Where men do take an interest in nutrition is in sport and fitness contexts. Body building is a classic example where men pay very close attention to food intake, calorie consumption and expenditure, and bodily consequences, perhaps influenced by muscular torsos adorning the covers of popular men's magazines more than health concerns [40]. Given the increased visibility of the male body in popular magazines, billboards, and society generally, it is likely that some (younger) men at least will be influenced or inspired by such images to work on attaining similar bodily definitions through taking up strict dietary regimes as well as exercise programs. It is likely too that in competitive sporting contexts, ranging from cycling to athletics and team sports, nutrition plays a key part in preparation for events [41]. Related to this is the upsurge in interest from men in fashion, grooming, and appearance concerns generally [42] since a desire to project and maintain a particular image is likely to involve dietary and other (e.g., exercise) programs. In studies of "metrosexual" men, for example (men interested in fashion, grooming, and self-care [43]) we see reference to food and alcohol in relation to the effects on skin appearance and a general concern with looking healthy [44]. As men become more interested in their physical appearance in Western youth-centered, image-conscious consumer-driven societies, then it is likely that disordered eating patterns may result, with more men presenting with traditionally "female" conditions such as anorexia and bulimia, with estimates ranging from 10% to 25% of eating disorder cases [45]. In the context of weight training and muscle-centered exercise, the use of steroids is significant with male gym users in pursuit of the modern lean-but-muscular ideal [42]. Compared to women, who are said to have a unidimensional relationship with body weight as they desire slimness, men have been found to have a bidirectional relationship with their weight in that some complain of being too large and some too small [46,47]. A Scottish study [48] on adiposity in men in low socioeconomic groups found that men of normal weight wanted to be larger, overweight men were happy as they were and only obese men wished to lose weight.

Conversely, bigger men who are medically defined as obese may well reject healthy eating advice in order to maintain a body size and shape deemed to be desirable. For example, in an interview study with gay male "bears"—typically large, hairy, "masculine" gay men—Gough and Flanders [49] encountered much resistance to mainstream health promotion, as one participant states:

> I think, the bear community does encourage you to remain the weight you are, provided you fit within these ranges, of overweight and obese, not skinny but not too big that you look ridiculous, The society BMI would like me at 12 stone [76.2 kg, or 168 pounds], the bear community wants me to be meaty, the bear community wins hand down because being this size changed my whole outlook on life, because I have, whether its [name of a northern city], the fact that I've matured, I've got more friends here, than I ever had in my whole life.

Within the bear community, it is larger bodies which are celebrated and eroticized, so any targeted health or nutrition advice would need to take account of the "alternative" group identity and norms which pertain here. Gay communities are particularly lacking in research on health-related lifestyle choices beyond safe sex, HIV, and AIDS.

Another societal phenomena has been the rise of cooking programs [50], and with it the heralding of the (male) chef hero. Again, it is likely that such programs and associated books will encourage some men into the kitchen to experiment with new ingredients and foodstuffs, and since a varied diet is often linked to a healthy diet, this development is perhaps to be welcomed. An area ripe for more research is the changing nature of men's relationship with food and its implications for health, with reference to the diversity of men's circumstances, relationships, and community influences. What are the eating habits of young working class men, and how do these compare with their more affluent counterparts? How relevant is health for men situated differently with respect to age, sexual orientation, and ethnicity? What role do marriage and similar commitments play in male nutritional behaviors? These and other questions are important to address in future research so that we can design effective interventions tailored to specific groups of men.

PROMOTING NUTRITION IN MEN'S HEALTH

The question of what works for men in terms of health promotion is vexed. We do not really have much evidence—there are few evaluations of existing initiatives. One thing is important though, and that is overcoming men's traditional antipathy toward "interference" in their lives. For example, Gough and Conner's [12] interview study with men revealed skepticism toward government and media-sponsored healthy eating campaigns, perhaps reflecting a "masculine" orientation to self-reliance and personal control. Other research has also encountered a strong theme around men making their own health-related decisions:

> I just think blokes will do it when they want to do it. They won't be told. It's like anyone could tell me I need to stop smoking but I'll do it when I'm ready to stop smoking and not when someone tells me to […] I watch all the adverts and I do think I should stop smoking. But I'm not ready to stop smoking, I might never be ready to stop. If a doctor tells me "you need to stop smoking" then it's my decision whether I do or don't (Robertson [17], pp. 122).

But this male emphasis on independence can be deployed in health promotion campaigns. For example, in the United Kingdom the Men's Health Forum has published a series of "man" manuals focusing on different aspects of men's health, and a prominent feature in these texts is the insistence on the individual's capacity to set and achieve personal goals. One of the manuals focuses on obesity reduction, and some extracts from different sections of the text pertaining to diet illustrate the centrality of male autonomy (see Ref. [51]):

> Make your decisions based on logical discussion with yourself rather than allowing them to be a fait accompli (Section 2.5)

> Knowing how powerful your thoughts are will give you another tool for your kitbag (Section 2.6)

> Weight management is just a matter of choosing the right foods (Section 4.11)

This emphasis on solitary decision making is peculiar in that other people and situational constraints are absent, as if men inhabit a private universe untouched by others or social pressures. However, the underlining of self-reliance makes sense from a masculine point of view. In fact, this text (and other manuals) invokes a range of masculinized attributes and activities in order to encourage men to lose weight and get fit. The theme of "goal setting" is of course familiar in other "masculine" domains such as sport, management, and the military [52]. Indeed, these three domains are variously invoked to help promote individual performance. For example, men are invited to "plan your attack" (Section 3.23) in order to increase physical exercise, to "fight the insulin resistance" (Section 4.12), and advised that "the key to winning the war of terror on fat is to boost your metabolic rate through diet and regular exercise" (Section 4.14). As well, the Football Association is cited in the context of advice on water intake (Section 4.10) and nutrition (Section 4.18). Indeed, the first page proper (Section 4.11) features a half-page photograph of five England footballers advertising the manual and an acknowledgment below the Football Association's "encouragement and assistance." The world of work is also presented at various points to highlight the problems and possibilities of healthy activities. For example, the case of policemen (Sections 4.10 through 4.16) is used to illustrate the health risks posed by a desk job with little opportunity for exercise of healthy eating combined with a male-centered drinking culture. Whatever the "masculine" context or discourse, men are consistently advised to use their logical minds and inner strength to achieve a healthy weight.

However, there is a debate here about the extent to which masculinity is promoted over health. It has been argued elsewhere [51] that although recourse to stereotypical notions of masculinity may help to gain mens' attention and may even encourage men to make beneficial changes to their lifestyle, there is a risk that masculinized discourse privileges, say, self-reliance, mental toughness, and mastery may end up maintaining or even regressing men's health promotion efforts as interpersonal, social, and cultural considerations are erased from the picture. For example, there is no point stressing the importance of personal goal setting without taking into account a man's work patterns, family responsibilities, social obligations, and so on. The situation is complex. For some men who live alone, we know that healthy living can be more difficult without the support of a partner [38], so merely being alone does not equate with a proactive achievement orientation. There are other suggestions that homosocial environments can be used to promote healthy eating in men. In one Canadian study, for example, men who learned to cook with other men improved not only their skills in the kitchen but also their healthy eating practices [53]. The role of men in supporting each other toward healthier lifestyles is complicated, however. One recent study has examined how men, signed up to an all-male online weight management group sponsored by the magazine Men's Health, support each other in their weight control efforts [54]. In total seven "threads" were analyzed, with those declaring their age ranging from 19 to 40 years; all participants self-defined or could be defined as overweight or obese from the information provided. It was found that support was couched in understated and indirect way, for example, "I understand what your saying mate" or "sod the heartbreak man you should be proud of what you are doing." As well, any display of emotion linked to struggling with diet and weight loss was dismissed as "girly":

> Harpsie 11 (thread 1: 09/01/2009 11:28AM 1–10) The reason that people believe you could be inspirational as there are a lot of guys out there that have punished their bodies so much to extent where you were: And are at rock bottom in weight and confidence, a lad who sees this post and reads it through to the end will be sat there thinking God

> if this guy can do it then so can I!!!! You are inspiring people like others on here that by saying and showing (in the words of Dys). Losing weight is not hard stop moaning and get to it. I think you need to read back this post my friend and see how far you have come. Any way enough of this girly stuff ….

Here, a pragmatic, action-oriented discourse is privileged over emotional expression, thereby reinforcing the masculine character of the homosocial support group environment. Such considerations would need to be borne in mind when designing "male-friendly" diet-based interventions.

Staying with weight loss, there have been similar moves to construe diet-based weight management programs as "male-friendly." Although primary care trusts in the United Kingdom have been keen to increase recruitment of men on to commercial diet organizations such as "Weight Watchers" or "Slimming World" [55], even when specifically targeted, the impact has been very modest. For example, "Slimming World" attempted to raise awareness in men about the problems with being overweight and set up a national network of men-only groups. However, the percentage of men compared to women attending the groups went from 3% to only 5% [56]. NHS weight loss interventions such as "counterweight" have been found to have only 26% of participants as male [55]. The literature is mixed on how to better recruit men onto weight loss interventions. Some success has been found with interventions designed specifically for men which highlight exercise and lifestyle changes rather than diet-based schemes, especially those which invite talk of emotional eating [57]. Occupational weight management programs have also been shown to be more successful in recruiting men [58]. Other research suggests that individualized programs are better, particularly with regards to diet [59].

There is some suggestion that men are unlikely to seek health advice or change their habits until or unless they experience a health scare [11]. Such medical events typically prompt men to reflect on and reevaluate their lifestyle choices, engendering behavior change in key areas such as diet. But even here the situation is complex. For example, in a recent study by Mróz et al. [60] men diagnosed with prostate cancer showed varying commitments to dietary change, ranging from little or no change to major overhaul. Most men opted for relatively minor changes:

> I'm just doing things a little more intensely, and maybe varying or supplementing what I used to eat with things such as blueberries and sardines and fish. That's really I think the only, the best way to say it is that I'm intensifying, always trying on a healthy diet, but now I'm just doing it a little bit more intensely and consciously

Moreover, men who self-define as healthy and/or can be categorized as leading a healthy lifestyle may be reluctant to cite health as a factor in their lifestyle practices. An interview study by Sloan et al. [61] with "healthy" men found that factors other than health were cited when describing health-relevant practices, such as following a particular diet regime, avoiding or minimizing alcohol intake, and exercise programs, including sporting performance. In the following extract, the interviewee ("Paul") is responding to a question about when he began to take account of his health:

> Paul: … when I started to take the basketball seriously. That's when I started to look at my health and kind of how my body reacts and stuff. And trying to learn and understand more about food and what it does to my body.
>
> Int.: Did you not think about it before then?
>
> Paul: No I never gave it a thought; I just lived and ate whatever.
>
> Int.: There is nothing that you can think of that made you change it?
>
> Paul: Well yeah I kind a used to smoke, not much, but playing basketball made me not want to smoke. Cos I knew that it was kinda abusing my body. I need my lungs to be at the full capacity rather than clogged and stuff. So I stopped smoking.

Here, Paul accounts for his transition to a healthier lifestyle in terms of enhancing his sporting performance—health is subordinated to a more valued sporting context, where the talk is functional and technical, treating his body as an instrument to be worked upon and refined. Other studies also indicate that when men take up traditionally feminized practice such as cooking and healthy eating, they tend to reframe the activity in question in conventionally masculine terms. For example, those men who advocate reduced meat diets may emphasize the rationality of their choice toward healthier living [62], while those who cook for other men at work or at home may imbue their cooking with hypermasculine discourse centered on competence [63]. For example, in Bennett and Gough's [54] analysis of postings to an online male-only weight loss forum, cooking healthy food was still centered around meat, alcohol, and homosocial bonding:

> in my opinion my kebab tastes better than the ones you get in the kebab house after a night out! Worked for me and two of me mates Friday night. Whu_1989 (thread 1: 12/01/2009 11:57AM 20–21)

In the same study, men also glossed the kitchen as a masculine space central to the manufacturing of manly (muscular) bodies:

> I think the saying "a sixpack is made in the kitchen and not in the gym" is 100% true. Matt14 (thread 5: 23/12/2008 2:24PM 2–3)
>
> Be a beast in the gym and a beast in the kitchen, that's where good bodies are made. Danroye (thread 1: 12/01/2009 2:55 6)

Similarly, media portrayals gloss kitchen-based activities as masculine, even in the seemingly innocuous context of breadmaking:

> But what's really remarkable is that in each case it's the man of the house who's up to his elbows in flour. Suddenly men who've never shown the slightest interest in matters culinary are talking Italian flour and sourdough starters. "I've become

> a baking widow," laments one friend, as another batch of breadsticks are proudly produced from the oven. "Why can't he take up golf like any normal husband?" Chef Richard Bertinet puts the appeal down to the hunter-gatherer thing. "It's like natural foraging. You transform a few base elements into something that will provide for your family. Seeing your child eat your own bread is very Satisfying. I think it's also that most men are natural show-offs in the kitchen. We may not like the day-to-day stuff, but we love to cook to impress." (The Times, Loafing about—Foodie at large, 15/10/05)

So, breadmaking, referenced as unusual for men ("remarkable"; not "normal"), is somehow transmuted into breadwinning and attributed to an evolutionary hunter-gathering instinct [29].

It is clear then that health promotion efforts around diet targeting men need to be designed with care and sensitivity to valued aspects of gendered identities. A blunt focus on outmoded and simplistic stereotypes of masculinity may well work to some extent in gaining mens' attention but risk reinforcing gendered norms linked to poor health in the first place. On the other hand to ignore salient masculinities may well miss valuable opportunities to engage men in changing their eating and related practices. What we must not do is assume that all men are the same when it comes to food intake [29]. Mens' ideas and practices around food will vary with respect to myriad factors including parental influence, social class, age, work patterns, and relationship status, to name a few. For example, for those men in long-term relationships the role of partners in supporting (or undermining) health promotion efforts needs to be factored in, along with any childcare responsibilities, work patterns, and financial pressures, while for single men it may be more important to establish supporting networks and resources to facilitate healthier eating. In general, we can develop more tailored and effective healthy eating initiatives for specific groups of men as research expands the understanding of mens' diverse preferences, practices, and priorities.

Urological diseases in men encompass a broad range of illnesses ranging from acute to chronic, benign to malignant, and medical to surgical. The economic burden of treatment reflects their broad scope: in 2000, over $1 billion, $1.2 billion, and $320 million were spent treating benign prostatic hyperplasia, prostate cancer, and erectile dysfunction (ED), respectively [1]. The primary care provider will most likely be the first to encounter men with urological complaints and can play a significant role in the prevention, diagnosis, and treatment of men with urological diseases. This chapter will highlight major urological health issues in men, with a focus on diagnostic and preventive measures useful for the primary care provider.

PROSTATE

Benign Prostatic Hyperplasia

Benign enlargement of the prostate is an age-dependent phenomenon and is directly related to exposure to androgens. As men age, androgens induce a variety of changes at the cellular level leading to hyperplasia of the stromal (smooth muscle) and glandular (epithelial) cell types of the prostate. This process may result in increased bladder outlet resistance, which has a variety of clinical consequences, the most important of which are bothersome lower urinary tract symptoms (LUTS)—symptoms related to the storage and elimination of urine from the bladder through the urethra—that can significantly impact upon a man's quality of life. LUTS may include complaints such as nocturia, frequency, urgency, hesitancy, intermittency, weak stream, and sensation of incomplete voiding, however do not typically include incontinence. The mainstay of evaluation and treatment of men with benign prostatic hyperplasia (BPH)-related LUTS is aimed at preventing the progression and bother of voiding symptoms.

Historically, men diagnosed with BPH had only one treatment option—surgical resection. Now transurethral resection of the prostate is reserved for men with cases refractory to medical management. If left untreated, BPH can result in persistent hematuria, recurrent urinary tract infection, urinary retention, and rarely chronic kidney disease. However, the most common clinical consequence of BPH is progressive LUTS related to dysfunctional urination.

While the relationship of LUTS and histologically confirmed BPH is not direct, the prevalence of BPH and LUTS increases as men age. In a large cross-sectional study in the United States, 13% of men aged 40–49 years complained of LUTS that were either moderately or severely bothersome and this number steadily increased up to 28% of men in their

seventh decade of life [2]. This increasing prevalence with age has been estimated to be about the same as autopsy-proven BPH; however, LUTS can be a result of other entities such as overactive bladder (OAB) [3,4].

Although most men complaining of LUTS have BPH, LUTS are not specific for BPH. Thus, the American Urological Association (AUA) recommends that the initial evaluation of LUTS involves a focused history, urinalysis, digital rectal examination (DRE), serum prostate-specific antigen (PSA) in selected patients (patients who have >10 years life expectancy), and the AUA symptom index (AUA SI or International Prostate Symptom Score [IPSS]) [5]. The AUA SI is a questionnaire that measures the severity of LUTS and is a useful instrument to help stratify patients with BPH-related LUTS who may benefit from treatment. The eight domains of the symptom index—frequency, urgency, nocturia, weak stream, hesitancy, intermittency, incomplete emptying, and impact of symptoms on quality of life are scored from one (least severe) to five (most severe). The AUA SI has been validated and shown to be effective in identifying men who would benefit from treatment and is a useful tool to follow their progress during or after treatment (Appendix A).

BPH-related LUTS have a significant impact on various measures of health. Men who develop progressive BPH-related LUTS that go untreated tend to report a worsening in their condition that has an increasingly negative impact on quality of life [6]. Additionally, men in nontreatment (placebo) arms of large randomized controlled trials involving medical treatment were shown to be at increased risk for acute urinary retention, urinary tract infection, urosepsis, need for invasive procedures to treat BPH, and most commonly worsening LUTS. Untreated BPH-related LUTS has also been shown to be associated with decreased quality and frequency of sexual activity and an individual's overall perception of general health [7,8]. Fortunately, less than 25% of men with BPH-related LUTS will demonstrate progressive disease [8].

The 2010 AUA guidelines enumerate multiple treatment options for men with LUTS related to BPH. Watchful waiting refers to the most conservative approach: patients who have mild symptoms (or patients with moderate to severe symptoms who are not significantly bothered by them) may be followed without intervention [5]. Dietary modifications such as reductions in alcohol and caffeine intake as well as decreasing overall fluid intake may also improve LUTS [9,10].

Medical therapy for BPH has been shown to be effective at reducing symptoms and halting disease progression. There are two different classes of medications—α-receptor blockers and 5α-reductase inhibitors (5-ARIs). α-Blockers primarily target the α1A receptors located in prostatic stroma and help to reduce overall prostatic smooth muscle tone, thus decreasing bladder outlet resistance [11]. These medications are most useful to improve the bothersome voiding symptoms in men with BPH-related LUTS. The other medication for the treatment of BPH-related LUTS, 5-ARIs, prevents the conversion of testosterone to dihydrotestosterone in the prostate. The lack of dihydrotestosterone reduces the proliferation of prostatic tissue and reduces prostate size by as much as 20%–40% after 6 months of treatment [12,13]. Similar to α-blockers, 5-ARIs improve BPH-related LUTS; however, they also reduce the risk of urinary retention and the need for surgical intervention by as much as 50% [8,13]. If medical treatment is chosen, those patients without obvious prostatic enlargement on DRE may be started on α-blocker therapy for symptom relief primarily. If there is evidence of prostatic enlargement on DRE (>30 mL or grams of prostate tissue), patients may be started on 5-ARIs either as monotherapy or in combination with α-blockers [5]. Treatment with a 5-ARIs in combination with an α-blocker has been shown to be more effective at reducing LUTS and preventing the progression of LUTS as compared to using either agent alone in men with significant BPH-related LUTS [8]. As with any treatment choice, a balanced discussion regarding the risks of medication including decreased volume of ejaculate, breast tenderness, and rarely ED should be held with the patient.

Although widely used, phytotherapeutics and dietary supplements such as saw palmetto, phytoestrogens, and African plum have not been proven to be effective at preventing or treating BPH-related LUTS. In addition to the lack of clear evidence demonstrating treatment efficacy, there is broad variation in the potency and concentration of such substances which makes it very difficult to track comparisons. The AUA therefore recommends that providers evaluating patients with BPH should not endorse dietary supplements or phytotherapy [5].

Patients who demonstrate evidence of kidney or bladder damage due to BPH, recurrent urinary tract infections, bladder calculi, hematuria, or LUTS refractory to medical management should be considered for treatment with more invasive measures [5]. While transurethral resection of the prostate (TURP) remains the "gold standard" for surgical intervention, a variety of other measures including laser vaporization, endoscopic enucleation, transurethral microwave thermotherapy (TUMT), and transurethral needle ablation (TUNA) have been shown to be effective at treating symptomatic BPH [5,14]. Open prostatectomy is also an effective surgical option; however, it is reserved for extraordinarily large glands [15].

The main thrust of treating BPH is symptom relief and prevention of disease progression; however, emerging evidence demonstrates that there may be ways to prevent BPH and BPH-related LUTS. Although to date there are no recommended preventive measures, modifiable lifestyle factors are linked to BPH and LUTS. Obese men have been shown to be 40% more likely to undergo prostate-related surgery and have a twofold increased risk of reporting LUTS than their nonobese peers [16,17]. Likewise, elevated fasting blood glucose and diabetes are both associated with BPH and BPH-related LUTS [18,19]. In contrast, exercise has been associated with up to 25% risk reduction from developing BPH and LUTS [20]. Therefore, in addition to the numerous other

health benefits of weight loss and physical activity, men may also reduce their risk for BPH and BPH-related LUTS with an active lifestyle.

Prostate Cancer

Accounting for over 25% of new cancer cases in the United States, prostate cancer remains the most commonly diagnosed, non-skin-related, malignancy in American men. The American Cancer Society estimates that in 2010, over 200,000 men will be diagnosed with prostate cancer and over 30,000 will die of their disease [21]. In North American and European countries, the absolute lifetime risk of prostate cancer is ~8% [22]. Clearly, prostate cancer poses a significant threat to male health; however, significant uncertainty remains in how to prevent, diagnose, and treat prostate cancer effectively. This is because there is broad heterogeneity with prostate cancer: low-grade disease behaves in a relatively indolent fashion, while high-grade disease can be expediently lethal. Although there is controversy over its usefulness, serum PSA testing has dramatically changed the diagnosis and treatment of prostate cancer over the past 30 years. In the era of PSA-related prostate cancer screening, most prostate cancers are now diagnosed in the early stage with metastatic disease at initial presentation relatively rare [23].

Age confers the greatest risk for prostate cancer. In the United States, autopsy studies demonstrated that 50% of men aged 50–59 years had microscopic foci of cancer in the prostate and this increased to 75% of men older than 85 years [24]. While the incidence of clinically detected prostate cancer is much lower, very few (<0.1%) patients diagnosed with prostate cancer are younger than 50 years old and about 85% of men diagnosed with prostate cancer are age 65 years or older [25]. In the United States, the risk of a white male being diagnosed with prostate cancer increases from about 2% in the fifth decade, and increases to 6% in the sixth decade and as high as 8% in the seventh decade [21].

Men with a family history of prostate cancer are two to five times more likely to be diagnosed with this disease when compared to the general population. First-degree relatives, namely a father or brother with prostate cancer, double a man's lifetime risk and increasing the likelihood of a younger age at diagnosis. There are also rare forms of hereditary prostate cancer, which can place a man as high as five times the normal risk for prostate cancer [22].

Race also impacts a man's risk for developing prostate cancer. In the United States, the lifetime risk of developing prostate cancer is 18%, or one in five for African American men as compared to white men with a one in six or 15% risk. Furthermore, African American men are almost twice as likely to die from prostate cancer as compared to whites [21]. This is likely due to multiple influences including genetics, socioeconomic status, and environmental factors such as diet and lifestyle, as immigrants of African descent have a different incidence of prostate cancer in other countries [26]. This has also been observed in other races, where Japanese American and Chinese American men have a higher incidence of prostate cancer as compared to their native Japanese and Chinese male counterparts [26]. This observation suggests that the American lifestyle plays a role in the pathogenesis of prostate cancer. Indeed, high-fat diet and obesity have been linked, although indirectly, to an increased incidence or clinical progression of prostate cancer [26,27]. Access to care may also play a role, as those cancers found in African American men are significantly more advanced than those found in a similar population of white men, suggesting that white men are more likely to get screened for prostate cancer [28]. In contrast, men with a Hispanic or Latino, American Indian, Alaskan Native, and Asian or Pacific Islander background living in the United States have a decreased risk of prostate cancer with respect to whites in the United States for reasons which are unclear [21].

Hormonal factors also play a role in the development of prostate cancer. Androgens directly influence the development and growth of the prostate, and although a direct relationship has not been established, there is some evidence suggesting that prostate cancer is related to circulating testosterone levels. In a large longitudinal study, men with testosterone levels in the upper quartile had a 2.6-fold increased risk of developing prostate cancer [29].

