researchers raised the critique that the USPSTF's emphasis on randomized controlled trials (RCTs) in the evaluation of validity of IPV screening studies is perhaps inappropriate. Because many researchers consider it unethical to conduct studies related to IPV where a control group of women being abused receives no intervention, many IPV-related studies are limited in their ability to use an RCT design. However, the Family Violence Prevention Fund points out that the USPSTF has recommended assessment and counseling services for various other health issues, such as alcohol and drug use among adolescents and unintended pregnancy, even though RCT evidence was lacking in these cases [66]. They further assert that "the public health benefit of identifying a history of victimization within the context of other psychosocial health problems and risk behaviors, giving supportive messages to patients who disclose abuse, and providing appropriate referrals could prevent future injuries, illness and improve overall quality of care" [66, p. 4].

The USPSTF limited its review to studies that examined the outcomes of morbidity, disability, and mortality. However, there are several outcomes that could be considered an indication of a successful result of IPV screening that were not considered. These include referral to support services such as legal or shelter services, the initiation of safety planning behaviors, and the receipt of advocacy services at the health care setting itself. Several studies exist in the literature that indicate that screening for IPV leads to risk reduction and public health benefits, but do not directly link screening to morbidity or mortality outcomes, and these were not included in the USPSTF's review [68–72]. For example, an intervention in an ED that implemented universal screening, on-site IPV advocacy, and telephone-based counseling by a case manager found that more than half of women identified as IPV victims were able to receive ongoing community-based services to address their IPV and nearly one-fourth reported a reduction in perceived risk of IPV by their abusive partner. While this study was not randomized and does not show clinical outcomes associated with IPV screening, it does suggest that IPV screening could be effective in helping women stay safe [68].

The USPSTF admittedly takes a "conservative evidence-based approach to this process, making recommendations that reflect primarily the state of the evidence and refraining from making recommendations when they cannot be supported by evidence" [73, p. 31]. The panel acknowledges that clinicians and policymakers might consider other issues, such as cost-effectiveness, resource priorities, ethics, and legal concerns, when deciding whether or not to accept their recommendations [73].

Recent RCT for Screening for IPV in Health care Settings

More recently, an RCT to investigate the effectiveness of universal IPV screening in health care settings was conducted in Canada [35]. This study recruited participants from 12 family practices and community health centers, 11 EDs, and 3 obstetrics/gynecology clinics and randomized them

by day or work shift. Women who had a male partner in the past 12 months and presented to the health care setting on a randomly assigned screening day or shift were given the eight-item WAST and asked additional questions about their socioeconomic characteristics. The WAST was included in the patient charts of women who screened positive for IPV before they saw their clinician. Women with male partners in the past 12 months who presented for health care visits on the assigned non-screening control days or shifts were asked about their socioeconomic characteristics only before seeing their clinician. After their visit, they were given the WAST to screen for IPV. Both groups of women were given an information card containing contact information for services available for women experiencing violence, and all women were followed up at 14 days, 6 months, 12 months, and 18 months.

Results from this study indicated that while women in both groups overall reported a reduction in the experience of IPV, there were no statistically significant differences in IPV recurrence over time between women who were screened for IPV before their clinical appointment and those who were not. The study concluded that there is not sufficient evidence indicating that universal IPV screening in clinical settings prevents or reduces women's experience of IPV. However, a critical point of importance is that this study tested the effectiveness of screening alone, not the effectiveness of screening followed by any type of referrals, intervention, or treatment. The clinicians were simply provided the positive screening tools in their patients' charts, and any subsequent referrals or discussion of violence during the clinical visit was left to the discretion of the clinicians. In fact, only 44% of women who were screened for IPV prior to their visit reported discussing the violence with their clinician during their visit.

Therefore, while this study agrees with the findings of the USPSTF and suggests that there is insufficient evidence to support universal screening for IPV, it does not adequately test the effectiveness of screening when accompanied by referrals to IPV services or interventions. As is the case with numerous other health issues, screening alone is not preventative, and it is the quality and effectiveness of the treatment or intervention made available to patients who are screened that can actually prevent a health issue or result in secondary prevention. The authors of this study suggest that a lack of evidence for effective IPV treatment and services exists, and therefore, no effort was made to control whether clinicians actually implemented any sort of treatment or intervention after a women screened positive for IPV. However, several studies of interventions in the health care setting to address IPV have shown promising results in the reduction of repeat IPV among women.

INTERVENTIONS TO ADDRESS IPV

Interventions in the Health care Setting

Despite the substantial impact of IPV on women health and their use of health care, there is a dearth of knowledge about what services would help women in this setting. The few intervention trials that have been reported are reviewed briefly here.

Parker et al. [74] tested the effectiveness of an intervention for pregnant women who were experiencing IPV in a clinical setting. The intervention was based on a model of empowerment to increase women's independence and control and was administered by masters or doctorate level nurses in prenatal clinics during scheduled clinical visits. The three 30 min intervention sessions focused on creating a safety plan, providing information about the cycle of IPV, offering phone numbers for community resources, and providing information on protective orders and filing criminal charges. Women were also provided a printed brochure with information covered in the intervention sessions. Half of the women who completed the intervention were also invited to attend group counseling and information sessions. Women in the comparison group were given a card with information about resources available in the community to address IPV. The findings from this study indicated that at 6 and 12 months after the intervention, women who received the intervention reported experiencing significantly less violence. However, women were not randomized into the intervention and control groups.

The effectiveness of three types of interventions to decrease IPV among pregnant women was examined in a study that implemented a randomized design. This study by McFarlane et al. [75] compared a brief intervention, a counseling intervention, and a counseling plus outreach intervention by randomly assigning pregnant women who reported IPV in the previous year or during their current pregnancy to each group. Women in the brief intervention group were given a resource card with the phone numbers of available community resources to address IPV, as well as a brochure. Women in the counseling intervention group were provided access to counseling services located in the clinic, which they could use at their own discretion. Professional counselors were available to provide counseling and education on IPV, referrals to services, and assistance with accessing these services. The final treatment group included the services available in the counseling intervention group as well as the availability of a nonprofessional mentor who offered education and support services and assistance with referrals and access to resources. These mentors were available to women in this treatment group through in-person and telephone contact. At 2, 6, 12, and 18 months after the interventions were delivered, women in all groups reported decreased threats of violence and physical violence. However, there were no significant differences in the experience of violence between the three intervention groups. The decrease in violence for all women, even those who were simply given a resource card, indicates that the IPV screening itself could have acted as an intervention. The authors note that by simply completing an IPV screen in a clinical setting and being offered resources, women might be alerted to the fact that their experience of IPV is serious and that their provider is available to assist them.

Similar interventions were also tested by McFarlane et al. in an RCT of women (not limited to pregnant women) who presented at public health care clinics and screened positive

for IPV in the past year using the AAS [67]. Women were randomized by weeks into two study groups. Those in the first group were screened for IPV and then given a resource card that contained information about creating a safety plan and resources available to address IPV. Women in the second group were screened for IPV and then provided nurse case management during the visit, which included supportive care, provision of referrals, and guidance in accessing resources. Findings from this randomized study showed that all women, regardless of the type of intervention they received, reported experiencing a reduction in threats of physical IPV, actual physical IPV, and risks for homicide. Additionally, the adoption of safety behaviors increased for women in both groups. Therefore, this study indicates that screening for IPV and referring women to available services, even by simply providing them with printed information, can reduce their experience of IPV.

A more recent study by Kiely et al. [76] evaluated the impact of an intervention for IPV that was integrated into a broader intervention to reduce cigarette smoking, environmental smoke exposure, depression, and IPV among pregnant women. This IPV intervention was based on the previously tested intervention by Parker et al. [74] and provided information on IPV, available resources, and assistance in developing a safety plan over a minimum of four sessions in prenatal clinics. Women were randomized to receive this integrated intervention or to receive usual care as was standard in the prenatal clinics. After completing the interventions sessions, women in the treatment group who experienced minor physical IPV were significantly less likely to experience IPV during the follow-up period of 8–10 weeks postpartum. However, this intervention did not show significant effects on the experience of more severe physical IPV and sexual IPV.

The studies described earlier have been generally grounded in an empowerment theory approach to IPV, which has been most prominent in the IPV advocacy movement from its inception. An alternative yet complementary approach that has been proposed is the application of a stages-of-change model [77]. The stages-of-change, more properly called the Transtheoretical Model (TM), was created by Prochaska and DiClemente and it describes behavior change as a dynamic, stage-based process [78,79]. The TM may be particularly appropriate for IPV interventions delivered in the health care setting because it provides a systematic approach to assessing an individual's readiness to change and tailoring patient counseling accordingly, and it has demonstrated its utility for changing a number of other health-related behaviors. Work by Brown [80] and Burke et al. [81,82] found that women describe their experiences living in and surviving abusive relationships in ways that are consistent with the stages of the model. Qualitative interviews with 78 IPV survivors followed by quantitative surveys of 96 IPV survivors led Burke et al. [82,83] to conclude that the TM model fits women's lived experiences and that women can be staged according to their readiness to end the relationship: (1) *Pre-contemplation—Does not want to end the violent relationship or is unsure;* (2) *Contemplation—Wants to end the violent relationship, but has not done anything to get ready to do so;* (3) *Preparation—Wants to end the violent relationship and has started taking actions, getting prepared;* (4) *Action—Has ended the violent relationship less than six months ago; and* (5) *Maintenance—Has ended the violent relationship at least six months ago.* The TM also incorporates influencing factors—i.e., 10 processes of change that describe how individuals move from one stage to the next, decisional balance (weighing the pros and cons of change), and self-efficacy (confidence on one's ability to change). This feature of the model is particularly useful from an intervention perspective because these factors can be "activated" through specifically designed counseling activities.

An eight-session, individually tailored counseling intervention based on the TM, using the stages and processes identified in the work by Burke et al. [81–83] was recently pilot tested with a small sample of 12 abused women recruited from a primary care clinic serving HIV-positive patients [84]. The curriculum focuses on goal setting, danger assessment, and safety planning as well as specific stage-based counseling activities to help women make informed decisions about their situation. Data from the six women who completed all the counseling sessions and a follow-up interview 2 weeks later found significant improvements in perceived control, perceived empowerment, and social support. The number of types of IPV events experienced decreased from 3.08 during the 3 months prior to the intervention to 0.50 during the 3 month intervention period. No adverse events occurred, and women's qualitative feedback on the counseling sessions was extremely positive. Although this is a small-scale test of the program, it shows promise and represents an innovation in individually focused interventions for IPV. If found to be effective on a larger scale, such a program could be implemented in a wide array of settings, both in and outside of the health care setting.

Interventions Outside of the Health care Setting

While screening and intervention for IPV in the clinical setting has the potential to prevent repeat IPV for many women, there are numerous activities and interventions taking place outside of realm of health care [85,86]. Decades of work by advocates and the criminal justice system has resulted in the creation of shelters, legal and counseling advocacy programs, national and local hotlines, community campaigns, and a plethora of laws designed to protect women and reduce IPV, including the Violence Against Women's Act enacted by Congress in 1993 [87]. Today, we have organizations such as the Family Violence Prevention Fund (endabuse.org), the National Coalition Against Domestic Violence (www.ncadv.org), and the National Domestic Violence Hotline (www.thehotline.org) that provide information and resources to both professionals and the public. The National Network to End Domestic Violence (www.nnedv.org/resources/coalitions.html) coordinates coalitions in every state and territory. Service programs at the local level, such as shelters, hotlines, legal advocacy programs, and counseling advocacy programs, have been

found to have varying levels of success, and their effectiveness is heavily dependent on their availability and accessibility to women who need them [86,88]. Wathen and MacMillian systematically reviewed the literature on interventions for women and concluded that there were no high quality evaluations of shelter stays, although they found fair evidence that a specific program of advocacy and counseling among women who spent at least one night in a shelter reduced their reported violence and improved their quality of life [65].

In the area of criminal justice interventions, several policies and protocols are thought to impact the prevention of repeat IPV among women. For example, implementing a policy of mandatory arrest for perpetrators of any misdemeanor intimate partner assault was found to result in a reduction in any repeat assault of 25% and a reduction in the number of assaults of 30% [89]. Webster notes the potential promise of special domestic violence courts that can both take into account the sensitive and complicated nature of the relationship between an IPV perpetrator and his victim as well as bring together and integrate additional resources to address IPV [88]. A court order of protection is a measure that a victim of IPV can pursue as well that has been found to lower the risk of repeat violence in some studies [90,91]. Policies that separate perpetrators of IPV from firearms have the potential of preventing severe IPV-related injury and intimate partner homicide. The odds of a woman being killed by her abusive partner has been found to be five times higher if her abusive owns a firearm [92]. Some research has indicated that the implementation of laws that require the removal of firearms from IPV perpetrators does result in a reduction in the IPV-related homicide rate, but the effectiveness of these laws are also impacted by whether judges and law enforcement actually implements them [93,94]. Bell calls for additional research on criminal justice interventions [95]. She emphasizes the need to strengthen the methodology used to include larger samples and longer follow-up periods and, importantly, to incorporate a broader array of outcomes that are informed by listening to victims' stories of the impact of the criminal justice system on their lives.

Finally, research has been conducted to evaluate the effectiveness of interventions targeted at the abuser. Many of these abuser intervention programs are mandated by the courts, although some are voluntary. While the evidence on the effectiveness of these programs does not seem particularly promising, many of the studies were quasi-experimental and were affected by high dropout rates. Webster notes that many programs might not be successful due to their inability to address underlying issues related to the perpetration of violence, such as mental illness and drug and alcohol abuse [88].

ROLE OF THE HEALTH CARE PROVIDER IN THE PREVENTION OF IPV

There are numerous roles for health care providers to play in helping to reduce the impact of IPV on women's health. Because IPV is associated with medical problems that span the spectrum from acute injuries to reproductive health to chronic diseases, all health care providers can contribute [15,22,32]. The evidence that abused women would welcome help from their health providers is clear [46–48].

Screening for IPV

The American Medical Association, American College of Obstetricians and Gynecologists, American Academy of Family Physicians, American Academy of Pediatrics, and American Nurses Association are among numerous medical organizations that recommend IPV screening as part of routine patient care [86,96–98]. Health care providers can play a crucial role in identifying women who are experiencing IPV and thereby take the first step in preventing repeat violence and reducing the negative health outcomes that can result. By integrating a universal screening policy into their standard clinical visit, providers can quickly assess whether their patients are safe in their current relationship or are at risk for repeat IPV. While a gold standard for IPV screening does not exist, numerous screening tools with relatively high validity, sensitivity, and specificity are available that can be implemented in a clinical encounter in a very short amount of time, and these screening procedures have been shown to be acceptable to women patients [46–48].

Implementing Interventions

Providers can also play a role in preventing IPV by implementing interventions in the clinical settings. As several studies have demonstrated, even a simple intervention of providing a referral card with available IPV resources may well decrease repeat IPV [67,74,99], and more intensive interventions could potentially result in an even greater IPV reduction [76]. Newer program models, such as those that integrate IPV within the context of other health-related issues and those that apply behavior change theory should be supported. The paucity of evaluated interventions demands attention, and health care providers should partner with academic researchers to address this gap.

Collecting Data to Inform Intervention Development and Policy

Much of the criticism of implementing universal screening policies has focused on the lack of evidence that universal screening along with effective interventions can result in the reduction of IPV over time [35,65]. In order to improve the body of research to support universal screening policies by agencies such as the USPSTF, health care providers can assist in collecting data on IPV and the impact of screening and interventions in their clinical practice. Future studies showing the potential success of screening paired with effective interventions could bolster the body of data used in systematic reviews and by the USPSTF in making their recommendations.

Act as Policy Advocates

In addition to improving services to individual patients, there are numerous opportunities at the policy level to strengthen domestic violence laws at local, state, and national levels. For instance, a quick search of the National Conference of State Legislatures database found that four states had introduced teen dating violence legislation in a single month, including one bill in Maryland that would change the definition of domestic violence [100]. By partnering with advocates, health care providers can add their influential voice to the policy discussion. Health care providers can also be advocates within their own professional societies. Policy statements by organizations such as the American Medical Association and others can carry considerable weight in policy debates.

CONCLUSIONS

This chapter has focused on ways in which IPV should be a critical concern for those interested in healthy lifestyles. The prevalence of IPV and its consequences makes it one of the most pressing women's health issues, yet it is rarely discussed in the context of healthy lifestyles and it is often ignored in the delivery of health care services. As described in this chapter, ways to improve the quality of women's lives by reducing their experience of violence do exist. Several validated screening tools can be used to identify women who are experiencing IPV. Women support such screening in the context of their health care. There are promising, if not yet widely available, programs that can be delivered to women who are found to be living in abusive relationships. There is an urgent need for additional resources for such programs and careful evaluations of their impacts. However, the health care setting cannot be expected to solve the problem of IPV alone. Indeed, the evidence suggests that strong policies, particularly those focused on holding abusers responsible and improving access to advocacy and counseling services for women, must be implemented as well. Health care providers can be strong advocates both within their organizations to ensure that women are being adequately and appropriately served as well as within their larger community to ensure effective policy solutions are implemented.

Because of its magnitude, economic and human impact, and preventability, traumatic brain injury (TBI) is a priority in public health. The Centers for Disease Control and Prevention (CDC) estimated that at least 1.7 million people sustain a TBI annually and there at least 1.4 million annual TBI-related emergency department (ED) visits [1]. With the increasing numbers of people engaged in sport and recreation (SR) activities in the United States, more people are at risk for SR-related injuries, including TBI. From 2001 to 2009, the CDC estimated that the number of TBI-related ED visits for those ≤19 years old from SR activities increased 62% from 153,375 to 248,418 [2].

PARTICIPATION IN SPORT AND RECREATIONAL ACTIVITY IN THE UNITED STATES

According to data from the 2009 United States Department of Labor, Bureau of Labor Statistics' American Time Use Survey, it was estimated that approximately 18.9% (57 million) of the United States population is engaged in sports, exercise, and leisure activities every day with more males (21.7%) than females (16.3%) regularly participating in those activities [3]. However, current estimates of participation in different activities are lacking making the calculation of rates of injury problematic. Often, rates are described using the population of that group; but not every member of a demographic group (e.g., age group, gender) participates in every SR activity. Participation-based injury rates are possible using data from organized activities. The High School Sports Injury Surveillance System collects information on participation (i.e., exposure) and injuries in organized high school activities [4]; similarly, the National Collegiate Athletic Association Injury Surveillance System collects participation and injury information at the collegiate level (www.ncaa.org). However, risks of injury in these organized activities may differ from participation in other less formal, structured, or regulated settings (e.g., recreation leagues, pickup or backyard games). Many recreational activities do not have comparable competitive organizations from which to estimate risk.

PATHOPHYSIOLOGY OF TBI

A TBI is an alteration in brain function, or other evidence of brain pathology, caused by external forces [5]. TBIs in SR activities can result from blunt (e.g., when the head strikes or is struck by something) or penetrating trauma (e.g., when something pierces the skull and breaches the duramater) to the head, or indirect acceleration and deceleration forces (e.g., a blow to the body moving the head violently without itself being subject to blunt trauma). These direct or indirect forces temporarily or permanently disrupt the functioning of the brain [6,7]. The extent and severity of a brain injury after an initial mechanical event depends on many factors including the magnitude of accelerating and decelerating forces applied to the head, the direction of the force, and the subsequent direction, duration, and amplitude of angular accelerations to which the brain is subjected [8–10]; other factors may include age, body size, and weight [11].

Even TBIs that are more mild on the continuum of injury severity can alter the brain's physiology for minutes, weeks, months and even indefinitely setting into motion a variety of pathophysiological processes [12] that seem to reverse in a large majority of people who sustain milder forms of TBI [13,14]. Conversely, sequelae observed in some persons with these mild forms of TBI, and in some animal studies, may reflect a degree of cell death after the injury [15,16].