As the cost of medical services continues to increase, disease prevention has become a major focus in both health care delivery and industry. Prostate cancer prevention has been the focus of several recent randomized controlled trials with over-the-counter supplements and prescription drugs. Vitamin E, vitamin D, and selenium, all proven antioxidants, have been purported to decrease carcinogenesis by reducing DNA mutation as a result of oxidative stressors [30–32]. However, in a large prospective randomized trial, neither vitamin E nor selenium was shown to be effective at preventing prostate cancer in men at normal risk and there actually may be an increased risk of prostate cancer for patients who take vitamin E [33].

Two different 5-ARIs have been evaluated for their use in prostate cancer prevention. Many investigators rationalized that since these drugs reduced intraprostatic androgen concentration, they may reduce carcinogenesis. Finasteride, a type 2 5-ARI, was shown to decrease the risk of being diagnosed with prostate cancer by almost 25% in a low-risk population of men (aged >55 years with PSA <3.0 ng/dL and a normal DRE). Another more recent trial demonstrated that dutasteride, a nonselective 5-ARI, conferred a 23% relative risk reduction for the diagnosis of prostate cancer [34]. Considerable controversy exists surrounding the overall benefit of chemoprevention of prostate cancer with either dutasteride or finasteride [35]. Although chemoprevention with 5-ARIs may provide a reduction in prostate cancer risk, side effects of these agents include sexual dysfunction, gynecomastia, and possibly an increased risk of cardiovascular events. Furthermore, there was also an increase in the incidence of high-grade prostate cancer in those patients taking finasteride or dutasteride, indicating

that chemoprevention may upgrade indolent cancers into more aggressive disease [33,36].

Despite these two large randomized controlled trials demonstrating that 5-ARIs reduce the risk of prostate cancer, their use in clinical practice is sparse. Over 60% of urologists and 80% of primary care providers do not use them for chemoprevention of prostate cancer [37]. In a joint statement written in 2008, the AUA and American Society of Clinical Oncology (ASCO) concluded that while selective men may benefit from a discussion of the risks and benefits of 5-ARIs for chemoprevention of prostate cancer, no chemoprevention agent could be recommended for widespread use [38]. Until there are further studies demonstrating a reduction in cancer-specific mortality as well as cost-effectiveness, chemoprevention will likely not be a recommended strategy toward the prevention of prostate cancer.

Prostate cancer screening is widely performed by primary practitioners as well as urologists. Screening with serum PSA and DRE, a practice that became pervasive in the early 1990s, has reshaped the landscape of prostate cancer diagnosis. Previously, prostate cancer screening was based on DRE alone, a notoriously poor method of detection, and cancers would often be found at an incurable stage. With the more sensitive PSA testing, there has been an attendant stage migration characterized by an increase in disease confined to the prostate and a decrease in the age at diagnosis [39]. Since the implementation of PSA screening, the lifetime risk of prostate cancer has increased from 9% in 1985 to 17% 2009 [35]. The ramifications of this stage migration have led to the much of the controversy surrounding prostate cancer diagnosis and treatment.

Given the heterogeneity and the widespread prevalence of the disease, many prostate cancers are not clinically significant—in other words, men will die from other causes rather than from their prostate cancer. Also, PSA is not a specific marker for prostate cancer and may be elevated in other conditions such as enlarged prostate, urinary tract infection, and prostatitis. Thus there is a risk for overdiagnosis and overtreatment as well as difficulty interpreting the test results. Two recent randomized controlled trials attempted to address the overall validity of PSA screening by testing its correlation with prostate cancer–specific mortality. The ERSPC, a European-based study, demonstrated that prostate cancer screening with PSA conferred a 20% reduction in the rate of death from prostate cancer; however, the authors concluded that there was significant overdiagnosis and overtreatment to achieve this goal [40]. The U.S.-based study, the prostate cancer portion of the PLCO trial, demonstrated that after 7–10 years of follow-up there was no difference in prostate cancer–specific mortality in men screened with PSA as compared to those who were not screened [41]. The major limitation with each of these trials is the relatively short follow time of <10 years. Since the mortality benefits of PSA screening may not be realized for 15–20 years, these studies may have been too short in their follow-up to specifically evaluate the utility of PSA screening.

The current AUA best practice guidelines for PSA testing recommend that the risks and benefits of prostate cancer screening with PSA testing be discussed with men aged 40 years and over. Those men agreeable to pursue screening should have a baseline PSA checked at 40 years of age as the risk of developing prostate cancer has been linked to baseline PSA level. Patients at higher risk, namely African Americans and those with a family history, should undergo annual screening starting at the age of 45 years. All men should undergo annual prostate cancer screening with PSA, at the age of 50 years [42]. DRE should always accompany serum PSA, as this increases the sensitivity for detecting prostate cancer [42].

PENIS

Erectile Dysfunction

Once thought to be predominantly due to psychological factors, the understanding of erectile has dramatically changed in the past two decades. Now we understand ED to be a complex interplay between vascular, neurological, hormonal, and psychological pathways. Erectile function appears to be an overall barometer for a man's health as data have demonstrated a correlation between self-reported ED and a poor overall perception of one's own health [43]. Whether ED contributes to self-perceived health status or is an end manifestation of systemic disease, it is one of the most common and important issues that can be addressed by the primary care provider.

Normal erectile function relies on a complex interaction between the vascular and neurological network within the penis. The paired penile arteries are the main blood supply to the corpora cavernosa, the erectile bodies of the penis. In the flaccid state, smooth muscle tone within these vessels is high, allowing a low blood flow state. During arousal, parasympathetic nerve input induces release of neurotransmitters such as nitric oxide (NO) that causes smooth muscle dilation within the penile arteries, allowing the corpora cavernosa to fill with blood, and eventual tumescence. In the erect state, the venous outflow is occluded due to the increased blood within the corporal bodies, allowing for the penis to remain erect until ejaculation occurs [44]. Any disease process that affects these pathways has the potential to cause ED.

In the United States, as many as one in four men between the ages of 20 and 75 years have ED and the estimated number of new cases diagnosed annually is over 600,000 per year [43,45]. The prevalence of ED increases with increasing age as only 7% of men up to 29 years have ED in comparison to 18% of men aged 50–59 years [46]. Importantly, the majority of men reporting ED also report other comorbid conditions such as diabetes, hypertension, hyperlipidemia, smoking, or depression [43,47].

Regardless of etiology, the frontline therapy for the treatment of ED has become phosphodiesterase type 5 inhibitors (PDE5i). Under normal conditions, NO is released by parasympathetic nerve endings located within the penile corpora in response to sexual stimulation, which generates the production of cyclic guanosine monophosphate (cGMP), a potent vasodilator. This process initiates and maintains an erection. Phosphodiesterase type 5 degrades cGMP, inducing vascular endothelial contraction, which leads to penile detumescence. PDE5i's inhibit the degradation of cGMP, thus increasing cGMP concentration within the cavernosal arterial endothelium resulting in vasodilation [48]. The AUA best practice guidelines on ED currently recommend that any PDE5i—sildinafil, tadalafil, or vardenafil—be offered as first-line therapy for ED unless patients are unfit for sexual activity or are taking nitrates for chest pain [49].

The link between depression and ED is well established and the two conditions can reinforce each other, making each one more severe [50]. Unfortunately, the mechanism of this interaction has not been well characterized [51]. Men with depression have less desire for and derive less satisfaction with sexual interaction. The lack of libido in these men may also be linked to hypogonadism, suggesting that low testosterone may relate to concomitant depression and ED [51]. Since these two conditions share many of the same symptoms such as fatigue, loss of libido, poor appetite, and dysphoria, a primary care provider may find it useful to check early morning serum testosterone and prolactin levels in men with such complaints.

The use of antidepressant medications has been associated with sexual dysfunction rates as high as 60%–70%, with pure selective serotonin reuptake inhibitors (SSRIs) faring the worst. Although not all sexual dysfunction related to SSRI use is specifically ED, paroxetine has the highest reported ED rate of 40% [52]. SSRI-related sexual dysfunction appears to be dose related, and manipulating the dosage and class of antidepressant medication has been shown to be effective at improving sexual function; however, this should be done with caution as doing so risks antidepressant withdrawal and the relapse of depression [53].

Sildenafil has been shown in several studies to improve SSRI-related ED. Men taking SSRI and sildenafil reported improvement of erectile function similar to men with ED not taking an SSRI [51]. Sildenafil and vardenifil may also be effective in treating men presenting with ED and untreated depressive symptoms. In two trials, men with mild depressive symptoms and ED reported significant improvement in both erectile function as well as depressive symptoms when given a PDE5i [51].

Perhaps the most well-understood cause of ED is cardiovascular disease. The onset of ED has been shown to be an early harbinger of cardiovascular disease, and some clinicians advocate that the discovery of ED during routine evaluation should prompt further cardiovascular evaluation [54]. Obesity, hypertension, heart disease, and diabetes have all been linked to ED [55,56]. Although less clear, other studies have found a correlation between smoking and ED, where smoking may potentiate the effects of other cardiovascular diseases on erectile function [47]. ED has also been linked to other modifiable risk factors such as alcohol consumption and sedentary lifestyle [55].

In addition to hypertension, antihypertensive medication may also lead to ED. β-Blockers appear to be associated with the highest risk, with a relative risk similar to men with untreated hypertension. A potential link between ED and thiazide diuretics for hypertension has been reported; however, this relationship is less established as compared to β-blockers [55,57]. Other medications for hypertension including angiotensin-converting enzyme inhibitors, calcium channel blocker, and α-blockers have not been shown conclusively to be associated with ED [55,57].

Lifestyle modification may also improve erectile function, or at least delay the progression of ED. In obese men with ED, without other cardiovascular risk factors, exercise and dietary modification aimed at weight loss was shown to improve erectile function [58]. Smoking cessation has been shown to improve ED, and appropriate glycemic control in younger patient with type 2 diabetics may also reduce the risk of developing ED [59,60].

The AUA Guidelines in 2005 recommend that men first presenting with ED be tested with morning serum testosterone, complete blood count, blood glucose, lipid levels, and renal function testing [49]. Initial medical therapy, if the patient is fit enough for sexual activity, should consist of any of the PDE5i. There have been no studies to date demonstrating the superiority of one PDE5i over another [44]. Absolute contraindications to PDE5i therapy include use of nitrates, high- or intermediate-risk cardiovascular disease, retinitis pigmentosa, and non-arteritic anterior ischemic optic neuropathy [44]. It may take up to eight uses before a PDEi is effective, and patients who do not respond to treatment may also benefit from discussion on patient and partner expectations as well as reminders on how to properly take the drug [61]. If these measures ultimately fail, referral to a urologist is indicated.

Circumcision

The only absolute indication for circumcision in the adult male is phimosis, a process referring to the inability to retract the foreskin. Relative indications include treatment of balanoposthitis, improved hygiene, prevention of penile cancer, and prevention of HIV transmission and other sexually transmitted diseases [62]. Unfortunately, there are no current evidence-based guidelines advocating circumcision for these conditions. Given that penile cancer is exceedingly rare (especially in industrialized countries), studies designed to show any reduction in its incidence related to circumcision would be very difficult.

Perhaps the strongest support for preventive circumcision is its relationship to the transmission of HIV. Three

randomized studies in Africa have demonstrated that circumcision is effective at reducing the transmission of HIV, where transmission is largely based on heterosexual intercourse. In all trials, risk reduction was over 50% at 2 years of follow-up. Clearly, circumcision does not replace other prevention measure such as abstinence or the use of barrier methods, as there were still many seroconversions in the control arms of each study [63]. In contrast, circumcision in homosexual men has not been clearly shown to decrease HIV transmission [64]. Currently, the U.S. Centers for Disease Control state that evidence is strong enough to inform heterosexual men on the potential benefits of circumcision for HIV prevention; however, it cannot be recommended as a potential benefit for homosexual men until further studies are done [65]. Regardless, conversations about circumcision should be approached with caution, as there is evidence that men may engage in higher risk behavior once circumcised due to an overestimation of the preventive efficacy of this procedure [63,64].

TESTES

Testis Cancer

Testis cancer is the most common solid malignancy in young males, and the incidence has been increasing over the past century. A white male in the United States faces a 1 in 500 lifetime risk of developing testis cancer, almost twice that as it was in the first half of the twentieth century. This trend appears to be increasing as we move into the twenty-first century [66,67]. In contrast, African American males carry a threefold less risk of developing testis cancer as compared to white males; however, African American men are approximately two times more likely to be diagnosed with testis cancer than African men [67].

In addition to racial and environmental influences, cryptorchidism (undescended testis) is thought to contribute to carcinogenesis in the testis [68]. By 6 months of age, both testes should be easily palpable within the scrotum. If the testis is not palpable, or is palpable but retracts into the inguinal canal, it is considered undescended. Orchiopexy is a safe procedure in which the testis is brought down into an anatomical location within the scrotum and should be performed at 6–12 months of age [69]. Until recently, evidence demonstrated that orchiopexy did not reduce the risk of testis cancer for an individual with cryptorchidism; it merely made the affected testes easy to examine [70]. However, a recent study showed that males with cryptorchidism who underwent orchiopexy after puberty were about twice as likely to develop testicular cancer than those who had surgery prior to the age of 13 years [71]. Additionally, patients with a history of undescended testis have a 5%–10% chance of developing testis cancer in the contralateral testis, warranting close follow-up [72].

Testicular microlithiasis, an asymptomatic and largely incidental condition diagnosed by ultrasound and characterized by multiple small echogenic foci within the testicular parenchyma, has also been suggested to be a risk factor for testis cancer [73]. Currently, there is controversy over the exact nature of this association and most experts advocate follow-up including regular physician visits and self-examination. Further testing in men with this condition should be reserved for high-risk patients such as those with infertility, cryptorchidism, or a history of testis cancer [74].

As late as 1970, the mortality rate from testicular cancer was as high as 17%; however, with the advent of multimodal therapy including chemotherapy, surgery, and radiation, testis cancer has one of the highest and most durable cure rates of all malignancies, with an overall survival rate of 96% in 2005 [21]. One of the most important factors in cure, and one in which primary care providers can exert a major influence, is preventing a delay in diagnosis. The most common presenting symptom of testis cancer is a painless lump or swelling of the testicle. Less commonly, patients may show other signs and symptoms including testicular pain, gynecomastia, or systemic manifestations related to distant metastases (e.g., cough due to pulmonary metastases) [75]. Unfortunately, young men may not seek evaluation at the initial onset of symptoms or signs. A delay in diagnosis is associated with more advanced disease as well as an increased risk of cancer-specific mortality. Men who waited more than 6 months after the first onset of their symptoms had a cancer-specific survival of ~85% as compared with those who sought treatment within 3 months of symptom onset who showed a 97% cancer-specific survival at 5 years [76].

Currently, experts do not advocate large-scale screening for testis cancer [77]. However, there is some evidence that patient education and testicular self-examination may lead to early diagnosis [78,79]. It seems prudent, therefore, for the primary care provider to educate young men about testis cancer and the possible benefits of testicular self-examination.

Androgen Deficiency in the Aging Male

Testosterone is a hormone predominantly produced in the testes and is under the regulation of gonadotropin luteinizing hormone (LH), which is secreted from the pituitary gland. Testosterone is responsible for development of secondary sex characteristics in males, and has numerous other effects in the musculoskeletal, nervous, and cardiovascular systems.

As men age, testosterone production decreases. It is now widely recognized that low testosterone, also known as androgen deficiency in the aging male (ADAM), can lead to a variety of symptoms and conditions that may improve with the administration of exogenous testosterone. Unfortunately, there are very few well-conducted studies to direct clinicians in the diagnosis and treatment of ADAM.

The true prevalence of androgen deficiency is not known, but a study borne out of the Massachusetts Male Aging Study predicts that in the United States, 2.4 million men age of 40–69 years likely have ADAM, and rates increase

with age [80]. Furthermore, the rate seems to be increasing with longer life expectancy. Thus, given the widespread prevalence, primary care providers should be familiar with presenting signs and symptoms of this condition. Recognized clinical characteristics of ADAM include ED, low or loss of libido, impaired cognition, depressed mood, fatigue, low hematocrit, increased fat mass, decreased muscle mass, decreased bone mass, and overall diminished quality of life [81].

Unfortunately, many of the signs and symptoms of androgen deficiency overlap with characteristics of other disease processes. There are two questionnaires that have been tested including the Androgen Deficiency in Aging Men questionnaire and the Aging Males' Symptoms Scale that have been shown to have sensitivities of 88% and 96%, and specificities of 60% and 30%, respectively [82,83]. Thus, while these questionnaires are useful screening measures, they fall short of being comprehensive diagnostic tools [84].

Along with a thorough medical history and physical examination, measurement of serum testosterone is a key component in the diagnosis of ADAM. Normal values are based on distributions of age-matched males; however, there may be variability depending on assay. When total testosterone is below 200 ng/dL, patients are most likely hypogonadal, whereas testosterone levels above 400 ng/dL are most consistent with the normal state [85]. Due to circadian rhythmic variations in its production, serum testosterone should be measured between 8:00 a.m. and 11:00 a.m. No other laboratory values are needed in initial testing; however, if testosterone levels are low or below normal, it is useful to recheck testosterone along with serum LH and prolactin [81]. Testicular examination may also be useful, as testis volume below 15 mL may be associated with androgen deficiency [86].

Exogenous testosterone replacement is the mainstay of treatment in men with ADAM. In the United States, several preparations are available. Intramuscular injections and transdermal preparations are the most widely studied and have been shown to be effective, while oral preparations are associated with unreliable hormone levels, aberrant lipid profile, and liver toxicity [81,87,88].

Proven benefits of testosterone replacement include lowered serum low-density lipoprotein, increased muscle mass/decreased fat mass, decreased bone turnover and increased bone density, and improvement of sexual desire and erectile function [89–92]. Furthermore, there is evidence that treatment of the metabolic syndrome with exogenous testosterone improves all associated parameters, namely a decrease in blood pressure, decrease in fasting blood glucose, decrease in abdominal girth, and improvement of serum lipid profiles [93].

The Sexual Medicine Society of North America currently recommends testosterone replacement therapy in men who have signs and symptoms of hypogonadism accompanied by low testosterone levels [94]. Furthermore, some experts suggest a 3-month trial in men demonstrating symptoms but have borderline normal testosterone levels [84]. Currently, there is no established target treatment testosterone level, but experts have recognized that patients with testosterone levels above 400 ng/dL are likely not to be hypogonadal [85]. Patients should be monitored for adverse effects throughout treatment. A baseline assessment of serum lipid profile, liver profile, and complete blood count should be obtained and monitored every 3–6 months after beginning treatment [94]. Furthermore, because testosterone can possibly exacerbate BPH-related LUTS and prostate cancer, DRE and serum PSA should be performed prior to treatment and then every 3–6 months thereafter for 1 year followed by yearly prostate evaluation on patients older than 40 years [94].

BLADDER

Overactive Bladder

The International Continence Society defines the OAB syndrome as "urinary urgency, with or without urge incontinence, usually with frequency and nocturia" [95]. Once thought of as a condition that primarily affected women, a growing body of recent research has identified that a significant proportion of men may suffer from OAB. The prevalence of LUTS suggestive of OAB in men over the age of 18 years old is about 10%, no different from that of women, and the likelihood of diagnosis increases as men age [96,97]. In contrast to women where LUTS are understood to be primarily due to bladder dysfunction, LUTS in men may be due to BPH, OAB, or both [98].

Due to this multifactorial etiology, diagnosis and treatment of men with OAB may be difficult. Currently, data are not robust enough to provide evidence-based guidelines to help clinicians with this condition. In addition to a history and physical examination, a urinalysis should be performed to rule out urinary tract infection, and a post-void residual urine should be checked prior to any treatment, as men who do not empty their bladder should not be started on therapy for OAB, given the risk of urinary retention with anticholinergic agents [98]. The AUA SI may also be a useful tool to assess OAB-related LUTS in men [99]. Within the AUA SI, storage symptoms (daytime frequency, nocturia, and urgency) may be more suggestive of OAB than voiding symptoms (weak stream, hesitancy, straining, and intermittency). However, no objective evidence currently exists to support this [95,99].

As with women, the mainstay of treatment for OAB in men is anticholinergic pharmacotherapy. In an attempt to maximize efficacy and minimize side effects, the use of nonselective anticholinergics such as oxybutinin have been largely supplanted by those agents selective for bladder receptors including tolterodine, solifenacin, fesoterodine, and darifenacin [100]. It appears that anticholinergics are most effective at treating LUTS suggestive of OAB when men have either failed α-blocker therapy or when anticholinergics are used in combination with α-blockers [101,102].

Anticholinergics in men appear to be well tolerated, and adverse effects, including urinary retention, are low in properly selected patients [102]. Further long-term studies are needed to confirm these findings.

Bladder Cancer

Urothelial carcinoma (UC), also known as transitional cell carcinoma, is a neoplastic process arising from the pseudostratified columnar (urothelial cell) epithelium lining the urinary tract. Although UC can occur anywhere in the lining of the urinary tract other than the distal urethra, the bladder is the most common location. The American Cancer Society states that bladder cancer is four times more common in men than in women and accounts for ~7% of all cancers, just behind prostate, lung, and colorectal malignancies [21]. White men are two times more likely to get bladder cancer as compared to African American men; however, African Americans have a significantly higher mortality rate than white men. This does not appear to be due to treatment disparities and the reason for this increased risk of mortality is unclear [103]. In the United States, the most common histotype of bladder cancer is UC, followed by squamous cell carcinoma, which is the most prevalent histotype in the Nile River Valley due to the presence of schistosomiasis.

Tobacco use plays a major role in the development of bladder cancer. Men who smoke are fourfold more likely to develop bladder cancer as compared to men who never smoked. Tobacco use may be responsible for anywhere from 30% to 50% of incident bladder cancer cases. The degree of inhalation and duration of smoking correlate directly with increased risk, while smoking cessation can decrease the risk of bladder cancer by up to 40% at 4 years [104]. The risk of secondhand smoke is less clear. It does not appear to be as important of a risk factor when the exposure happens during adulthood, however could be when exposure occurs during childhood [104–106]. Other less common risk factors include occupational exposure to chemicals including aromatic amines, pelvic irradiation, and exposure to cyclophophamide [107]. Occupations that have been associated with bladder cancer are individuals who work with organic chemicals as well as autoworkers, metalworkers, and machine workers [108,109].

The most common sign of bladder cancer is painless gross hematuria; however, hematuria associated with bladder cancer can be intermittent or microscopic. The AUA Best Practice Statement, written in conjunction with the American Academy of Family Physicians, does not advocate for routine urine screening for blood given that microscopic hematuria can be the result of a variety of different processes, including benign conditions. To date, no data indicate that widespread urinalysis screening for blood is useful, even in the smoking population [110]. Although screening urinalysis is not advocated for bladder cancer, the primary care provider should carefully evaluate microscopic hematuria found on routine examination. If risk factors such as age greater than 40 years, smoking history, irritative voiding symptoms, exposure to industrial chemicals, history of gross hematuria, or history of a urological disorder are present, patients should have a complete evaluation including upper tract imaging of the kidneys and ureters as well as cystoscopy to evaluate the lower urinary tract. Upper tract imaging can include renal ultrasonography, intravenous urography (IVU), computed tomography (CT) urogram, or retrograde pyelography. Although no imaging modality has been shown to be superior, CT urography is emerging as the treatment of choice [111]. Cystoscopy includes complete evaluation of the bladder and urethra, and can be performed by a urologist as an office procedure with minimal risk. Urine cytology should also be collected through a voided specimen or during cystoscopy [110].

The majority of bladder cancers are noninvasive at presentation and most will not progress to locally invasive or metastatic disease in the United States [112]. Although most bladder cancer can be treated with minimally invasive techniques, there is a high propensity for this cancer to recur. Therefore, patients with a history of bladder cancer should have routine long-term follow-up including cystoscopy and upper tract imaging with their urologist [113].

KIDNEY

Urolithiasis

The term urolithiasis refers to stones formed anywhere in the upper or lower urinary tract. Lower urinary tract calculi, namely bladder stones, are predominantly a result of urinary stasis due to incomplete bladder emptying, largely due to bladder outlet obstruction from prostatic growth. As we now have effective ways of managing BPH, the incidence of bladder stones has dramatically decreased. Upper urinary tract calculi are formed in the kidney and can become lodged in the narrow diameter of the ureter. In contrast to lower urinary tract calculi, urinary stasis plays only a minor role in upper tract calculi formation. Other metabolic factors are much more important and will be the focus of this section.