After the initial mechanical event, depending on the injury severity, there may be direct or primary mechanical alterations of the brain tissue such as laceration of the brain or diffuse axonal injury. These primary mechanical alterations are generally followed by secondary brain injuries that can include brain edema or elevated intracranial pressure. Secondary brain injuries arise from complications initiated by the primary injury itself and/or via other mechanisms, including inflammation, cell receptor-mediated dysfunction, free radical and oxidative damage, and calcium or other ion-mediated cell damage [17]. In turn, these secondary processes modulate gene expression and/or protein regulation that lead either to cell death or repair [17,18]. Additionally, there is epidemiological evidence indicating that synergy exists between permanent neurodegeneration after a TBI and the possession of apolipoprotein Eε4 allele, a risk factor for Alzheimer's-like neurodegeneration [17–20] and poorer outcomes [21]. These processes and their consequences are beyond the scope of this chapter.

Although the current understanding of the underlying pathology of concussion, a form of a potentially less severe TBI, involves a paradigm shift away from a focus on anatomic damage to an emphasis on neuronal dysfunction involving a complex cascade of ionic, metabolic, and physiologic events [22,23], some of these events may involve physical disruption in the neuronal synapses [23] and even cell death [15,16]. However, while changes in metabolic processes and gene expression have been reported in more severe TBIs, more research is needed in the area with respect to milder forms of TBI [22].

In SR activities, the external forces may cause linear, rotational, or angular movement of the brain or a combination of these motions. In rotational forces, for example, the magnitude of this force may be an important factor to cause a concussion [24] and may even contribute to its severity [13]. It has been estimated that angular accelerations ranging from 4600 to 7900 rad/s^2 may increase the risk of developing a mild TBI from 25% to 80% [25]. Although many areas of the brain can be affected by rotational forces, these may primarily affect the midbrain and the diencephalon [26,27] disrupting parts of reticular activating system, which in turn, may result in loss of consciousness (LOC) [27]. It is thought that concussion results from a diffuse brain injury affecting mainly axons distributed over a widespread area of the brain [13,26,28] or inadequate blood flow to the brain due to other concurrent injuries [29].

Acute and chronic neuronal and glial cell lesions have been documented in boxing and football-related literature. Boxers may present with acute elevations of the tau protein, neurofilament light protein, and glial fibrillary acidic protein in the cerebrospinal fluid [30], with sustained release of neuron-specific enolases detectable in serum for up to 2 months [31]. Chronic traumatic encephalopathy manifests primarily by increased tau phosphorylation and patchy distribution of neurofibrillary tangles especially in the frontal and temporal lobes [32]. More recently, findings from studies of the brains of deceased National Football League (NFL) athletes with history of concussion or TBI suggested there was lasting damage to the brain after experiencing at least one concussion leading to a variety of other health outcomes [32,33]. The scope, complexity, and heterogeneity of the pathophysiology of TBI, including mild TBI, present challenges for developing precise, sensitive, and accurate diagnostic tools, severity classification, surveillance tools, and effective medical and health interventions.

TBI SEVERITY AND DIAGNOSIS

TBI results in a constellation of clinical manifestations that range in severity from mild physical, cognitive, emotional, or sleep-related symptoms that may or may not involve a LOC to coma and, in some cases, even death. Survivors present with symptoms that may last from several seconds to days or persist for weeks or months or may continue indefinitely [34,35]. This section will address issues related to TBI severity, diagnosis, and reinjury.

Determining Severity

Based on the clinical manifestations and injury severity scoring systems, TBI is classified as mild, moderate, and severe. The Glasgow Coma Scale (GCS) [36], a clinical tool originally designed to assess coma and impaired consciousness, is one of the most commonly used severity scoring systems. Persons with GCS scores of 3–8 are classified with a severe TBI, those with scores of 9–12 are classified with a moderate TBI, and those with scores of 13–15 are classified with a mild TBI. Other classification systems include the Abbreviated Injury Scale (AIS), the Trauma Score, and

the Abbreviated Trauma Score. Despite their limitations [37], these systems are crucial to understanding the clinical management and the likely outcomes of this injury because the prognosis for milder forms of TBIs is better than for moderate or severe TBIs [34,38,39]. Although mild TBI historically has been considered trivial, studies have demonstrated that its consequences can be devastating in some patients [35].

Mild TBI and Diagnostic Issues

Although mild TBI is one of the most common neurological disorders, there is no single definition for this condition that is universally accepted [35]. The CDC defines mild TBI as an injury to the head resulting from blunt trauma or acceleration or deceleration forces with one or more of the following conditions: any period of observed or self-reported transient confusion, disorientation, or impaired consciousness, dysfunction of memory (amnesia) around the time of injury; LOC lasting ≤30 min; posttraumatic amnesia lasting up to 24 h; GCS scores ranging from 13 to 15; and an AIS Scale score of 2 for the head region [35]. Cases of TBI with intracranial lesions demonstrated by neuroimaging or with selected focal neurological deficits may also be considered as mild if there is no penetrating craniocerebral injury, posttraumatic amnesia lasting longer than 24 h, or LOC lasting longer than 30 min; CDC recommends that these cases of mild TBI with intracranial lesions or focal deficits be analyzed separately to predict outcome [35]. Symptoms among older children and adults, such as headaches, dizziness, irritability, fatigue, and poor concentration, when identified soon after injury, can be used to support the diagnosis of mild TBI but cannot be used to make the diagnosis in the absence of LOC or altered consciousness [35]. Due to advances in the field, this definition should be periodically evaluated and revised as appropriate.

There are, however, recognized issues with the combination of clinical indicators used to measure severity and to predict outcome among those with mild TBI. For example, persons with GCS scores of 13–15 who also present with focal brain lesions and/or even depressed skull fractures may have comparable outcomes as patients with more severe TBI [39]. To overcome the challenge of discharging patients with clinically diagnosed mild TBI, the American College of Emergency Physicians and CDC produced neuroimaging and decision-making guidelines for adults with mild TBI in the acute setting [40]. These guidelines, however, apply to persons aged ≥16 years old who have a nonpenetrating brain injury and a GCS score between 14 and 15 [40].

In most cases, mild TBI is characterized by acute physiological changes that result in at least some acute cognitive difficulties that typically resolve within 3 months post injury [35]. The course of cognitive recovery remains controversial as 7%–33% [35,41–43] may have persistent problems even 1 year after the injury. A "post-concussion syndrome" has been described based on a group of disparate somatic (e.g., headache, dizziness), psychological (e.g., depression, anxiety), and cognitive (e.g., decreased concentration, forgetfulness) signs and symptoms [16]. Long-term consequences of mild TBI may present with neuropsychological dysfunction [44,45] or structural [32,33,46,47] changes to the brain. Recent data from high school athletes who were concussed or sustained a TBI suggested that symptom complexes differed between males and females [48]. Males reported more cognitive symptoms, whereas females reported more neurobehavioral and somatic symptoms. Symptom resolution time and time to return-to-play did not differ between sexes.

Mild TBI and Concussion: Diagnostic Issues

There is confusion among practitioners in the use of the terms mild TBI and concussion. Some definitions for mild TBI, for example, the CDC definition, allow the inclusion of selected nonpenetrating intracranial injuries [13,35,49]; these intracranial injuries do not constitute part of the classical definition for concussion [22,50,51]. The Concussion in Sport Group [22,52], a group of researchers organized by the Ice Hockey Federation, the Federation of Internationale de Football Association Medical Assessment and Research, and the International Olympic Committee Medical Commission, defined concussion as a "complex pathophysiologic process affecting the brain, induced by traumatic biomechanical forces secondary to direct or indirect forces to the head." According to this group [22,52],

1. Concussion may be caused either by a direct blow to the head, face, neck, or elsewhere on the body with an "impulsive" force transmitted to the head.
2. Concussion typically results in the rapid onset of short-lived impairment of neurologic function that resolves spontaneously.
3. Concussion may result in neuropathological changes, but the acute clinical symptoms largely reflect a functional disturbance rather than a structural injury.
4. Concussion results in a graded set of clinical symptoms that may or may not involve LOC. Resolution of the clinical and cognitive symptoms typically follows a sequential course; however, it is important to note that, in a small percentage of cases, postconcussive symptoms may be prolonged.
5. No abnormality on standard structural neuroimaging studies is seen in concussion [22,52].

To improve medical management and follow-up, reporting, and study comparisons, public health practitioners, clinicians, researchers, and stakeholders need to reach consensus to standardize these terms and their definitions.

Repeat Impact Syndrome

Repeat impact syndrome, also known as second-impact syndrome, is a rarely reported condition, in which the brain is thought to swell catastrophically after a person suffers a repeat concussion before symptoms from an earlier

concussion have resolved [53]. This condition may lead to permanent brain damage or even death [53–56]. The second brain injury may occur minutes, days, or weeks after an initial concussion of any severity [54–56]. While its cause is unknown, it is thought that the arterioles in the brain lose their ability to regulate their diameters and lose control over cerebral blood flow, causing cerebral edema [55]. Young athletes are thought to be especially vulnerable [57] as are people with a history of multiple head injuries [58]. Although controversy exists about whether this condition is a valid diagnosis, it is recognized by physicians [59]. To reduce the likelihood of this condition, CDC and other organizations have established return-to-play guidelines that will be discussed later in the chapter.

SPORTS-RELATED TBI EPIDEMIOLOGY AND SURVEILLANCE

Traumatic brain injuries in SR activities are a major public health problem. An estimated 44 million boys and girls participate in an organized sport each year [60] and every day close to 19% of all persons aged 15 years old or older in the United States participate in some type of non-work-related physical activity [3]. In the 1990s, it was estimated that 300,000 sports-related TBIs occur annually [61]; this statistic, however, only included TBIs that involved a LOC. Recent reviews have estimated the annual number of SR-related TBIs in the United States as 1.6–3.8 million, which includes those who did not seek medical assistance [62,63]. From 2001–2009, approximately 179,285 patients were seen and treated in EDs for SR-related TBI annually, the highest population-based rate for either sex was found in those aged ≤4 years old closely followed by those aged 15–19 years old [2].

CDC estimated that approximately 80% of all TBIs reported in the United States were mild, 10% were moderate, and 10% were severe [34,35]. In sports, these statistics are similar [34,64,65]. Concussions are considered to be the most common athletic head injury [66] and can occur in any SR activity in the United States [67]. A study of high school and collegiate athletes found that concussions accounted for approximately 8.9% of all high school athletic injuries and 5.8% of injuries in college [68]. Some researchers reported that, among high school soccer players, boys had higher concussion rates than girls [69]; while others suggested girls sustained higher concussion rates than boys while playing comparable sports (basketball, soccer, and baseball/softball) at the high school and collegiate levels [68].

Although increased media attention has highlighted the issue of concussions among the collegiate and professional ranks, high school athletes may be most at risk both due their high degree of sport participation and level of brain maturity. Estimates of high school sports participation in 2009–2010 by the National Federation of State High School Associations suggests that approximately 7.6 million students participated [70] with 11-man football (N=1,109,278), basketball (N=540,207), and baseball (N=472,644) as the top three. Although these estimates may include limitations such as double counting, they provide vital information on the potential levels of exposure for youth athletes.

CDC estimated that annually 6.5% of all SR-related ED-visits are for those ≤19 years old who sustained a TBI. For those ≤19 years old between 2001 and 2009, football-related TBI ED visits (N=25,376) ranked highest among all organized sports followed by basketball (N=13,987) and soccer (N=10,436; Table 128.1) [2]. Additionally, non-contact SR activities, such as bicycling (N=26,212) and playground (N=16,706), are also associated with large numbers of TBI-related visits to EDs (Table 128.1). TBI comprised 15.3% of all injuries seen in an ED related to horseback riding, which was the highest ratio to all injuries among the reported activities [2]. Bicycling, however, ranked highest in the number of TBIs seen in an ED at 26,212 annually, or 7.7% of all injuries seen for that activity (Table 128.1). Approximately, 17.1% of patients with SR-related TBI ED-visits result in hospitalization.

Children and teens may be more likely to be injured in SR participation [71]. Children have a larger surface area to mass ratio with larger heads compared with the rest of their bodies [71]. Additionally, complex motor skills needed for certain skills may not be fully developed in children [71]. Finally, proper management of a SR-related TBI among youth is vital because the brain is still developing [62].

LIMITATIONS OF SPORTS-RELATED TBI SURVEILLANCE

The burden of TBI might be vastly underestimated because medical data sources are limited and many people do not seek care for their symptoms. Lack of appropriate diagnosis is concerning as those who are involved in SR activities may not understand the potential dangers of a TBI. Although the national databases used by CDC and others to estimate the burden of TBI in the United States have relatively good reliability for moderate and severe TBIs [72], they are less effective in capturing milder cases as they rely on an interpretation of information documented by health care providers in the medical records. Bazarian et al. found that cases of mild TBI that were clinically apparent to the health care providers often were not coded as such because of poor medical record documentation [73].

Additionally, information about the activities resulting in TBI, as with other diagnoses, rely on external cause of injury codes in the International Classification of Diseases (ICD); these, for sports, are very generic and not to be improved. When specific SR activities are available in ICD external cause codes, they are often not reliably used by coders to appropriately describe the circumstances of injury [74,75]. To improve TBI surveillance, CDC has recommended steps to enhance external cause coding such as evaluation of the completeness, accuracy, and specificity of coding; and training hospital admissions staff, health care providers, and coders on the importance of documenting circumstances of injury [76].

TABLE 128.1
Estimated Annual Number of Emergency Department Visits for All Nonfatal Injuries and Nonfatal Traumatic Brain Injuries (TBIs) Related to Sports and Recreation Activities among Persons Aged ≤19 years, by Type of Activity—National Electronic Injury Surveillance System—All Injury Program, United States, 2001–2009

	All Ages		All Visits for Sports and Recreation–Related Injuries		% of All Visits for Injuries that were TBIs
Activity	No.*	95% CI (±)	No.*	95% CI (±)

*Estimates might not sum to totals because of rounding.

†Includes ice hockey, field hockey, roller hockey, and street hockey.

§Includes lacrosse, rugby, handball, and tetherball.

¶Includes other two-wheeled, powered, off-road vehicles and dune buggies.

**Includes cheerleading and dancing.

††Includes boxing, wrestling, martial arts, and fencing.

§§Includes injuries related to golf carts.

¶¶Includes rides and water slides (not swimming pool slides).

***Includes tennis, badminton, and squash.

†††Includes water skiing, surfing, personal watercraft, snow skiing, snowmobiling, snowboarding, camping, fishing, archery, darts, table tennis, nonpowder/BB guns, and billiards.

Additionally, as electronic medical record systems are implemented by health care providers in the United States, the electronic algorithms that accurately automate physician documentation as well as ICD diagnoses, mechanisms of injury, and injury locale is needed.

TBI EPIDEMIOLOGY BY SPORT

This section will focus on three sports that receive intense media coverage worldwide—soccer, football, and boxing, a combat sport.

Soccer

Worldwide, approximately 200 million persons actively play soccer; 20% are women [77]. In the United States, 13.6 million people aged 7 years old and older [78], 43% of whom are female [79], participated in soccer more than once in 2009 [78]. Although most of the soccer-related injuries affect the lower extremities [80,81], head injuries may account for 4%–22% of all soccer-related injuries [82] with goalkeepers tending to have more head, face, neck, and upper extremity injuries [83]. Among high school players in the 2005–2006 school year, an estimated 20,929 concussions occurred among males and 29,167 among females with rates of 0.22 and 0.36 per 1000 athlete exposures, respectively [68]. Among collegiate players from 1988 through the 2003–2004 school year, concussion represented 3.9% of soccer injuries among males and 5.3% among females with rates of 0.28 and 0.41 per 1000 athlete exposures, respectively [84]. It has been estimated that approximately one concussion occurs per team per season [85,86]. In the United States, an estimated 10,436 soccer-related TBI ED visits were reported annually between 2001 and 2009 for those ≤19 years old [2]. These TBI ED visits accounted for approximately 7.7% of all soccer-related visits to EDs in the United States (Table 128.1) [2].

Although brain injuries in soccer may arise from the head contacting other body parts, goalpost, ground, or ball [86], most of the concussions reported in this sport derive from head-to-head contacts, head-to-elbow contact, hit in the head by full force kicked balls at close ranges, and less frequently from head-to-knee and head-to-foot contacts [86,87]. A study of elite Division I college soccer players found that approximately 76% of concussions in males occurred in forward or midfield positions; whereas in women, 67% of concussions occurred in defensive positions [86]. In a study of collegiate athletes from 1998, headaches, that in some cases persisted up to 4 days, were the most frequent TBI-related manifestation reported (93%); others included, confusion or disorientation for up to 30 min (76%), inability to concentrate (62%), nausea (52%), posttraumatic and retrograde amnesia (28%), and LOC (28%) [86].

Data on the impact of "heading," a player purposely redirecting a ball with their head, in producing concussion and cognitive impairment are inconclusive. Neuropsychological studies of chronic TBI among professional and highly competitive amateur adult soccer players conducted in the 1990s reported that impairments in selected aspects of cognitive functioning was inversely related to the number of concussions and to the frequency of ball heading [87,88]. Prospective controlled studies among collegiate and elite soccer players that included clinical examination, imaging, or neuropsychological tests found no evidence of cognitive impairment in soccer players associated with heading [89–91]. While the evidence suggests that the actual act of heading the ball may not be injurious, the situation of heading may put athletes at risk of their heads striking body parts and objects other than the ball, which may lead to concussions and other bodily injuries [92].

Football

During 2009–2010, an estimated 1.11 million preadolescent and adolescent boys and 1249 girls participated in high school football [70]. Among those ≤19 years old, injuries sustained while playing football are the second leading cause of SR-related visits to EDs in the United States ($N = 351,562$) after basketball ($N = 375,601$; Table 128.1) [2]. Of the football-related ED visits, 7.2% ($N = 25,376$) were TBI-related (Table 128.1) [2]. Additionally, for males 10–19 years old, football was the highest ranked SR activity associated with TBI-related visits to EDs [2]. Severe and fatal injuries do rarely occur; in 2010, the death rate was 0.27 per 100,000 participants [93], and the rate of severe neurologic disability was 1.65 per 100,000 [56].

A three-season study that included 693 different high school football players with a mild TBI examined reinjury of athletes. Seventy-two were reinjured; 65 sustained two mild TBIs, 6 had three mild TBIs, and 1 had four mild TBIs. Most (47/72) injuries occurred during the same season as the first injury; 14 occurred in the next season, and two persons had three and four mild TBIs each in the same season [94]. The authors also reported four cases of subdural hematoma and two of intracerebral hemorrhage; of these six players, three returned to play the following season and three changed to other SR activities [94].

In football, as from other causes, even milder brain injuries have the potential for negative consequences [35]. A large scale case-control study of 2300 football players with history of mild TBI without LOC that involved preseason baseline and serial post-injury assessments showed that players with mild TBI had subjective complaints of dizziness, headache, memory dysfunction, and mild deficits in the areas of sustained attention and visuomotor speed that tended to resolve within 5–10 days after the injury [95]; while the effects of concussion may resolve, some individuals have persistent symptoms and cognitive deficits [96]. Similar to results observed in boxing, the severity of cognitive outcomes after football-related TBIs is associated with the number, frequency, and recurrence of head injuries.

Boxing

The objective of boxing and other combat-related sports is rendering an opponent unable to defend themselves, which in

some instances may lead to TBIs that can range in severity from mild to severe or even death. Depending on the weight category of the opponents, impact speeds of at least 10 m/s generating forces of up to 5000 N impact to the opponent's head resulting in translational acceleration forces to the brain of more than 50 g [97,98]. The shearing and acceleration forces may result in lesions affecting the central pathways in the upper brainstem or produce *coup* and *contrecoup*-related lesions [11,99]; the latter lesions are injuries that occur under the site of the impact (*coup*) or in the site opposite to the impacted area (*contrecoup*). Besides presenting acute signs and symptoms of brain injury in a knockout situation, up to 10% of boxers may present with persistent forgetfulness, headaches, and other symptoms [11,100]. Chronic manifestations of repeated brain injury in professional boxers include declines in cognitive performance, tremor, dysarthria, Parkinson's disease, memory disorders, dementia, depression, irritability, aggression, criminality, and addiction [19,32,101,102]. A condition termed dementia pugilistica or chronic boxer's encephalopathy has been reported among boxers with a history of fighting for 12–16 years [103,104]. This condition is considered a variant of chronic traumatic encephalopathy. Symptoms include gait ataxia, speech and hearing problems, tremors, progressive dementia, and multiple neurobehavioral problems [103,104].

In addition to lasting and substantial brain dysfunction due to participation in boxing, boxers may face increased risk of death. In a recent and comprehensive review of the boxing-related literature, Förstl et al. found that on average worldwide, approximately 10 boxing-related deaths occur annually; the absolute figures may also be higher. Two-thirds of those who died were professional boxers, and three-quarters of the boxers died in the boxing ring. More than 80% of the deaths were caused by injuries to the head and neck, such as ruptures or thromboses in larger brain vessels, epidural hemorrhages, or subdural hematomas. Other causes of death can include cardiac complications and tears to the liver or spleen [11]. Risk factors that may be associated with boxing-related death include age, comorbid conditions (e.g., hypertension, diabetes, bleeding disorders), medication (e.g., anticoagulants, steroids, erythropoietin), dehydration, weight loss, large number of punches striking the head during the match, and repeat impact syndrome [11].

PREVENTION

Sports and recreation-related TBI can be prevented using a variety of approaches. For instance, the Haddon matrix, an analytic tool, is demonstrated in this section. Additionally, this section presents information on primary prevention, personal protective equipment, available educational materials, return-to-play guidelines, and legislation.

Sports Injury Prevention and the Haddon Matrix

The Haddon matrix is considered a powerful analytical tool for injury prevention. The matrix clarifies that the event leading to the injury can be separated from the injury itself and from the emergency response to it. The matrix can help identify (1) factors that can prevent the event from occurring in the first place, (2) factors that can mitigate or minimize the injury once the event occurs, and (3) factors that can contribute to immediate and effective care after the injury. [105–107]. Haddon applied the elements of disease causation to injury agent or vector (e.g., a tackle to the head), host (e.g., the player who was tackled in the head), and environment (e.g., a football field with poor officiating and poor ground surface). The matrix also helps to visualize the previous three phases to help formulate the steps that should be considered for preventing the event, reducing injury damage when an event occurs, and minimizing further damage to decrease morbidity and disability [105–107]. Prior to an injury (the *pre-event phase*), the physical and medical condition of an athlete and his or her knowledge of the activity, skill level, appropriate use of equipment, as well as consistent practice of good sportsmanship all influence risk of injury before it occurs. The presence of effective coaches, referees, and other professionals, in addition to community medical resources, all contribute to the level of safety. Examination of pre-event factors can help determine what can be done to reduce the likelihood of injury. Examples may include remediation of playing surfaces, securing equipment, enhancing training techniques, or enforcing use of protective gear. If an injury event does occur (the *event phase*), the preexisting physical condition of the individual and the circumstances of the event, such as protective equipment use, help to determine the extent and severity of the injury. Following the event (*postevent phase*), the emergency response, quality of care, and any environmental factors that may slow the treatment and rehabilitation affect the potential consequences of the injury. Use of this matrix by SR organizations and policy makers, in conjunction with public health practitioners and health care providers, can provide a framework for prevention efforts (Table 128.2) [108].

Personal Protective Equipment Use

One of the best prevention strategies to reduce the potential for a SR-related TBI is the proper use of personal protective equipment [67]. However, sports helmets are designed to prevent severe and fatal injuries (e.g., skull fracture, penetrating injuries, and severe brain injuries) rather than preventing all concussions [92]. Sports helmets may reduce the incidence or severity of SR-related head injuries [62] by reducing potential impact forces [109]. Helmets and other protective equipment should fit properly, be appropriate for the position or activity, be well maintained, and be consistently and correctly used [108].

Among skiers and snowboarders, wearing protective equipment, like helmets, has effectively diminished the potential head injuries [110]. Studies focusing on newer football helmet technologies have found decreases in absolute and relative risk for sustaining concussions [111] and a potential 10%–20% reduction in risk of concussion in recreated collisions from the NFL [112]. Despite advancements

TABLE 128.2
Examples of the Haddon Matrix Applied to Sport-Related TBI

	Agent (Sport)	Host (Athlete)	Physical Environment	Social Environment
Pre-event phase	Institute rules preventing dangerous physical contact	Teach appropriate skills training and conditioning	Ensure playing surface is in good condition	Support parents, coaches to encourage good sportsmanship
Event phase	Require use of appropriate protective equipment	Minimize impacts through physical characteristics (e.g., reaction time and strength)	Ensure that goalposts, backboards, and other obstacles are padded	Support athletic trainers to monitor athletes
Postevent phase	Train coaches to recognize concussion	Follow appropriate rehabilitation and return-to-play	Ensure access to emergency services	Teach parents, coaches to support appropriate return-to-play

in protective equipment, those who engage in SR activities are still vulnerable to injuries. The use of effective protective equipment is not always mandatory or available in non- or partial-contact sports such as lacrosse or field hockey. Some of the difficulties in the prevention of concussion and TBI in SR activities may stem from the lack of a universal definition and a common belief that they are "part of the game" [113].

Prevention Education

CDC, along with partner organizations, has developed guidelines and management techniques to help prevent SR-related TBI. Education is essential as many people do not understand the signs/symptoms and potential consequences of this injury. For example, in one study, only 61% of youth coaches correctly identified concussion signs and symptoms and 26% of coaches returned athletes to competition before symptoms resolved [114].

CDC created the "Heads Up" initiative with a series of products designed to specifically address sports concussions by providing coaches, school and health professionals, parents, and athletes information on prevention, recognition, and proper response [67]. In particular, the "Heads Up" initiative focuses on (1) providing prevention strategies to help reduce the risk for concussion and other injuries, (2) stopping an activity if a TBI is suspected and seeking medical evaluation and approval before returning to play, and (3) learning TBI signs and symptoms and encouraging athletes and others to report a suspected TBI. To assist with concussion management, the CDC has also developed educational materials for those who may encounter injured athletes including one for physicians "Heads Up: Brain Injury in your Practice" and for school nurses, counselors, and teachers "Heads Up: Know your concussion ABCs" (www.cdc.gov/concussion). These free materials may help with clinical diagnosis of mild TBI, including concussions, and may improve outcomes through early diagnosis and appropriate management of injured participants (http://www.cdc.gov/concussion/sports/index.html).

CDC's "Heads Up" initiative and other educational resources are helping to create momentum on this issue. National evaluation studies of the CDC coaches' resources have demonstrated a positive impact on coaches' knowledge, attitude, and behavior toward concussion [115]. After use of CDC's educational materials, 50% of high school coaches reported viewing concussions more seriously and 38% reported changing their management of concussion [115]. Moreover, a study of CDC's materials for youth sports demonstrated that 77% of coaches reported being able to more easily identify athletes with a suspected concussion and 72% of coaches reported educating others about preventing and managing concussions [116].

Return-to-Play Guidelines

Implementation of return-to-play decisions can depend on a multitude of factors such as the level of sufficient resources including team physicians or staff members who are experienced in concussion management [52]. In some instances, return could be a quick process, but many cases should follow a graduated return-to-play protocol. Each step is designed to allow ample time for full physical and cognitive recovery; the athlete can progress as long as the athlete remains asymptomatic [52]. A 6 day gradual return-to-play protocol after the athlete is symptom-free at rest is suggested [52]. If any concussion symptom returns during any of the activities, the athlete should rest for 24 h then return to the previous level [52]:

- Day 1: no activity; complete physical and cognitive rest
- Day 2: light aerobic exercise (walking, swimming, or stationary cycling). No resistance training
- Day 3: sport-specific exercise. No head impact activities
- Day 4: non-contact training drills
- Day 5: full-contact practice; participate in normal practice activities
- Day 6: return to competition; normal game play

Return-to-Play Legislation

Multiple states across the United States have taken action to address the issue of return-to-play through legislation. As of July 2012, approximately 42 states have enacted laws regarding sports concussion among school-aged athletes. One of the first and most comprehensive laws, Washington State's *Zackery Lystedt Law*, requires the immediate removal of any athlete who is suspected of sustaining a concussion with return to participation only after evaluation and clearance by an appropriate medical professional [117]. Of the 42 current laws, 39 include similar language as the Lystedt law which includes requirements for concussion education materials for coaches, parents, and student athletes, removal from play, and return-to-play. Sustaining a repeat TBI before the brain recovers could potentially slow recovery and increase the risk of long-term consequences [67]. The results, both intended and unintended, of these legislative efforts in protecting athletes are yet to be determined.

CONCLUSIONS AND FUTURE DIRECTIONS

TBI is a major public health issue affecting millions of Americans participating in sports and recreational activities annually. Studies have shown SR-related TBI to be a fairly common yet underreported injury affecting primarily young participants. Proper use of appropriate protective equipment for specific sports or activities, following the rules of the game, appropriate training in the skills of the sport, and portraying good sportsmanship can be simple prevention strategies. While not all TBIs can be prevented, accurate and consistent case ascertainment and medical management have the potential to minimize reinjury and reduce TBI-related impairment and disability. Additionally, continued education of medical professionals, coaches, trainers, parents, athletes, and other stakeholders, could help reduce the risk of long-term consequences and potential catastrophic injuries. Further research, however, is needed to identify primary prevention strategies to decrease TBI and associated morbidity and mortality.

Currently, the definitions of concussion or TBI utilized are not consistent and a national injury surveillance system in the United States that covers SR activities, resulting in a poor understanding of the epidemiology of SR-related TBI especially among younger participants. To fully understand SR-related TBI in the United States and globally, strategies for improved surveillance and reporting are needed. These data could inform the incidence, severity, risk factors, mechanisms, and outcomes of TBIs. There is also the need to translate research findings into usable knowledge and evidence-based prevention interventions so coaches, trainers, team physicians, and clinical and public health practitioners can counsel athletes and the public [118]. Additionally, future research should examine not only contact and organized sports such as football and basketball but also recreational activities such as bicycling and horseback riding.

The Patient Protection and Affordable Care Act, often known as the Affordable Care Act (ACA) of 2010, was signed into law on March 23, 2010. This attempted overhaul of the U.S. health care delivery system is still being implemented and debated within the halls of Congress as well as within state legislatures and halls of justice. However, elements of the ACA will no doubt continue to be implemented. These elements include components within ACA that promise to have an impact on lifestyle medicine and primary prevention through the health care delivery system itself [1]. Such components include increased Medicaid payments in fee-for-service and managed care for primary care services provided by primary care doctors (family medicine, general internal medicine, or pediatric medicine) including a 10% bonus payment to primary care physicians in Medicare from 2011 through 2015 [1]. These actions are intended to provide greater incentives for primary care providers to integrate preventive care services into their practices. Included in ACA is the establishment of a National Prevention, Health Promotion, and Public Health Council to coordinate federal prevention, wellness, and public health activities. This council will develop a national strategy to improve the nation's health, create a Prevention and Public Health Fund to expand and sustain funding for prevention and public health programs, and create working groups associated with the Clinical Preventive Services and Community Preventive Services Task Forces to develop, update, and disseminate evidence-based recommendations on the use of clinical and community prevention services. Further efforts will be made to provide coverage of preventive services that have been shown to be effective and further modification and possible elimination of cost-sharing for preventive services in Medicare and Medicaid. Finally, there will be an increase in Medicare payments for certain preventive services up to 100% of actual charges or fee schedule rates, which are intended to include lifestyle medicine services such as obesity prevention services [1].

The ACA legislation also authorizes the establishment of a Patient-Centered Outcomes Research Institute (PCORI). This non-federal institute is charged with setting research priorities and promoting research that provides a clinical evidence base to help physicians, other primary care providers, and patients make informed decisions about a patient's health care; to assist health care delivery systems in providing evidence-based, efficient, and safe health care; to ensure that evidence is dependent on and applied to racially and ethnically diverse and geographically distributed communities; and to develop broad prevention and screening strategies that promote health across such diverse populations. Much reporting about the PCORI research agenda has focused on the term "comparative effectiveness research" (CER). Although the intellectual underpinning of effectiveness research has existed for over half a century, the legislation lays out a far more expansive and inclusive role for CER. In addition to comparing therapeutic treatments, CER is intended as the rigorous application of science to evaluate and compare health outcomes, clinical effectiveness, and risks and benefits of a much broader set of interventions—from new health care delivery methods to medical procedures and devices, to drugs and biologicals, to integrative health practice strategies, as well as prevention strategies. Moreover, the legislation directs that CER must include broad participation across the nation to create a representative evidence base that could help identify and address health disparities and inform decisions by patients in special population groups. CER is expected to extend beyond academic health centers and teaching hospitals to include research in partnership with community-based care settings and practice-based networks, as well as with community-engaged research, which provides for the engagement with communities as partners in research [2]. Such a focus on CER and similar methods that embody rigorous science to determine what interventions/treatments work best for whom, in what settings, and under what circumstances supports lifestyle medicine by translating preventive care and disease management evidence into changes in practice and behavior at the level of individuals, populations, and health care delivery systems [3].

The reestablishment of primary care as the first line of medical care and preventive care practice is critical to the success of health care reform success [4,5]. The ACA takes important, although modest steps, in addressing critical primary care needs: payment reform, enhancing the training pipeline, transforming practice, and buttressing the primary

care safety net. ACA provisions include establishment of a National Health Care Workforce Commission, increased support for workforce training (Title VII and the Prevention and Public Health Fund), cultural competency training, enhanced payments, expansion of health centers, and piloting of new care models. ACA also provides bonus payments to primary care physicians under Medicare and eliminates differences in payments between Medicaid and Medicare for primary care. It further provides Medicare bonuses to primary care physicians who work in shortage areas, helping to minimize geographically related disparities. These reforms may begin to minimize disparities in resources between primary care practices whose patient populations differ by social disadvantage. These reforms could also conceivably reduce de facto segregation in health care by insurance type (e.g., faculty practices vs. clinics) although federal regulations prohibiting intra-institutional segregation of care by insurance type within systems receiving federal funding may be needed. To be sure, modest increases in payments alone will not be sufficient to address the maldistribution of primary care physicians, much less avert a primary care shortage [6].

Although the recently enacted ACA legislation contains elements that could advance lifestyle medicine and primary prevention, a large segment of the population is clearly opposed to expansion of the government's role in regulation of the health care delivery system and private health plans. Critics have argued that the government mandate for expanded private health plan coverage has already resulted in higher costs and will ultimately lead to unsustainable cost increases that will drive employers to abandon sponsorship of a health plan as an employee benefit. Understanding the role of employers is central to understanding the U.S. health care system. At present, almost two-thirds of American citizens under the age of 65 years are covered by an employer-sponsored health plan. The sudden disappearance of employer-sponsored health insurance would create chaos [7].

The historic linkage of health insurance to employment for over 80 years has presented a problem of access to affordable health care services for unemployed individuals, but the private sector system does promote innovation and value through its influences on competing providers [8,9]. Furthermore, the availability and generosity of health care coverage for Americans ultimately depend on the economic fortunes of private companies. Government-sponsored health insurance relies on individual and corporate taxes, which are directly linked to employment and economic growth. The less tax revenue collected by the federal and state governments, the greater will be the necessity to ration care among the population that relies upon a government-sponsored program [7]. If Medicare and Medicaid costs continue to grow at the current rate, they will consume 20% of the gross domestic product by 2050 [10].

Because businesses currently have a major role in directly financing a large portion of health care services, they have a substantial influence on the overall efficiency and quality of the U.S. health care delivery system. Traditional fee-for-service reimbursement creates an incentive for providers to supply a high volume of expensive services as long as the payment exceeds the cost of the service delivery [11]. Capitation (i.e., prospective payment of a fixed compensation amount for medical management of a case) places a high level of financial risk on providers, which encourages restriction of services as a means to maximize profits [12]. Value-based purchasing and pay-for-performance are terms that have been applied to employer initiatives that hold health care providers accountable for effective and efficient management of the health-related needs of employees and dependents. An example of a strategy for improving the value of health care services is the combination of payment bundling (i.e., aggregation of all fees for services provided to manage a case by multiple providers) and subsequent payment of a bonus that is based on the difference between the total cost of the bundled fee payments and a prospectively developed budget for medical management of the patient's condition. The case budget incorporates a patient-specific severity adjustment and an allowance for potentially avoidable complications. Such a payment model encourages collaboration among providers and it incentivizes both conformity to clinical practice guidelines and efforts to minimize potentially avoidable complications [12].

Value-based purchasing and pay-for-performance represent employer-initiated innovations that Medicare has begun to use on an experimental basis [11]. The Medicare Physician Group Practice (PGP) Demonstration introduced "shared savings" as a mechanism to reduce costs and improve quality of care provided to its beneficiaries. Participating PGPs received regular fee-for-service reimbursements but were also eligible to receive an additional performance payment if a Centers for Medicare and Medicaid (CMS)-specified cost target was achieved (i.e., an 80% share of the difference between the actual cost of services provided and a risk-adjusted spending trend for treatment of the given condition in a given market). The Medicare PGP Demonstration served as the model for a provision of the ACA legislation that establishes the Accountable Care Organization (ACO) as a mechanism for providers to become eligible for participation in the Medicare Shared Savings Program [13,14].

The specifications for ACO certification were not clearly defined in the new law, but Department for Health and Human Services has issued a notice of proposed rule-making that will define the manner in which physicians, hospitals, and other providers can create an affiliation that will be collectively accountable for delivery of high-value services. Although the intent of the ACA legislation is to reduce the cost and improve the quality of health care for all Americans, CMS payment policies have historically resulted in cost-shifting to private payers. An analysis of the PGP Demonstration suggested that most provider groups would experience a financial loss as a result of participation in a similar shared savings program, which poses a risk to the entire value-based purchasing movement initiated by employers [15]. The creation of ACOs by dominant providers through mergers and acquisitions could drive up costs for private payers. Market consolidation can also have an adverse effect on the ability of private payers to obtain the service quality data that are

essential to value-based purchasing [13]. Although the inclusion of a hospital in an ACO is needed for optimal coordination of health care services, a potentially serious conflict of financial interests exists between physician groups and hospitals with regard to the necessity for hospitalization of many patients. Some experts believe that hospital-centric provider organizations adversely affect the potential for physician groups to benefit from a shared savings program [14] and that they will not serve the best interests of the country [12].

Each of three parties—the provider, the payer, and the patient—has a role in determination of the value that is realized from medical services. A major issue affecting the potential for success of the ACO concept in the private sector is the interrelated matter of provider control over the various services needed to manage a patient's condition and the patient's willingness to accept a service delivery system that precludes the option of seeking care from providers outside the organization [16]. Because past managed care cost-containment strategies have not adequately addressed quality of care issues, many consumers have become reluctant to accept restrictions on provider selection. Consumers will need access to cost and quality information to understand the benefits that will be derived from voluntary enrollment in an ACO.

Modification of patient behaviors is central to the practice of lifestyle medicine and primary prevention, but the patient's responsibility to ensure that a high degree of value is derived from clinical medical services has only been emphasized by employer-sponsored health plans. Patient consumerism is promoted by high-deductible health plans that are combined with health savings accounts to incentivize healthy behaviors and through employer-sponsored worksite health management programs. Because impaired glucose metabolism is the primary underlying cause of numerous high-cost conditions, regular physical activity and health dietary behaviors can profoundly influence employers' self-insured health plan costs [17,18]. Because poor employee health decreases corporate profitability through high health plan costs, work absenteeism, and suboptimal productivity, employers have a strong interest in promoting personal responsibility for healthy lifestyle choices and informed utilization of health care services. Unless commercial insurance and government-sponsored health plans incentivize healthy behaviors and health care consumerism, no type of provider payment model is likely to produce long-term control of cost escalation.