Recent studies estimate that up to 10% of men in the United States will at some point form a kidney stone, a rate at least twice that of females. Stone formation risk increases with age and peaks at the sixth decade of life. Most recently, there appears to be an overall rise in the incidence of stone formation within all age groups in the United States [114]. Morbidity from stone disease can range from minor flank pain requiring oral analgesics to renal failure or life-threatening urosepsis. Annual health care expenditures in the United States for the diagnosis and management of urolithiasis exceed $2 billion [114].

There is little known about primary prevention of kidney stones, since routine imaging on asymptomatic

patients is not usually performed. We can, however, glean information on stone prevention from studies addressing secondary prevention—measures to deter stone formation in patients with a previous episode of urolithiasis. Between 35% and 50% of first-time stone formers will have a repeat episode, making prevention in this population of paramount importance [115]. While all patients with more than one stone episode should be followed by an urologist, primary care providers can help identify risk factors for stone disease and assist patients in preventive lifestyle changes.

Fluid intake is one of the most important modifiable risk factors in kidney stone formation. Randomized studies have shown that fluid intake of 3 L/day or taking in enough fluid to produce >2.5 L of urine per day can reduce the risk of stone recurrence by over 50% when patients are followed for up to 5 years after their initial stone episode [116].

The type of fluid may influence stone formation as well. Stone-forming patients who decrease the amount of soft drinks they consume, particularly those that are acidified by phosphoric acid such as colas, likely decrease their risk of stone recurrence by about 30% [117]. In contrast, increasing liquids high in citrate content, particularly lemonade, may prevent stone recurrence. Lemonade intake has been demonstrated to increase urinary citrate, which is known to prevent stone formation; however, better studies are needed to confirm a direct link between lemonade consumption and decreased stone formation [118,119].

The concomitant increase of stone disease and obesity has led many researchers to investigate a link between the two conditions. Although there have not been any large longitudinal studies performed to date, retrospective analysis strongly suggests that obesity is a risk factor for stone formation. One study demonstrated that patients with a body mass index (BMI) over 30 kg/m^2 had a twofold increased risk in developing symptomatic nephrolithiasis [120]. Although the pathophysiological mechanism is not clear, some studies suggest that an increase in BMI leads to a decrease in urine pH which is a major risk factor for multiple different types of kidney stones [121]. It stands to reason that weight loss would reduce the risk of stone formation; however, to date there has been no published evidence to support such a preventive measure.

While weight gain likely induces metabolic changes leading to increased risk for stone formation, surgically induced weight loss measures can also place patients at a higher risk for developing urolithiasis. Patients who undergo Roux-en-Y gastric bypass have a 1.7-fold increased risk of stone formation due to increased absorption of oxalate through the gut [122]. This leads to hyperoxaluria (increased urinary oxalate) and hypocitraturia (decreased urine citrate), both risk factors for the development of kidney stones [123]. Gastric banding for weight loss may not be associated with the same risk of increased urinary oxalate and decreased urinary citrate after Roux-en-Y gastric bypass; however, further studies are needed to confirm this [124].

Kidney Cancer

Renal cell carcinoma (RCC) is the most common malignant neoplasm of the kidney, and one of the more lethal urological cancers. Historically, RCC commonly presented with the classic triad of flank pain, hematuria, and a palpable abdominal mass, and this uniformly represented advanced disease. Fortunately, this is rarely observed today. The proliferation of abdominal imaging with CT and magnetic resonance imaging (MRI) has led to a stage migration, with the majority of RCC diagnosed in the United States at a clinically localized stage [125,126]. Concomitant with this stage migration is an increase in the incidence of RCC and a decrease in its mortality rate [127].

Risk factors for RCC include familial cancer syndromes, hypertension, obesity, and smoking. Familial cancer syndromes including Birt–Hogg–Dube syndrome, hereditary papillary renal carcinoma, hereditary leiomyomatosis, and most commonly von Hippel–Lindau syndrome are associated with RCC [128]. There appears to be a dose–response relationship with developing RCC and the comorbid conditions of hypertension and obesity. Fortunately, controlling hypertension appears to reverse this risk, while it is unclear whether weight loss can do the same [129]. Likewise, there is likely a dose-dependent relationship with exposure to tobacco. Very little evidence exists to attest to a decrease in risk with smoking cessation; however, if smoking cessation does modify risk, it likely does not do so until 10 years from cessation. No definitive studies have shown a link between RCC and passive smoke inhalation [130].

There are currently no recommended screening modalities for RCC; however, some incidental renal masses may be followed conservatively. Most small renal malignancies have a slow growth rate (about 3 mm/year) as well as a low risk of metastasis (1%–2%). Clinical stage T1 renal masses, in particular those under 4 cm, may be cautiously watched with serial CT scans in patients who are not surgical candidates or do not desire surgery [131]. The primary treatment modality for RCC, especially clinically localized disease, is surgical resection of the kidney, as RCC is refractory to radiotherapy and currently available chemotherapeutic agents [131]. Surgical cure rates for clinical stage 1 disease (<7 cm with no nodal involvement) exceed 90% with either radical or partial nephrectomy. Laparoscopic radical nephrectomy has been shown to be effective at managing clinically localized disease and is less morbid than open radical nephrectomy [132]. However, recent studies have suggested that radical nephrectomy may place patients at higher risk for developing chronic kidney disease; thus nephron surgery (i.e., partial nephrectomy) should be performed whenever possible [131,133]. While open partial nephrectomy remains the treatment of choice, laparoscopic approach, including robotic-assisted partial nephrectomy, appears to have similar success rates in the hands of experienced surgeons [131,134].

APPENDIX A: THE AUA SYMPTOM INDEX

Patient Name:_____ DOB:_____ ID:_____ Date of assessment:_____

Initial Assessment() Monitor during:_____ Therapy () after:_____ Therapy/surgery ()_____

AUA BPH Symptom Score

	Not at all	Less than 1 time in 5	Less than half the time	About half the time	More than half the time	Almost always	
1. Over the past month, how often have you had a sensation of not emptying your bladder completely after you finished urinating?	0	1	2	3	4	5	
2. Over the past month, how often have you had to urinate again less than two hours after you finished urinating?	0	1	2	3	4	5	
3. Over the past month, how often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5	
4. Over the past month, how often have you found it difficult to postpone urination?	0	1	2	3	4	5	
5. Over the past month, how often have you had a weak urinary stream?	0	1	2	3	4	5	
6. Over the past month, how often have you had to push or strain to begin urination?	0	1	2	3	4	5	
	None	1 time	2 times	3 times	4 times	5 or more times	
7. Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	0	1	2	3	4	5	
						Total Symptom Score

The past several decades have witnessed escalating public health concern about the status of men's health. Reflecting this growing alarm, discussions about the hazards of masculinity have grown increasingly high pitched.[1–11] This state of alert is not without merit. Indeed, most health metrics reveal a decided masculine disadvantage, marked by high risk, morbidity, and premature death.[12–15] Unfortunately, this "live fast, die young" pattern shows no sign of ameliorating any time soon.[8,13–26]

Although research has only just begun to unravel the complex web of contributing dynamics, crosscutting biological, psychological, and social forces all have been implicated. Nevertheless, evidence increasingly highlights the primacy of lifestyle behaviors.[1–4,9,10,14,17,26] Accordingly, this chapter considers evidence-based perspectives on the health-promoting and risk-reducing behaviors that affect men's health.

GENDER SOCIALIZATION

Among the many influences on men's health-related lifestyles, probably none has been more widely discussed than masculine socialization. Most cultures provide a basic blueprint for the differential socialization of boys and girls, the precise contours and boundaries of which vary across communities and cohorts. These cultural imperatives set acceptability limits for certain socially constructed gender roles.[1–4,27–32] Through a confluence of interacting forces, these stereotypes are inculcated through social modeling and direct reinforcement of sex-typed behaviors that are progressively shaped across development.[3,27,28,30,33] Because these societal ideals are telegraphed in various ways, through myriad communication channels, and interpreted through each man's idiosyncratic biopsychosocial filter, the incorporation and enactment of these collective values differ considerably.[28,33–38] Through the intricacies of this socialization process, each man's "masculine identity" evolves based on a multidimensional set of gendered schema encompassing, for instance, subjective satisfaction with his masculine gender, perceived pressure for masculine gender conformity, self-appraised congruence with masculine stereotypes, and salience of masculinity to his broader self-concept, just to name a few[28,38–40] (see Tobin et al.[38] for a recent review). Interestingly, each potentially orthogonal facet of this masculinity multiplex may have different health implications.[32,33,35,38–40]

As noted earlier, background characteristics (e.g., ethnicity, social class, age, biological attributes, etc.), other life roles, and concurrent identities add further heterogeneity to men's conceptualizations of masculinity, the behavioral idioms through which they are expressed, and their repercussions on health.[10,19,31,41–55] As an illustrative case in point, masculine health risk disparities are especially acute among socially disenfranchised men (e.g., low SES, ethnic and sexual minorities).[12,56–66] Likewise, across the life span, masculinity may pose in different guises based on cohort

effects, shifting developmental influences, contemporaneous life experiences, and perceived norms.[19,32,36,53,54,67–75] Consequently, averaged data purporting to describe men's health, masculinity, or socialization will not accurately capture the experience of every man.[41,44,52,53,68–70]

Notwithstanding widespread acknowledgment of men's heterogeneity, considerable study has been devoted to elucidating normative trends in gender development.[33–36,38,76,77] Although a comprehensive review of the extensive gender development literature is beyond the scope of this chapter, it generally is accepted that gender role contingencies are ubiquitous very early in life. For instance, male baby shower announcements, nursery decorations, and birth congratulation cards commonly are illustrated with sports designs and other action patterns whereas those for girls often are decorated in muted tones with passive silhouettes and delicate accessories.[27,30,78,79] Throughout early childhood, these gender scripts become more fully articulated in the context of daily life, as sex-typed conduct and attitudes are progressively incentivized and rewarded.[27,30,76]

For example, despite some incongruous findings,[76,77,80] differences have been reported in parenting behavior as a function of child gender. Illustratively, during infancy, boys may be handled more robustly than girls.[3,79,81] In the preschool years, independence, aggression, and risk behaviors may be tolerated more in boys than girls (for whom safety and hygiene often are prioritized).[27,29,30,79,82] Moreover, some parents may be more likely to encourage active problem solving and the inhibition of expressed vulnerability (such as feelings of dependency, fear, and anxiety) in male versus female children.[29,82–84] Through repeated exposure to these and other gendered contingencies, socially constructed masculine norms gradually become internalized, at least to some extent.[27,29,79,82]

Beyond the family, peers play an especially pivotal role. Consistent with the concrete cognitive processes and rule-governed behavior characteristic of early childhood, elementary school students' gender stereotypes often appear somewhat exaggerated and rigidly held.[81,35–38,85] During these early years, sex aggregation in peer relationships typically becomes evident as boys' and girls' interests and play patterns diverge.[35,36,76,86] In contrast to girls' more interpersonal priorities, boys are more likely to prefer competitive group activities (e.g., sports, games) that provide an opportunity for demonstrating competence and status in the male group hierarchy.[27,33,76,77,86] In this regard, boys may be especially prone to prefer more strongly sex-typed peers and to penalize gender nonconformity in their social groups.[27,29,30,33,82,87] This developmental phase of same-sex propinquity provides important opportunities to rehearse basic masculinity scripts as a scaffold for subsequent elaborations.[27,76,77,86]

During adolescence, converging biopsychosocial processes (e.g., changing physiology and appearance, reorganization of social roles and family relationships) set in motion cascading demands for readjustment. Chief among these developmental tasks is identity formation. At this time, social networks typically expand to include more opposite-sex relationships, providing chances to try on different masculine roles for goodness-of-fit with broader self-conceptualizations still under construction. Often, the aspects of masculinity adopted during adolescence reflect both continuities and discontinuities with earlier development,[33,34,76,77,88] yielding an individualized, but still evolving, pattern of masculine ideals with the potential to color health appraisals and decisions for better or worse.[1–4,32–34,38,64,89]

Contrary to the popular emphasis on masculinity's downside risks, research has started to accentuate the potential benefits of traditional masculine socialization. Illustratively, stereotypical orientations toward achievement, self-reliance, and persistence may be used adaptively in the service of promoting men's illness coping, recovery, and empowerment for important self-care regimens.[44,48,63–65,67,90] These recent findings have suggested it is not masculinity per se that may be detrimental to health but rather the specific configuration of masculine attributes that may differentially predict health vs. harm.[19,32,63–65,67,90] It is to this topic that the discussion now turns.

SYMPTOM REPORTING AND HEALTH CARE UTILIZATION

Men's general tendencies to minimize somatic and emotional symptoms have been widely discussed and reported. Indeed, caricatures of traditional masculinity often center on notions of "toughing out," "manning up," or otherwise projecting an image of strength and invulnerability.[82,91–94] For instance, although men generally demonstrate high tolerance to a range of noxious stimuli (perhaps based on complex interactions of biopsychosocial mechanisms),[91,92,95–98] men adopting traditional masculine identities may be most likely to minimize symptoms, especially in the presence of women.[99,100]

A corollary of this idealized toughness is a parallel tendency to eschew wellness and preventive self-care as excessively feminine.[2,4,10,21,22,24,101] An illustrative case in point is men's suboptimal adherence to preventive cancer recommendations ranging from screening to early intervention for incipient symptoms, all of which exact a high toll on cancer survival.[16,18,20,25] To the extent that perceived vulnerability is a critical prerequisite to self-care, the need to defend an invincible self- and public image may interfere with the adoption of preventive health practices, perception of emerging symptoms, and likelihood of professional consultation.[16,17,25,102]

This tendency to avoid help seeking is epitomized by recent data indicating that many men have no regular health care provider and do not access health services regularly.[14] For example, results of the 2009 National Health Interview Survey[14] revealed that 22% of men (vs. 12% of women) reported having no usual place of health care and 26% (vs. 13% of women) had no office visits in the last year. Among those identifying a regular health care venue, men were more inclined to use hospital emergency rooms or outpatient departments than women.[14]

Men not only have less frequent contact with health practitioners, but also may be less active participants in

patient–provider exchanges (e.g., requesting less information, clarification, and advice) than their female peers. Perhaps as a consequence, men may receive less professional guidance on health-relevant matters, including lifestyle.[103–108] In addition, at least some men may face special barriers acknowledging emotional problems and accessing psychological services, even for common concerns such as substance abuse, depressed mood, and interpersonal difficulties.[21,70,109–112]

Beyond the social stigma still associated with psychological issues generally, some men may perceive psychological interventions as especially off-putting given their learned penchant (based on parental admonitions, peer censorship, and media images) to privilege action over feeling.[21,70,109–116] Accordingly, targeted outreach efforts increasingly seek to breach the traditional wall between help seeking and masculinity.[16,19,20,25,49,94,116–119]

As an interesting marquee case, the National Institute of Mental Health (NIMH)-sponsored "Real Men, Real Depression Campaign" provides education about aspects of depression relevant to some men (e.g., substance abuse, risky sexual practices, aggression/violence) and peer models of diverse men sharing their experiences and treatment for mood disorders.[110,120] By helping to reshape perceived masculine norms, these kinds of social marketing approaches help promote a masculine ethos of acceptance for addressing health concerns. However, unless these types of broad-based initiatives are coordinated with more customized approaches, the benefits of reaching "every man" could be offset by a proper fit for none.[11,49,93,94,97,110,116,120]

STRESS AND COPING

Although the health-detrimental consequences of chronic life stress are well documented, the influence of individual appraisal and management strategies often is underappreciated.[121–125] Given the typical discrepancies between men's and women's lived experiences, it is not surprising that gender may mediate stress appraisal and reactivity.[126–129]

Early in development, masculine child-rearing patterns tend to incentivize the acquisition of active problem-solving skills over those related to emotional processing and communication.[77,83,130] Other socialization experiences (e.g., peers, media) reinforce this traditional masculine propensity in which agency figures prominently and emotionality is constrained.[29,84,116,130] These motivational priorities differentially heighten the salience of certain cues such that perceived threats to mastery or social dominance may be appraised as especially stressful, provoking a cascade of psychoneuroimmunological dysregulations. Paradoxically, masculine tendencies to inhibit stress-related emotionality actually may heighten physiological arousal and risk of externalizing behavior problems (discussed later).[29,77,84,89,130] By comparison, traditionally socialized women may be somewhat more likely to appraise perceived challenges to interpersonal relationships and intimacy as particularly stressful.[27,131]

In addition to biasing attention and responsiveness to certain cues, socialization experiences contribute to the management of stress-related demands. Although the coping repertoires of most well-adjusted individuals contain assorted strategies applied flexibly depending on the situational vagaries, certain gendered coping propensities have been reported in the literature.[77,128,132–136]

One of the most robust findings centers on the use of social support. Specifically, during stressful transactions, men seem especially prone to react with "fight or flight" (i.e., active interpersonal aggression or distancing to defer hostilities), perhaps in part based on men's learning histories in which emotional displays of vulnerability were ridiculed as excessively feminine.[29,77,84,137] By comparison, women may favor a "tend and befriend"[136] strategy, in which nurturing relationships are sought out and emotions are shared.

Both approaches offer potential advantages and disadvantages.[77,134,136,137] For example, active problem solving that provides relief from negative emotional processing may be associated with a more rapid stress response and recovery compared to passive rumination about upsetting circumstances and emotions, which may prolong distress.[77,126,127,132,134,137–144] However, the benefits of emotional distancing may come at the expense of social support's potentially health-enhancing effects.[132,145–147]

Specifically, because men typically have more superficial social networks than their female counterparts, men tend to have fewer intimate support resources. Indeed, for many men, a spouse or romantic partner may be the only or primary source of sustained encouragement and inspiration for healthier lifestyle choices.[77,148–152] Consequently, partner support has been a somewhat better predictor of men's physical and emotional well-being than that of women. However, it is worth noting that some mixed findings and cohort differences recently have been observed, perhaps reflecting a narrowing of gender-differentiated social roles and expectations among younger groups.[77,136,148,150–152]

Interestingly, these gendered coping tendencies have been associated with disparate risk and resilience trajectories. To the extent that active coping boosts self-efficacy and perceived control, prototypically masculine agentic orientations may bode well for certain types of psychological and somatic well-being (e.g., reduced probability of depression and anxiety, better odds of chronic disease adjustment).[71,134,139,141,144] At the same time, however, the tendency to act out during stressful encounters may contribute to men's heightened risk for externalizing problems such as disruptive, aggressive, and other antisocial behaviors, especially among those adhering to traditional masculine roles.[2,10,29,53,77,89,130,134,137,153–156]

SUBSTANCE USE BEHAVIORS

Smoking

Abundant evidence documents the significant morbidity and mortality associated with smoking.[157,158] Despite the incessant public dissemination of these risks, 23% of men still smoke.[14,26] In addition, men are prone to engage in especially hazardous patterns of use with high levels of

dependence.[14,159–161] According to recent data from the Centers for Disease Control (CDC), men not only smoke more cigarettes per day (7% of men vs. 3% of women usually smoke ≥35 cigarettes per smoking day) but also typically initiate the habit earlier, with more than one-third starting before the age of 16 years (35.1% of men vs. 28.5% of women).[14,26]

Accordingly, considerable scientific effort has been dedicated to pinpointing sex-typed mechanisms of tobacco initiation, dependence, and cessation. Although multiple age-related smoking trajectories have been identified based on complicated biopsychosocial interactions, research has highlighted social influence processes as especially critical components of smoking onset, particularly during adolescence when emerging masculinity scripts may combine synergistically with normative developmental tendencies toward impulsivity and sensation seeking to heighten men's smoking susceptibilities.[158,162,163] These propensities may be further incentivized and reinforced by the smoking habits of personally relevant models (e.g., family members, peers, and media celebrities).[74,162] For instance, popular media that subtly glamorize smoking shape not only the masculine cultural zeitgeist but also individual opinions, expectancies, and perceived norms toward smoking acceptance.[74]

Indeed such collective pressures have been identified as among the most potent risk factors for smoking initiation and progression, probably exerting their influences through a variety of mechanisms.[66,162,164] For example, to the extent that smoking is perceived as more or less culturally acceptable, an individual smoker's social status may shift either toward or away from the mainstream.[164,165] In addition, the smoking behaviors of intimate others (e.g., partners, roommates) also provide proximal cues that may prompt experimentation among the uninitiated or trigger smoking urges among current or former smokers, thereby foiling individual quit intentions and self-regulation efforts.[149,164,165]

Galvanized by substantial evidence that creating a norm of nonacceptance actually facilitates risk reduction, masculine smoking portrayals increasingly have been appropriated in the service of abstention and cessation.[74,166] Some especially interesting recent initiatives have capitalized on the masculine archetype of "father as family protector" to motivate men's smoking cessation prior to the impending birth of a child.[167,168] Although much of this work remains preliminary, life transitions often present teachable moments that enhance receptivity to lifestyle modification advice, as seen in smoking cessation interventions with pregnant women either alone or with their partners.[73,167–171]

However, much more remains to be learned about the potential interpersonal transmission of smoking processes.[149,164,165] To the extent that male audiences may be somewhat harder to reach professionally[158,172] (as discussed earlier), combined with empirical hints that men's smoking attitudes and behaviors may be especially influenced by the smoking status of significant women in their lives (e.g., romantic partners or supportive female peers),[173,174] women who either do not smoke or have quit with professional assistance may be well positioned to support men's abstinence or cessation efforts.[158,173,174]

Yet, emerging findings have sounded a cautionary note. Specifically, the beneficial effects of partner support may depend on men's perceptions of their significant others' intentions. Partner behaviors that are perceived as collaborative and encouraging of men's self-control skills and self-efficacy have been shown to enhance healthy behavior change, whereas partner behaviors appraised as coercive or overprotective actually may yield counterproductive outcomes, perhaps by triggering resistance and/or by spiking perceived self-efficacy.[102,175] In short, although dyadic approaches hold considerable promise, the nuances inherent in couples support demand more rigorous study.[164,172,173]

Beyond collective dynamics, considerable interest has focused on potential intrapersonal sources of smoking disparities given the myriad biopsychosocial differences that potentially could impact sex-typed tobacco dependence and cessation processes. Unfortunately, despite the proliferation of studies, few actionable mediators consistently have emerged to date.

For instance, although gender differences in smoking motivations, relative strength of different relapse cues, and cessation barriers all have been reported, these gender differences have not consistently predicted treatment outcome or relapse.[157–160,176–179] Moreover, despite some suggestions that men may have higher rates of successful cessation and may benefit more from nicotine replacement than their female counterparts,[157,160,176–179] the preponderance of available evidence has highlighted roughly comparable treatment outcomes between men and women.[157,159,161]

Consequently, even though sensitivity to gender-specific concerns and barriers is an important clinical consideration for enhancing perceived treatment relevance,[157] gender per se may not be the most robust predictor of outcome. For this reason, growing research interest has coalesced around the advantages of redirecting interventions away from umbrella variables such as gender in favor of more proximal predictors such as specific tobacco-dependent behaviors (e.g., time to first cigarette, previous quit attempts, number of cigarettes smoked each day) and cognitive-behavioral change processes (e.g., stage of change, self-efficacy, and smoking expectancies).[157,158,161,163]

Alcohol

According to the CDC, alcohol-induced morbidity and mortality are on the rise in the United States. In 2007, 23,199 U.S. deaths were alcohol-induced, representing a 4.3% increase over 2006. Compared to their female counterparts, men's 2007 age-adjusted rates of alcohol-induced mortality were 3.2 times higher.[15]

Men's hazardous drinking (including excessive use and binge drinking) raises their odds for alcohol dependence (17% men vs. 8% women) and scores of associated problems as reflected in more alcohol-related hospitalizations, injuries (resulting from traffic crashes, physical assaults, etc.), and disproportionate rates of certain alcohol-linked sequelae (e.g., reproductive and sexual dysfunction, cancer of the

mouth, throat, esophagus, liver, and colon).[26,180–185] Because the topic of this chapter centers on lifestyle, the scope is intentionally focused on modifiable risk and protective factors, notwithstanding widespread recognition that a full appreciation of men's risks requires consideration of complicated biopsychosocial synergies including sex differences in alcohol pharmacokinetics and genetics.[186–188]

Suffice it to say, no single set of risk factors uniquely predicts specific alcohol use disorders (AUDs) in all men. Confirming suspicions based on the clinical heterogeneity long-observed among AUDs, evidence increasingly highlights multiple alcohol trajectories across development based on individualized risk–resilience patterning. Although a variety of nonspecific liabilities have been identified (including genetic and neurobiological markers, positive alcohol expectancies, and personality traits such as impulsivity and antisociality), others may be especially relevant to AUD pathways in men.[184,185,189]

Interestingly, in contrast to the gender disparities reflected in adult AUD prevalence data (discussed earlier), alcohol experimentation rates and patterns typically appear roughly comparable between early adolescent males and females. However, as youth negotiate the developmental transition from adolescence into early adulthood, gender-specific trajectories become more pronounced, paralleling socialization influences that may heighten men's risks for excessive alcohol use.[184,185,190,191] As an example, alcohol use is seen as a culturally normative part of traditional masculinity that is modeled pervasively (e.g., media, family, peers) and rewarded by social contingencies that typically tolerate more alcohol use in men versus women.[74,162,192] Because parents tend to allow boys more autonomy with looser monitoring than that of their sisters, boys may have earlier opportunities for unsupervised alcohol access. In addition, given the masculine cultural norms discussed previously, boys may experience more peer encouragement for risky alcohol use and suffer less general social censure for excessive drinking. Hence, compared to the potentially restraining influence of cultural admonitions that stigmatize women's overconsumption (especially in public), social contingencies may exacerbate risk for men with other biopsychosocial vulnerabilities.[49,184,185,193–195] Although some of these cultural risks may attenuate as masculinity scripts become progressively diverse and social changes continue to soften gender role boundaries,[88,182] tackling the problem of alcohol misuse will require a coordinated multidisciplinary "effort of societal change … [that addresses] alcohol use early, continuously, and in the context of human development using a systematic approach that spans childhood through adolescence into adulthood." (Ref. [191, pp. iii–vii]).