Years of fee-for-service reimbursement have produced a provider-centered and process-oriented system for the delivery of clinical services that is highly resistant to change. Both CMS and commercial insurance pay-for-performance initiatives have defined quality of care on the basis of process-of-care measurements (e.g., provider adherence to clinical practice guidelines), rather than patient outcomes [19,11]. Value should be defined as the outcomes achieved per dollar spent. Measuring the total costs over a patient's entire care cycle and relating them to the outcomes realized from the collective set of services could lead to future reallocation of spending among the various types of services. For example, greater frequency of physical activity among obese individuals has been documented to produce greater claims costs related to treatment of musculoskeletal disorders [20]. Primary and preventive care of obese patients might provide greater value (i.e., better long-term outcomes at lower cost) through substantial involvement of a clinician who possesses expertise in exercise prescription for avoidance of musculoskeletal disorders. Different patient populations (e.g., obese children, healthy adults, patients with multiple chronic conditions) will need different bundles of services, which require different types of outcomes measurement. Condition-specific outcomes measurement instruments are needed and no single outcome can fully capture the results of care [19]. The outcomes that are most important to the patient should provide the numerator for the value equation, and the denominator should be the total cost of all services that jointly determine success in meeting the patient's needs [19].

Although the term "patient-centered care" is widely used, the existing provider-centered and disease-oriented health care system often fails to devote sufficient attention to the needs, concerns, and preferences of patients. Patient-centered care involves efforts to inform, educate, and communicate with individual patients, shared decision making, and continuous advocacy of injury and disease prevention. Clinical care is delivered to one patient at a time, but a "population health" perspective is essential for improvement of the quality of care that is provided to individual patients. Identification of the needs of specific patient populations can be achieved through systematic collection and analysis of patient-centered outcomes data, but it is difficult to accomplish without utilization of appropriately designed health information technology (HIT). Unfortunately, the current organizational structure of the health care system and prevailing financial incentives have focused HIT development on systems for documentation of billable events, rather than collection of data to support continuous quality improvement [21]. The HIT for Economic and Clinical Health Act clearly supports development of a mechanism for secure exchange of electronic data between providers, but such a platform is not likely to facilitate meaningful improvements in health care value without financial incentives that reward patient-centered care.

The American health care system faces three interrelated problems of cost, quality, and access to services [7]. The respective roles of government programs, commercial health insurance, and self-funded employer health plans as separate sources of reimbursement for health care services greatly complicates efforts to reorganize the system. The federal government clearly plays the major role in determination of access to services for a large segment of the American population, but universal coverage will not solve the problems of rising costs and quality concerns. Overzealous pursuit of universal access could diminish the private sector's positive influences on the health care delivery system. As the proportion of services financed by government programs grows beyond 50%, a tipping point may be reached. Continued escalation of costs may cause increasing numbers of employers to discontinue sponsorship of a health plan, which would further increase the proportion of people relying on the government for access

to care. Provider cost-shifting to private payers as a means to compensate for lesser reimbursement amounts from government programs would yield progressively lower levels of compensation. Lacking a robust private health care market, providers are unlikely to have a sufficient financial incentive to reorient the system to a patient-centered approach. Lacking outcomes data, the likely result would be a single-payer system that rations care on an irrational basis.

Competitive markets and consumer choice have historically provided value in other sectors of the economy, whereas government programs have historically been plagued by bureaucratic processes and the influences of special political interests. The private sector's flexibility and inventiveness are probably essential for realization of greater health care value [8]. There are clearly many challenges to the achievement of an effective and fair realignment of provider financial incentives. For example, mechanisms are needed to clearly distinguish random variations in patient outcomes and patient mix from variation in practice patterns and avoidable complications [11]. Assuming that providers are compensated fairly for provision of high-value services, and that they are not financially penalized for circumstances beyond their control, the potential for a sudden and dramatic shift toward a patient-centered approach to care might be realized.

Regardless of whether the ACA is repealed, declared unconstitutional, modified, or fully implemented, traditional fee-for-service reimbursements to individual providers are unlikely to continue. If an optimal balance is achieved between government-mandated initiatives and private sector influences on the U.S. health care delivery system, perhaps the cost, quality, and access problems can be collectively resolved. In any case, physicians and other health care practitioners who are committed to delivery of patient-centered clinical care should welcome payment reform that rewards excellence and facilitates realization of optimal patient outcomes.

In keeping with policy reform in support for lifestyle medicine, the CMS in 2004 established obesity as a recognized disease, thus allowing Medicare to consider covering payments for obesity-related treatments [22]. Despite Medicaid being a state administered program, the Medicare decision has stimulated a number of states to extend their Medicaid programs' coverage of services to include both prevention and treatment of obesity. Examples from the states include West Virginia [23] and Tennessee [24] who offer both full and partial reimbursement for Weight Watchers© programs.

Another set of policy supports for lifestyle medicine have occurred through the National Committee for Quality Assurance starting in early 2006 with the approved Healthcare Effectiveness Data and Information Set (HEDIS) measures of health plan performance regarding the measurement of physical activity and body mass index as "vital signs" among adults, children, and adolescents. In addition, nutrition and physical activity assessment and counseling for adults, children, and adolescents were also recommended. Most U.S. health plans use HEDIS measures to monitor provider performance associated with patient care and services and report to providers, purchasers of health care plans, and consumers on the quality of health care throughout the nation [25]. The new chronic disease prevention and obesity-related measures attempt to target improvements in providers' practice behaviors related to chronic disease and obesity prevention, care, and treatment. The launching of such chronic disease/obesity-related HEDIS measures demonstrates the role that a policy intervention can potentially impact preventive care practice behaviors among providers and health behavior change among patients [25].

Current policies and practices supporting the delivery of health care do not provide adequate incentives, both monetary and otherwise, directed toward providers to integrate lifestyle medicine and preventive care into their existing practices [5]. Indeed, one of the highly held ideals among preventive care advocates, the potential cost savings afforded by preventive care to the health care system as a whole, has been questioned by many within the medical community [26,27]. However, these positions often confuse early detection and treatment with primary prevention and public health efforts, where the latter appear to provide the best evidence for cost savings and prevention of premature morbidity and mortality [28–30].

Indeed, those policies and evidence-based interventions outlined within this section of *Lifestyle Medicine* seek to identify primary prevention strategies of active living and healthy eating that hold significant promise in alleviating premature suffering from disease and early death. In addition the practices outlined can also greatly benefit the patient with an existing chronic condition by effectively using lifestyle medicine to manage and control disease.

Community-based approaches to promoting physical activity were initially assessed systematically for effectiveness by Kahn et al. [1] and Heath et al. [2]. Within these systematic reviews, the authors identified three major domains of community-based physical activity interventions. These domains include, informational, behavioral/social, and policy/environmental approaches to promoting physical activity in community settings [1,2] (see Table 130.1). This chapter seeks to identify evidence-based interventions that address policy and environmental supports for promoting physical activity that can reinforce a healthy lifestyle and active living assessment and counseling. An intervention strategy that falls under the domain of policy and environmental supports is creating or enhancing access to places for physical activity, combined with informational outreach activities [1,3]. Interventions within this strategy include creating/enhancing existing walking/biking trails or exercise facilities and increasing access to existing facilities by reducing barriers (e.g., increasing safety, enhancing affordability). These efforts often include personnel and/or participant training, social support, and further integration of these structures, facilities, and programs into participants' communities. An exemplary intervention of this type, described by Linenger et al. [4], included new infrastructure (i.e., bike paths), access to facilities (e.g., expanded hours of operation, lighted and integrated paths), and improved programming on a residential Naval base [4]. Recent studies have documented that developing such infrastructure is reasonable from a cost perspective [5].

An emerging strategy within the domain of policy and environmental approaches was more recently described by Hoehner et al. [6]. This strategy consists of community-wide policies and planning that place physical activity within the public policy agendas of communities, emphasize promotion of physical activity guidelines, provide organizational incentives, address institutional and environmental barriers, and use media effectively [6]. An example of this promising intervention approach comes from the work of Gómez et al. [7] on Muvete Bogotá, a community-based physical activity program in Bogotá, Colombia, SA. This multisector physical activity promotion intervention conducted throughout Bogotá, Colombia, consisted of infrastructural change including cycle pathways, pedestrian walkways, and public transport corridors. Worksite- and school-based physical activity programming was also instituted along with neighborhood-specific programming at community centers, public parks, and childcare centers. The health sectors, both public and private, were engaged in awareness and support of community programming. Finally, a series of citywide events were strategically carried out throughout the year to reinforce local and site-specific programming [7].

Policy- and environmental-based interventions that are designed to create or provide access to places where people can be physically active often involve the combined efforts of worksites, schools, coalitions, government agencies, and community members [1]. These interventions are characterized by providing improved access to existing exercise facilities, such as fitness centers (both proprietary and nonprofit), community centers, and walking/bicycle trails, and providing access to school grounds [1,2]. In addition to promoting access, many of these interventions incorporate components such as supervision of equipment use, health behavior education and counseling, risk factor screening, referrals to health services, buddy systems, and promotion of facility use [8].

A more detailed discussion of each of these areas of intervention follows.

TABLE 130.1
Task Force for Community Preventive Services: Physical Activity Intervention Recommendations

Informational approaches

- Community-wide campaigns: These large-scale, highly visible, multicomponent campaigns direct their messages to large audiences using a variety of approaches, including television, radio, newspapers, movie theaters, billboards, and mailings. ***Recommended with strong evidence***

Behavioral and social approaches

- Individually adapted health behavior change programs: These programs are tailored to a person's specific interests or readiness to make a change in physical activity habits. Teaching behavioral skills such as goal setting, building social support, self-rewards, problem solving, and relapse prevention, the programs help people learn to incorporate physical activity into their daily routines. ***Recommended with strong evidence***
- School-based physical education (PE): This approach seeks to modify school curricula and policies, to increase the amount of time students spend in moderate to vigorous activity while in PE class. Schools can accomplish this either by increasing the amount of time spent in PE class or by increasing students' activity levels during PE classes. ***Recommended with strong evidence***
- Social support interventions in community contexts: The goal of this approach is to increase physical activity by creating or strengthening social networks. Examples include exercise buddies, exercise contracts, and walking groups. ***Recommended with strong evidence***

Environmental and policy approaches

- Creating or improving access to places for physical activity combined with informational outreach: Examples include building walking or biking trails or making it possible for people to use exercise facilities in community centers or in the workplace. Informational outreach includes activities such as providing training on equipment, seminars, counseling, risk screening, and health forums and workshops. ***Recommended with strong evidence***
- Point-of-decision prompts to encourage stair use: These signs are placed by elevators and escalators and encourage people to use nearby stairs instead. ***Recommended with sufficient evidence***
- Community-scale urban design land use policies and practices: Examples involve the efforts of urban planners, architects, engineers, developers, and public health professionals to change the physical environment of urban areas of several square miles or more in ways that support physical activity. ***Recommended with sufficient evidence***
- Street-scale urban design and land use policies: Examples involve the efforts of urban planners, architects, engineers, developers, and public health professionals to change the physical environment of small geographic areas, generally limited to a few blocks, in ways that support physical activity. ***Recommended with sufficient evidence***

SCHOOLS

School physical education and health education curricula now provide methods of promoting youth physical activity, and many of these strategies have been shown to be effective [9]. However, currently within the United States, a frustrating paradox often exists in many communities. Although school building and grounds may be the most widely available public resources for physical activity within the community and the design of these facilities are often effective for engaging in physical activity, yet these facilities are often underutilized. A study of 24 middle schools evaluated the relation between the school social and physical environment with students' physical activity [10]. The observers coded environmental characteristics including the accessible play areas; their size; improvements, such as basketball hoops, soccer goals, and playground markings; and the presence of play equipment, supervision, and organized activities. Students' physical activity was observed during periods when they could choose to be active: before school, after lunch, and after school. Although student activity levels generally were low, they were strongly related to the social and physical environments at school. For example, about 10 times as many students chose to be active when supervision and improvements were high than when those supports were absent. There were also interesting sex differences observed in this investigation, which suggests a need for further exploration. In their study, boys tended to be the most active on outdoor courts, whereas girls were most active in indoor facilities. Further understanding these gender differences may create the opportunity to tailor policy and environmental needs for boys and girls.

Most schools have policies in place that restrict access to school grounds by students and community members outside of school hours. Thus, these abundant public resources are underused, and these policies may have the most negative impact on low-income communities, which lack other resources. There are a number of community advocacy groups around the country seeking solutions to change this situation. Among the groups seeking solutions is the Denver Learning Landscapes Alliance (http://thunder1.cudenver.edu/cye/lla/home.html). This group seeks to transform school grounds into community parks, with a focus on low-income communities. Their goal is to transform vacant playing fields surrounded by fences into school grounds that become community parks with play equipment, areas of natural vegetation, gardens, and welcoming gates. The addition of more pleasing landscapes encourages participation and has the potential to improve physical, mental, and social well-being [11].

Active transport by walking and cycling to and from school can provide substantial physical activity for children and youth. One example of leveraging available federal dollars set aside to promote cycling and pedestrian activities in communities through assistance from state departments of transportation. Such an example is the California Department of Transportation (DOT), which provided $66 million in funding over 3 years for "Safe Routes to Schools" grants to 270 schools [12]. Such funding was used to make physical improvements such as sidewalk and bike lane construction or enhancements, traffic calming, and street crossing improvements around schools. Some schools added promotional and educational programs to encourage people to use the improved streets. In Marin County, CA, walking to school increased 64% and biking increased 114% after a combined intervention [13]. A statewide evaluation of 10 schools found that students who passed by the improvements on their way to school increased walking and biking by 15% compared to 4% for those who did not pass the improvements [12].

WORKSITES

The importance of the worksite as a venue for the promotion of physical activity through policy and environmental supports was systematically reported by Heirich et al. [14]. The relative impact of three different approaches to physical fitness promotion at the worksite on cardiovascular risk reduction was examined based on before-and-after health screening of employees and employees' reports of participation in physical activities [14]. Within the setting of an automobile plant, three approaches to promoting physical activity for cardiovascular risk reduction were tested at three sites: (1) a staffed physical fitness facility, (2) one-to-one counseling with at-risk employees, and (3) a combination of one-to-one counseling with employees plus organization of the worksite to encourage peer support and mutual exercise and physical activity at work. A fourth site served as a control site. The program that was centered on a physical fitness facility had little measurable impact on cardiovascular risks and showed results similar to those at the control site. The programs that included a combination of counseling and plant organization, which provided greater access to opportunities to be physically active, were more effective and provided better health outcomes in terms of frequency of exercise, adequacy of blood pressure control (among people with hypertension), weight loss (among the overweight), and smoking cessation. These results provide evidence that systematic, ongoing outreach to enlist employees in various types of exercise programs is more effective than the presence of fitness facilities without such outreach. Moreover, significant increases in the frequency of exercise can be sustained without a substantial investment in facilities. Two more recent worksite-based studies demonstrating the role of policy and environmental approaches to promoting physical activity are the Los Angeles Lift-Off [15] and Move to Improve [16]. Yancey et al. [15] conducted a randomized, controlled, posttest-only trial to evaluate the level of participation in a physical activity promotion program designed to integrate a single 10 min exercise break into regularly occurring meetings or events during work time at Los Angeles County Department of Health Services' worksites. In addition, measures of psychological effects were also examined among participants. The investigators sought to demonstrate that individuals could be engaged in brief bouts of moderate intensity exercise across the weight status and physical activity level continuum, and that this exercise participation would be associated with positive changes in psychological affect. The unique focus of this study included a "minimal" environmental change that was specifically targeting underserved populations. Results indicated that more than 90% of meeting attendees participated in the exercises. Significant improvement in activity levels and self-perceived health status was seen among participants who at baseline were completely sedentary and whose self-perceived health status ratings were significantly poorer than controls. Even more significant was that among intervention participants who initially were not regularly physically active, levels of satisfaction with fitness significantly correlated with self-ranked physical activity stage of change following the intervention. The investigators concluded from their results that captive audiences, such as those attending mandatory meetings and events, may be engaged in brief bouts of exercise as a part of the workday, regardless of physical activity level or stage of change. The results of this experience among attendees may also erode sedentary individuals' inaccurate self-perception of good health and fitness, providing additional motivation for the adoption of a more active lifestyle [15]. Dishman et al. [16] recently reported on the efficacy of a multisite randomized controlled trial consisting of a 12 week intervention that increased moderate to vigorous physical activity (MVPA) among employees of a large retail company by targeting features of the workplace environment as well as employee motivation using personal and team goal setting. Based on management theory, 24 different employee ratings of perceived management support and employee involvement were assessed to confirm implementation and impact of the organizational action component of the intervention. Participants in the intervention had greater increases in MVPA and walking compared to participants in a health education control condition. The proportion of participants that met the *Healthy People 2010* recommendation for regular participation in either moderate or vigorous physical activity remained near 25% at control sites during the study but increased to 51% at intervention sites. During the last 6 weeks of the study, intervention participants exceeded 300 weekly minutes of self-reported MVPA and 9000 daily pedometer steps. The authors concluded that their results support the feasibility and efficacy of the *Move to Improve* intervention and the role of environmental supports and goal setting for attaining increased physical activity levels among worksite employees.

COMMUNITY ORGANIZATIONS

Many community organizations provide physical activity facilities or programs, or they could do so. In the private sector, health clubs, dance studios, martial arts organizations, swimming clubs, and sports leagues are familiar examples. Nonprofit organizations include YMCAs/YWCAs and Boys' and Girls' Clubs as well as sports leagues. Faith-based organizations often have physical activity facilities and programs for their members, which could be made available to others in the community. Private and public housing developments have recreational and fitness facilities. Thus, many resources throughout the nation can be used for recreational physical activity, and with improved promotion, they can become better utilized. However, there do not appear to be any well-designed systematic studies of how the facilities and programs within these community organizations contribute to the physical activity levels of individuals' in surrounding communities. Although there are undoubtedly many exemplary programs in these organizations, there currently are no programs that have been systematically evaluated regarding changes in physical activity behaviors due to policy and environmental supports to promote physical activity.

The public health impact of these facilities and programs can be maximized by increasing the number of participants, by increasing the frequency and duration of activity sessions, and by sponsoring year-round programs, especially for sports organizations. Making resources available to the general community and having reduced fees for low-income participants could help contribute to reduced disparities in physical activity.

PUBLIC RECREATION FACILITIES

Public parks and recreation facilities are widely used, with about 80% of the population making some use of municipal facilities and a smaller but substantial percent using park programs and services [17]. Various studies have shown that 30%–65% of park users were engaged in physical activities or sports [17]. The contribution of public recreation facilities and programs to physical activity could be enhanced by optimizing the design of the facilities to support physical activity of various population groups and promoting use of the facilities. The potential impact of improved park design was indicated by an Australian study that found adults with very good access to large and attractive public open space were 50% more likely to be regular walkers than those without such access [18].

The National Recreation and Park Association has partnered with the National Heart, Lung, and Blood Institute on the Hearts N' Parks Program, whose goal is to promote physical activity in parks to reduce the occurrence of chronic diseases. Interested recreation agencies became magnet centers because of their interest in contributing to public health improvement and their ability to serve high-risk population groups. Youth efforts emphasized after-school and summer camp programs. Adult target populations were senior center attendees, city employees, and the general population of adult park users. A recent evaluation of magnet centers that developed multiple physical activity promotion programs found that 50 Hearts N' Parks magnet centers were operating in 11 states. Participants in programs were found to improve knowledge, attitudes, and physical activity behavior using standardized survey procedures (http://www.nrpa.org/content/default.aspx?documentId=2683). The Hearts N' Parks magnet center program was conducted for 3 years with coordination but no funding from the national partners. This appears to be a valuable national effort that needs to be more widely disseminated.

There is some evidence that park and recreation professionals are enthusiastic about participating more in promoting physical activity. A survey of 44 recreation center directors in San Diego County found that most center directors wanted to provide more physical activity programs to youth, 75% were willing to partner with health professionals to train staff in physical activity leadership, and 59% wanted to improve the marketing of their programs [19]. The most frequently cited barriers to offering more physical activity programs for youth were inadequate staff and training, departmental support, and funding [19]. Increased collaboration between public health and recreation professionals to maximize the use of public recreation facilities for physical activity is indicated.

PROMOTING THE USE OF FACILITIES

According to Missouri state Behavioral Risk Factor Surveillance System data in 1997, 60% of the state population were overweight and 65% were not sufficiently active to meet public health recommendations. To address this health problem, the state health department, with the assistance of a community heart health coalition, helped to fund construction of walking trails in two communities through the DOT. Although a formal evaluation was not conducted, DOT staff had heard that trails were underutilized because of safety concerns and lack of amenities such as playground equipment and well-maintained restrooms. Because other communities were requesting funds to build trails, the state needed to know if the investment would be worthwhile. To promote use of the existing trails, the state funded the health department to conduct an awareness campaign and trail enhancement activities in one of the communities with a year-old trail. If community members were not more physically active after having both access to a walking trail as well as information about the trail and about the benefits of regular physical activity, then the state probably would not fund additional trails.

The health department and a heart health coalition conducted the resulting Take Our Trail Campaign for 3 months [20]. The campaign kicked off with a 3 mile Family Fun-Walk, with t-shirts and refreshments donated by local businesses. For the length of the campaign, signs were placed throughout the community to raise awareness of the trail. A simple brochure was sent to all programs in the local health department, as well as to clinics, church leaders, and the heart health coalition. The brochure contained information about the importance of physical activity, tips to increase walking, safety information, information about the trail, and who to contact for walking club information. The local television station created a public service announcement during the evening news to promote the trail and the importance of regular physical activity. The public transportation system placed signs inside buses. The heart health coalition helped develop walking clubs at worksites, churches, and social organizations. Local law enforcement officials agreed to patrol the walking trail periodically. The coalition worked with local business, city government, and churches to raise money to enhance the trail, adding amenities to the trails such as lights, benches, mile markers, painted lanes, and a water fountain.

The primary purposes of the evaluation were to determine whether a promotional campaign would increase the use of existing trails and increase the number of individuals who met recommended levels of physical activity. The Take Our Trail community had a 35% increase in trail use between 1 month before and 1 month after the springtime campaign compared with a 10% increase in the community without the campaign. Data from the walking trail counter indicated that trail usage was very high during Take Our Trail events.

Use increased more with the formation of walking clubs in both communities (note: in the "control" community, several walking clubs formed on their own and were recorded in the event log system) but the increase in the Take Our Trail community was significantly higher. In addition, Sunday afternoon and Wednesday evening use increased with the creation of the church-based walking clubs.

Interviews with stakeholders revealed that individuals in the campaign community felt safer while walking than people in the community with a trail and no campaign due to walking with partners (e.g., walking clubs), trail lights, and police patrols. More than 60% of trail users in both communities indicated an increase in walking since the trail existed.

All types of people used the trail, but especially women, older adults, athletes recovering from injuries, and people with medical conditions that required a low-impact activity. These included many of the groups who were targeted for use, especially older adults and lower income people. When asked about how they became aware of the trail, most of the respondents indicated that they lived or worked near the trail or they heard about it at church or work, from their physicians, or from friends or family. Very few trail users had seen the fliers or public service announcements and generally were unaware of the promotional campaign.

Evaluation of the Take Our Trail program suggested that the construction of walking trails increased physical activity and the implementation of a campaign to promote trail use further increased physical activity. These findings were shared with DOT with a recommendation to build additional walking trails and support campaigns aimed at increasing trial usage. The report to DOT also suggested that the focus of these campaigns include community-wide involvement in promoting the trail and walking and enhancement of the trails. Increasing safety and security is a must.

Costs/Benefits and Funding

King et al. [21] suggested an environmental and policy intervention should be chosen based on likely potency and cost effectiveness. However, evidence supporting the cost effectiveness is limited. Two economic evaluations of interventions to create or enhance access to places for physical activity have been completed. One 4 year study conducted at a fitness facility in Houston, Texas, for employees of an insurance company conducted a cost-benefit analysis of a structured physical fitness program [22]. The program included regularly scheduled classes in aerobic dancing, calisthenics, and jogging; seminars on obesity, smoking, alcohol abuse, and stress reduction were also offered. Program benefits included savings in major medical costs, reduction in average number of disability days, and reduction in direct disability dollar costs. Program costs included personnel, non-salary operating expenses, and medical claims. The adjusted estimates for benefits and costs for 1 year of the program are $1106 and $451, respectively. Based on the quality assessment criteria used in the *Community Guide*, this study was classified as good [23].

Wang et al. [5] examined the cost of trail development and the number of users of four trails in Lincoln, Nebraska. The first year of trail development cost $289,035, of which 73% was construction cost. Of the 3986 trail users, 88% were active at least 3 days a week. The average annual cost for people becoming more physically active was $98; for people who became active for general health improvement, it was $142; and for those who became active for weight loss, $884. This study provides a set of basic cost-effectiveness measures by compiling actual cost items of trail development, estimating the number and type of trail users, and identifying several physical activity-related outcomes and items. Similarly, in another recent investigation on trail cost effectiveness [24], using multiple days of objective trail counts and community surveys found a slightly higher annual cost of becoming more physically active of $117.29 using the same formula proposed by Wang et al. [5,24]. Nevertheless, in summary, it would appear that the trail benefit to cost analysis suggests that building an unattractive, poorly designed trail with limited useful life may be the perfect storm for ineffective public health spending.

Roux et al. [25], using econometric modeling of data from a list of exemplary community-based interventions, including interventions shaped by policy and environmental supports, concluded that such programs provide a good return on investment in their effectiveness in bringing about improvements in physical activity among persons exposed to such programs.

Undoubtedly, policy and environmental approaches are essential for sustaining improvements in physical activity behaviors within communities. By creating connections across disciplines including land use planning, transportation, public health, and economic development, substantial policy changes may be gained. Improving policy along with engaging community members may be the important formula for enhancing success.

The national *Healthy People 2010* fruit objective and vegetable objective are to increase the proportion of Americans aged at least 2 years consuming daily ≥2 servings of fruit to 75% and ≥3 servings of vegetables to 50%.

INTRODUCTION

According to the Centers for Disease Control and Prevention (CDC), 63% of the adult population is overweight or obese and fewer than 25% of Americans eat fruits and vegetables five or more times per day [1]. More than one in seven children and adolescents aged 6–17 years are considered obese [2]. Currently, research suggests the childhood dietary habits are influenced by various environmental factors that include availability of fast foods and soft drinks, availability of soda and unhealthy food on school campuses, and limited access to healthy foods compared to ready availability of unhealthy foods. Furthermore, the prevalence of advertisement of low-nutrient foods to children and their families encourages unhealthy eating and overconsumption [2]. Many of these contributing factors to healthy eating are even more challenging in low-income communities since healthy and affordable food options are limited. Although most Americans know the relationship between diet and health, eating attitudes remain unhealthy and the consumption of fruits and vegetables remain low [1]. Consequently, public policy and environmental behavior change, and not just individual behavior change, have become a major focus to improve healthy eating. Fruits and vegetables, important components of a healthy diet, are important for child growth, weight management, and chronic disease prevention. Environmental and public policy supports to increase fruits and vegetable access, availability, and affordability are key strategies to help increase healthy food consumption and ultimately improve the overall nutritional status of Americans.

OVERVIEW OF HEALTHY EATING TRENDS

Morbidity and Obesity

Currently, sixteen million Americans have diabetes and the number is significantly rising particularly in Latinos. Currently, African American and Latinos adults are 1.3–1.9 times more likely to have diabetes than white adults [3]. Similarly, the U.S. is facing a childhood obesity epidemic as more than one in seven children and adolescents, aged 16–17 years, are considered obese [2]. Due to the increase of unhealthy food consumption and decrease of physical exercise, the rate at which childhood obesity has grown has been two-fold in the past 20 years. Specifically, African American and Hispanic children are twice as likely to be obese as white and Asian children.

Availability and Affordability of Healthy Foods

Healthy eating recommendations, such as substituting "lite" bread and diet soft drinks, made by associations such as the American Diabetes Association, does not mean that healthier eating choices are available to all neighborhoods. There is evidence to show that grocery stores in low-income and non-white neighborhoods have limited supply of healthy eating choices. The lack of availability of healthy foods makes it challenging for clinicians to prevent and control chronic diseases such as diabetes, a treatment that requires an increased intake of healthier foods, fruits, and vegetables [3]. Furthermore, grocery stores in predominantly black and lower income place the food behind glass storage, which does not allow consumers to easily access healthy food. As a health care professional, it is important to understand that environment support is necessary for a change in dietary practices to occur. For instance, primary and secondary intervention of chronic illnesses such as obesity and diabetes may be more difficult if the recommended food is unavailable in the neighborhood [5].

Health Behavior in Healthy Eating

A study conducted in 2007 found that "the health concern of consuming too many calories from food has a greater effect on healthy eating attitudes than did health concern of developing diseases" [1]. Given that food choice is not definitively associated with having a positive attitude towards healthy eating, it is recommended that health professionals focus on the importance of health and calorie intake instead of weight control. Particularly the eating behavior of an adolescent is important in the maintenance of their health and in their physical development and, thus, why the intake of nutrients needs to be higher than any other growth period. Moreover, adolescence is a time where behavior patterns are developed and consequently have an impact on their eating behaviors in the future as there is an increase of independence and autonomy. Studies show that the eating practices one develops as an adolescent have long-term effects on health status once in adulthood. It is critical as a health care professional that one incorporates healthy eating behaviors into the daily routines of adolescence to reduce the risk of chronic diseases such as heart disease, diabetes, and particularly obesity in adulthood. Although there are standards and guidelines set out by nutrition professionals of a diet low in saturated fat and cholesterol, high intake of fruits and vegetables, and whole grains, adolescents are having nutritional problems due to their inconsistent eating behavior and unhealthy eating.

Studies show that adolescents have a lack of concern for healthy eating patterns, which is attributed to their perception of healthy eating recommendations and the health implications. In 2001, a study was done to determine perception of health and unhealthy foods, eating behaviors, and the importance of healthy eating. The adolescents suggested that "limiting junk or high-fat food and "watching fat and calories" constitates a healthy eating behavior. Most adolescents associated unhealthy eating with their peers but that healthy foods were associated with eating at home with their families. However, despite their awareness of healthy eating, adolescents are not consistently following the nutrition recommendations, and this may be due to barriers that prevent them from developing healthy eating practices. It is important to understand that peer norms play a role into the healthy eating choices of adolescents. For instance, a study in California revealed that 85% of teen girls had a health concern of weight control but only 8.5% had concern over healthy eating. This data were then compared to the National Health Interview Survey Teenage Attitudes and Practice Survey, which showed that weight concern was the second most important, whereas healthy eating was ranked last as a concern [6].

These findings suggest that healthy eating messages based on the Dietary Guidelines for Americans are reaching adolescents, but interventions are needed that assist adolescents with the translation of this knowledge into what it means to have a healthy eating behavior. Interventions should help make healthy eating easy for youth to apply and explain the consequences of unhealthy eating in terms that they value, stressing meaningful short-term benefits [6]. "Eating behavior is carried out with little regard to intention or self-regulation. However, deliberating over a menu seems to be an occasion when cognition plays a role and thus when rational food decisions might be made" [7].

Disparities/Inequities in Healthy Eating

In 2005, the Dietary Guidelines for Americans took note of the low intake of fresh fruits and vegetables, low-fat dairy products, and whole grain food of the U.S. population. It noted that race and income may be a contributing factor to the level of healthy food intake. Due to residential segregation in the United States, it is likely that there is a difference in food choices as a result of their environment. For example, the type of and amount of food stores in a neighborhood varies by race and income. A study conducted in 2008 found that there were more supermarkets that carried healthy food in predominantly white and high-income neighborhoods compared to black low-income neighborhoods. There are

disparities in obesity rates existing among ethnic groups. Black, Hispanic, and Native American children and adolescents have higher rates of diabetes and obesity than do white children and adolescents [2].

According to a recent study in 2010, there is no statistically significant difference in obesity prevalence between 2001 and 2007. However, the income disparity in obesity prevalence more than doubled between 2001 and 2007 when adolescents with family incomes below the poverty line were compared with those with family incomes at or above 300% of the federal poverty line. It also found that male adolescent obesity rates were higher than female rates across income group, especially among Hispanic adolescents, in the United States [8]. Currently, the increasing disparity in obesity prevalence by socio economic status (SES) places lower-income adolescents at a disproportionate risk for adulthood obesity as well as related conditions such as diabetes, hypertension, heart diseases, stroke, and cancer. It is important to identify that physical inactivity, sweetened beverages, and skipping breakfast are targets of intervention to reduce disparities in obesity prevalence.

However, breaking down the barrier of accessing resources for those who have a low socio economic status, particularly African Americans and Latinos, would require environmental and public policy support. Without which, eating healthier will remain a challenge, ultimately preventing the reduction of obesity [8]. Nonetheless, studies show that there are disparities based on income, race, ethnicity, and urbanization in neighborhood access to healthy foods [9].

ENVIRONMENTAL FACTORS

Food environment is affected by many different factors, including price of food, food distribution channels, the perception and knowledge of store managers, and policies affecting the location of various types of stores [5]. The physical environment has an effect on the individual weight status by impacting both energy intake and energy expenditure. The two most important environmental influences are the availability of food retail and type and location of food establishment [10].

Availability of Full-Service Grocery Stores

A study conducted in East Harlem, "Barriers to Buying Healthy Foods for People with Diabetes: Evidence of Environmental Disparities" [3], explored the difference in availability and cost of healthy food in low-income, minority neighborhoods and affluent all-white neighborhood in New York. The results showed that although East Harlem had twice as many food stores per capita than the Upper East Side, only 18% of the food stores carried all five recommended food items of fruits, vegetables, and whole grains compared to 58% of the food stores in the Upper East Side of New York. In areas that have a smaller population, there are food stores that are conveniently located in the neighborhood for its residents. In neighborhoods that have a density of small grocery stores, the average amount of shelf for fruits and vegetables has shown to be smaller than the shelf space for snack food. Furthermore, quality of the fruits and vegetables tend to be poor in food stores in lower-income areas. Consequently, it is difficult to eat healthier if there are not quality food options. Research has shown that small grocery stores are prevalent in poorer, urban areas, thus making it more difficult for those to access healthy food [10].

Food Purchasing Options

Retail Food Stores

Supermarkets tend to have the most variety of high-quality food at the lowest cost, whereas convenient stores typically sell high-calorie, prepared food, and limited fresh fruits and vegetables but at a higher cost. Studies have shown that having the option of a supermarket where you can buy high-quality, low-cost fresh produce is associated with increased daily intake of healthy food. It has been shown that purchasing food at a convenience store is associated with lower intake of fresh fruits and vegetables. Neighborhoods that have large chain food stores or medium-sized non-corporate-owned food stores have only a 21% obesity level compared to neighborhoods that have no access at 32%–40% obesity level. Low-income and rural residents often have limited access to supermarkets or chain grocery stores that provide healthy food options. Rural and farm areas have 14% less chain supermarkets compared to urban areas [9].

Similarly, there are findings that showed that a greater number of convenience stores were located by secondary schools in lower-income neighborhoods.

Restaurants

Currently, the majority of our meals and snacks are purchased at restaurants, which tend to have food high in calorie and food that is low in quality. Food eaten at restaurants typically does not provide nutritional information to encourage healthy eating choices. Studies show that frequently eating outside the home leads to higher intake of fat, sodium, and sugary beverages and lower intake of fruits and vegetables. However, full-service restaurants offer lower food prices, encourage higher food consumption, yet has shown to be associated with fruit and vegetable intake. Full-service restaurants in affluent neighborhoods have more healthy options on the menu. For example, a study conducted in South Los Angeles showed that 40% of restaurants in high-income areas provide at least five healthy food choices. In fact, there was a study that showed proximity to fast food restaurants increases the likelihood of gaining more than 20 kg during pregnancy [10].

Food Vending

Studies show that the number of vending machines present in a school is negatively associated with healthy eating as "preferred food" of sweetened drinks and high-fat foods are being provided to students. The more machines at school represent more low-nutrient snack selections and more opportunity to purchase such items [11]. Similarly, mobile food vendors sell a much smaller range of food options. The mobility of the

vendor means that it can reach areas that otherwise would not have access to food stores and establishments. However, mobile vendors are more prevalent in rural and low-income communities especially in large Latino immigrant populated neighborhoods. Rather than selling nutritious food, more high-fat, energy-dense foods are sold, contributing to the low intake of five servings of fruits and vegetables. Historically, food vendor catered to the poor and foreign immigrants by offering affordable prices, while indoor retail stores catered to the middle and upper class customers. Since the 1800s, mobile vendors face challenges of competing with local business and being prohibited to sell in upscale neighbors. Currently, efforts are being made to change permits, fee, and regulations to encourage "healthy food" vendors that meet the nutritional needs of the residents [12].

HEALTHY FOODS POLICY

School

Studies show that there is an association between school "a la carte" programs and the average daily consumption of fruits, vegetables, and saturated fat. Those who do not have an "a la carte" program tend to eat more closely to the dietary recommendations and thus the quality and variety of food in "a la care" programs have been in need of attention. Schools have become more dependent on the revenue of "a la carte" sales, and students enjoy the tastiness and convenience of fast food, making it challenging to improve healthy eating. School food programs are being encouraged to provide more fruits and vegetables [11]. In 2005, the California Endowment's Healthy Eating, Active Communities Program was established to prevent childhood obesity and diabetes in low-income communities. That is, school policies that targeted improving overall quantity and the quality of food given to students. There was a set of policies proposed that targeted improving the availability and quality of healthy foods.

The following are some of the policies adopted as a result of the *California Endowment's Healthy Eating, Active Communities Program*:

1. Setting standards for quality of nutrition and physical education on campus
2. Regulations on food and beverage marketing and advertising
3. Quality of food offered at fundraisers and classroom parties
4. Eliminating sports drinks
5. Eliminating sale of trans fat foods [2]

Currently, policy makers and public officials are focused on sustainable environmental improvements despite the fact the current economic state has limited the amount of resources public school have access to improve healthy eating at their school. However, these is an increasing demand for effective environmental and policy strategies that focus on mobilizing more efforts in community-based intervention strategies to improve healthy eating.

Moreover, organizational policy, that is, policy changes in a school or work environment, has been shown effective through the "Students Today Achieving Results for Tomorrow" program. The program targeted high-risk populations and low-income and ethnic minority children to increase fruit and vegetable intake during snack time. The snacks contained a (1) dairy product, (2) a serving of meat, (3) a serving of vegetables or fruits or vegetable or fruit juice, and (4) serving of whole grain. By using what was called "5 A Day Guidelines" they were able to increase the intake of five daily servings of fruits and vegetables by 83%. This was accomplished by changing the food vendor at their school. It is important for physicians to encourage their patients to use snack times to eat fruits and vegetables [13].

Geographic Availability of Full-Service Grocery Stores

Studies show that neighborhoods that have a density of small groceries are significantly related to obesity and body mass index of its residents in urban areas. This raises the question of whether it is more effective to offer incentives offer incentives for food retail stores to increase the availability of healthy food or other policies that foster the creation of neighborhood stores specializing in healthy food would be expected to improve food choices and health outcomes for neighborhood residents [10]. There have been policies proposing a tax on high-fat foods at grocery stores to decrease the purchasing of high-fat foods and to increase the intake of fresh fruits and vegetables.

Food Labels

It is recommended that food and beverage manufacturers limit levels of saturated fats, trans-fatty acids, free sugars, and salt in products sold. It is also recommended that they develop new products with more nutritional value and limit the amount of promotion and marketing of processed products. For instance, PepsiCo. permits advertisement of its products to children of all ages although its products are high in fat, saturated fat, cholesterol, sugar, and sodium that exceed the limits recommended by the World Health Organization. Food and beverage advertisement is encouraging consumption of high levels of calories in soft drinks, overeating, snacking instead of eating a full balanced meal, and eating while in front of the television. Rather, there needs to be an effort of encouraging of meals and cooking and discouraging the fact that happiness does not equate to spending.

Restaurant Menus

The United States is spending nearly half of food expenditures in meals in restaurants, which tend to be higher in calories and in fat. Unfortunately, the food descriptions provided on menus do not enable the consumer to make

healthier food choices. It is becoming increasingly difficult to determine which food items on the menu contain the most calories and in fact most tend to underestimate calorie content, specifically in high-calorie items. Although nearly half of the chain restaurants in the United States publicize nutrition information, it is typically not noticed by customers because of where it is displayed. It has been recommended by the state and local governments to require nutrition and calorie labels on restaurant menus, and in fact the 2010 Health Care Reform law includes requiring chain restaurants to label their menus.