DIETARY HABITS AND WEIGHT REGULATION

Eating Attitudes and Practices

Imprudent dietary habits confer significant health risks across the life span, adversely impacting most leading causes of morbidity and mortality, including cardiometabolic diseases (e.g., hypertension, heart disease, stroke, diabetes) and certain cancers.[75,196,197] In yet another bid to foster more mindful eating habits, the CDC has renewed its continuing outreach efforts with a recent publicity surge imploring Americans to more carefully consider their food selections and portion sizes.[198] Unfortunately, imprudent food-related habits and their associated repercussions are not showing much improvement, especially among men.[75,196,199–201]

Evidence has long suggested that men's eating attitudes and practices tend to be less health promoting than those of their female counterparts.[5,75,196,202] By and large, men acknowledge the benefits of healthy eating, but often claim less interest in food matters generally and nutrition in particular compared with other food selection criteria (such as taste and convenience). Accordingly, men's eating patterns may tilt more toward palatable but unhealthy choices translating into disproportionate intakes of unhealthy fats and sodium relative to fruits, vegetables, and fiber.[5,75,196,202,203]

Consistent with the observations that men may be somewhat less focused than women on curbing their intakes of palatable but unhealthy food, preliminary brain research has indicated that exposure to high-calorie images (e.g., waffles with whipped cream and syrup, chocolate cake) provokes more heightened cortical responding in the cognitive processing/behavioral control regions of women than men.[204,205] Moreover, some reports also have raised the possibility that men may be somewhat less inclined to alter eating habits in response to medical issues (e.g., gastrointestinal problems, overweight, and obesity), even when such modifications offer symptom relief.[75,206,207]

To be sure, myriad factors jointly contribute to men's food-relevant attitudes and practices. However, the most frequently discussed centers on cultural influences. For instance, given that meal planning and preparation traditionally have been considered part of women's domestic work, traditionally socialized men may not see these activities as within their domain of interest or responsibility. In a similar vein, the notion of carefully measured portion sizes ("eating light") has a decidedly delicate flair that runs counter to the stereotype of hardy meals suitable for hardworking men ("man-sized").[5,75,203,208] This masculine idiom is animated by ubiquitous media depictions of men displaying immoderate eating behaviors without the real-world, health-detrimental repercussions.[74,75]

Although not specifically male-focused at the present time, extant evidence has highlighted psychological mediators of eating habits and change processes that may inform research on gender differences. For instance, accumulating findings have suggested that emotional and cognitive styles may predict differential attentiveness and responsiveness to health communications. Specifically, fear (and its associated risk-centered perceptions) may heighten the salience of potential threats and receptiveness to appeals framed in terms of loss. In contrast, anger (and related perceptions involving personal control) may bias attention more toward potential rewards, thereby increasing responsiveness to messages emphasizing potential gain.[209] To the extent that traditionally

socialized men (vs. women) may be more inclined toward anger (vs. anxiety, as discussed earlier), there may be some merit to further investigating the potential impact of gender role on reactions to different food-related messages.

Other separate but relevant research has indicated that food perceptions and expectations about calorie content may be associated with altered metabolic responses. As an illustrative case in point, Crum and colleagues recently reported distinctive ghrelin hormone profiles mediated by expectancies about the nutritional content of two identical milk shakes (labeled high-fat, high-calorie "indulgent" or low-fat, low-calorie "sensible"). These findings raise the possibility that food labels touting an item's healthful qualities actually may have the downside potential of reducing perceived satiation and increasing intake.[210,211] These findings are especially provocative when taken together with evidence (discussed earlier) suggesting that at least some men may be prepared to favor food's flavor qualities over its health attributes.

Obesity

The ominous public health implications of imprudent dietary attitudes and practices are conspicuously embodied in the skyrocketing trajectory of men's obesity and related cardiometabolic comorbidities, the risks of which climb with body mass index (BMI).[199,200] Unfortunately, because men may be especially prone to accumulate fat intra-abdominally, their BMI-associated health risks may be further exacerbated.[206,212] Yet, only about 30% of men's BMIs fall within the "healthy" range (BMI ≥18.5 to <25).[14]

Notwithstanding men's high prevalence of overweight and obesity (averaging roughly 42% and 28%, respectively, with substantial variation by race/ethnicity),[14] some men may be reluctant to participate in weight control interventions. This hesitancy may be partially rooted in men's general disinclination to seek help.[94,110,114–116] However, the traditionally feminine clientele and thrust of many programs also may contribute.[206,212] In response to these potential barriers, some preliminary reports tentatively have suggested that tailoring interventions to men's specific weight concerns may increase participation rates. For instance, program features such as men-only groups held in alternative settings (e.g., workplace, gyms, male-oriented practices) promoting "masculine" goals (such as muscularity, strength, and performance) may be especially well received.[75,196,203,206,208,212] To the degree that these kinds of masculine trappings enhance perceived relevance and appeal, they may serve an important foot-in-the-door function for men who would otherwise not access professional services. However, the real measure of their potential benefit ultimately will depend on the extent to which these "male-friendly" programs actually help men achieve and sustain healthy weight regulation.

Regrettably, converging evidence has indicated that individual approaches alone may not be the most cost-effective strategies for slowing obesity's progression given the omnipresent cues for overindulgence and underactivity that saturate modern life.[200,201,213–216] Considering that an accumulation of small lifestyle corrections can translate into clinically meaningful cardiometabolic improvements, coordinated multilevel approaches (from the individual to the ecological) are being advocated to consistently incentivize more healthy eating habits across multiple life domains.[199,212,215,217–221]

PHYSICAL ACTIVITY, SPORTS-RELATED INJURY, AND BODY DISSATISFACTION

The benefits of regular physical activity have been well established across the intervention spectrum from primary prevention efforts promoting population-wide health to secondary and tertiary care aimed at reducing risks and optimizing the management of chronic conditions (including cardiovascular disease, cancer, multiple sclerosis, psychological distress, age-related cognitive and mobility decline).[222–236]

Men's Exercise Prevalence

Generally speaking, men tend to be somewhat more active than women overall.[14,237] However, too few American men consistently maintain optimal exercise amounts and levels.[232,238–240] Although precise prevalence estimates vary depending on the specific criteria, recent CDC data indicate that only about one-third of adult men *regularly* engage in leisure-time exercise (operationalized as light–moderate activity ≥5 times/week on average for ≥30 min or vigorous activity ≥3 times/week for ≥20 min)[26] and half *never* engage in bouts of vigorous activity ≥10 min/week.[14]

Exercise prevalence is highest among young adult (18- to 24-year-old) Caucasian men compared to those who are older, ethnic/cultural minorities, and/or members of other socially disenfranchised groups.[14,26] For instance, probability of leisure-time physical activity consistently covaries with education and income such that men ranked in the highest SES categories are the most likely exercisers.[14,26]

Of course, physical activity patterns are complexly influenced by myriad biopsychosocial factors that may shift across the life span. However, athletic prowess (especially in competitive body contact sports) figures prominently in men's socialization as a critical part of traditional masculine identity.[3,241]

Boys' socialization toward vigorous activity begins early in the family, where activity preferences and habits are incentivized and shaped through direct experiences and observations of significant others' behaviors and attitudes.[27,33,76,77,242–245] Indeed, boys typically receive more parental encouragement for sports involvement than their sisters.[242,243] Depending on each boy's adoption of traditional masculine ideals (discussed earlier), these early familial experiences bolstered by broader social contingencies throughout childhood and adolescence (e.g., peers, media, etc.) may contribute to boys' generally higher exercise self-efficacy, which predicts actual activity levels.[24,241,242,244,246,247] Interestingly, social support for exercise may be a stable feature of men's lives well into adulthood, which could at least partially contribute to men's relative activity advantage.[248]

Sports-Related Injuries

Despite the benefits of physical activity, dominant competitive norms may increase men's susceptibilities to certain sports-related hazards. One of the most actively researched and discussed has been the relationship between masculinity and sports injury risk. Consistent with men's generally higher rates of unintentional injury across the life span,[30] masculine competitive propensities in body contact sports may heighten the probability of sustaining serious high-impact injuries (including head, neck, spine, joint, ligament damage) and their sequelae (such as post-concussive syndromes).[249–258]

Body Dissatisfaction

Adding to competitive masculine pressures, shifting cultural conceptualizations of the ideal physique may be pushing the desire for muscularity to unhealthy levels.[259,260] As the gap broadens between the typical and idealized appearance of a healthy male body, the odds of body dissatisfaction escalate along with related problems such as psychological distress (e.g., manifested as low self-esteem, mood problems, dysfunctional eating) and unintended consequences of harmful body-sculpting strategies (e.g., excessive exercise, use of anabolic–androgenic steroids, imprudent dietary practices, and unapproved supplement use).[208,261–265] In this regard, numerous studies have observed a recent trend toward body dissatisfaction and body image concerns among boys and men, with some suggestion that boys' efforts to attain a lean, muscular body may be evident as soon as the early elementary school years.[261–266]

Although just beginning to emerge, research tracking predictors of youngsters' body dissatisfaction have explored a variety of potential influences including social (e.g., demographic, familial, peer, and other contextual characteristics), psychological (personality attributes, cognitive biases, internalization of cultural appearance ideals, propensity toward social comparison), and biological (e.g., body mass) factors.[263,265,267] Unfortunately, because studies have differed in participants' ages, predictors examined, and the length of follow-up, it is difficult to trace a conclusive path at the present time. However, consistent with broader life span literature, longer studies tentatively have suggested a shifting pattern of risk and resilience as youth navigate through different developmental periods.[263] Taken together, converging evidence underscores the importance of introducing young men to the advantages of health-promoting exercise goals over more misguided priorities, including evidence-based, customized strategies to actualize each man's potential.

Maintaining Active Lifestyles

As noted, adult men's exercise levels tend to decline with age. Illustratively, 2005–2007 CDC data indicate that the percentage of men who regularly engage in leisure-time physical activity plummets from roughly 42% in young adults (ages 18–24 years) to approximately 23% in seniors (≥75 years of age).[26] Accordingly, considerable attention has focused on the potential proximal influences that may sustain active lifestyles.

Although evidence-based conceptualizations of exercise adoption and maintenance tend not to be gender-specific, interventions targeting social cognitive factors have shown promise both generally and specifically for men.[236,268] For instance, research with male participants has supported the benefit of personally meaningful goals to improve exercise participation, with some studies suggesting that men may be oriented toward competence-building activities, particularly when these pursuits coincide with existing recreational preferences and resources.[268–270] Other research on exercise barriers has highlighted life transitions and stressful life events (e.g., marriage/divorce, SES changes, neighborhood relocation, parenthood, retirement) as potential obstacles to initiating and maintaining exercise habits.[268,269,271,272]

Intrapersonal attributes also have been studied with considerable recent attention to the relationships among activity, mood, and well-being. Although reciprocal and dynamic influences have been acknowledged across the life span,[273] some research has prospectively linked emotional status to subsequent activity changes, with negative mood states predicting activity declines and positive emotions forecasting increases.[246,273,274] Of course, given that negative emotional states (e.g., depression) are partially defined by feelings of fatigue and reduced self-efficacy, particularly when symptoms reach clinical significance, the exercise-derailing effects of dysphoric moods are not surprising. Likewise, it makes sense that positive emotions fueled by their associated optimism, energy, and positive outcome expectancies could be harnessed in the service of motivating and sustaining active living.[246,274–277]

More interesting, however, are emerging suggestions that emotional status may have special relevance for exercise promotion in sedentary men. For instance, Baruth et al.[246] recently reported that positive emotional outlook on life was especially predictive of subsequent physical activity increases among initially inactive men compared to women, for whom other influences may have predominated. Findings such as these call attention to the importance of comprehensively assessing the full range of influences that may impact men's readiness to change.[201,246]

As an illustration of one such comprehensive framework, Bryan et al.'s transdisciplinary model of voluntary exercise[278] considers multiple domains of possible mediators. Although not specifically male-oriented but consistent with the broader literature,[201,223,246] this model has incorporated the potential contributions of physiological exercise responses (e.g., body temperature, cortisol, lactate concentration), subjective experiences (e.g., mood changes, perceived exertion), and social cognitive motivations (e.g., attitudes, intentions, self-efficacy). Research driven by this kind of forward-leaning perspective has merit for further exploring the complex dynamics that may promote, sustain, or derail active lifestyles for different men across the life span.[201,228,278]

CONCLUSION

The evidence base on men's health has progressed by leaps and bounds over the last decade. Although foundational research sought to simply document between-gender differences, contemporary perspectives now explore the mediators and moderators that may explain men's lifestyle disparities. In the process, the conceptual understanding of masculinity has moved away from being seen as one-dimensional hazard to a complex dynamic of personalized processes and outcomes that may confer both risks and resiliencies.[10,28,72,73,279]

This more sophisticated take on "men's health" shifts the focus away from male sex per se to the more proximal person–environment contingencies that shape the acquisition, disruption, or solidification of different lifestyle options across the life span.[73] Indeed, as discussed throughout this chapter, culturally constructed gender roles may heighten the prepotency of some risks, but their actualization depends on the complicated ways idiosyncratic masculinity schema interact with other health-relevant factors.

Despite the whirlwind of enthusiasm touched off by early interventions aimed at the generic man, real-world implementation has yielded predictably suboptimal results, as witnessed by the largely disappointing outcomes associated with decades of public health appeals for multiple risk factor reduction.[280–283] Although broad-based initiatives may raise men's awareness, remodel perceptions of health-detrimental group norms, and nudge some men closer to readiness for lifestyle improvement, one size will not come close to fitting all. In the end, the promise of promoting men's health rests less on targeting men's average or typical risks and more on increasing the personal relevance of strategies that recognize men's heterogeneity and comprehensively address different risk and resilience profiles.[72,157]

INTRODUCTION

It is estimated that in Westernized countries, 25%–35% of the population has insulin resistance or health problems associated with this metabolic disorder.[1] Insulin resistance is a condition that represents the presence of an impaired biological response to insulin. In muscle and adipocytes, it is manifested by a decreased insulin-stimulated glucose transport and metabolism. In the liver, there is an impaired suppression of hepatic glucose output.[2] Insulin resistance has both genetic and acquired components. A number of factors influence the sensitivity to insulin. They include age, weight, ethnicity, abdominal fat (especially visceral fat), physical activity, and medications.[3] Insulin resistance is seen in a number of clinical conditions including diabetes mellitus, obesity, hypertension, dyslipidemia, cardiovascular disease, and polycystic ovary disease.[4–10] Type 2 diabetes is rarely seen in insulin-resistant people without some degree of β-cell dysfunction. However, first-degree relatives of people with type 2 diabetes have insulin resistance at a time when they are nonobese, implying a strong genetic component in the development of insulin resistance.[11–13] Cross-sectional studies suggest that genetic factors, intrauterine environment, early childhood, and adult environmental factors are relevant in determining insulin resistance.[14] Long-term predictors of insulin resistance looking at the influence of lifestyle and metabolic factors have been reported. In a large (n = 770) population-based study, the Uppsala Longitudinal Study of Adult Men, multiple factors were found to be operative. Metabolic, lifestyle, and socioeconomic factors independently contributed to predict insulin sensitivity, supporting a complex background of insulin resistance. Saturated fat intake and socioeconomic status were independent predictors that appeared to be as important as physical activity. However, after 20 years of follow-up, body mass index (BMI) was still the strongest predictor of insulin sensitivity following adjustment for lifestyle factors and homeostasis model assessment for insulin resistance (HOMA-IR), even in men with a normal BMI.[15]

OBESITY: A PREDICTOR INSULIN RESISTANCE

Obesity is a significant predictor of risk for insulin resistance, particularly visceral as opposed to subcutaneous adiposity.[16] As global obesity has become more evident, concern has increased. At least 1 billion people worldwide are thought to be overweight or obese (BMI $\geq$ 25 kg/m^2) and at least 300 million people are thought to be obese (BMI $\geq$ 30 kg/m^2).[17] Data from the U.S.-based 2007–2008 National Health and Nutritional Examination Survey (NHANES) shows that 32.2% of men and 35.5% of women are obese. The presence of obesity increases with age and is highest for non-Hispanic black men (37.3%) and non-Hispanic black women (49.6%). A significant linear increase in obesity has occurred in the last 10 years. Of considerable concern, 5% of Americans have a BMI of >40 kg/m^2 or are morbidly obese.[18] Previously, the increase in obesity defined by BMI has been matched by increases in abdominal obesity.[19–22] This has been true for both adults and children.

The epidemic of obesity that is occurring in the United States and in other Westernized countries can be explained in large part by the increasing availability of energy (abundant food) and falling requirements for physical activity. In this environment, insulin resistance occurs at two primary levels: The first is energy balance which is the balance between how much energy an individual takes in and how much

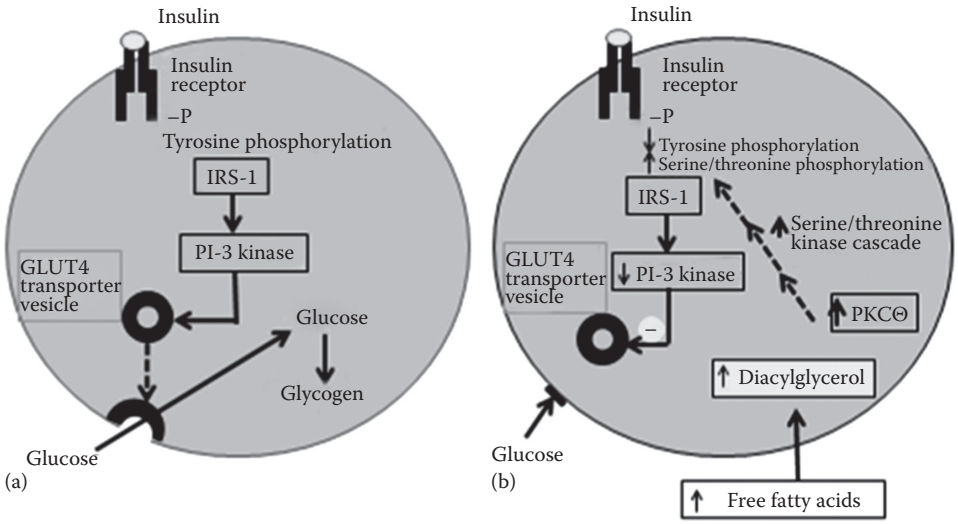

FIGURE 33.1 Mechanisms of insulin sensitivity (a) and resistance (b) in muscle. IRS, Insulin receptor substrate; PI3, phosphatidylinositol 3-kinase; PKCΘ, protein kinase CΘ; GSK3, glycogen synthase kinase 3; GS, glycogen synthase; circle with minus indicates inactivation; dotted line indicates inhibition. (Adapted from Shulman, G., *J. Clin. Invest*., 106, 171, 2000; Samuel, V. et al., *Lancet*, 375, 2267, 2010.)

one expends. When individuals have ceased linear growth, but remain in positive energy balance, they accumulate fat. There are both genetic and environmental influences on energy balance. For example, identical twins tend to achieve similar degrees of overweight, whether raised together or apart. On the other hand, populations that have changed from traditional diets low in calories and fat to more Westernized diets higher in both have an increasing prevalence rate of obesity, demonstrating the importance of environmental influences on energy balance. The second level at which insulin resistance occurs is fat accumulation. Fat accumulation is important in the development of insulin resistance with at least two general factors determining the degree to which individuals accumulate fat and develop insulin resistance. The first factor is where the fat is deposited. Deposition in adipose tissue is associated with less insulin resistance than localization in liver or muscle. The second factor is a number of cytokines and hormonal factors that are secreted by adipose tissue, particularly visceral adipose tissue (VAT). Tumor necrosis factor-α (TNF-α), resistin, and adiponectin are three factors made by adipose tissue that appear to act as hormones to regulate insulin sensitivity in muscle and/or liver.

Elevated Free Fatty Acids, Muscle, and Insulin Resistance

Chronically elevated blood levels of free fatty acids (FFA) have been linked to the onset of insulin resistance in skeletal muscle and liver.[23–26] A direct and causative relationship between intracellular fat metabolites and insulin resistance appears to be mediated via alterations in the insulin signaling pathway. In normal skeletal muscle, insulin binds to its receptor, activating the receptor tyrosine kinase activity, with the subsequent phosphorylation and activation of insulin receptor substrate 1 (IRS-1). When phosphorylated, IRS-1 activates phosphatidylinositol 3-kinase (PI3K); this enzyme through signaling promotes the docking and fusion of GLUT4-containing vesicles to the plasma membrane and the transport of glucose into the cell (Figure 33.1a).[27] In skeletal muscle, the proposed mechanism for alteration in insulin signaling is as follows: increased delivery of FFA to the muscle leads to an increase in intracellular fatty acid metabolites to include fatty acyl CoA, ceramides, and particularly diacylglycerol. These activate a serine/threonine kinase cascade initiated by protein kinase CΘ (PKCΘ) which leads to the phosphorylation of serine/threonine sites on IRS-1. The serine/threonine phosphorylations reduce the ability of IRS-1 to activate PI3K. As a result, glucose transport activity and other events downstream of insulin receptor signaling (e.g., glycogen synthesis and glycolysis) are decreased[28,29] (Figure 33.1b).