A study was conducted to see if labeling menus influenced eating choices in restaurants. The results showed that restaurant menus were associated with calorie, fat, and sodium reduction [7]. Menu labeling would permit health-based food choices in restaurants, but its absence makes such choices virtually impossible. However, menu descriptions alone are inadequate for guiding nutrient-based food decisions. That is, people are typically bias in judging which food items on the menu are unhealthy. It is also important to take into consideration that, for instance, a Reuben sandwich at various restaurants can range from 480 to 1730 cal, 19 to 83 g of fat, and 39 to 182 g of carbohydrates. The variation comes from the differences in side dish, portion size, and ingredients [7].

According to the *CDC State Indicator Report on Fruits and Vegetables 2009 National Action Guide*, the following are key policy recommendations:

1. *Promote the availability of healthier food retail in communities*
   Strategies and policies to improve the food environment can aid fruit and vegetable access, availability, and affordability. The indicators in the subsequent text represent key areas in which policy and environmental support can help make changes in people's community access to fruits and vegetables.
2. *Promote the availability of healthier foods and nutrition services in schools*
   Schools are uniquely positioned to model and reinforce healthful eating behaviors such as increasing knowledge of and access to fruits and vegetables on the school campus and at school-related activities. Schools have the ability to provide fruits and vegetable not only to youth but also to teachers, other school staff, parents, and community members.
3. *Encourage food system support*
   A systems approach to food considers the many factors involved in getting fruits and vegetables from farm to consumer including aspects of food production, processing, and distribution. Also included in a food system approach are the participants in that system, including farmers, processors, industries, workers, governments, retailers, institutional purchasers, communities, and consumers.

HEALTHY EATING RECOMMENDATIONS

What Counts as a Cup?

In addition to fruits and vegetables, a healthful diet also includes whole grains, fat-free or low-fat milk and milk products, lean meats, poultry, fish, dry beans, eggs, and nuts and is low in saturated fats, trans fats, cholesterol, salt, and added sugars [14] (Figure 131.1).

Practical eating guide for patients: "Making Small Steps That Don't Require Major Lifestyle Change"

1. *Make half your grains whole*, grains that contain the entire grain kernel by eating [14]
   a. Oatmeal
   b. Brown rice
   c. Whole wheat tortilla
   d. Whole wheat pasta
   e. Whole wheat crackers
2. *Focus on fruits*
   a. Berries
   b. Cherries
   c. Melons
   d. Apples and bananas
   e. Raisins, plums, peaches, and pears

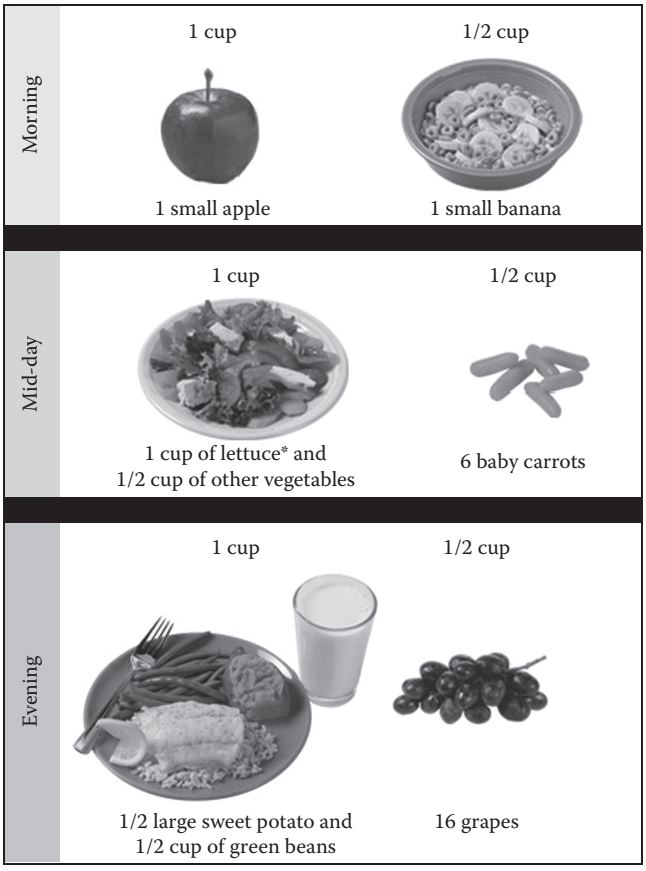

FIGURE 131.1 Fruit and veggies matter. What counts as a cup? (From CDC. http://www.fruitsandveggiesmatter.gov/)

3. *Vary your vegetables*
   a. Dark green vegetables—broccoli, spinach, collard greens, and bok choy
   b. Orange vegetables—carrots, sweet potatoes, and butternut squash
   c. Dry bean and peas—kidney beans, black beans, and black-eyed peas
   d. Starchy vegetables—potatoes, corn, and green peas
4. *Get your calcium-rich foods*
   a. Milk—fat-free (skim), low-fat (1%)
   b. Cheese—fat-free, low-fat
   c. Yogurt—fat-free, low-fat
5. *Go lean with protein*
   a. Low-fat cuts of meat
   b. Lean cuts of poultry—chicken, turkey, ground chicken or turkey
   c. Fish with omega-3 fatty acids such as salmon, trout, and herring
   d. Eggs

An effective tool to help patients integrate the practical eating guide is "My Pyramid Tracker" developed by the United States Department of Agriculture *http://www.mypyramid.gov/tools.html*.

My Pyramid Tracker is an online dietary assessment tool that provides information on one's diet quality, nutrition messages, and links to nutrient information. Once one provides a day's worth of dietary information, one will receive an overall evaluation by comparing the amounts of food eaten to current nutritional guidance. It gives a better understanding of diet over time which can be tracked up to a year.

SALES PROMOTION AT GROCERY STORES

It is important to understand that food is marketed to patients, which influences their dietary behavior, for instance, "buy one get one free" foods that are displayed in the front of the store, free samples provided while grocery shopping, or even "reduced price with purchase" and bonus sized packages. These sale promotion strategies are having more of an impact on what foods we buy and how much we eat. This makes behavior modification more challenging since the sales typically are not on low-fat healthy food items [15].

SUMMARY

Given the obesity epidemic, more attention has been given to how the food environment plays a role. There is a need for better access to healthy food and limits on energy dense, high fat food with poor nutritional value. The availability of healthy food in local food stores is associated with a higher intake of fresh fruits and vegetables and a limit on processed food. While there are methods to increase the purchase of fruits and vegetables within large corporate supermarkets and grocery stores, sales promotions and food advertisements make it challenging by encouraging overeating. Although supermarkets typically sell fresh produce, they are less available and affordable in low income and ethnic minority neighborhoods. Similarly, residents in rural areas have even less access to healthy food at supermarkets compared with urban neighborhoods. Areas without supermarkets, instead have convenience stores and corner stores that typically do not carry food with high nutritional value. It is unreasonable to expect behavior change in eating healthier when there are social, cultural, and environmental factors that do not support such change [16]. Most importantly, encourage eating products of nature and not of the food industry.

Health-promoting changes to community environments that support physical activity and good nutrition are vital to reducing obesity prevalence, and consequently, to preventing the onset or progression of several chronic diseases correlated with obesity (e.g., heart disease, diabetes, arthritis). Research has demonstrated that in order to effectively change behaviors associated with chronic disease, it is necessary to address individual and cultural factors as well as broader social and environmental conditions [1–4]. In other words, the context within which individuals live needs to change to facilitate rather than hinder healthy choices [5]. Interventions that address multiple levels of the ecological framework are also more likely to be successful in slowing the obesity epidemic because they can benefit all individuals exposed to the environment rather than focusing on improving the health of one person at a time [1–5]. Thus, there is broad recognition of the need for environmental and policy change to promote healthy behaviors [3,6–13].

To create environmental and policy changes, it is important to utilize approaches that build on community strengths and acknowledge the interdependence of individuals, their social networks, and the community structures, norms, cultures, history, and values [14–16]. Because of the importance of these more multilevel, multisectoral changes, many federal, state, and nongovernmental agencies are calling for the development of strategic alliances (i.e., partnerships, coalitions) to promote healthy eating and active living.

Clinicians have a key role to play in strategic alliances to promote healthy behaviors and environments, and there is a growing recognition that involvement in these types of efforts is a professional responsibility. Within the clinical setting, most physicians focus their time and energy on individual and social or family level factors to enhance the health of their patients. This may involve testing, counseling, and referrals to other clinicians and clinical resources (e.g., nutritionists, physical therapists, etc). While these traditional clinical roles are absolutely critical to patient care, many physicians have found that they want to have a role in addressing the other factors that impact the health of their patients. At the same time, professional expectations and spheres of influence are changing to reflect the important responsibility physicians have in advocating for health outside the bounds of the typical patient encounter or the walls of the clinic [17,18] (Figure 132.1).

Physicians are seen as natural leaders in today's society. Their expertise and leadership can help to enhance the work of local, state, national, and international strategic alliances or coalitions seeking to create change. To do so, it is important that physicians understand the role of strategic alliances in community-based work, the characteristics, and the development of alliances to ensure that they are successful in creating environmental and policy changes.

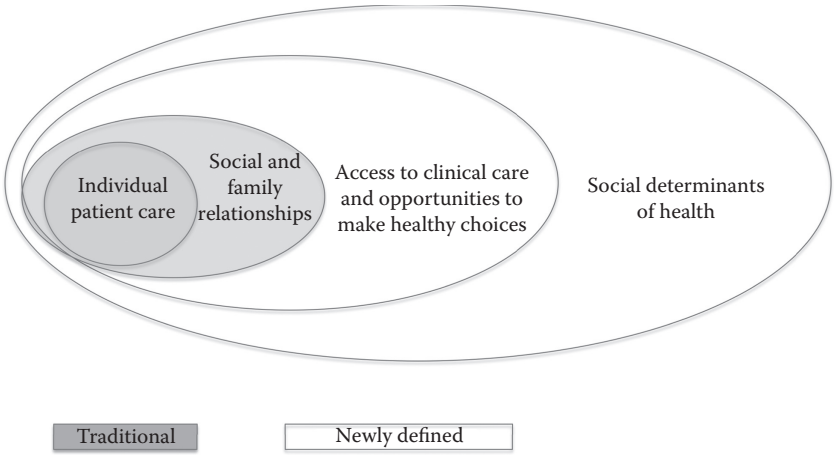

FIGURE 132.1 Physician's spheres of influence: Traditional and newly defined. (Adapted from Gruen, R.L. et al., *JAMA*, 291, 94, 2004.)

STRATEGIC ALLIANCES

Bringing organizations and individuals together from a range of disciplines and sectors of society is necessary to create environmental and policy changes to enhance healthy eating and active living. The resultant groups have been called strategic alliances, coalitions, or partnerships. Each group may go through various stages of development; progressing from initial conversations, regular meetings, development of an organizational structure, development of partnership capacity, development of a mission and vision, action planning, implementation, evaluation, and eventually to sustainability and maintenance. Their intent may be to fulfill a range of operations, each representing a different level of collaboration. The first level of collaboration might include sharing information and referrals (e.g., between clinics and community programs). The next level might be to jointly define a goal with each partner acting individually toward this shared goal (e.g., sending letters to encourage healthy choices at school events). A third level might be to contribute or exchange resources (i.e., money, space, equipment, or personnel) for a common goal. The last and often most difficult level is collaborating on planning, funding, implementing, and evaluating policy and environmental change activities [19,20]. The benefits of these partnerships are wide ranging. Having a variety of partners from different sectors (i.e., transportation, elected officials, schools, businesses, land use planning, etc.) can help navigate unique systems and processes and translate professional jargon. As a result, partnerships can improve their ability to respond to demands and increase information, resources, communication, community input, and utilization of services to improve outcomes [21–23].

PARTNERSHIPS IN ACTION

When physicians and primary care providers join community partnerships to address health, it's typically a win-win arrangement. First, partnerships benefit because physicians command professional respect in most cultures within the United States. Many have earned additional respect from their long-standing position in the community and the trust they have established with their patients. Thus, a physician's voice may add credibility to an alliance's cause. Physicians also provide a unique perspective from their daily interactions with patients dealing with the consequences of lifestyle-related diseases. Seeing so many individual cases and knowing there's a bigger context at play often motivates physician advocates and can enhance the commitment of other partners.

Physicians also benefit from community-based partnerships working to change policy and environments to enhance opportunities for daily physical activity and healthy eating. They help extend the physician's ability to advocate for the health of their patient population. Without reducing the barriers to health that many people face, only the symptoms can be treated. Telling people to be physically active who have no safe places to play or to eat a healthy diet when there are no supermarkets nearby that sell fresh, affordable produce can be counterproductive. Changing the community environments to be more conducive to health may help increase the effectiveness of a physician's counseling for healthy behaviors.

Across the nation, there are many examples of practitioner involvement in community-based alliances. A few examples in the subsequent text describe what led practitioners to these initiatives, how they participated, and some benefits of this participation.

CHARLESTON, WEST VIRGINIA

Significant barriers to healthy lifestyles face residents in the Appalachian community of Charleston, West Virginia. Culturally fat-laden diets and sedentary living combined with low access to healthy foods and places to be active for many residents have resulted in pronounced obesity and poor health, exacerbated by high rates of poverty. Virtually, none of the low-income neighborhoods have enough stores selling affordable healthy foods or safe parks. Sidewalks are nonexistent in many areas or are aging and in disrepair. However, strong neighborhood associations exist along

with recent urban renewal efforts to improve housing and community amenities. Furthermore, a new initiative called KEYS 4 HealthyKids (K4HK) is working to improve odds for Charleston children, particularly those at most risk. K4HK is supported by a strong partnership, the Kanawha Coalition for Community Health Improvement. Partners include health care providers, nonprofit organizations, and local and regional agencies. The project director is Dr. Jamie Jeffrey, a local pediatrician and the Medical Director of the Children's Medicine Center and HealthyKids Pediatric Weight Management Program at Women and Children's Hospital, a division of Charleston Area Medical Center.

Jeffrey approached childhood obesity as a diagnosis until she realized patients couldn't fulfill health-related goals because of barriers in their home, neighborhood, and school environments. Youth told her, for example, their school lunch salad bar only had potato salad and macaroni salad. Parents supported long hours on video games and in front of the TV to keep their children safely inside as opposed to dealing with the threats of crime and violence in their neighborhood. Under Jeffrey's leadership, Charleston is working on policy and environmental change strategies to increase access to healthy food and physical activity. K4HK is focused on childcare nutrition and physical activity policies and practices, developing community gardens infrastructure and joint use agreements, formal agreements between two government entities—often a school and a city or county—regarding the terms and conditions for shared use of public property or facilities.

Jeffrey's role as a pediatrician brings credibility to K4HK and contributes to the diversity of disciplines within the partnership. She also contributes local and national research outcomes and serves as a media spokeswoman. Furthermore, her involvement with community outreach helps her understand the struggles her patients and families face, how difficult it is in Charleston to lead a healthy and active lifestyle especially for low-income families. She believes the only way to reduce pediatric obesity is to treat it within the chronic care model that includes these various environments.

CUBA, NEW MEXICO

In the rural village of Cuba, New Mexico, people have limited access to fresh fruits and vegetables and places to walk and play. Of the nearly 8000 who live within a 35 mile radius, over two-thirds are Hispanic or Native American. Few roads have safe sidewalks or walkways and U.S. Highway 550 cuts through the village without even a stop sign. A local coalition, the Step into Cuba Alliance, and a local 501(C)3 nonprofit, the Nacimiento Community Foundation, are working to change this picture. The alliance includes federal and state agencies (forestry, parks and land management, transportation, and health), the University of New Mexico Prevention Research Center, and local partners such as the Village of Cuba, Sandoval County, the Cuba school district, and many citizen volunteers. Dr. Richard Kozoll, a long-standing, semi-retired local physician, led the development of this group. With dual specialties in family and preventive medicine, he attempts to address the root causes of clinical problems at the community level in addition to their consequences in his clinic. Furthermore, in a small rural community, he knew local and external partners were necessary to accomplish needed change.

Kozoll utilized many connections acquired through the years to coalesce partners under the umbrella of the local nonprofit. The foundation acquired a variety of small grants to improve trails and greenways and work on broader-scale efforts to increase active living and healthy eating. The vision for Step into Cuba is to create a "greener," healthier, and more pedestrian-friendly community with opportunities for extraordinary walking and hiking on surrounding scenic Federal land. The initiative is based on the Center for Disease Control and Prevention's evidence-based recommendations for improving public health in community settings. They are implementing strategies such as improving the built environment, increasing access to the natural environment (including trail connections to the Continental Divide National Scenic Trail), providing social support for walking and hiking, and providing point of decision prompts.

Related initiatives are underway through the award of a multiyear, Robert Wood Johnson Foundation Healthy Kids, Healthy Communities grant. Strategies related to this effort include expanding a community garden to include youth; increasing access to fresh healthy foods in arid, isolated areas; increasing the number of safe play spaces for children; making the village more pedestrian friendly, especially along the stretch of Highway 550 that serves as Cuba's four-lane "Main Street"; and identifying safer and healthier ways for children to get to school on foot.

Kozoll's role as a local physician makes him an effective champion and advocate for change. Many of the residents have been his patients and the rural setting makes for strong relationships through the years. He understands the need for community preventative services and serves as a credible spokesperson. At the area's only clinic network, the diabetes caseload typically runs 500 plus, a number he shares with policy makers when making the case for environmental change. The respect he has earned as a long-standing physician and tireless leader to improve the community for health strengthens his messages and helps him leverage resources for the cause. He recently obtained a donation of private land that was critical to connect the town to the nearest corner of National Forest and obtained partner assistance to create a new trail and trailhead area. With the Alliance and the Foundation, Kozoll extends his reach as a primary care provider far beyond the office.

PORTLAND, OREGON

Dr. Minot Cleveland, the Medical Director for Employee Health and Integrated Leave within Legacy Health in Portland, Oregon, was working to save his children's physical education program during school budget cuts in the early 1990s. Cleveland and other parents testified unsuccessfully

at the local school board meeting. They went to the Oregon Department of Education who told them state lawmakers set curriculum and funding policy. Undeterred, the group enlisted help. Cleveland, as a long-standing volunteer for the American Heart Association, recruited them, and the growing coalition, self-named Physical Education for All Kids (PEAK), advocated for statewide standards for physical education. Again, the group was unsuccessful but more determined than ever.

The Oregon legislature meets every 2 years, so PEAK spent time strengthening their coalition and their strategies. They recruited more nonprofits like the American Diabetes Association, Oregon Medical Association, and the Oregon Sports Authority. They also grew their citizen volunteer base. The additional partners brought staff support, and in 1997, PEAK convinced lawmakers to pass a bill for statewide standards in physical education. Ten years later, another bill set the minimum number of minutes required per week and included $1 million earmarked for tracking minutes statewide and supporting physical education instruction training.

Recently, the coalition came full circle and mobilized locally again because Portland School District (the state's largest district) proposed elimination of all physical education specialists from elementary and middle school. PEAK rallied to "Save Portland PE." Business and corporate entities like Nike, Oregon Public Health Institute, and the Portland Trailblazers helped ramp up their advocacy efforts through social media and paid advertisements. Together with a strong citizen voice, they greatly reduced cuts and worked with federal legislators to acquire Federal Stimulus money supporting physical education.

Cleveland's status as a physician helped when speaking to legislators, who value input from the medical community. Some legislators responded poorly to physical education professionals who testified believing they were simply trying to save their jobs. Cleveland presented data about the value of physical education and the importance of prevention, tying things to health care costs, and other values. He also reminded people that this is a social justice issue as the most disadvantaged students receive the least amount of PE.

While this was clearly a group effort, Cleveland believes policy work is one of the most important things he has done as a physician. In his work as a staff physician in Legacy Emergency Departments, he knew he wasn't dealing with the underlying problems that brought people there. As an advocate for physical education, he can help ensure that hundreds of thousands of children have the opportunity to be healthy and equipped to be active for life.