Elevated Free Fatty Acids, the Liver, and Insulin Resistance

Ectopic lipid accumulation in the liver is termed hepatic steatosis. It is associated with elevation of liver enzymes, obesity, insulin resistance, and type 2 diabetes. Elevated FFA from visceral fat and chylomicron remnants from dietary lipids enter the liver through the portal circulation. Accumulation of triglycerides in hepatocytes results from this increase in FFA and chylomicron remnant inflow and also de novo from lipogenesis of absorbed carbohydrates. Normal insulin action in the liver has many similarities to insulin action in muscle. In the liver, insulin activates the insulin receptor kinase, which phosphorylates IRS-1 and IRS-2, leading to the activation of PI3K and ultimately Akt2. Akt2 activation promotes glycogen synthesis and inhibits gluconeogenesis (Figure 33.2a).[23] In the liver, the precise effect of FFA levels remains an area of ongoing discussion and investigation with the sequence of events and the mediators linking FFA to insulin resistance and liver disease progression being better defined.[25,26] A proposed model for hepatic insulin resistance

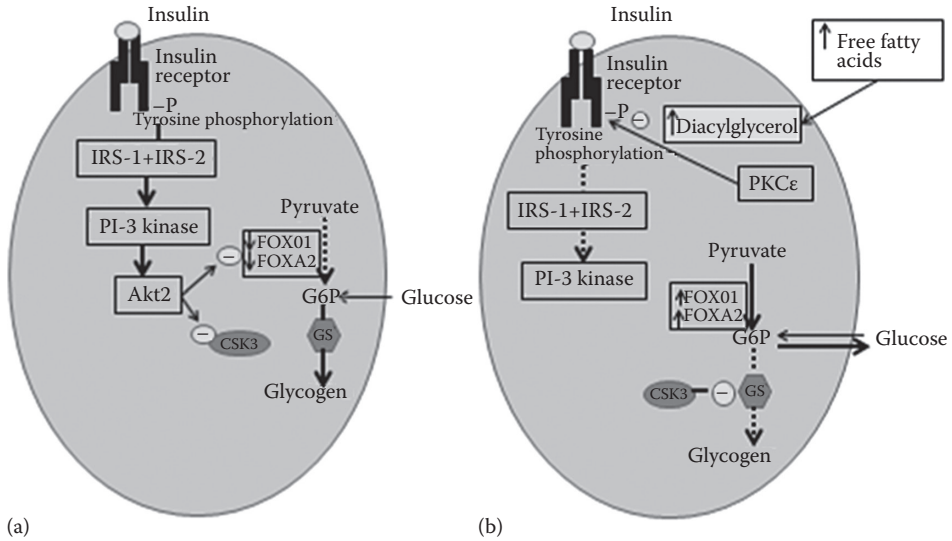

FIGURE 33.2 Mechanisms of insulin sensitivity (a) and resistance (b) in liver. IRS, Insulin receptor substrate; PI3, phosphatidylinositol 3-kinase; PKCε, protein kinase Cε; FOX01, forkhead box 01; FOXA2, forkhead box A2; GSK3, glycogen synthase kinase 3; GS, glycogen synthase; circle with minus indicates inactivation; dotted line indicates inhibition. (Adapted from Shulman, G., *J. Clin. Invest*., 106, 171, 2000; Samuel, V. et al., *Lancet*, 375, 2267, 2010.)

involves interference of insulin signaling, with decreased IRS-1 and IRS-2 phosphorylation by the insulin receptor impairing the ability of insulin to activate hepatic glycogen synthesis and suppress hepatic glucose production (HGP). As in muscle, PKC and in particular PKCε appears to play an essential role in the pathogenesis of hepatic insulin resistance (Figure 33.2b).[26] HGP is increased in insulin resistance. The brain needs glucose in order to function, with ~50% of glucose utilization in the fasting state accounted for by brain utilization. Glucose production by the liver, and to a lesser extent by the kidneys, supplies the brain with this glucose. In people with type 2 diabetes, basal HGP is increased. As the rate of basal HGP increases, so also does the fasting plasma glucose. In type 2 diabetes, glucose overproduction by the liver is accompanied by a 2.5- to 3-fold increase in fasting plasma insulin levels indicative of severe insulin resistance relating to the insulin suppressive effect on HGP. This increase in basal HGP is explained by an increase in gluconeogenesis.[29]

Adipose tissue in obesity is stressed resulting in enlarged adipocytes, the activation of inflammatory responses, and the recruitment of macrophages. Enlarged adipocytes are resistant to the antilipolytic effect of insulin and have a diminished fat-storing capacity.[30,31] This leads to the prolonged elevation of plasma FFA. When the adipocyte-storing capacity is exceeded, the chronic, prolonged elevation of plasma FFA levels which, as previously reviewed, induces hepatic and muscle insulin resistance, stimulates gluconeogenesis, and impairs insulin secretion.[32–40] These dysfunctional adipocytes produce excessive amounts of insulin resistance–inducing inflammatory and atherosclerosis-provoking adipocytokines (TNF-α, interleukin-6 [IL-6], plasminogen inhibitor-1 [PAI-1], monocyte chemoattractant protein-1 [MCP-1]) and fail to secrete normal amounts of insulin-sensitizing adipocytokines such as adiponectin. The secretion of the adipocytokines and the increased lipid overflow into the arterial circulation not only induce insulin resistance but also effect vascular smooth muscle cells leading to acceleration of the atherosclerotic process.[41,42]

Obesity, Free Fatty Acids, and Insulin Secretion

Obesity and the chronic elevation of FFA levels impair insulin secretion.[43,44] Studies have demonstrated that elevation of FFA for 48 h in offspring of two type 2 diabetic parents markedly impairs both first and second phase insulin secretion. Conversely, a sustained reduction in the FFA concentration by the use of acipimox in nondiabetic subjects with a strong family history of type 2 diabetes improves insulin secretion.[45] Exposure to FFA has been shown to cause a marked inhibition of insulin mRNA expression, decreased glucose-stimulated insulin release, and reduction of islet insulin content.[46] Obesity and chronic FFA elevation not only bring about insulin resistance, but also can decrease insulin secretion.

Insulin Resistance in Obesity

The prevalence of insulin resistance in obesity is not precisely known. In studies of insulin resistance and obesity, the study populations have been too small to evaluate prevalence.[47–49] In Pima Indians, insulin sensitivity measured by insulin clamp technique has been shown to decline with increasing BMI.[50] This finding was, however, nonlinear with most of the decrement in insulin sensitivity occurring for small increments in BMI. In a study of 1146 obese individuals in the database of the European Group for the Study of Insulin Resistance using the euglycemic clamp technique, the nondiabetic, normotensive obese subjects had a relatively low prevalence of insulin resistance. When insulin-mediated glucose utilization

was normalized by the metabolically active (lean) mass, the obese group was only 15%–25%, on average, less sensitive to insulin than the lean group, with no difference between men and women. Also the prevalence of insulin resistance among the obese subjects was low with only one in four individuals insulin resistant at the bottom decile of the lean group. In the presence of definite obesity (BMI 28–50 kg/m^2), only one in two individuals was insulin resistant. Although obesity is the quintessential insulin-resistant state, in simple obesity, insulin resistance may not be as prevalent as once thought. This may affect the response to weight loss as it relates to the risk of diabetes and cardiovascular disease.[5]

LIFESTYLE AND INSULIN RESISTANCE

Lifestyle may be defined differently by patients, health care professionals, educators, or research investigators. Lifestyle in the context of this chapter will be defined generally as the modifiable environmental factors of physical activity, nutrition, smoking, and stress. All of these factors have been demonstrated to affect insulin resistance.[51–54] Four factors, food choices and portion size, inactivity, tobacco use, and stress have been reported to account for 75% of chronic disease.[55]

Physical Activity and Insulin Resistance

Physical activity and health have been positively associated for well over 50 years. The beneficial effects of moderate to vigorous physical activity have been more clearly defined in recent years.[56–60] Humans are designed for movement. Obtaining dietary energy and nutrients from the environment has traditionally required expenditure of energy through human body movement. In the Western world, modern humans have relatively low levels of energy expenditure compared with contemporary hunter-gatherers.[61] Morris et al. in the early 1950s conducted studies among London Transport Executive and Post Office employees. The results demonstrated that the physically active men (bus conductors and postmen) had lower mortality rates from heart disease than less active workers (bus drivers and telephone switchboard operators).[62] These early studies provided epidemiological evidence for a role of physical activity in averting premature mortality. More recently, the Harvard Alumni Study and the Aerobics Center Longitudinal Study have demonstrated the benefits of physical activity and fitness in decreasing the relative risk of mortality.[63,64] In intervention trials, physical exercise has variably decreased body weight, visceral fat, and insulin resistance.[65–68] Molecular mechanisms of insulin-stimulated glucose uptake involve the main insulin-responsive glucose transporter GLUT-4. GLUT-4 is primarily located in muscle and adipose cells. Muscle is the principal site of insulin-stimulated glucose disposal with less glucose being transported into adipose tissue. GLUT-4 is recycled between the plasma membrane and intracellular storage pools. GLUT-4 differs from other glucose transporters in that about 90% of it is sequestered intracellularly in the absence of insulin or other stimuli. Insulin-stimulated intracellular movement of GLUT-4 is initiated by the binding of insulin to the extracellular portion of the transmembrane insulin receptor. Its binding activates tyrosine kinase phosphorylation at the intracellular portion of the receptor. The chief substrate for tyrosine kinase is insulin receptor substrate 1 (IRS-1). In both adipocytes and skeletal muscle, subsequent activation of phosphatidylinosital-3 kinase is necessary for the stimulation of glucose transport by insulin.[27,69,70] This is sufficient to induce at least partial translocation of GLUT-4 to the plasma membrane[71–73] (Figure 33.1a). The mechanism by which bouts of exercise effect glucose transport involves the stimulation of GLUT-4 transporters. The signals that mediate exercise-induced GLUT-4 recruitment differ from those that mediate insulin-induced recruitment, in that phosphatidylinosital-3-kinase activity is not required for the exercise effect.[74,75] Exercise-induced stimulation of GLUT-4 translocation is normal in insulin-resistant subjects. Thus in subjects who are insulin resistant, or at high risk for type 2 diabetes, regular physical activity can be of significant benefit.

Both aerobic and resistance exercise have been demonstrated to decrease insulin resistance and improve glucose tolerance.[76,77] Davidson et al. in a randomized controlled trial of overweight and obese older, white adults demonstrated the benefit of aerobic and combined resistance and aerobic exercise for simultaneous reduction of insulin resistance and functional limitation.[78] Although this study found combined resistance and aerobic exercise is an optimal exercise strategy to decrease insulin resistance, considerable improvement was observed in response to aerobic activity alone.

Nutrition and Insulin Resistance

Type 2 diabetes is a classical example of an insulin-resistant state. Numerous lifestyle intervention studies have demonstrated the benefit of physical activity and nutrition in the prevention[79–81] and treatment of type 2 diabetes.[82] These studies demonstrate both a primary and secondary (weight loss) effect of lifestyle on insulin resistance.

Over the last 20–25 years Dietary Guidelines for Americans (DGA), dietary recommendations intended to decrease chronic disease among American adults have been published.[83,84] Insulin resistance is an important risk factor in the pathogenesis of cardiovascular disease and type 2 diabetes. Fogli-Cawley et al. examined the relationship between a diet consistent with the 2005 DAG and insulin resistance in the Framingham Offspring Cohort. A dietary adherence index which excluded weight and physical activity was used to measure nutritional adherence. The study was controlled for adiposity, overweight, and physical activity. Their findings suggested that women who consumed a diet more consistent with the 2005 DGA had better insulin sensitivity than those who did not. The reason for this observed difference was not apparent. This finding may have been secondary to the adjustment for waist circumference, a strong predictor of insulin resistance, or to a difference in dietary patterns or adherence between men and women. This relationship was not demonstrated in men.[84] It appeared that those individuals

who fully met the intakes for fiber, whole grains, dark green vegetables, *trans*-fat, and alcohol had significantly less insulin resistance as measured by HOMA-IR than those who did not meet the intakes. However, an overall healthy diet pattern was more strongly associated with less insulin resistance than any individual component.[84]

Nutrition has an important influence on insulin resistance in addition to weight gain secondary to caloric excess.[84–86] Several nutrients appear to influence insulin sensitivity although not to the extent of that observed with weight loss. Those foodstuffs include total amount of fat, nature of dietary fatty acids, nature of carbohydrate, and amount of protein. The habitual intake of fat, regardless of the nature of the fatty acids, correlates positively and significantly with plasma insulin concentrations.[87] This finding has been reported in several large studies.[88–90] In these studies, when body mass was taken into account, the significant relationship between fat intake and insulin levels diminished. In the Insulin Resistance Atherosclerosis Study, the insulin-sensitivity index remained significantly and inversely related to the fat intake in obese but not nonobese individuals.[90] The mechanisms are uncertain because the quantity of fat eaten does not necessarily cause obesity. Triglyceride accumulation in skeletal myocytes is a feature of insulin resistance and obesity.[91] The amount of physical activity also attenuates the adverse effect of fat on insulin sensitivity.[89,90] Insulin sensitivity appears to be influenced more by saturated fatty acid intake than polyunsaturated fatty acid intake.[90,92] Vessby from analysis of fatty acids concluded that increases in saturated fatty acids, such as palmitate, are linked to insulin resistance versus high levels of polyunsaturated fatty acids which are neutral or oppose insulin resistance.[93] The relationship of saturated and polyunsaturated fatty acids to insulin sensitivity has been reported in a number of studies.[94–96] In well-controlled dietary intervention trials, decreasing saturated fatty acids, and increasing monosaturated fatty acids improved insulin sensitivity, though only when total fat intake was not excessive.[97,98] Although all studies have not come to the same conclusion, experimental human and animal studies have demonstrated that dietary fat, especially saturated fat, can affect insulin sensitivity.

In a nested substudy of Prevencion con dieta Mediterranea (PREDMED), a multicenter, randomized, parallel-group primary prevention trial in Spain, 418 nondiabetic subjects aged 55–80 years were randomized to a low-fat diet (control group) or one of two Mediterranean diets supplemented with either extra virgin olive oil (1 L/week) or mixed nuts (30 g/day). Diets were without limits, with no advice on physical activity given. The main outcome was diabetes incidence as diagnosed by 2009 criteria. Following a median follow-up of 4 years, the diabetes incidence was 10.1%, 11%, and 17.9% in the Mediterranean diet with olive oil, with mixed nuts, and the control group, respectively. This is a 52% reduction in the incidence of diabetes. The initial explanation for the results of decreased incidence of diabetes without weight loss was that monounsaturated fats in olive oil and nuts are less oxidized and contribute to reduced insulin resistance and that the components of the Mediterranean diet are rich in antioxidant compounds with anti-inflammatory effects.[99]

The role of dietary fiber has been difficult to assess due to other carbohydrate moieties and the large number of bioactive nutrients and nonnutrients in plant foods. However, evidence does exist that there are links between the amount of ingested fiber and plasma insulin concentration. In the Coronary Artery Risk Development in Young Adults (CARDIA) study, dietary fiber was linearly but inversely correlated with post-glucose load plasma fasting and 2 h insulin concentrations, BMI, and waist–hip ratio.[100] Intake of whole grain foods is reported to be associated with a lower level of VAT whereas eating more refined grains is linked to a visceral adipose increase.[101] A significant inverse association was found between the intake of whole grain foods and waist measurement after adjusting for age, sex, smoking status, total energy, and alcohol consumption. Whole grain consumption had an inverse association with subcutaneous adipose tissue (SAT) and VAT. In multivariable models, refined grain intake demonstrated a positive relationship with SAT and VAT. In joint evaluations, the SAT *p* value was attenuated and nonsignificant whereas the VAT had a relationship with whole grains and refined grains. Causality for these findings will require further study.

Diets low in carbohydrates and enriched with protein have been popularized due to their short-term weight loss effects. In a controlled trial of a low-carbohydrate versus a low-fat diet, obese subjects who were insulin resistant or overtly diabetic showed greater weight loss when carbohydrates were reduced and insulin sensitivity in the diabetic individuals improved.[102] Increasing the proportion of protein relative to carbohydrates within an energy-restricted diet resulted in weight loss with less reduction in lean muscle mass and greater reductions in blood glucose and triglycerides.[103]

Smoking and Insulin Resistance

Smoking and the use of nicotine-containing products have an effect on insulin resistance and insulin sensitivity. Chronic cigarette smokers were found to be insulin-resistant, hyperinsulinemic, and dyslipidemic when compared with matched groups of nonsmokers.[104] In people with type 2 diabetes, smoking markedly aggravated insulin resistance.[105] Nicotine abstinence appears to improve insulin resistance, and smoking cessation methods relying on nicotine replacement appear to decrease insulin sensitivity.[106,107] Smoking remains a significant modifiable lifestyle risk factor.

Stress and Insulin Resistance

Stress and the physiological response to stress play an important role in insulin resistance and insulin sensitivity. Acute stress is associated with a severe, yet reversible form of insulin resistance.[108,109] Psychological stress also can be associated with insulin resistance.[110]

Stress has been defined as a state of threatened homeostasis or disharmony caused by intrinsic or extrinsic forces or stressors.[111] Chronic stress is defined as a pathological state

of prolonged threat to homeostasis by persistent or frequently repeated stressors and is felt to significantly contribute to the pathophysiology of disease.[112] The body's response to stress relies on the integrity of the neuroendocrine, cellular, and molecular infrastructure located in the central nervous system (CNS) and periphery. Centrally, the hypothalamic–pituitary–adrenal (HPA) axis and the efferent sympathetic/adrenomedullary system represent the effector links through which the brain influences various organs and tissues during stress. Activation of the HPA is accomplished by arginine vasopressin (AVP) and corticotrophin-releasing hormone (CRH) release from the hypothalamus, activation of adrenal corticotropic hormone (ACTH) in the pituitary with subsequent increased secretion of the glucocorticoid, cortisol from the adrenal gland. The glucocorticoids exert pleiotropic effects through their many intracellular receptors throughout the body. The autonomic nervous system provides a rapid response system that controls a wide variety of functions since most body systems are affected by either the sympathetic nervous system, parasympathetic nervous system, or both. Recently, it has been demonstrated that cytokines and other humoral mediators of inflammation are potent activators of the central stress–response neurotransmitter circuits providing the afferent limb of a feedback loop by which the CNS and immune system communicate in order to defend homeostasis under conditions of systemic inflammation. In inflammatory sites, TNF-α, IL-1, and IL-6 are secreted in a cascade fashion into the general circulation. All of these proinflammatory cytokines have the ability to directly or indirectly enhance the activation of the HPA. Indirect activation by the HPA is also induced by cytokine-mediated stimulation of the central noradrenergic stress system.[113] Mobilization of the stress response by activation of the HPA and the sympathetic nervous system is normally programmed to be of limited duration. Chronic stimulation of the stress–response leads to the syndromal state that Selye described in 1936.[114,115] Continued action of glucocorticoids on metabolic pathways leads to increased visceral adiposity, decreased lean body mass, and insulin resistance. With a continuous supply of proinflammatory cytokines to the systemic circulation, there can be a chronic stimulus for activation of the HPA axis, creating a cycle of hypercortisolism inducing adipocyte accumulation and vice versa. With the inflammatory nature of obesity and the interplay among HPA, proinflammatory cytokines, and adipose tissue, a reciprocal link appears to underlie the impact of chronic stress to the development of obesity and conversely the contribution of obesity to the chronic activation of the stress system.[116–118]

In postsurgical stress, insulin resistance is characterized by normal sensitivity but decreased responsiveness of glucose oxidation, lipolysis, and plasma FFA oxidation. Glycogen synthesis and direct FFA oxidation are virtually unresponsive.[108]

SUMMARY

Insulin resistance is associated with numerous clinical conditions that contribute to decreased quality of life and chronic illness. Insulin resistance can be brought about, increased, ameliorated, or eliminated by changes in lifestyle. Providing effective lifestyle intervention including stress management programs, clear and appropriate prescriptions for physical activity, nutrition, and weight loss that result in decreased visceral adiposity and proinflammatory cytokines offer an effective approach to decrease insulin resistance and its deleterious effects on the body, health, and quality of life.

In the United States and worldwide, the prevalence of diabetes and prediabetes has increased dramatically. In 2011, the total prevalence of diabetes in the United States in all ages was 25.8 million people or 8.3% of the population. Of these, 18.8 million are diagnosed and 7.0 million are undiagnosed. This is an increase from 4.9% of the population in 1990 and 7.3% in 2000. In U.S. adults aged 65 years and older, 10.9 million, or 26.9% had diabetes in 2010. Of great concern are the estimated 79 million U.S. adults with prediabetes who are at high risk for type 2 diabetes and cardiovascular disease (CVD) [1].

In no other disease does the role of lifestyle—healthy and appropriate food choices and physical activity—play a more important role in both prevention and treatment than in diabetes. Multiple studies have shown that lifestyle strategies implemented in individuals at risk for diabetes (prediabetes) can effectively prevent or delay type 2 diabetes [1]. Type 2 diabetes is known to be a progressive disease and although lifestyle interventions are effective at any time in the disease process, they have their greatest impact earlier in the course of the disease [2]; thus the importance of intervening early with lifestyle approaches in both the prevention and treatment of diabetes.

The progression of type 2 diabetes and the changes in lifestyle interventions and medications that must occur over the continuum of prevention and management are illustrated in Figure 34.1 [3]. Preventing obesity and increasing physical activity is a high priority for the prevention of diabetes and other chronic diseases. Identifying individuals with prediabetes and implementing prevention interventions is essential. However, as the disease progresses the goal of nutrition therapy is to prevent and manage the long-term complications of diabetes.

First-line therapy for disease reduction for diabetes and CVD includes stopping cigarette smoking and reducing glucose, LDL cholesterol, and blood pressure to recommended goals. Nutrition therapy includes a reduction of body weight by 5%–10% in overweight and obese individuals, an increase in physical activity to 30–60 min/day of moderate-intensity activity, and implementation of a cardioprotective diet, which includes an increase in whole grains and fiber and a decrease in saturated and *trans*-fatty acids and dietary cholesterol.

OVERWEIGHT AND OBESITY: HALTING THE EPIDEMIC

Overweight and obesity are strongly associated with insulin resistance and the hope is that slowing the rising prevalence of obesity will have a positive impact on slowing the epidemic of diabetes and other chronic diseases. Body mass index (BMI = kg/m^2) and waist circumference (WC) are used to classify overweight and obesity and associated disease risk (Table 34.1) [4,5]. Although some obesity researchers suggest that it may not be possible to decrease the current numbers of overweight and obese persons in the United States, preventing the increase that has been occurring at an increasing rate is an important goal [6]. In programs designed to increase physical activity and decrease energy intake, the physical activity goal is to increase the number of steps an individual takes throughout the day by about 2000 steps above baseline and the decreased energy intake goal is to eat 100 fewer calories per day [7].

PREDIABETES: PREVENTING DIABETES

The increase in diabetes worldwide has made prevention of type 2 diabetes a top priority. Prediabetes is defined as hyperglycemia not sufficient to meet the diagnostic criteria for diabetes (Table 34.2) [8]. Categories of increased risk for diabetes (prediabetes) are listed in Table 34.3 [8]. Impaired fasting glucose (IFG), impaired glucose tolerance (IGT), and hemoglobin A1c (A1C) values in the 5.7%–6.4% identify persons at increased risk for diabetes as well as CVD. They should be counseled about effective strategies to lower their risks [8]. As A1C rises, the risk of diabetes rises disproportionately. Individuals with A1Cs between 6.0% and 6.49% are considered to be at very high risk for diabetes.

Diabetes Prevention Trials

Five clinical trials—Finnish Diabetes Prevention Study (DPS) [9], Diabetes Prevention Program (DPP) [10], Da Qing [11], Toranomon Study [12], and Indian DPP [13]—have compared lifestyle interventions to a control group with risk reduction for type 2 diabetes ranging from 29% to 67% from lifestyle interventions. The two most frequently cited are the Finnish Prevention Study and the DPP, both reporting a risk reduction of 58% from lifestyle interventions compared to a control group. In both, structured education programs emphasizing a reduced energy and reduced fat (~30% of total energy) intake, regular physical activity, and regular participant contact resulted in a weight loss of 5%–7% of baseline weight and a 58% reduction in risk of developing diabetes. This amount of weight loss was also associated with improvements in hypertension and lipid profiles.

Intensive lifestyle interventions are the safest, most efficacious, and usually the least expensive way to prevent diabetes; however, several clinical trials have shown that medications

TABLE 34.1
Classification of Overweight and Obesity by BMI and WC and Associated Disease Risk

		WC-Associated Disease Risk[a]	
Classification	**BMI (kg/m^2)**	**≤WC Cut Point (≤40 in. [102 cm] for Men and ≤35 in. [88 cm] for Women)[b]**	**>WC Cut Point (>40 in. [102 cm] for Men and >35 in. [88 cm] for Women)**
Underweight	<18.5		
Normal	18.5–24.9		Increased[c]
Overweight	25.0–29.9	Increased	High
Obesity (Class I)	30.0–34.9	High	Very high
Obesity (Class II)	35.0–39.9	Very high	Very high
Extreme obesity (Class III)	≥40	Extremely high	Extremely high

Sources: Data are from National Heart, Lung, and Blood Institute, *Clinical Guidelines on the Identification, Evaluation and Treatment of Overweight and Obesity in Adults*, National Institutes of Health, Bethesda, MD, 1998; Alberti, K.G.M.M. et al., *Circulation*, 120, 1540, 2009.

[a] Disease risk is for type 2 diabetes, hypertension, and CVD and compares with risk for an individual with normal BMI.

[b] Lower WC cut points (≤35 in. [90 cm] in men and ≤31 in. [80 cm] in women) seem to be more appropriate for assessing increased disease risk in Asian Americans.

[c] Even in persons of normal weight, WC can be associated with disease risk.

[a] For all three tests, risk is continuous, extending below the lower limit of the range and becoming disproportionately greater at higher ends of the range.

(i.e., metformin, acarbose, orlistat, rosiglitazone, voglibose, pioglitazone) can also prevent or delay progression from prediabetes to diabetes. The American Diabetes Association recommends that only metformin be considered as drug therapy for individuals with prediabetes [8]. Metformin is most effective in individuals with a BMI of at least 35 kg/m^2 and who are under the age of 60 years. Cost, side effects, weight gain, and lack of persistence of effect in some studies are concerns with other medications.