CHICAGO, ILLINOIS

In Chicago, physicians have played a key role in the successes of the Consortium to Lower Obesity in Chicago Children (CLOCC; www.clocc.net). CLOCC has been recognized as one of the largest and most effective obesity-centered strategic alliances in the country since it was formally created in late 2002. The work of two physicians is at the roots of CLOCC's successes. Dr. Katherine Kaufer Christoffel launched CLOCC with support from a local foundation (the Otho S.A. Sprague Memorial Institute) and housed the offices of the coalition within Children's Memorial Hospital. A few months later, Dr. Matt Longjohn became CLOCC's founding executive director. Together, these two advocates worked to build a coalition that has ultimately engaged dozens of physicians at multiple stages of medical education and practice (i.e., medical students, residents, private and academic practitioners, clinical researchers). As a result, numerous CLOCC-sponsored projects and studies have centered on improving the quality and connectedness of clinical interventions by engaging physicians in public education, community networking, and advocacy activities.

The effectiveness of this large partnership, which was built on the need to connect physicians and medical providers into all other sectors of Chicago life for the purposes of preventing childhood obesity, is evident. CLOCC's work has involved a total of over 3000 individuals from more than 1200 organizations over the past 9 years. Consortium partners, often physician leaders, have engineered numerous policy and environmental changes at the city and state level in that time. A great deal of community-based research, capacity building, and community organizing has also been funded because of CLOCC's efforts. In just 1 year of its work (2004–2005), CLOCC organized state-level advocacy efforts to design and advocate for five new laws in Illinois. For the past 5 years, CLOCC has facilitated the work of the City of Chicago's Interdepartmental Task Force on Childhood Obesity. CLOCC is currently the fiduciary agent for the city's 2-year, $5 million Communities Putting Prevention to Work project, which was funded by the Centers for Disease Control and Prevention. As a group, physicians involved in CLOCC have been an important voice within its efforts to curb pediatric obesity in Chicago.

MAKING THE MOST OF YOUR ENGAGEMENT

As the examples mentioned earlier demonstrate, there is a spectrum along which physicians can become engaged in strategic alliances to effectively connect their clinical work (and patients) to advocacy and health-promoting resources. In order to most effectively partner with a community-based strategic alliance, it's important to understand the key characteristics identified as helping strategic alliances to be successful [22–27]. These include components of how the alliance is structured and functions (group processes) and the way they carry out the work (action planning, implementation, and evaluation).

GROUP PROCESS

In terms of group process, it is important for the partnership to develop a common mission and vision. The group will need leadership with formally defined roles and responsibilities, as well as explicit problem solving, decision making, and conflict management structures. To be most effective,

the partnership should include a wide variety of organizations from different sectors, racial/ethnic backgrounds, and geographic areas/neighborhoods. Any group that is likely to be affected by the partnership's activities should have a place at the table. As new partners join, there need to be processes in place to share the group decision making, problem solving, and conflict management strategies. Meetings should be structured with an agenda, an opportunity to review the minutes of the previous meetings, and time should be allowed for questions and discussion. Communication between meetings should reflect the desires of the group in terms of the frequency and the method of communication (e.g., email, phone). Depending on the level of collaboration, there may need to be resources allocated to ensure that the alliance can be appropriately managed.

In terms of action planning, implementation, and evaluation, it is important that the alliance partners thoroughly assess the issue to be addressed and develop a common understanding of the implications of the assessment. From there, an action plan can be developed, implemented, and evaluated. This may involve individuals who are part of the alliance or may require the hiring of new staff or consultants. The types of activities might include anything from monthly meetings to development of new initiatives to create policies or environmental changes. The activities chosen should reflect the alliance's stage of development. It is often best to start small and focus on sharing of information and contributions that each organization can make prior to planning large interorganizational initiatives.

CHALLENGES

There are certainly many challenges that strategic alliances face, which can minimize their success. First, if any of the aforementioned factors for success are absent, the challenges are greater. In addition, it is important for alliances to consider the contextual and structural factors that can impede success [28]. For example, the way municipal structures have been historically created can cause challenges for regional policy change. Similarly, school district policies may have restrictions that impede easy policy or environmental changes. Moreover, economic and racial disparities may hinder policies from being truly inclusive.

Keeping these attributes and challenges in mind, there are many places one can start to become involved in policy and environmental change work to improve access to healthy eating and active living.

ADVOCACY STARTS AT HOME

As physicians and primary care providers see the community as part of the equation for their patients' health and wish to extend their reach, an easy first step is to assess the immediate environment of the clinic or practice. Consider ways to show consistency when advocating for a healthier environment. Are there policies that can be institutionalized to remove soft drinks from the waiting room? Is the importance of physical activity and eating healthier food consistently shared with patients, and is material readily available (perhaps produced by local partnerships) about where to be active and find fresh fruits and vegetables in the community? Is there a policy within the medical institution that establishes advocacy for obesity prevention as an expected part of the job?

KNOW THE NEIGHBORHOOD ENVIRONMENTS

Primary care providers, especially those serving low-income communities and areas of high health disparities, are faced daily with the consequences of poor environments. However, physicians are unlikely to have a full understanding of the specific nature of these environments. It may be helpful to ask clients where they shop for fruits and vegetables, where their children play, how they get to work. Better yet, physicians may benefit by walking the neighborhoods and communities to experience the environments first hand. Walking from a school to a park allows one to immediately understand safety concerns, dangerous traffic, and the saturation of unhealthy food retail that lines the street, for example. Some new medical schools are training residents about the social determinants of health. Florida International University's College of Medicine in Miami, for example, is utilizing a community-based medical curriculum, pairing each medical student with a neighborhood in the Miami area and a family from that neighborhood. Their goal is improve the health of the family and the quality of life in the neighborhood [29].

SUPPORTING PARTNERSHIPS

There are many opportunities for providing testimonials or advocating for change without being the lead champion for the cause. Community engagement is an important component of the work for multidisciplinary partnerships. During public meetings, it is helpful to have a credible, trusted voice of authority supporting the vision and goals of the group or sharing relevant data and experiences that build the case for change. Testimonials before policy makers at the local, regional, and state level are also powerful ways to be involved.

Physicians are also in a position to help leverage the medical community, talk to hospital administrators, health insurers, and clinics about their own policies as well as their potential role in supporting community partnerships. Physicians might refer patients to community resources or programs that are operating in their neighborhood as a way to support partnerships while encouraging behavior changes. In addition, alliances often need to disseminate information to community members, need in-kind or financial support, evaluation assistance, or other support that aligns well with the strengths of physicians and related institutions.

LEADING COMMUNITY CHANGE

As stability in a practice increases and time becomes more flexible, some physicians are taking the lead around this type of policy and environmental change work. Strong existing

connections are leveraged to develop a partnership that can expand over time. With strong partners, physicians can help organize and step up as credible spokespersons without being consumed by the effort. Drawing on institutional supports and other community leaders helps distribute the load and ensure that the strengths of all partners are well utilized.

SUMMARY

Physicians can play a key role with strategic alliances in creating environmental and policy changes that are critical for the health and well being of their patients and the community as a whole. Furthermore, there is growing recognition that this involvement is a professional responsibility. Participation can be achieved through a variety of roles and levels of involvement. Regardless of the role, it is helpful to be aware of how alliances can be structured to be most effective in accomplishing their goals. The support of physicians (through participation and/or leadership) can greatly enhance the success of strategic alliances, and their community-based work can also extend the physician's ability to advocate for the health of their patient population and increase the effectiveness of a physician's counseling for healthy behaviors.

The obesity epidemic represents an enormous global health problem affecting both developed and underdeveloped nations, both genders, and every ethnicity [1–4]. As discussed in other chapters in this section, and later in this chapter, obesity is typically defined utilizing body mass index (BMI) criteria. According to criteria from the National Heart, Lung, and Blood Institute, healthy weight range for adults is a BMI of 19–28.9 kg/m^2 and obesity is a BMI $\geq$ 30 kg/m^2. By any criteria, obesity has reached worldwide epidemic proportions. In the United States, for example, the prevalence of obesity is currently 32.2% in adult men and 35.5% in adult women [5]. In European countries, obesity ranges from 20% to 30% of the population and it is even higher in Polynesia, Australia, and South America [6]. The World Health Organization estimates that, if current trends continue, there will be 1.5 billion obese individuals worldwide by 2015 [6].

The most recent estimates from 2010 in the United States indicate that 33.8% of adults, over 66 million individuals, are obese (30 million men and 36 million women), while an additional 74 million (42 million men and 32 million women) are overweight. The prevalence of obesity has grown a shocking 40% in the past 30 years [7].

While the rate of increase in obesity has appeared to have leveled off over the past 2 years in the United States [5], these are, nonetheless, sobering data, which carry enormous health consequences. Furthermore, the prevalence of severe obesity (BMI $\geq$ 40 kg/m^2) and very severe obesity (BMI $\geq$ 50 kg/m^2) have grown disproportionately rapidly during this period of time [8].

Obesity not only carries adverse health consequences in and of itself but it is also strongly associated with multiple other metabolic abnormalities. For example, obesity is strongly and independently associated with coronary heart disease (CHD), the leading killer of both men and women in the United States [9,10]. Moreover, obesity is also associated with a number of risk factors for CHD including hypertension, dyslipidemia, diabetes, physical inactivity, and poor nutrition [11,12].

It is estimated that 80%–85% of all type 2 diabetes (T2DM) is related to obesity [13]. Obesity is associated with over 35% of cancers, and it is predicted to become the leading lifestyle-related risk factor associated with cancer in the next decade surpassing even cigarette smoking [14–16]. According to data from the Framingham Heart Study, over

50% of hypertension is associated with obesity [17] and approximately 50% of lipid abnormalities are associated with obesity [18]. The metabolic syndrome (MetS), which is strongly associated with obesity, is currently estimated to affect 25%–35% of the adult population in the United States [19]. Moreover, 35%–40% of the adult population has glucose intolerance, which is also a strong predictor of diabetes and closely associated with obesity [20].

Obesity is in many ways the quintessential lifestyle disease. It is abundantly clear that obesity is a complicated multifactorial problem resulting from numerous internal and external influences, which impact on the obese individual. It has been argued that in the United States and most of the Western world, we live in an obesogenic (some have even called it a "toxic") environment for weight gain. In addition to individual choices related to nutrition and physical activity, there are also significant impacts on the risk of developing obesity from family, culture, community, government, and world food policies [21]. Genetic influences clearly play a role since some individuals are more likely to gain weight than others and some ethnic groups (e.g., Hispanic and black women) [5] are much more affected than others, although all ethnicities and both genders are affected by obesity.

The fact that obesity represents an urgent national health imperative has been underscored by numerous evidence-based documents. For example, the Dietary Guidelines for Americans 2010 characterizes obesity as the "leading nutritional health problem" facing the United States [22]. The Healthy People 2010 document originally set a goal of limiting obesity to no more than 15% of the adult population [23]. This lofty goal can now be seen in retrospect to be wishful thinking. In the United States, we are moving rapidly away from this goal rather than toward it. The goal of reducing obesity prevalence to 15% of the adult population has also been incorporated into the Healthy People 2020 Guidelines [24].

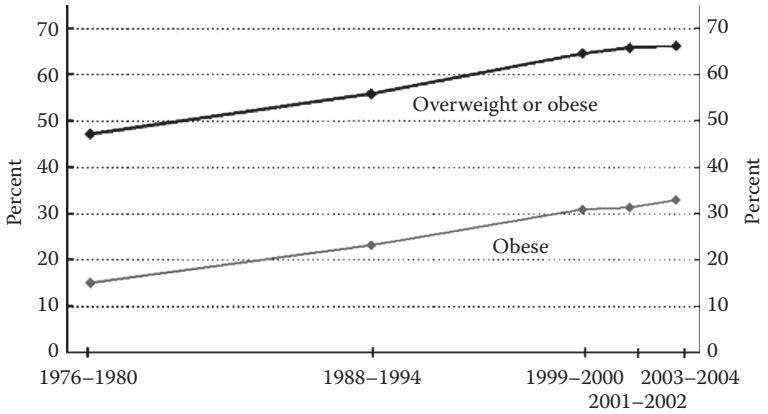
With all this as background, it is no longer a viable option for health care professionals to remain on the sidelines as both individual practitioners and community leaders when it comes to the urgent problem of both adult and childhood obesity.

In this chapter, we will summarize some of the known evidence linking obesity to adverse health consequences. We will also briefly discuss potential initiatives and frameworks seeking solutions. The chapter will close with recommendations for individual health care professional involvement to help stem the epidemic of obesity with a particular emphasis on the interaction of healthy eating and active living as key components of energy balance.

DEFINITIONS OF OVERWEIGHT AND OBESITY

Adults

Overweight and obesity in adults are generally defined using BMI, which is a measure of weight related to height, which is also correlated to total body fat and health outcomes. The National, Heart, Lung, and Blood Institute defines healthy weight for adults as a BMI of 19–24.9 kg/m^2, overweight as a BMI of 25–29.9 kg/m^2, obesity $\geq$ 30 kg/m^2 and extreme obesity $\geq$ 40 kg/m^2 [25]. It is important to note that body fat distribution also impacts on risk of chronic disease [26–29] with abdominal obesity particularly strongly correlated with risk of diabetes and heart disease. For this reason, both waist circumference and waist to hip ratio are added in some guidelines.



Children and Adolescents

Several different criteria are utilized in children and adolescents up to the age of 20 years to define "overweight" or "obese." The Centers for Disease Control and Prevention (CDC) uses the term "overweight" for children and adolescents with BMI at or above the 95th percentile for sex-specific BMI for age values from the 2000 CDC Growth Charts [30]. The CDC uses the term "at risk" for overweight for children and adolescents who are between a BMI of 85th and 95th percentiles. The American Medical Association and other organizations have recommended that this terminology be changed so that children and adolescents who are over the 85th percentile for BMI values be classified as "overweight" and over the 95th percentile classified as "obese" [31].

Epidemiologic data related to obesity in the United States are based almost exclusively on BMI derived from measured height and weight. The National Center for Health Statistics of the CDC conducts standardized physical examinations on large representative samples of children, adolescents, and adults through the National Health and Examination Survey Program (NHANES). NHANES includes oversampling of African Americans, Mexican Americans, as well as other groups to improve estimates for these groups. The description of obesity rates and trends in the United States presented in this chapter is based on NHANES data.

Rates of overweight and obesity have risen dramatically over the past 30 years in the United States (see Figure 133.1). During this timeframe, the prevalence of obesity more than doubled in adults (from 15% to 33%), while the prevalence of obesity and overweight in children tripled (from 6% to 19%) [5,7]. Estimates from 2010 indicate that 33.8% of adults are obese and that 17% (or 12.5 million) of children and adolescents are obese [5,7]. The population rates of obesity in some segments are substantially higher, which may be a result of interactions between culture, environment, and genetics. A particularly alarming trend is the increase in extreme obesity (Grade 3; BMI $\geq$ 40 kg/m^2) [7]. Over a most recent 7–8 year span, the percent of extreme obesity in adults 20 years of age or older has increased from 4.7% to 5.7%, which equates to about 2 million additional people in the extreme obesity category in the United States [7].

There are also demographic characteristics associated with overweight and obesity. Age-adjusted prevalence rates of obesity are generally higher in older versus younger cohorts, women versus men, and in racial/ethnic groups compared to Caucasians. Approximately 35.5% of women (16.0% of female children and adolescents) and 32% of men (18.2% of male children and adolescents) were obese according to

Note: Age-adjusted by the directed method to the year 2000 US Bureau of the Census estimates using the age groups 20–39, 40–59, and 60–74 years. Overweight defined as BMI >= 25; Obesity defined as BMI >= 30.

FIGURE 133.1 Trends in adult overweight and obesity ages 20–74 years. (Courtesy of The National Center for Health Statistics, Hyattsville, MD.)

NHANES 2007–2008 [5,7]. The odds of being obese are higher in adult women than men but not related to gender in children and adolescents. Mexican Americans and non-Hispanic blacks display higher rates of obesity compared to Caucasians. The most extreme example is found in women where non-Hispanic black women had a rate of obesity exceeding adult Caucasian women by 24% (53.9% vs. 30.2%) [5,7]. Age also brings about increases in obesity, particularly for non-Hispanic Caucasian men and Hispanic females [7]. For example, the prevalence of obesity for Caucasian males between 20 and 30 years of age is 26.3% but increases to 38.4% after the age of 60 years.

HEALTH EFFECTS OF OBESITY

Role of Adipocytes

Historically, adipocytes were thought to be primarily storage sites for excess fat. Research over the past two decades, however, has demonstrated that adipocytes are, in fact, highly complicated, inflammatory, endocrine, and metabolic cells. Thus, adipose tissue essentially serves as a complex endocrine organ and a potent source of inflammatory molecules such as tumor necrosis factor-α, interleukin-6, and many others [32–35]. These complex properties of adipocytes may underlie the strong linkage between obesity and chronic metabolic conditions such as diabetes, CHD, and the MetS. Adipocytes located in the abdominal region appear to be particularly complicated and active from a metabolic and inflammatory point of view [26–29].

HEALTH EFFECTS OF OBESITY IN ADULTS

Obesity and Diabetes

An estimated 9% of Americans (26 million individuals) have diabetes, and over 79 million adults display evidence of "pre-diabetes" [36]. There is a clear association between obesity and T2DM. Individuals with a BMI of >35 kg/m^2 have 42.1 times the risk of T2DM in men and 93.2 times the risk in women compared to normal BMI controls. The risk of developing T2DM diabetes is elevated the longer one is obese [37–39]. A meta-analysis pooling data from 32 studies between 1966 and 2004 found that the relative risk of T2DM was 1.87, 1.87, and 1.88 per standard deviation of BMI, waist circumference, and waist to hip ratio, respectively [40].

The Nurses Health Study, which followed over 80,000 female nurses over a 16 year span, demonstrated that being overweight or obese is the single most important predictor of T2DM [41]. In another meta-analysis that studied BMI across categories (normal to overweight to obese), relative risks were 3.9 and 12.4 for overweight and obese women, respectively, and 2.4 and 6.7 for overweight and obese men, respectively [42].

The relationship between obesity and diabetes in children is also potent. In the SEARCH for Diabetes in Youth Study, it was estimated that approximately 3700 adolescents per year are now diagnosed with T2DM and that this number is increasing [43]. T2DM is now the most prevalent form of diabetes diagnosed in adolescents [44]. Insulin, fasting insulin, and insulin to glucose ratio are significantly higher in obese versus control 8–11 year olds and impaired insulin sensitivity becomes more apparent as the duration of obesity increases [45–47].

A detailed discussion of the relationship between obesity and diabetes is found in Chapters 33, 34 and 107 and has been reviewed extensively elsewhere [48].

Obesity and Heart Disease

Multiple large-scale studies have linked obesity to risk of cardiovascular disease. In a recent meta-analysis, the relative risk among obese men and women compared to normal weight men and women was 2.4 for CHD, 2.1 for hypertension, 1.5 for stroke, 1.8 for congestive heart failure, and 3.5 for pulmonary embolism [38]. Longitudinal data from the Framingham Heart Study found that age-adjusted relative risk for cardiovascular disease was 1.64 in women and 1.46 in men comparing obese to normal weight individuals.

Obesity is also associated with multiple other established risk factors for CHD including hypertension, dyslipidemia, diabetes, and an inactive lifestyle. The multiple links between obesity and heart disease as well as the risk factors for CHD is beyond the scope of the current chapter and has been reviewed extensively elsewhere [49].

Obesity and Cancer

Multiple prospective studies have established a significant association between obesity and cancer [38]. In one large, 16 year longitudinal study involving nearly one million subjects, all-cause mortality for all cancers was 62% higher in women and 52% higher in men with a BMI > 40 kg/m^2 compared to subjects with a normal BMI [50]. In another study involving 1.2 million women between the ages of 50 and 64 years, obesity was associated with significantly higher rates of 10 of the 17 most common types of cancer [51]. Current evidence suggests that obesity prevention may be more advantageous than weight loss in reducing incidence of obesity-related cancer [52]. The relationship between obesity and cancer has been extensively reviewed [53].

Obesity and MetS

MetS, which represents a clustering of risk factors related to impaired glucose and lipid metabolism is strongly associated with obesity in general and abdominal obesity in particular [54–56]. MetS is a significant risk factor for both diabetes and heart disease. Current estimates suggest that MetS is present in 25%–35% of the adult population in the United States [19]. Weight reduction by itself or occurring in combination with lifestyle changes, such as increased exercise, is associated with a significant drop in the prevalence of MetS [57,58]. Even moderate amounts of weight loss (20 lb) result in a significant reduction in the prevalence of MetS [58]. The pathophysiology of MetS and its linkage to obesity has been extensively reviewed elsewhere [59].

Obesity and Arthritis

There are strong linkages between obesity and multiple forms of arthritis, but particularly osteoarthritis [60,61]. Obesity is the leading cause of osteoarthritis in women and the second leading cause of osteoarthritis in men [61]. The linkage between obesity and arthritis appears to be partially mediated through increased pressure on weight bearing joints but also may relate to the systemic inflammation that often accompanies obesity [61]. The linkage between obesity and arthritis has been extensively reviewed elsewhere [62].

Obesity and Other Medical Conditions

Obesity is significantly associated with multiple other risk factors and diseases in both men and women. A partial listing of these conditions is found in Table 133.1. Obesity is related to multiple maternal and fetal problems in pregnancy [63–65].

TABLE 133.1
Medical Conditions Associated with Obesity

- Metabolic conditions
  - Type 2 diabetes
  - Metabolic syndrome
  - Glucose intolerance
- Cardiovascular disease
  - Coronary heart disease
  - Stroke
  - Heart failure
  - Deep venous thrombosis
- CHD risk factors
  - Dyslipidemia
  - Hypertension
  - Inflammation
  - Hypercoagulability
- Pulmonary diseases
  - Obstructive sleep apnea
  - Hypoventilation syndrome
  - Asthma
- Cancers
  - Colorectal
  - Esophageal
  - Endometrial
  - Breast (post menopausal)
  - Kidney
- Gastrointestinal diseases
  - Non alcoholic fatty liver disease
  - Gallstones (cholecystitis)
  - Gastroesophageal reflux
- Other conditions
  - Gout
  - Kidney stones
  - Osteoarthritis
  - Psychological disorders
  - Fertility and pregnancy complications
  - Erectile dysfunction

Obese individuals are also at increased risk of depression and other psychiatric disorders [66–68]. Obesity is strongly related to the increased prevalence of gallbladder disease [69,70] and obstructive sleep apnea [71]. NHANES data suggests that individuals with a BMI of ≥35 kg/m^2 lose an average of 9–13 years of life compared to normal weight individuals [72].

Obesity is also related to a number of disease of risk factors and diseases in children and adolescents [73]. Obesity is strongly related to MetS in children and adolescents [56] as well as a variety of cardiovascular complications including hypertension, left ventricular hypertrophy, dyslipidemia, and sleep apnea [74–79]. Obese children and adolescents also experience more psychological abnormalities including loneliness, poor self-perception, depression, and anxiety disorders [80–83]. Furthermore, obesity in adolescent years carries a significant increased risk of severe obesity in adulthood [84].

ECONOMIC IMPACT OF OBESITY

In addition to the enormous health toll attributed to obesity, substantial costs are being driven by the obesity epidemic. For example, in the United States, it is estimated that obesity may cost as much as $147 billion per year [85]. Some of this burden of these expenditures is shared by the government (i.e., taxpayers), while the rest is largely paid through private insurers [86]. Thus, taxes and employee insurance premiums (which are paid by all employees regardless of weight) finance most of the cost of treating obesity or its related conditions.

It is estimated that an obese individual costs a health plan 47% more in health care expenditures, and an overweight individual generates 16% more costs than healthy weight individuals [87]. During the period between 1998 and 2006, direct annual medical costs associated with obesity increased from 6.5% to 9.2% of total health costs [88,89]. This computes to obese individuals spending an average of $1429 annually in 2006 for medical care, which equates to more than 42% more annual costs compared to individuals of average weight [90].

For all of these reasons, multiple stakeholders including taxpayers, the government, employers, and employees all have significant motivation to restrain the rising costs of obesity if only for its financial impact.

PUBLIC HEALTH IMPLICATIONS

Obesity was first recognized as a public health issue by the National Institutes of Health in 1985 [91]. Recent data for the CDC indicate that obesity in the United States remains a major health problem [88,89]. Obesity now outranks both smoking and drinking alcohol in its adverse effects on morbidity and mortality as well as health costs. Obesity is associated with a 36% increase in in-patient and out-patient health care costs compared to a 21% increase in spending for smoking and excessive alcohol consumption [92]. As already indicated, the Healthy People 2010 objectives related to obesity stated the goal of reducing prevalence of obesity in adults in the United States to 15% [49]. This goal has been carried over to the Healthy People 2020 objectives. However, no state in the United States has achieved this objective [31].

One significant public health concern related to obesity is the increased risk of premature mortality. A number of investigations have clearly demonstrated that as body weight increases so does mortality from diabetes, cancer, and heart disease [51,93,94]. If the American population were able to lose its excess body weight, mortality would be reduced by 15%, which corresponds to 3 years in average life expectancy for every citizen in the United States [93].

As already indicated, obesity is a complicated chronic condition with multiple underlying causes including, lifestyle, culture, genetics, socioeconomic, and psychological factors all contributing. For this reason, obesity should be viewed as a chronic condition similar to heart disease and diabetes and its treatment must be multifactorial, focusing not only on the individual level but also from the public health perspective of the community and national level.

A comprehensive and coordinated approach will be required to reverse the epidemic of obesity in the United States including policy and environmental changes to transform communities to support and promote healthy lifestyle choices for all U.S. citizens. The CDC recently convened an expert panel, which identified 24 recommended strategies for obesity prevention together with suggested measurements for each strategy that communities can utilize to track progress [95]. A list of these strategies is found in Table 133.2. To help accomplish this, the strategies together with implementation and measurement guide will be published and made available through the CDC website: http://www.cdc.gov/nccdphp/dnpao/publications/index.html.

In addition to the CDC initiative, multiple other private and governmental initiatives have been announced in an attempt to reduce the health impact of obesity in general and childhood obesity in particular. For example, First Lady Michelle Obama's "Let's Move" campaign has established the goal of ending childhood obesity within the next generation [96].

TABLE 133.2
CDC Task Force Recommendations for Steps That Communities Could Take to Help Combat Obesity

- Increase availability of healthier food and beverage choices in public service venues
- Improve availability of affordable healthier food and beverage choices in public service venues
- Improve geographic availability of supermarkets in underserved areas
- Provide incentives to food retailers to locate in and/or offer healthier food and beverage choices in underserved areas
- Improve availability of mechanisms for purchasing foods from farms
- Incentives for the production, distribution, and procurement of foods from local farms
- Restrict availability of less healthy foods and beverages in public service venues
- Institute smaller portion size options in public service venues
- Limit advertisements of less healthy foods and beverages
- Discourage consumption of sugar-sweetened beverages
- Increase support for breastfeeding
- Require physical education in schools
- Increase the amount of physical activity in PE programs in schools
- Increase opportunities for extracurricular physical activity
- Reduce screen time in public service venues
- Improve access to outdoor recreational facilities
- Enhance infrastructure supporting bicycling
- Enhance infrastructure supporting walking
- Support locating schools within easy walking distance of residential areas
- Improve access to public transportation
- Zone for mixed-use development
- Enhance personal safety in areas where persons are or could be physically active
- Enhance traffic safety in areas where persons are or could be physically active
- Communities should participate in community coalitions or partnerships to address obesity

Other efforts such as the collaboration between the William J. Clinton Foundation and numerous health care and commercial organizations in the "Partnership for Healthy America" have articulated similar goals and an increased sense of urgency [97].

PUBLIC POLICY AND ENVIRONMENTAL STRATEGIES

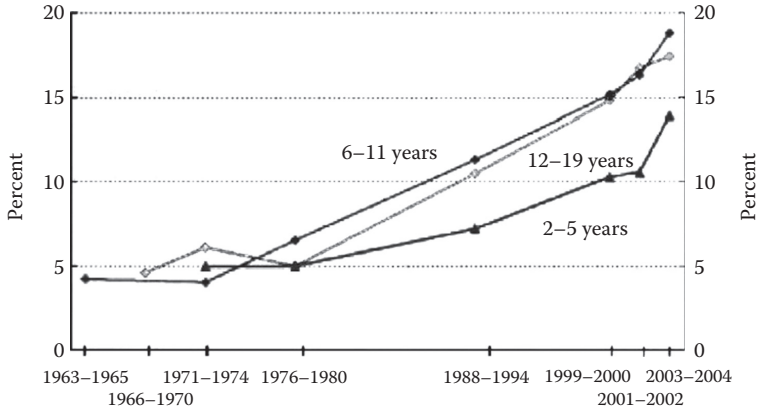
Policies and policy-informed environmental supports will all be required on a national, state, and local level to promote active living, healthy eating, and the prevention of obesity. These strategies have been discussed by Heath elsewhere [98]. Heath divides these public policy and environmental initiatives into the following four areas:

- Agricultural and food supply policies that support healthy eating
- Health care service policies
- Educational and school-based policies
- Urban design, land use, and transportation policies for active living/health eating

Initiatives in all these areas will be required to improve energy balance behaviors for active living and healthy eating to help combat the obesity epidemic.

Searching for Solutions

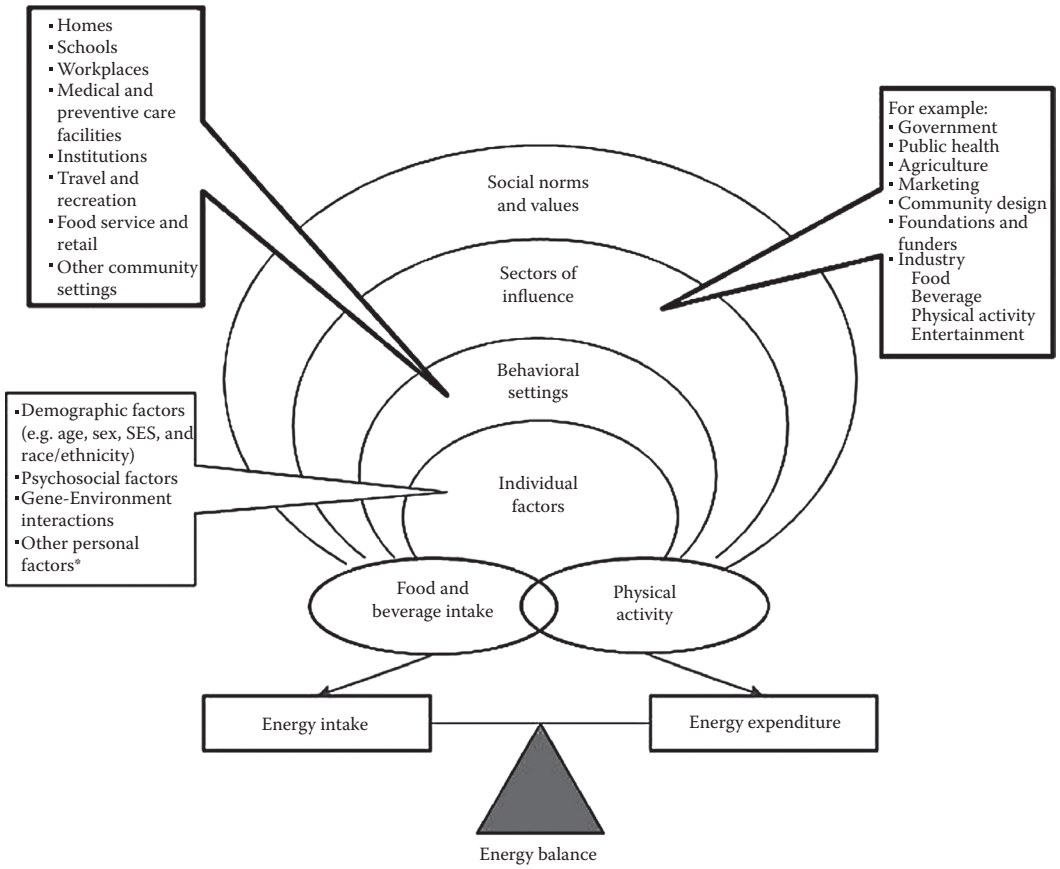
Given the complexity of underlying causes for the obesity epidemic, comprehensive solutions will be required to ameliorate this problem. Such approaches must involve multiple levels of influencers and involve multiple areas of intervention. One framework for approaching obesity and weight management has been proposed by the Dietary Guidelines Advisory Committee [99]. Figure 133.2 depicts the socioeconomic framework offered by the Dietary Guidelines Advisory Committee (DGAC) for approaching the obesity epidemic. This framework stresses that maintaining proper energy balance is complicated and factors influencing this issue are multiple and interconnected, thus mandating a multifaceted approach to amelioration.



Food Environment

A comprehensive approach to the modern food environment will clearly be required to help solve the global obesity problem. In the United States, for example, the average caloric consumption has dramatically increased over the past 40 years [100]. As depicted in Figure 133.3, the average daily caloric consumption in the United States has increased from 2057 kcals in 1970 to 2674 kcals in 2008.

While significant increases have occurred in virtually every category of food, the increases are particularly prominent in the areas of added fats and oils, flour, and cereal products [100]. It has been argued by Swinburne et al. [101] that increased caloric consumption in the United States during the past four decades alone is more than sufficient to explain the U.S. epidemic of obesity. Other investigators, however, have challenged this notion and argue that other aspects of the environment such as diminished physical activity have also contributed significantly to the obesity epidemic [102,103].



It is clear, however, that individuals in the United States are not adhering to the guidance from various iterations of the Dietary Guidelines [104]. As shown in Figures 133.4 and 133.5, the American population is falls far short when it comes to fruit and vegetable and dairy consumption compared to MyPyramid recommendations [105].

It has also been argued that both the increased number of meal occasions and increase in portion sizes both play significant roles in the obesity epidemic in the United States [106]. While the number of meal occasions appears to be relatively stable over the past 25 years [107], the number of calories consumed in snacking has increased by approximately 25% during this period of time [107]. There is ongoing debate about whether snacking per se significantly contributes to the weight gain in the American

Note: Overweight is defined as BMI >= gender- and weight-specific 95th percentile from the 2000 CDC Growth Charts.

TABLE 133.3
Changes over Time in the Average Portion Size of Selected Food Items Sold in the U.S. Marketplace

	Portion Size (Year)	Portion Size (Year)	Percent Increase
Beer, can	12 oz (1936)	8–24 oz (2002)	33–100
Beer, bottle	7 oz (1976)	7–40 oz (2002)	0–471
Chocolate bar, milk chocolate	0.6 oz (1908)	1.6–8 oz (2002)	167–1233
French fries	2.4 oz (1955)	2.4–7.1 oz (2002)	0–196
Hamburger	3.9 oz (1954)	4.4–12.6 oz (2002)	13–223
Soda, fountain	7 oz (1955)	12–42 oz (2002)	71–500
Soda, bottle, and can	6.5 oz (1916)	8–34 oz (2002)	23–423

Source: From Report of the DGAC on the Dietary Guidelines for Americans, 2010, available at www.cnpp.usda.gov; Young, L.R. and Nestle, M., *J Am Diet Assoc*., 103, 231, 2003.

population [108,109]. There is general agreement, however, that increases in portion size have contributed significantly to overall increase in caloric consumption [110]. As demonstrated in Table 133.3, portion sizes of common foods sold in the United States have increased between 100% and 1000% over the past 50 years [110].

While these data support that the food environment does not currently support healthy eating patterns in the United States, solutions to this issue will require participation of many stake holders in the food system including not only individuals themselves but also supermarkets, the commercial food industry, and farmers.

Physical Activity

The U.S. population remains far too sedentary. The Dietary Guidelines for Americans 2010 concluded that there was "strong, consistent evidence" that physically active people are at reduced risk for becoming overweight or obese." [22] In addition to the benefits related to prevention of obesity and assistance in long-term weight maintenance, multiple other benefits accrue to physically active people. These have been summarized in detail in the Physical Activity Guidelines for Americans 2008 [104].

Genetics

There is no question that genetics play an important role in the modern obesity epidemic. Most investigators conclude that about 40% of obesity may be related to an individual's genetic make-up [111–113]. The interaction between genetic make up and the environment plays a particularly prominent role. A detailed discussion about obesity and genetics is beyond the scope of this chapter and has been reviewed extensively elsewhere [111–114].

While specific areas of the genome controlling food intake, physical activity, and weight gain are under active investigation, this work is far from ready for clinical application. Researchers anticipate, however, a time when genetic research may yield important information to help make issues of weight control more individualized and precise.

Closing the Energy Gap

It has been argued by Blackburn et al. that health care professionals should focus first on individuals with extreme obesity (BMI of $\geq$40 kg/m^2) since this is the segment of the obese population, which is most rapidly increasing [115]. These investigators have put forth the concept that interventions for obese individuals should address the "energy gap."

By their estimates, an energy gap of approximately 400 kcals per day exists currently in the United States, which was not present in the 1970s. These investigators further suggest that an approach involving improved dietary composition, calorie restriction, and increased physical activity as key components of a comprehensive lifestyle intervention to close this energy gap.

Small Steps Approach

A recent task force report from the American Society of Nutrition concluded that current initiatives designed to combat obesity have not succeeded in reversing the obesity epidemic [116]. An alternative strategy was presented by this panel based on promoting small changes in physical activity and nutrition to prevent further weight gain rather than focusing on weight loss. Such approaches are supported by a variety of lines of evidence and appear to hold some promise to help combat obesity.

NEED FOR HEALTH CARE PROFESSIONAL INVOLVEMENT

Given the severity of the obesity epidemic and its potential significant adverse health consequences, it is critically important that health care professionals become actively involved and knowledgeable in multiple aspects of this issue. Clearly, this is an area where components of lifestyle medicine will play critically important roles. After all, the goal of *Lifestyle Medicine* is to help people understand how their daily habits and practices impact on their short- and long-term health and quality of life and their likelihood of developing chronic diseases such as obesity.

As we have already indicated, obesity represents the quintessential lifestyle disease. It carries significant health risk both to individuals and to our population as a whole. It is, therefore, incumbent upon health care providers to take actions now. Some specific steps that individuals and clinicians can make are outlined by Utter et al. [117] who offer the following recommendations:

Health care providers and medical clinicians should counsel their patients to

- Eat more fruits and vegetables and fewer foods high in fat and sugar. See http://www.choosemyplate.gov/
- Drink more water instead of sugary drinks
- Limit TV watching in children to less than 2 h a day and do not put a TV in their room at all
- Support breastfeeding
- Promote policies and programs at school, at work, and in the community that make the healthy choice the easy choice. This includes policy and environmental supports for both healthy eating and active living.
- Try going for a 10-min brisk walk, 3 times a day, 5 days a week [117]

SUMMARY/CONCLUSIONS

There is no longer any serious doubt that we are in the midst of a worldwide pandemic of obesity. Both adult and childhood obesity represent health problems for all nations. Obesity is strongly linked to a variety of co-morbidities including diabetes, heart disease, cancer, the MetS, and arthritis. Obesity also results in an enormous psychological and financial burden both for its individual sufferers and for the health of every nation. For all of these reasons, it is incumbent for health care professionals to become knowledgeable about and assist in the treatment not only of individual patients who are obese but also help influence public health, public policy, and environmental changes to provide a multifaceted approach to this major health problem.

MEDICINE

Lifestyle Medicine

SECOND EDITION

There is no doubt that daily habits and actions exert a profound health impact. The fact that nutritional practices, level of physical activity, weight management, and other behaviors play key roles both in the prevention and treatment of most metabolic diseases has been recognized by their incorporation into virtually every evidence-based medical guideline. Despite this widespread recognition, physicians and other healthcare workers often cannot find a definitive and comprehensive source of information on all of these areas.

Designed for physicians and other healthcare workers, *Lifestyle Medicine, Second Edition* brings together evidence-based research in multiple health-related fields to assist practitioners both in treating disease and promoting good health. Sections cover nutrition and exercise, behavioral psychology, public policy, and management of a range of disorders, including cardiovascular disease, endocrine and metabolic dysfunction, obesity, cancer, immunology and infectious diseases, pulmonary disorders, and many more.