Although medical professionals are often skeptical about the ability of individuals to make permanent lifestyle changes, support for the role of lifestyle interventions comes from follow-up of participants in three large prevention studies. A sustained reduction in the rate of conversion to type 2 diabetes of 43% was reported at 20 years in the Da Qing study [14], a 43% reduction at 7 years in the Finnish DPS [15], and 34% reduction at 10 years in the DPP [16]. Lifestyle intervention resulted in sustained lifestyle changes and a reduction in diabetes incidence, which remained after the individual lifestyle counseling was stopped [15]. A cost-effectiveness analysis suggested that lifestyle interventions as delivered in the DPP are cost-effective [17]. Group delivery of the DPP intervention in community settings has the potential to be less expensive while still achieving similar weight loss [18].

Nutrition Therapy for Prediabetes

The goal of nutrition therapy for prediabetes is to prevent or delay the progression to type 2 diabetes. Interventions proven to be effective include a reduced energy intake leading to moderate weight loss and increased physical activity. Weight loss (5%–10% of body weight) and regular physical activity (30 min daily) are the recommended goals. To be effective requires individual or group counseling and continued support until lifestyle changes become permanent.

Weight Loss Interventions

To determine expected weight loss from weight loss interventions, a systematic review and meta-analysis of randomized clinical trials for weight loss with a minimum duration of 1 year was undertaken [19]. Eighty studies with a total of 26,455 subjects, primarily completers, were identified and the data pooled to determine mean weight loss from eight different interventions used in the trials—diet alone, diet and exercise, exercise alone, meal replacements, very low-calorie diets, orlistat, sibutramine, and advice alone. A mean weight loss of 5–8.5 kg (5%–9% of baseline weight) was observed in the first 6 months from interventions involving a reduced energy diet and/or weight loss medications. A plateau in weight loss was observed between ~6 and 12 months and in studies extending to 48 months, a mean 3–6 kg (3%–6%) of weight loss was maintained with none of the groups experiencing weight regain to baseline. In contrast, advice-only and exercise-alone groups experienced minimal weight loss at any time point.

Adaptive mechanisms that occur with a reduced energy intake—such as hormonal regulation of appetite [20], adaptive thermogenesis requirements leading to a decrease in energy expenditure [21], and a decline in weight maintenance energy requirements [22]—appear to prevent the majority of "dieters" from achieving an ideal body weight. However, the weight loss that can be achieved is important in reducing risk of diabetes. Therefore, individuals should be counseled on weight loss strategies to improve health (decreased risk of diabetes and CVD) and not for cosmetic reasons.

There is no "miracle diet" for weight loss. A large, long-term trial tested the efficacy of weight loss diets that were high or low in carbohydrate, protein, or fat [23]. The 2 year trial involved 811 individuals with 80% completing the study. Weight loss from each diet averaged 6 kg (7% of baseline weight) at 6 months with an average weight loss of 4 kg at 2 years. All diets reduced risk factors for diabetes and CVD. Satiety, hunger, satisfaction with the diet, and attendance at group sessions were also similar for all groups.

Of importance for weight management is a reduced energy diet that an individual can follow long term. Attendance at group sessions; support from family, peers, or health care

professionals; setting realistic weight loss goals; monitoring food intake by food records; and regular physical activity have been shown to assist in accomplishing weight management goals.

Carbohydrates and Insulin Resistance

It is often assumed that a high carbohydrate intake contributes to insulin resistance and to increases in triglyceride concentrations. Observational and intervention studies provide support for the concept that high-carbohydrate diets, at the very least, do not adversely affect insulin sensitivity and may be beneficial for insulin sensitivity [24,25]. Furthermore, carbohydrate appears to only increase triglyceride levels when energy intake and weight are constant and carbohydrate intake is ~55% of total energy intake [26]. In low-carbohydrate diets, energy from carbohydrate is generally replaced with energy from fats, usually saturated fatty acids (SFA). As discussed later, high intakes of dietary fats, especially SFA and *trans*-fatty acids, are associated with a decline in insulin sensitivity. Excess energy intake, regardless of the energy source, and positive energy balance contribute to insulin resistance through the production of obesity.

Of concern is the increased consumption of sugar-sweetened beverages (SSB), which includes soft drinks, fruit drinks, iced teas, and energy and vitamin–water drinks. A meta-analysis of 11 studies that included 310,819 participants and 15,043 cases of type 2 diabetes found that individuals in the highest quartile of SSB (most often one to two servings per day) had a 26% greater risk of developing type 2 diabetes than those in the lowest quartile (none or less than one serving per month) and a greater risk for metabolic syndrome [27]. SSBs can contribute to weight gain and obesity and therefore healthy alternative beverages are recommended.

Mediterranean Diets

A traditional Mediterranean Diet (MedDiet), characterized by high consumption of vegetables, legumes, grains, fruits, nuts, and olive oil; moderate consumption of fish and alcohol; and low consumption of red and processed meat and whole fat dairy products, has been reported to have a protective effect against diabetes [28]. In prospective cohort study, 13,380 Spanish university graduates without diabetes at baseline were followed for a median of 4.4 years. Participants with the highest adherence to a traditional MedDiet food pattern had the lowest risk of developing diabetes [29]. Recently, implementation of a non-energy-restricted traditional MedDiet supplemented with either extra virgin olive oil or mixed nuts was compared to a low-fat diet among individuals without diabetes but at high cardiovascular risk. After a follow-up of 4 years, the MedDiet reduced the incidence of diabetes by 52% [30]. It is encouraging to note that changing foods eaten can substantially reduce diabetes risk without weight loss.

Prediabetes and metabolic syndrome have multiple similar components—enlarged WC, lipid abnormalities, hypertension, insulin resistance, and an elevation in fasting glucose levels. A meta-analysis of 50 studies (epidemiological and clinical trials) with 534,906 participants showed that adherence to the MedDiet was associated with decreased risk of metabolic syndrome and improvements in WC, lipids, blood pressure, and glucose [31]. Therefore, adherence to a MedDiet can effectively prevent both the metabolic syndrome and diabetes.

Whole Grains and Dietary Fiber

In a number of studies, primarily observational, increased intake of whole grains and dietary fiber is inversely associated with insulin resistance and risk of type 2 diabetes [32]. In a meta-analysis of data from 14 cohorts comprising ~48,000 participants, greater whole grain intake was associated with lower fasting glucose and insulin concentrations independent of demographics, other dietary and lifestyle factors, and BMI [33]. The Dietary Guidelines Advisory Committee (DGAC) reviewed whole grain/fiber evidence and concluded that limited evidence shows that consumption of whole grains is associated with a reduced incidence of type 2 diabetes in large prospective cohort studies [34]. Whole grain–containing foods have been associated with improved insulin sensitivity, independent of body weight; increased intake of dietary fiber has also been associated with improved insulin sensitivity. Persons at risk for diabetes are encouraged to meet the Dietary Guidelines for Americans 2010 recommendations which are to consume at least half of all grains as whole grains and to limit the consumption of foods that contain refined grains, especially grain foods that contain solid fats, added sugars, and sodium [34].

Dietary Fats

Prevention studies have focused on reduced dietary fat as a key component of the intervention. However, since their implementation, it has become clear that the type of fats consumed is of importance as well as their contributions to total energy intake. The DGAC reviewed fatty acid and cholesterol evidence and concluded that strong evidence indicates that intake of SFA is positively associated with (1) increased serum total and LDL cholesterol and increased risk of CVD and (2) increased markers of insulin resistance. Conversely, decreased SFA intake improves measures of both CVD and type 2 diabetes risk. A 5% energy decrease in SFA, replaced by monounsaturated fatty acids (MUFA) or polyunsaturated fatty acids (PUFA), decreases risk of CVD and type 2 diabetes in healthy adults and improves insulin responsiveness in insulin-resistant and type 2 diabetes individuals [34]. The effect assumes no change in energy intake when MUFA and/or PUFA are substituted for SFA and may result from changes in membrane lipid profiles related to type of fatty acids ingested. The DGAC concluded that growing data support a risk of type 2 diabetes from SFA consumption and these support the need for fat-modified diets in persons with prediabetes and those with established type 2 diabetes. The recommendation is to reduce intake of SFA and replace them with MUFA and PUFA [34].

Of interest is the DGAC conclusion on the effect of dietary cholesterol intake on risk of CVD. Overall the evidence shows that consumption of dietary cholesterol in the

amount of one egg per day is not harmful and is not associated with risk of CVD or stroke in healthy adults, although consumption of more than seven eggs per week is associated with increased risk [34]. However, they note an important distinction among individuals with type 2 diabetes in which increased dietary cholesterol is associated with CVD risk. Therefore, the recommendation is to limit dietary cholesterol to less than 200 mg/day for persons with or at high risk for CVD and type 2 diabetes.

Glycemic Index/Glycemic Load

The role of the glycemic index (GI) and glycemic load (GL) and risk of diabetes has been controversial. The evidence for benefit of low GI/GL diets was reviewed by the American Diabetes Association [26], and it was concluded that there is not sufficient, consistent evidence to conclude that low GI/GL diets reduce the risk of diabetes. The DGAC reviewed 10 longitudinal prospective observational studies published since 2000. In five studies, high GI was positively associated with type 2 diabetes, four reported no association of GI with type 2 diabetes, and one reported an inverse association. Only one study found a positive association between GL and risk of type 2 diabetes; six studies found no relationship; and two studies found an inverse association. The DGAC concluded that when selecting carbohydrate foods, there is no need for concern with their GI or GL. What is important to heed is their calories, caloric density, and fiber content [34].

Alcohol

Observational studies suggest a U- or J-shaped association between moderate consumption of alcohol and increased risk of diabetes [35–37]. A meta-analysis based on 32 studies found that compared to no alcohol use, moderate consumption (one to three drinks per day [15–45 g alcohol]) was associated with a 33%–56% lower incidence of type 2 diabetes and a 34%–55% lower incidence of diabetes-related coronary heart disease. However, compared with moderate consumption, heavy consumption (more than three drinks per day [45 g alcohol]) was associated with up to a 43% increased incidence of type 2 diabetes [35]. Another meta-analysis of 15 studies reported that compared to lifestyle abstainers, the risk for type 2 diabetes among men was most protective when consuming 22 g/day alcohol and became deleterious at just over 60 g/day alcohol. Among women, consumption of 24 g/day alcohol was most protective and became deleterious at 50 g/day alcohol [36].

Despite the benefit of alcohol when consumed in moderation, when consumed in excess, alcohol can cause serious health problems and increased diabetes risk. Therefore, if alcohol is consumed, it should be consumed in moderation—up to one drink per day for women and two drinks per day for men—and only by adults of legal drinking age [34]. The biological response for the benefits of alcohol may be that in small clinical trials and observational studies light to moderate amounts of alcohol have been shown to improve insulin sensitivity and raise HDL cholesterol levels. The type of alcoholic beverage does not make a difference.

Micronutrients

Two micronutrients of interest in the prevention of diabetes are chromium and vitamin D. Generally, supplements are most likely to be beneficial in persons with known deficiencies. Chromium deficiency is difficult to determine and ideal vitamin D blood levels have been controversial. The 2010 Institute of Medicine (IOM) challenged the assumption that many Americans are vitamin D deficient. Many laboratories consider a vitamin D blood level of 30–40 ng/mL to be ideal, but the IOM report stated a vitamin D level of 20 ng/mL was sufficient [38].

Two systematic reviews of randomized controlled trials examined the effect of chromium supplementation on glucose metabolism [39,40]. Data from the trials showed no effect of chromium on glucose or insulin concentrations in persons without diabetes. A randomized, placebo-controlled trial using 800 μg/day chromium picolinate in subjects with IGT also found no significant beneficial effect of the supplement on glucose, insulin resistance, or lipids [41].

Several but not all epidemiological studies have shown an association between low serum 25-hydroxy (OH) vitamin D and impaired glycemia; vitamin D interventions trials have had conflicting results [42,43]. The Women's Health Study found a significant inverse association between total (food plus supplements) vitamin D intake and risk of type 2 diabetes when adjusted for age [44]. A study using data from disease-free adults in the National Health and Nutrition Examination Study also reported increased risk for prediabetes and prehypertension in individuals with lower vitamin D levels (≤28.6 vs. >26.6 ng/mL) [45]. In contrast, the Nurses' Health Study found no relationship between vitamin D intake from supplements and incident type 2 diabetes after further adjustment for confounders [46]. The Women's Health Initiative (WHI) Clinical Trials and Observational Study also examined whether low levels of serum 25-OH vitamin D are associated with increased risk of developing type 2 diabetes. In this racially and ethnically diverse population of postmenopausal women, regardless of the cut points used or as a continuous variable, lower 25-OH vitamin D levels were not associated with increased risk of developing diabetes [47].

Several trials have not found benefit from vitamin D supplementation. The WHI calcium plus vitamin D intervention trial found that supplementation with 400 IU vitamin D_3 and 1000 mg calcium was not associated with a reduced risk of developing diabetes over an average follow-up period of 7 years [48]. In the RECORD trial, a substudy examined whether oral vitamin D_3 (with or without calcium) was associated with a reduction in the development of diabetes and did not find evidence that vitamin D_3 in a daily dose of 800 IU, or in combination with 1000 mg calcium, was able to prevent the development of diabetes [49]. The results of ongoing trials of higher doses of vitamin D supplementation are needed before recommendations for vitamin D supplementation for the prevention of type 2 diabetes can be made.

Physical Activity

Increases in physical activity significantly reduce the risk of type 2 diabetes and, independent of weight loss, improve insulin sensitivity [50,51]. In a meta-analysis of 20 prospective cohort studies, individuals who regularly engaged in physical activity of moderate intensity had an ~30% lower risk of type 2 diabetes as compared with sedentary individuals even in those who did not lose weight [51]. A post hoc analysis of the Finnish DPS examined the association between walking and incidence of type 2 diabetes. After adjustment for other activities, dietary factors, and BMI, at least 2.5 h/week of walking was associated with a 63% lower risk of type 2 diabetes as compared with <1 h/week [52]. Protection from diabetes occurs from moderate-intensity activities, such as brisk walking, as well as from vigorous physical activity. Benefits of exercise are particularly apparent in overweight individuals and in those at greatest risk for diabetes.

Biological mechanisms have been identified for beneficial effects of physical activity on glucose metabolism independent of body fatness. Exercise increases insulin-stimulated glycogen synthesis through an increased rate of insulin-stimulated glucose transport by GLUT4 glucose transporters and increased glycogen synthase activity [53]. In addition, increased muscle mass may contribute to the beneficial effects.

Physical activity recommendations for cardiovascular fitness and reduced risk of chronic health problems including type 2 diabetes include

- Moderate-intensity aerobic physical activity a minimum of 30 min 5 days/week (150 min/week) (i.e., walking 3–4 miles/h) above usual activity
- Vigorous-intensity aerobic physical activity a minimum of 20 min 3 days/week (90 min/week)

The physical activity should be distributed over at least 3 days/week, with no more than 2 days without activity. Muscle-strengthening activities involving all major muscle groups two or more days/week are also recommended [54].

To prevent weight gain, 60 min of moderate- to vigorous-intensity activity most days of the week (increase energy expenditure by ~150–200 kcal) is recommended. To prevent regain of weight loss, at least 60–90 min of daily moderate-intensity physical activity while not exceeding food caloric requirements may be required.

Bariatric Surgery

Studies suggest that for morbidly obese subjects, bariatric surgery can reduce the incidence of diabetes. Sjoström et al. published 2 and 10 year data from the Swedish Obese Subjects (SOS) study that included 407 morbidly obese subjects who underwent bariatric surgery and matched controls. The majority had vertical banded gastroplasty (~70%), some had simple banding (~24%), and a few gastric bypass (~6%). At 10 years, the incidence of diabetes was 7% in the surgery group compared to 24% in the control group. Weight loss was maximal after 1 year in the surgical groups (~26% in the vertical banded gastroplasty) whereas the maintained weight change after 10 years in the vertical banded gastroplasty group stabilized at 16%. The 2 and 10 year incidence rates of hypertriglyceridemia and hyperuricemia (along with diabetes) were lower in the surgery groups than in the control group; however, the incidence of hypertension and hypercholesterolemia did not differ between the groups [55]. Bariatric surgery was also associated with a reduction in overall mortality as compared to the control group [56]. However, the majority of the research involves the role of bariatric surgery in patients already diagnosed with type 2 diabetes and not in persons with prediabetes [57].

Because improvement in glucose and insulin sensitivity occur rapidly and before significant weight loss, it has been suggested that the decreased risk is related to the diversion of nutrients away from the gastrointestinal tract and by delivery of incompletely digested nutrients to the ileum rather than to weight loss per se [58]. Of increasing interest is the study of enterohormonal changes that occur after bariatric surgeries and their influence on appetite, continued reduced food intake, and prevention of weight regain [57].

DIABETES: IMPROVING METABOLIC OUTCOMES

There are important nutrition therapy intervention differences between preventing and treating diabetes. For example, although weight loss is an important strategy for prevention, nutrition therapy for diabetes focuses on interventions shown to improve and maintain metabolic outcomes related to glucose, lipids, and blood pressure. As the disease progresses, weight loss may or may not be of benefit for achieving glycemic goals [59]. However, there are other nutrition therapies, independent of weight loss, that contribute to improved metabolic control.

Improving health through food choices and physical activity is the basis for nutrition recommendations for diabetes [26]. Randomized controlled trials and observational studies of diabetes nutrition therapy provided by registered dietitians have demonstrated decreases in A1C of ~1% to 2% (range = −0.5% to −2.6%), depending on the type or duration of diabetes [60]. These outcomes are similar to those from glucose-lowering medications. Nutrition therapy is reported to lower LDL cholesterol by 15–25 mg/dL, or by 9%–12%, compared to baseline values or to a Western diet [61]. Nutrition therapy for hypertension is reported to decrease both systolic and diastolic blood pressure ~5 mm Hg [62].

Outcomes of nutrition therapy interventions are evident by 6 weeks to 3 months. Central to these interventions are multiple encounters to provide education and counseling on a continued basis. Just as there is no one medication or insulin regimen that is effective for all individuals with diabetes, there is not one type of effective nutrition intervention. Shown to be effective interventions are reduced energy/fat intake, carbohydrate counting, simplified meal plans, guidelines for healthy food choices, individualized meal planning

strategies, exchange lists, insulin-to-carbohydrate ratios, physical activity, and behavioral strategies [59]. Choosing nutrition interventions that individuals with diabetes can implement is essential.

Nutrition Interventions for Type 1 Diabetes

The first priority for persons requiring insulin therapy is to integrate an insulin regimen into their lifestyle. The food/meal plan is developed first and is based on the individual's appetite, preferred foods, and usual schedule of meals and physical activity. An insulin regimen can then be integrated into the food and physical activity schedules. Persons are encouraged to learn carbohydrate counting. An insulin-to-carbohydrate ratio can then be used to adjust bolus (mealtime) insulin doses based on planned carbohydrate intake [26,59].

Nutrition Interventions for Type 2 Diabetes

As individuals move from prediabetes and being insulin resistant to type 2 diabetes and insulin deficiency, one of the goals of therapy is to achieve near-euglycemia in hope of slowing β-cell exhaustion. Moderate weight loss may be beneficial for some individuals, primarily those who are still primarily insulin resistant, but for many it is too late for weight loss to improve hyperglycemia. At later stages of the disease when medications—including insulin—need to be combined with nutrition therapy, weight gain often occurs and preventing this becomes important.

Persons receiving either nutrition therapy alone, glucose-lowering medications, or fixed insulin doses generally do better if carbohydrate intake is consistently distributed throughout the day on a day-to-day basis. Diets too low in carbohydrate may eliminate too many foods that are important sources of vitamins, minerals, fiber, and energy [59]. Teaching individuals how to make appropriate food choices (often by means of carbohydrate counting) and using data from blood glucose monitoring to evaluate outcomes are interventions that can be implemented for successful nutrition therapy.

Regular physical activity is encouraged, primarily from the benefits associated with enhanced cardiorespiratory fitness that are independent of weight, but exercise must be undertaken regularly to have continued benefits [63]. It is important to monitor metabolic outcomes to determine if medications need to be added (or adjusted). Many individuals with type 2 diabetes also have dyslipidemia and hypertension, so decreasing intakes of saturated and *trans*-fats, cholesterol, and sodium should also be a priority.

SUMMARY

Nutrition therapy for both prediabetes and diabetes begins by developing rapport with the individual. Whether provided individually or in groups, nutrition therapy involves a common process: (1) assessment (evaluation at follow-up visits)—what lifestyle changes is the individual willing and able to make; (2) diagnosis of nutrition-related problems—used to develop nutrition interventions; (3) nutrition interventions—implemented using self-management education and counseling; and (4) monitoring and evaluation of nutrition-related outcomes. Planned follow-up and ongoing education and support is essential for continued success.

It is important that all health care providers understand nutrition therapy issues and guide and support the individual's efforts to make and maintain lifestyle changes. Evidence supports the importance of referring patients with prediabetes or diabetes for medical nutrition therapy as soon as the diagnosis is made, promoting and reinforcing the importance of lifestyle modifications to patients, and providing support for the nutrition therapy process.

Glucose intolerance from prediabetes to frank type 2 diabetes mellitus (T2DM) is a major public health problem. T2DM is an economically costly disease[1] and a major contributor to morbidity and mortality. Uncontrolled T2DM can lead to renal dysfunction, peripheral and autonomic neuropathy, vision problems, and cardiovascular disease.[2] Fortunately, there is strong evidence that lifestyle interventions, programs promoting behavior change to improve diet, increase physical activity, and reduce weight, can prevent or delay the development of T2DM in high-risk populations and result in better disease management and improved outcomes in patients with T2DM. This chapter discusses the scope of glucose intolerance worldwide, describes how lifestyle choices affect insulin action, and examines the effects of lifestyle interventions on T2DM prevention and control.

SCOPE OF GLUCOSE INTOLERANCE

Glucose intolerance ranges from prediabetes to diabetes. Prediabetes, a precursor to and a risk factor for T2DM, includes (1) impaired fasting glucose (IFG), a fasting plasma glucose (FPG) of 100–125 mg/dL following the American Diabetes Association definition used in the United States or 110–125 mg/dL following the World Health Organization definition used elsewhere, or (2) impaired glucose tolerance (IGT), a 2 h post-load glucose of 140–199 mg/dL in a 75 g oral glucose tolerance test (OGTT). Diabetes is defined as FPG >125 mg/dL, 2 h post-load glucose >199 mg/dL, or both.[3]

Glucose intolerance is a global problem, affecting an increasingly large percentage of the population. Worldwide, the number of adults aged 20–79 years with diabetes (~95% of all cases of diabetes are T2DM) is estimated to be 285 million (prevalence: 6.6%); by 2030, it is expected that 438 million will have diabetes (prevalence: 7.8%).[4] The United States, India, and China share the bulk of the diabetes burden, with more than 70 million people with diabetes in 2000, an estimate projected to increase to nearly 152 million by 2030.[5] These estimates likely underestimate the actual number of cases of T2DM worldwide, due to underreporting and because they do not include the most recent data from China that report a prevalence of diabetes in adults of 9.7% (92.4 million people).[6] Furthermore, projections estimating the future burden of diabetes are likely to rise given the overall population trends of increasing weight, aging, and urbanization.[5]

Traditionally, T2DM has been thought of as a disease of affluence; this is no longer the case. T2DM prevalence is increasing at an alarming rate in rural and aboriginal communities[7–9] and ~70% of people with diabetes live in low- and middle-income countries.[4] For example, in India, a country where 70% of the population lives in rural communities, there are over 40 million cases of T2DM.[10] In 2005–2006, a study in Sri Lanka reported that the prevalence of diabetes for adults aged 20 years or older was 11.0% in rural communities and 13.6% in urban settings.[11]

In the United States, it is estimated that 12.9% of the population aged 20 years or older has diabetes (including both diagnosed and undiagnosed diabetes).[12] Prevalence of diagnosed diabetes, which is now 7.7%, is expected to rise to 12% by 2050.[13] Diabetes affects some racial groups disproportionately; the prevalence of diabetes is 17% for non-Hispanic blacks, 14.7% for Mexican Americans, and 12.2% for non-Hispanic whites.[12] Native Americans have even higher rates of diabetes,[12,14] and in one study of Asian Indians living in a major U.S. city, the prevalence of diabetes was 18%.[15]

Furthermore, T2DM is often asymptomatic, which results in a delay in disease diagnosis with many people with T2DM only identified when secondary complications have developed. Global estimates of the prevalence of undiagnosed

diabetes are high. In the United States, the proportion of diabetes cases that are undiagnosed for all age adults is 40% and ranges from 32.5% for 20- to 39-year-olds to 46.0% for individuals 75 years of age or older.[12] Another study comparing 13 European cohorts reported the opposite trend. In men, undiagnosed diabetes rates were highest in the youngest age ranges (70% in men aged 30–39 years and 60% in men aged 40–49 years) and decreased with increasing age. In women, the highest proportion of undiagnosed diabetes (58%) was in middle-aged individuals (aged 40–49 years), although there was no clear trend of increasing or decreasing prevalence over age.[16] In Australian adults, approximately half of all people with diabetes were previously undiagnosed.[17] The DECODA study (Diabetes Epidemiology: Collaborative Analysis of Diagnostic Criteria in Asia), an analysis of 11 Asian cohorts, found that undiagnosed diabetes prevalence ranged from 1.0% to 6.5% among Chinese and Japanese people and from 1.9% to 7.2% among Asian Indians.[18] The prevalence of undiagnosed diabetes in Thailand is estimated to be even higher: 9.6%.[19]

Data for the prevalence of prediabetes, especially the prevalence of IFG, are scarce. Worldwide, it is estimated that the prevalence of IGT is 7.9% (344 million people).[4] In the United States, the prevalence of prediabetes is 29.5% among people over 20 years and varies by race/ethnic group, ranging from 25.1% for non-Hispanic blacks to 31.7% for Mexican Americans. IFG is more common than IGT; the prevalence of IFG is 25.7%, compared to 13.8% for IGT.[12] In Europe, the prevalence of prediabetes rises with age (<15% for ages 30–59 years and between 15% and 30% after 60 years of age) and differs by gender.[16,20] For Asian populations, prediabetes prevalence is less than 18% for ages 30–59 years and 18%–26% after 60 years of age in Chinese and Japanese populations and less than 24% for Asian Indians aged 30–59 years and 20%–27% for Asian Indians 60 years of age or older.[18] The Korean prevalence of prediabetes by IFG criteria is 23.9%, or roughly 8.1 million people.[21]

SUSCEPTIBILITY TO DIABETES: HOW LIFESTYLE FACTORS CAUSE THE DEVELOPMENT OF PREDIABETES AND DIABETES

The increasing global prevalence of diabetes reflects both genetics (an expansion of nonwhite populations who have a predisposition to develop diabetes) and the environment (increases in both age and lifestyle-related factors—overweight and sedentary activity). Changes in lifestyle behaviors, namely excessive caloric intake and physical inactivity, lead to increases in insulin resistance which increase the risk of developing prediabetes and T2DM.[22] Higher body mass index (BMI) and lack of physical activity are both independently and strongly associated with increased risk of diabetes.[23] Aging also plays a role in increased insulin resistance; however, this appears to be attributable mainly to age-related obesity and inactivity, since older individuals who are nonobese and physically fit are not insulin resistant compared to nonobese, fit, younger individuals.[24]

Understanding the factors that make an individual susceptible to T2DM is an important area of study. Susceptibility to T2DM can be related to genetic predisposition and temporal susceptibility to epigenetic modulation.[25,26] The underlying genetic makeup of individuals and their experiences during pregnancy and childhood impact their susceptibility to diabetes development. Temporal modulation of genetic factors, often described as "metabolic programming," results from specific metabolic and nutritional influences that foster metabolic adaptations persisting throughout life.[27–29] The heritable changes that lead to chronic disease might occur during gametogenesis, preimplantation of embryogenesis, fetal and neonatal periods of development, puberty, or aging.[25]

In individuals with a genetic susceptibility to glucose intolerance, obesity and inactivity increase the risk of T2DM. This is illustrated clearly in the Pima Indians of the Southwest United States.[30] Adult Pima Indians living on a reservation in Arizona have a high prevalence of obesity (69%), little physical activity, and the highest prevalence of T2DM of any race/ethnic group in the United States (37.5%, see Figure 35.1). In contrast, Pima Indians living in Mexico, with the same genetic background but less obesity and more physical activity, have an 8.0% prevalence of diabetes, and non-Pima Mexicans, with levels of obesity and physical activity comparable to Pima Indians living in Mexico, have only a 2.5% prevalence of diabetes. When obesity and physical activity are comparable (Mexican Pimas compared to other Mexicans), genetics results in an approximately threefold increase in diabetes prevalence. Within the same genetic group (Pima Indians living in the United States or in Mexico), lifestyle factors ("environment") increase the diabetes prevalence almost fivefold.

Furthermore, changes in lifestyle factors can increase T2DM risk even in populations with low baseline genetic risk. The prevalence of diabetes is approximately four times higher among second-generation Japanese Americans than among native Japanese.[31] Japanese Americans display changes in lifestyle factors related to diabetes; Japanese Americans weigh more than their Japanese counterparts, though this is not statistically significant, and Japanese Americans consume a statistically significantly greater percentage of daily calories from animal protein compared to similarly aged men from Japan.[32]

Lifestyle factors can modify the balance needed between insulin secretion and insulin action, the two factors needed for normal glucose tolerance (NGT). Across a range of insulin action, glucose homeostasis can be maintained if insulin secretion is adequate. Figure 35.2 shows that if insulin action decreases (e.g., insulin resistance increases due to weight gain and/or inactivity) but β-cells can compensate for insulin resistance by an increase in insulin secretion, NGT is sustained and progression to diabetes does not occur. In contrast, individuals with impaired β-cells have inadequate compensatory secretion of insulin. If individuals with impaired β-cells become insulin-resistant, hyperglycemia ensues, potentially resulting in prediabetes

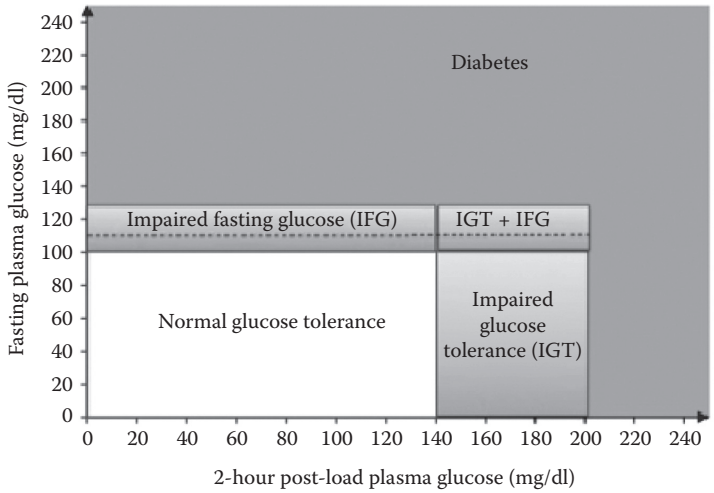

FIGURE 35.1 According to the definitions used by the American Diabetes Association, fasting plasma glucose levels of 100–125 mg/dl indicate impaired fasting glucose (IFG). A 2-hour post-load glucose of 140–199 mg/dl, as measured during an oral glucose tolerance test, indicates impaired glucose tolerance (IGT). IGT and IFG can occur in isolation or together. These two clinical phenotypes are known as prediabetes, a precursor for diabetes. Fasting or 2-hour glucose below these levels is considered normal; levels above IFG or IGT are diagnostic for diabetes. The dashed line indicates the definition for IFG used by the World Health Organization (110–125 mg/dl), a narrower range than that used by the American Diabetes Association.

Genetically susceptible population

	Pima indians living in the U.S.	Pima indians living in Mexico	General Mexican population
Diabetes prevalence	37.5%	8.0%	2.5%
Obesity rates	69.3%	13.2%	17.7%
Physical activity in hours/week	7.6	27.4	27.1

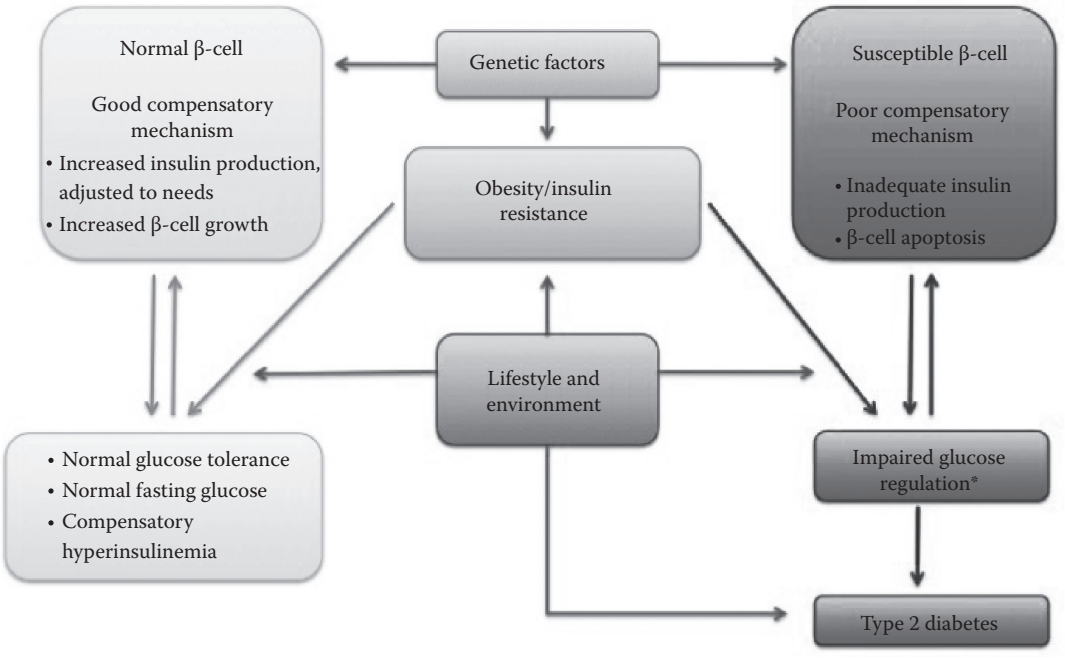
Low obesity, more physically active

FIGURE 35.2 Interaction between genetic susceptibility and lifestyle factors in type 2 diabetes risk: The Pima Indian Example. A healthier lifestyles can mitigate genetic risk for type 2 diabetes. (Adapted from Schulz, L.O. et al., *Diabetes Care*, 29, 1866, 2006; Weber, M.B. et al., *Am. J. Lifestyle Med*., 4, 468, 2010.)

and, with time, T2DM. Abnormalities of insulin secretion in persons with frank diabetes include reduced or absent first-phase responses to intravenous glucose,[34] delayed and blunted secretory responses to ingestion of a mixed meal,[35] alterations in the patterns of insulin secretion,[36] and increases in the plasma concentrations of proinsulin relative to those of insulin.[37]

While most individuals with diabetes or prediabetes have both impaired insulin secretion and impaired insulin action, and while hyperglycemia most often develops in people who already have insulin resistance phenotypes (e.g., overweight and/or sedentary), some slim, fit people also develop diabetes. Moreover, first-degree relatives of individuals with diabetes—those with NGT but at increased risk of developing diabetes—may exhibit insulin resistance and/or impaired insulin secretion.[38,39] Such observations have led to controversy as to whether insulin resistance or impaired insulin secretion is the "primary" cause of hyperglycemia in different individuals.[40] While such distinctions may not be essential for clinical management, they are important for both pathophysiological understanding and the development of health policies aimed at prevention. However, in part because of the lack of noninvasive methods to measure β-cell mass and function, at present we do not know whether the development of insulin resistance can "cause" β-cell failure over time in individuals whose β-cells were truly normal before insulin resistance developed. Regardless of the "primary" cause of hyperglycemia, the great majority of individuals with diabetes exhibit decreases in β-cell mass and function, leading to subsequent insulin deficiency.

Obesity increases insulin resistance via two mechanisms: (1) nonphysiological deposition of fat in visceral, hepatic, and



intramyocellular sites and (2) intracellular sequestration of GLUT4 glucose transporters in unexercised muscle, resulting in reduced glucose uptake.[41] Free fatty acids, produced more readily in visceral abdominal fat, decrease insulin sensitivity, impair vascular reactivity, and also increase endothelial dysfunction. "Toxic messages" from the adipose organ, such as free fatty acids, cytokines (e.g., an increase in tumor necrosis factor-α and a decrease in adiponectin), and oxidative stress, impair insulin action to restrain glucose production in the liver and promote glucose disposal in muscle.[42] The recent work of Shulman and colleagues has established increases in intracellular diacylglycerol (DAG) as an important mechanism of free fatty acid–induced insulin resistance in muscle,[39,43] disproving the "Randle hypothesis" of action via inhibition of pyruvate dehydrogenase.[44,45]

Reducing body weight and increasing exercise are key lifestyle factors to counter the effects of obesity on hyperglycemia. Diet and exercise can reduce adipose tissue and plasma concentrations of free fatty acids, improving glucose uptake. Exercise decreases concentrations of fatty acid metabolites (e.g., DAGs) to improve fatty acid–induced insulin resistance in humans.[39,46] In addition, exercise also stimulates the translocation of GLUT-4 to the plasma membrane, using signals that differ from the signals involved in insulin-induced GLUT-4 translocation.[41,47] As such, exercise improves glucose uptake and provides its own therapeutic benefit for those experiencing insulin resistance.[41,48]

The development of hyperglycemia (inadequate β-cell compensation for insulin resistance) reflects both impaired pancreatic β-cell function and loss of β-cell mass. The loss of β-cell mass is due to apoptosis, and β-cell mass is about 60% of normal in individuals with prediabetes, and 40% of normal in individuals with diabetes.[49] Accordingly, the extent to which lifestyle change to reduce insulin resistance can restore normoglycemia in individuals with prediabetes or diabetes depends on the β-cell defect, which is reflected by the clinical phenotype. As shown schematically in Figure 35.3, the highest insulin concentrations are required to promote glucose disposal into fat and muscle, the next highest to restrain glucose production in the liver, and the lowest to restrain lipolysis and ketogenesis. Thus, a mild β-cell defect presents as postprandial hyperglycemia, a moderate defect as fasting hyperglycemia, and a severe defect as ketoacidosis.

If the β-cell defect is mild, as in patients with prediabetes, lifestyle change to reduce insulin resistance can often restore normoglycemia and help prevent progression to diabetes. But if the β-cell defect is more severe, as in patients who are later in their natural histories and exhibit marked fasting hyperglycemia, lifestyle change is important to help control glucose excursions but may not restore normoglycemia, and pharmacological therapy will be needed. Lifestyle change also tends to improve postprandial hyperglycemia more than fasting hyperglycemia, because exercise can reduce insulin resistance in muscle (the major target of glucose disposal), but has less effect on the liver (the source of glucose production).

Different categories of prediabetes carry different risks of progression to frank diabetes. A 2004 study demonstrated that people with IGT are more insulin resistant than

*Impaired fasting glucose (IFG) and/or impaired glucose tolerance (IGT)

FIGURE 35.3 Early susceptibility to impaired β-cell function and development of type 2 diabetes mellitus. Genetics, obesity, insulin resistance, lifestyle factors, and β-cell health interact to determine an individual's risk for developing type 2 diabetes. Normal β-cells are able to increase insulin secretion and maintain glucose homeostasis. On the other hand, β-cells that have poor compensatory mechanisms are unable to adjust insulin production in response to increased glucose levels or decreased insulin sensitivity, resulting in impaired glucose regulation and, eventually, frank type 2 diabetes. (Adapted from Kahn, S.E. et al., *Nature*, 444, 840, 2006.)

people with IFG and that IGT is more strongly associated with increases in cardiovascular disease[50]—an important distinction because IGT can only be identified through an OGTT, a test which is currently underutilized in the United States. Even within the category of IFG, people with FPG levels of 100–109 mg/dL have been shown to be at less risk of progression to diabetes than people with FPG levels of 110–125 mg/dL, likely because patients in the former category are earlier in their natural histories.[51] More studies are needed to see if lifestyle improvements can differentially impact those with IGT compared to IFG.

Thus, the development of glucose intolerance depends on both the degree of insulin resistance and the extent of β-cell reserve. Everyone who develops insulin resistance will not develop prediabetes, and everyone who develops prediabetes will not develop T2DM. However, because of the rising rates of obesity and sedentary activity and the resulting increase in insulin resistance, it is essential to emphasize healthy lifestyles to reduce insulin resistance and limit the development of glucose intolerance in individuals who are at risk, in order to minimize the effects of these conditions on the health of individuals and society. Furthermore, as glucose levels increase over the natural history of T2DM (insulin resistance to prediabetes to T2DM), β-cell mass and function decrease, making it harder for the body to sustain normal glucose. Accordingly, it is particularly important to utilize lifestyle change to "buy quality life-years of normoglycemia" early in the natural history of T2DM, via decreased insulin resistance and reduced β-cell challenge, since lifestyle change alone is less likely to restore normoglycemia later in the natural history.

LIFESTYLE INTERVENTIONS FOR DIABETES PREVENTION

Participation in lifestyle interventions that teach participants how to prevent diabetes and other chronic diseases through weight loss, increased physical activity, behavior change, and improvements in diet quality is related to significant decreases in T2DM incidence.[52–56] A meta-analysis of randomized, controlled, lifestyle intervention trials for T2DM prevention found that compared to control or placebo groups, lifestyle intervention participants had a 50% decrease in 1-year T2DM incidence (RR 0.55, 95% confidence interval: 0.44–0.69) and a 0.84 mmol/L decrease in 2 h plasma glucose (95% confidence interval: 0.39–1.29) compared to participants in the control or placebo groups.[57] Except in cases where there is an extreme weight loss (e.g., after bariatric surgery[58]), lifestyle modifications have shown little effect on fasting glucose, most likely because post-load, 2 h glucose reflects peripheral insulin resistance, while fasting glucose primarily reflects hepatic insulin resistance and a more severe β-cell defect.[59]

The Finnish Diabetes Prevention Study (DPS) and the U.S. Diabetes Prevention Program (DPP) showed a 58% reduction in diabetes incidence in study participants in the lifestyle group compared to those in the control group.[54,55] These studies were similar in several ways. Both were multicenter, randomized trials of diabetes prevention through lifestyle change, achieving weight loss (≥7% of baseline weight in the DPP and a ≥5% in the DPS) and increasing physical activity levels (at least 150 min of moderate physical activity per day in the DPP and ≥30 min/day of moderate physical activity in the DPS). However, there were key differences in the study design, participant goals, and lifestyle education curriculum between these two programs.

In the DPS, participants (522 middle-aged, overweight men and women with IGT from one of five study centers) were randomized to either the lifestyle intervention or usual care, and lifestyle participants were given additional dietary goals during the program: a reduction in dietary fat (total fat <30% of total energy, saturated fat <10% total energy) and an increase in dietary fiber (≥15 g/1000 kcal).[54] A nutritionist met with participants for seven individual sessions with phone calls between consultations to educate the participant on diet change (based on feedback from the participant's 3-day food record), physical activity, goal setting, and behavior change. In addition, participants were encouraged to attend voluntary group sessions (e.g., lectures, cooking classes, supermarket visits), and they were given the option of following a very low-calorie diet at months 6–7 to boost weight loss.

The DPP was a much larger study with 3234 overweight people, aged 25 years or older with IGT and IFG randomized to a placebo arm, metformin (850 mg twice daily), or an intensive lifestyle intervention. A troglitazone study arm was discontinued early due to potential liver toxicity associated with the drug. Diet change was not a primary goal of the DPP lifestyle intervention; however, participants were counseled on dietary fat reduction as a tool for weight loss. Participants in the lifestyle intervention met individually with a case manager once per week for 16 weeks followed by eight monthly maintenance sessions. Each lesson was individualized and culturally appropriate and covered topics including behavior change, goal setting, diet change (with a focus on fat reduction), and physical activity.[55,60]

Other studies have shown similar, albeit attenuated, results to the DPP and DPS. The Da Qing IGT and diabetes study,[53] another multicenter, diabetes prevention study for individuals with IGT, randomized participants by clinic to receive standard of care (control), diet education, exercise education, or both diet and exercise education. Depending on study arm, physicians counseled intervention arm participants to follow a low-fat diet with personal calorie and food group intake goals and/or taught participants to increase leisure-time physical activity by 1–2 units/day (units were defined as 30 min of mild-intensity exercise, 20 min of moderate-intensity exercise, 10 min of strenuous exercise, or 5 min of very strenuous exercise). Compared to the control group, individuals in the diet, exercise, and diet-plus-exercise groups had reductions in diabetes incidence of 31%, 46%, and 42%, respectively. Furthermore, the benefits of the lifestyle interventions were seen in all participants, even those who were not overweight at baseline.

Like the Da Qing IGT and diabetes study, the Indian Diabetes Prevention Programme (IDPP)[52] showed that lifestyle interventions are effective tools for diabetes prevention in low- and middle-income country settings. The IDPP included

531 subjects randomized to received standard health care advice (control), metformin, lifestyle advice, or metformin plus lifestyle advice. The lifestyle intervention in the IDPP had a lower effect on diabetes prevention than seen in the DPP or the DPS (28.5% reduction in diabetes incidence in the lifestyle arm compared to controls). In addition to the high rate of conversion to T2DM in the Asian Indian population and the lack of weight loss in study participants, this might be due to several key differences between the lifestyle curriculum in the IDPP and the other studies: (1) the IDPP was a worksite-based program while the other programs were community based, and participants might have been less motivated to make lifestyle changes; (2) IDPP participants with "active" jobs or who walked or biked to work were not counseled to increase their daily activity, so these people would not have done any added exercise; and (3) the IDPP was less intensive, with less frequent contact with study staff and dietary advice (maintain energy balance; reduce total fat, saturated fat, simple sugars, and refined carbohydrate intake; and increase fiber intake) was given only during monthly calls, which may not have been sufficient to lead to lasting behavior change. A pooled analysis of participants in the IDPP and the IDPP-2 studies showed that the lifestyle intervention was equally effective for T2DM risk reduction in participants with isolated IGT and those with both IGT and IFG.[61]

The Japan Diabetes Prevention Program[62] assessed the effectiveness of delivering lifestyle interventions in a primary care setting using existing resources. Patients aged 30–60 years with IGT were randomized to receive either standard of care treatment or group and individual diabetes prevention and lifestyle improvement education delivered by clinic staff. At 3 years, participants in the intervention arm had significant decreases in body weight and BMI and increases in insulin sensitivity (as measured by the Matsuda Index[63]), compared both to baseline and the control group. Although the relative risk reduction for T2DM was 53% for the intervention group compared to the control group, this reduction was not significant. These results show that clinic-based education can be beneficial for patients; however, the large loss to follow-up in this study (28%) is a reminder that maintaining motivation for lifestyle change in clinic patients is a challenge.

Continued follow-up of participants in lifestyle intervention trials show that the effects of lifestyle interventions on diabetes incidence are reduced but significant over the long term, even when participants gain back some of the weight lost during the intervention program.[53–55,64,65] After 7 year median follow-up in the DPS, the reduction in relative risk of diabetes was 36%[64], and in the Da Qing study, there was a 43% reduction in diabetes incidence in the combined lifestyle intervention groups compared to controls after 20 years of follow-up.[66] The reduction in the effectiveness over time might indicate that lifestyle interventions can only partially prevent or delay T2DM,[67] perhaps due to the inability of lifestyle inventions to affect β-cell function.[68] Over time, an age-related increase in insulin resistance might counteract the decrease in insulin resistance conferred by lifestyle change, allowing hyperglycemia to emerge because of the underlying β-cell defect. However, this does not detract from the importance of lifestyle change as a tool for increasing an individual's disability- and disease-free life-years and improving the general health of the population.

In addition to deducing diabetes risk, lifestyle interventions improve insulin responses,[69] whole body insulin sensitivity,[70] markers of inflammation (C-reactive protein [CRP], interleukin 6 [IL-6],[71] and plasminogen activator inhibitor[72]), aerobic capacity,[68] blood pressure, and plasma lipid levels.[73] Comparisons of data within and between studies of lifestyle interventions for diabetes prevention show that the beneficial effects of lifestyle change are consistent across gender, race/ethnic groups, and setting (e.g., see Refs. [52,55,68,73–75]) and are sustained in populations with increased diabetes risk (e.g., women with history of gestational diabetes[76] and participants with high levels of insulin resistance[77]). Furthermore, lifestyle interventions reduce diabetes risk and improve health behaviors in older participants and in people with normal BMI, populations often excluded in prevention trials. In the DPP, the reduction in diabetes incidence for those in the lifestyle intervention compared to the placebo group was greater for those in the oldest age group (71% for individuals aged 60 or more years, compared to 48% for those aged 25–44 years) and for individuals with the lowest BMIs (65% for people with BMIs of 22 to <30 kg/m^2, compared to 51% for those with BMIs of ≥35 kg/m^2).[55] The increased benefits for older populations are likely due to lifestyle interventions overcoming age-related increases in peripheral insulin resistance (as reflected by higher 2 h post-load glucose values).[78] The difference in effect based on BMI is probably attributable to the same percent weight loss having less effect on insulin resistance for people with more body fat than for individuals with less baseline body fat. Finally, lifestyle interventions can overcome genetic susceptibility to T2DM,[52,55] further supporting the importance of lifestyle change for diabetes prevention.[79]

It is important to note, however, that the large randomized trials of lifestyle interventions for diabetes prevention included participants with IGT or both IGT and IFG; none included participants with isolated IFG. Although it is yet to be seen if these results extend to all people with prediabetes, lifestyle participants in the DPP had an increase in fasting glucose over time that was significantly lower than the FPG increase in the placebo group,[55] indicating that lifestyle change might also be effective for individuals with IFG. Future studies will help to answer this question.

Diabetes is an economically costly disease; the estimated annual increase in expenditures attributed to diabetes for a person in the United States is $6649/year.[1] Conversely, lifestyle interventions, at various levels of intensity (from the very intensive DPP to the less intensive IDPP), are cost-effective for preventing diabetes.[80–82] For example, in the DPP, the cost of the lifestyle intervention from a societal perspective was $24,400 per case of diabetes delayed or prevented, less than the cost per case of diabetes prevented or delayed for metformin ($34,500); from the perspective of the health system, compared to placebo, the cost was $15,655 per case of diabetes prevented for the lifestyle intervention and $31,338 per case of diabetes prevented for metformin.[82]

Based on the findings of lifestyle intervention trials and other related studies, expert organizations, including the American Diabetes Association,[83] the International Diabetes Federation,[84] the European Society of Cardiology and the European Association for the Study of Diabetes,[85] and the Canadian Diabetes Association,[86] recommend lifestyle changes (e.g., increased physical activity, weight loss) for T2DM prevention.

Given the strong evidence for the effectiveness of existing lifestyle interventions for diabetes prevention, future research in this field should focus on translational research. Translational research seeks to bridge the gap between basic science and effectiveness studies and implementation of proven research in clinics and the community.[87–90] Several translation trials of lifestyle interventions for T2DM prevention are ongoing. The Finnish National Diabetes Prevention Program (FIN-D2D),[91] based on the DPS lifestyle intervention, seeks to prevent T2DM in the Finnish population with targeted strategies for high-risk individuals, early treatment, and population prevention. Participants in this diabetes prevention program for high-risk individuals who lost ≥5% of baseline weight (17.5% of the 2798 person sample) had a 69% reduction in diabetes risk and significantly greater improvements in blood pressure, plasma lipids, and lipoproteins compared to the group that maintained their baseline weight. The Diabetes in Europe—Prevention using Lifestyle, Physical Activity, and Nutritional Intervention (DE-PLAN)—is a European Union project to create a model to identify individuals at high risk for T2DM and establish the cost-effectiveness of translating T2DM prevention research into the existing health care systems of EU countries. Participants in the Greek study site,[92] which testing the translation of diabetes education at health clinics and worksites, had significant weight loss, and individuals at highest risk of converting to T2DM, those with both IGT and IFG, attended the most education sessions and lost the most weight of any subgroup in the study. Pilot studies of Diabetes Prevention Program translations in the United States, a faith-based program for African Americans held an African American church,[75] the Diabetes Education and Prevention with a Lifestyle Intervention Offered at the YMCA (the DEPLOY study),[93] and the PILI 'Ohana Project in Hawaii,[94] have shown promising results with participants displaying decreases in body weight, blood pressure, FPG, and total cholesterol and/or increasing in physical functioning. The Tehran Lipid and Glucose Study in Iran was a nonrandomized trial comparing community-based lifestyle education (nutrition education classes, public conferences, talks at mosques, distribution of educational materials, and the use of trained community health educators) and standard of care. Although loss to follow-up was high, participants in the lifestyle arm had lower increases in diabetes risk factors (e.g., weight, waist circumference, FPG) than controls, and there was a significant reduction in relative risk of T2DM in the intervention arm compared to the control (RRR = 65%, $p < 0.003$).[95]

LIFESTYLE INTERVENTIONS AND MANAGEMENT OF DIABETES

Similarly, T2DM patients receiving lifestyle interventions in community or clinical settings exhibit improvements in insulin sensitivity and resting energy expenditure and decreases in fasting glucose, HbA1c, body weight, BMI, low-density lipoprotein (LDL) cholesterol, and blood pressure.[96–102] In one trial, physicians counseled their T2DM patients on lifestyle changes at a baseline visit and over the phone in the following months. Patients who increased their levels of physical activity the most had improvements in health outcomes (significant reductions in weight, BMI, waist circumference, FPG, heart rate, and LDL; significant increases in high-density lipoprotein (HDL); and a 4%–5% reduction in 10-year coronary heart disease risk) and significant reductions in medical and indirect social costs related to T2DM.[103] However, these effects may be less pronounced in individuals with long duration of T2DM or poorly controlled T2DM. The Japan Diabetes Complications Study[104] randomized a hospital-based population of T2DM patients (N = 1304, mean duration of T2DM: 10.9 ± 7.2 years) to conventional treatment or a lifestyle intervention program delivered through individual counseling by medical professionals focusing on physical activity, adherence to diabetes treatment, and dietary habits. The goal of the study was to determine if a lifestyle intervention affected the incidence of T2DM-associated vascular complications. After 8 years of follow-up, the researchers found that the intervention had little effect on glycemic control and no appreciable effect on risk factors for secondary T2DM complications; however, participants in the intervention arm had a significantly reduced risk of stroke (HR 0.62, $p = 0.04$). Participants in the intervention arm (a group-care model for intensive lifestyle intervention for patients with T2DM) of the Rethink Organization to iMprove Education and Outcomes (ROMEO)[105] study had increased self-reported quality of life; improvements in plasma lipids, health behaviors, and diabetes knowledge; and decreased weight, BMI, HbA1c, FPG, blood pressure, and creatinine ($p < 0.001$ for all) compared to controls in individual care, indicating that group-based lifestyle education for T2DM patients may further improve diabetes management and reduce risk factors for secondary diabetes complications.

The Look AHEAD (Action for HEAlth in Diabetes)[106] study randomly assigned overweight and obese subjects with T2DM to receive either usual care or an intensive lifestyle intervention that focused on weight loss and increased physical activity. The lifestyle intervention included group-based classes, individual monthly meetings with a lifestyle counselor, calorie reduction through diet change and a liquid meal replacement plan, and increased physical activity. In addition, select participants were prescribed a weight loss drug, Orlistat. At 1 year, lifestyle intervention participants lost significantly more weight than those in the control group (6.15% weight loss vs. 0.7% ± 4.8% weight loss) and had significant improvements in insulin sensitivity, fasting glucose,

and free fatty acids and decreases in weight, body fat, and hepatic fat.[107,108] The odds of reaching the weight loss goal of 7% were highest for participants in the highest quartiles of physical activity, consumption of meal replacements, and attendance at study classes. High self-reported physical activity correlated strongest with weight loss.[108] At 4 years, the lifestyle intervention participants continued to show marked improvements in health compared to the controls, maintaining a greater percent weight loss (6.15% vs. 0.88%) and showing larger improvements in physical fitness level, blood pressure, HDL cholesterol, and triglyceride levels, and glucose control (HbA1c level decreased by 0.36% in the lifestyle group compared to 0.09% in the standard of care group).[109] Furthermore, spouses of Look AHEAD intensive lifestyle intervention participants had greater reductions in body weight, total energy and total energy from fat, and reported more low-fat and less high-fat foods in their homes than control participants' spouses.[110] Trials which are currently under way of lifestyle interventions for people with T2DM in the United States[111] and abroad[112] will add to the literature on the long-term effects of lifestyle interventions on diabetes care and prevention of secondary complications of T2DM.

COMMON COMPONENTS OF LIFESTYLE INTERVENTIONS PROGRAMS

The lifestyle interventions used in the randomized trials discussed earlier have several unifying features, which are summarized in Figure 35.4; in each, participants were counseled on (1) weight loss; (2) increasing physical activity; (3) a healthy, well-balanced diet; and (4) tools for behavior change.

Weight loss, changes in body fat distribution, and increases in physical activity (independent of weight loss) have been shown to be determinants of T2DM risk reduction in lifestyle intervention trials.[113–115] Excess weight and obesity are strongly correlated with T2DM risk.[116] Lifetime diabetes risk increases as BMI increases[117]; overweight- or obese-level BMIs are associated with increased T2DM risk[118]; and diabetes risk increases by 12% for each unit of BMI increase.[119] Conversely, a 10% weight loss reduces the risk of T2DM by 0.5%–1.7% (depending on gender, BMI, and age).[120] The Look AHEAD study, the DPP, and the DPS advised lifestyle arm participant to lose at least a 5%–7% of their baseline bodyweight.[54,60,111] In the DPP lifestyle intervention group, BMI, waist and hip circumference, weight, and waist-to-hip ratio predicted diabetes incidence in both sexes, and diabetes risk reduction in the lifestyle intervention arm was significantly predicted by weight, BMI, and waist reduction in women and by weight, BMI, waist-to-hip ratio, waist circumference, and subcutaneous and visceral fat reduction in men.[113] In Look AHEAD, among participants in the intensive lifestyle intervention, changes in weight and fat mass, as well as decreases in hepatic fat, best predicted improvements in peripheral insulin sensitivity.[107]

Weight loss is accomplished by inducing a calorie deficit through increasing physical activity, decreasing calorie intake, or, ideally, both. Most lifestyle interventions recommend at least 150 min/week of moderate- to vigorous-level physical activity.[53,113–115] An increase in moderate to vigorous physical activity is associated with a reduction in diabetes risk of 63%–65%,[114] and even short-term interventions that increase moderate-intensity exercise have increased participants' fitness level[121,122] and reduced cardiovascular[123–126] and diabetes[127,128] risk factors. Furthermore, the addition of resistance training exercises in T2DM patients and patients with IGT enhances insulin sensitivity compared to aerobic exercise alone.[98]

Even so, regular physical activity is low in the general population (only 49.7% of men and 46.7% of women in the United States engage in regular physical activity[129]) and in

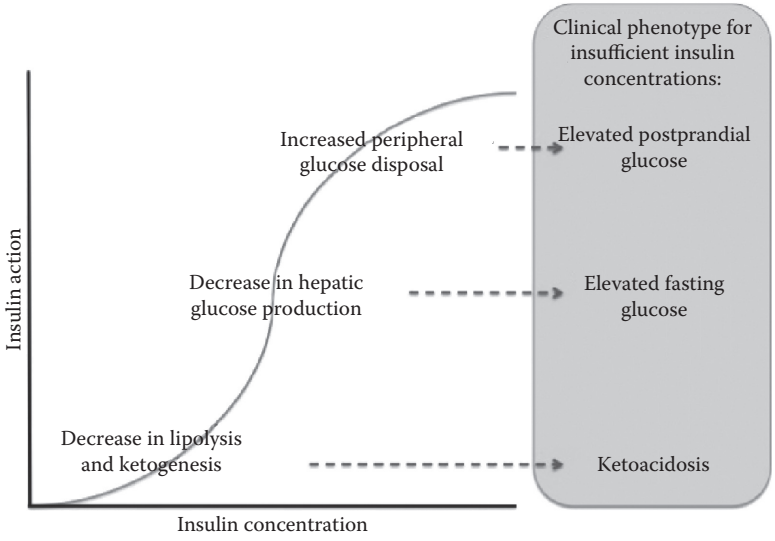


FIGURE 35.4 Degree of insulin deficit explains clinical phenotype. (a) The relative progression of insulin concentrations required for different actions of insulin and (b) the clinical phenotypes corresponding to insulin concentrations insufficient for that aspect of insulin action. (Adapted from Weber, M.B. et al., *Am. J. Lifestyle Med*., 4, 468, 2010.)

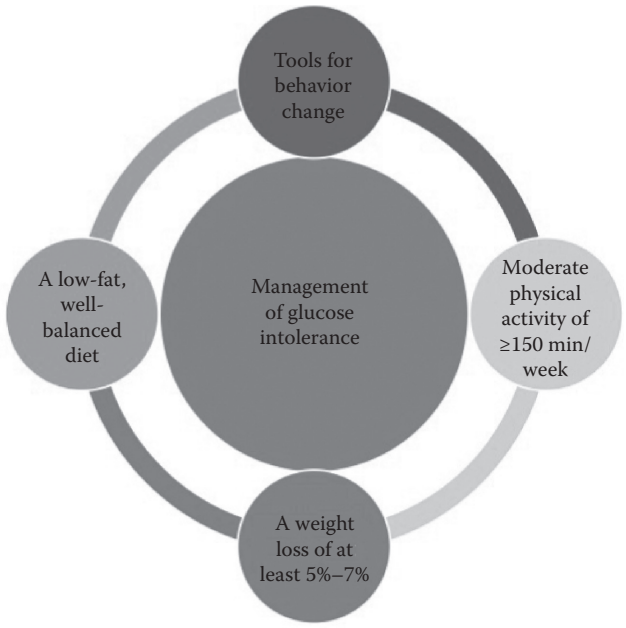

FIGURE 35.5 Components of successful lifestyle interventions for diabetes prevention and management. Randomized trials of lifestyle interventions for diabetes prevention and management include tools for behavior change based on established behavioral health theories; recommendations to participate in at least 150 min of moderate- to vigorous-level physical activity per week; a weight loss of at least 5%–7% of baseline weight; and advice to follow a well-balanced, low-fat diet.

individuals with T2DM.[130] For individuals who are reluctant to participate in an exercise program, gradually increasing exercise quantity will likely increase adherence and acceptability,[131] and programs including both endurance and resistance exercises increase compliance, probably because they increase interest by allowing participants to do a variety of exercises.[132] Simple tools, like pedometers, can be used to monitor and encourage activity. Pedometers have been shown to increase physical activity levels in T2DM patients.[96] In the Prediabetes Risk Education and Physical Activity Recommendation and Encouragement (PREPARE) Programme,[133] overweight or obese individuals with IGT were randomized to receive a control intervention or a single, group-based education program with or without pedometers. In the pedometer group, 2 h and fasting glucose decreased significantly at 3 and 12 months compared to both baseline levels and the control group. In the group with intervention only, there was no significant difference in fasting or 2 h glucose at any time point. Furthermore, self-reported overall moderate-to-vigorous activity and walking was significantly greater for the pedometer group compared to the control group at all time points.

Decreasing calorie intake and improving diet quality are important for diabetes prevention and management; specifically, individuals who wish to prevent diabetes or diabetes-related complications should consume a well-balanced diet rich in whole grains, fruit, and vegetables with <30% total fat and no more than 10% saturated fat. A prospective analysis of the Whitehall II cohort compared risk of cardiometabolic disease and mortality for several different diet patterns: an unhealthy diet pattern (full-fat dairy products, refined grains, processed meat, and fried foods), a sweet dietary pattern (high-fat dairy, dessert items, processed meats, and refined grains), a Mediterranean-like diet (fruits and vegetables, rice, pasta, and wine), and a healthy diet (low-fat dairy, whole grains, fruits and vegetables, and moderate alcohol). The analysis showed that the healthy diet, a low-fat diet rich in fiber, reduced the 15 year risk of diabetes and death from a coronary event or nonfatal myocardial infarction, compared with the unhealthy diet and only the healthy diet significantly reduced diabetes risk (HR 0.71, 95% confidence interval: 0.51–0.98).[134] Similarly, the DASH dietary pattern (a low-fat, high-fiber diet rich in vegetables, fruit, and low-fat dairy products) was inversely associated with diabetes risk.[135] In the DPS, consuming a low-fat, high-fiber diet had a dose-dependent affect on sustained weight loss and was also associated with reduced diabetes risk.[136] Diets low in saturated fat and high in unsaturated fat, fruit, vegetable, and fiber intake (e.g., the Mediterranean Diet) have also been shown to be beneficial for glucose control for patients with T2DM compared to diets with higher contents of simple sugars and carbohydrates.[137] The PREDIMED-Reus Nutrition intervention randomized trial[138] randomized healthy individuals aged 55–80 years old to one of three noncaloric restrictive diets: a low-fat diet or a Mediterranean-style diet (high intake of vegetables, beans, fruits, nuts, fish and olive oils with a low consumption of meat, high-fat dairy products, and processed foods) supplemented with either free extra virgin olive oil or mixed nuts. Even without significant changes in weight or physical activity in any group, incident diabetes was 51% lower in the olive oil group and 52% lower in the mixed nut group compared to the low-fat diet group; however, since only 21% of participants in the low-fat group reached the goal of reducing fat to <35% total energy, this group better represented a standard diet. In addition, diets reduced in glycemic index and glycemic load may also be useful in helping for preventing the development of T2DM,[139] and decreasing intake of simple sugars alone (without weight loss) results in improvements in glycemic control in obese T2DM patients.[140]

Dietary changes should also be made gradually over time starting with small behavior changes (e.g., eating fried foods only on occasion or switching from white to whole grain breads). Even gradual changes can be difficult if individuals do not have the tools to make lasting behavior changes. That is why successful programs, like Look AHEAD, the DPP, and the DPS, included information on health behavior change that is based on proven behavioral health theories (e.g., Prochaska's Stages of Change Model[141] and the Health Beliefs Model[142]).

In order to change behavior, individuals must have the ability to problem solve, a belief in their ability to succeed, and the tools to overcome barriers to behavior change. Self-efficacy, an individual's self-perception of his/her ability to change, is a mediator of behavior change.[143] In the DPP, exercise self-efficacy was significantly and positively correlated with mean leisure-time physical activity throughout the study.[144] Patients

with low self-efficacy for changing diet or increasing physical activity should be encouraged and provided with information or resources to aid them in their attempts at change. Also, health care providers should help patients to identify barriers and ways to overcome these barriers.[145] Social support, such as that provided in group-based weight loss programs or walking groups, is an effective tool to help people succeed in making and sustaining behavior changes[146] and could be used to help patients at greatest risk of failing in their attempts at lifestyle change. Research has indicated that patients with higher BMI, anxiety, depression, or stress might require extra support and encouragement to make and sustain behavior changes.[144] Finally, lifestyle messages should be culturally appropriate to improve acceptability and adherence. When people are approached in a culturally sensitive way, they are more receptive to health messages.[147,148] In addition, culturally appropriate advice can be easier to utilize immediately, as participants do not have to modify the advice on their own to account for common food and activity choices in their community.

Even though lifestyle interventions have been shown to be highly effective for reducing the risk of T2DM, they may not prevent the development of diabetes in individuals whose prediabetes involves a more severe β-cell defect. It is therefore vital that these patients be monitored closely. Furthermore, for these patients and in those who begin lifestyle change later in their natural history of glucose intolerance, glucose-lowering drugs might be needed earlier to complement the lifestyle interventions and to reduce insulin resistance. The American Diabetes Association recommends that individuals with both IFG and IGT and one additional risk factor for progression to diabetes (age <60 years, BMI ≥ 35 kg/m^2, family history of diabetes in a first-degree relative, elevated triglycerides, reduced HDL cholesterol, or HbA1c > 6.0%) be considered for treatment with metformin, in addition to lifestyle modification.[149]

CONCLUSION

T2DM is a global public health problem, brought on in large part by secular trends in lifestyle choices (decreasing physical activity and increasing body weight), which increase insulin resistance. Conversely, improvements in lifestyle, namely weight loss, behavior change, diet improvement, and increased physical activity, can effectively decrease insulin resistance leading to reductions in diabetes incidence in high-risk populations and improvements in disease management in people with T2DM. Successful lifestyle interventions should include tools for behavior changed based on existing health behavior models and recommendations to lose 5%–7% of baseline body weight, increase physical activity to at least 150 min/week, and follow a balanced, low-fat, high-fiber diet. Clinicians should advise patients at risk of developing T2DM and patients already diagnosed with T2DM to modify their lifestyle while continuing to monitor glucose levels to chart the patients' progress and identify deteriorations in glucose tolerance that might signal a need for pharmacological therapy.

INTRODUCTION

Metabolic syndrome refers to a clustering of traditional cardiovascular disease (CVD) risk factors that include insulin resistance, dysglycemia, abdominal obesity, atherogenic dyslipidemia, and hypertension, plus the nontraditional CVD risk factors such as proinflammatory and prothrombotic states.[1] Individuals with metabolic syndrome are five times more likely to develop type 2 diabetes and twice as likely to have CVD.[2,3] According to the National Health and Nutrition Examination Survey (NHANES) 2003–2006, ~34% of the adults in the United States have this syndrome.[4] The metabolic syndrome increases with age and body mass index (BMI); however, BMI appears to have a more dramatic effect.[4] Similarly, other countries have experienced an increased prevalence of the metabolic syndrome, suggesting the syndrome is a worldwide problem, possibly attributable to an increase in obesity and sedentary lifestyle.[5–10] This worldwide problem underscores the urgent need to develop therapeutic interventions for the prevention and treatment of this syndrome, thus reducing the societal burden of CVD and type 2 diabetes.

Pharmacological therapies targeted to treat the individual components of metabolic syndrome have been the conventional therapeutic approach. However, lifestyle interventions can be as effective as medication, but without the untoward side effects. In this review, the definition and pathophysiology of metabolic syndrome, and the numerous lifestyle interventions used to treat the syndrome will be discussed.

METABOLIC SYNDROME: DEFINITION

Due to the vague underlying pathophysiological processes leading to the metabolic syndrome's development and the perplexity between the numerous conceptual definitions, the syndrome continues to be a source of medical controversy. Throughout the years, several definitions for the metabolic syndrome have been proposed by various organizations such as the World Health Organization (WHO),[11] International Diabetes Federation (IDF),[12] American Heart Association and National Heart Lung and Blood Institute (AHA/NHLBI),[1] and National Cholesterol Education Program Adult Treatment Panel III (NCEP-ATP III).[13] Recently, a unified definition of the metabolic syndrome was proposed by the Joint Interim Societies (JIS) which includes the IDF Task Force on Epidemiology and Prevention, NHLBI, AHA, World Heart Federation, International Atherosclerosis Society, and International Association for the Study of Obesity.[14]

All of the renowned health organizations concur with the decision to include the CVD risk factors, such as fasting glucose, obesity, blood pressure, triglycerides, and high-density lipoprotein cholesterol (HDL-C), in the definition of the metabolic syndrome. However, the groups differ in the combined risk factors that are used to diagnose the metabolic syndrome and the cutoff points for each risk factor. The various definitions of metabolic syndrome are compared in Table 36.1.

METABOLIC SYNDROME: PATHOPHYSIOLOGY

The concept of metabolic syndrome was first introduced as syndrome X by Dr. Gerald Reaven in 1988.[15] He proposed insulin resistance as the driving force of the syndrome.[15,16] Insulin resistance occurs when tissues cannot effectively respond to insulin, resulting in a decreased uptake of glucose into muscle and adipose tissues.[15] Insulin resistance is important in the natural history of type 2 diabetes and metabolic syndrome. Specifically, insulin resistance is a key pathophysiological parameter associated with both obesity and type 2 diabetes, as well as with other traditional and nontraditional CVD risk factors. Initially, insulin resistance exists in the prediabetic state and necessitates hyperinsulinemia in order to maintain normal glucose tolerance. However, if hyperinsulinemia is not compensated, insulin resistance can lead to progression from prediabetes to type 2 diabetes and CVD.[15,17–19] Since the metabolic syndrome may precede the development of type 2 diabetes, the

TABLE 36.1
Definitions of Metabolic Syndrome

	WHO	NCEP-ATP III	AHA/NHLBI	IDF	JIS
Required for diagnosis	Insulin resistance: type 2 diabetes, IFG (>110 mg/dL[a]), IGT (2 h > 140 mg/dL), or low insulin sensitivity[b]; plus ≥2 of the following risk factors	≥3 of the following risk factors	≥3 of the following risk factors	Central obesity (increase WC country/ethnic specific) plus ≥2 of the following risk factors	≥3 of the following risk factors
Obesity	W/H: men, >0.9; women, >0.85; and/or BMI >30 kg/m^2	WC: men, ≥102 cm, women, ≥88 cm	WC: men, ≥102 cm or women, ≥88 cm	Required (see previous text)	WC: country/ethnic-specific

WHO, World Health Organization; NCEP-ATP III, National Cholesterol Education Program Adult Treatment Panel III; AHA/NHLBI, American Heart Association/National Heart, Lung, and Blood Institute; IDF, International Diabetes Federation; JIS, Joint Interim Societies; BMI, body mass index; 2 h, 2 h post glucose load of 75 g; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; T2DM, type 2 diabetes mellitus; WC, waist circumference; W/H, waist–hip ratio.

[a] The 2001 definition identified IFG of ≥110 mg/dL as elevated. This was modified in 2004 to be ≥100 mg/dL in accordance with the American Diabetes Association's updated definition of IFG.

[b] Insulin sensitivity measured under hyperinsulinemic–euglycemic conditions; glucose uptake below lowest quartile for background population under investigation.

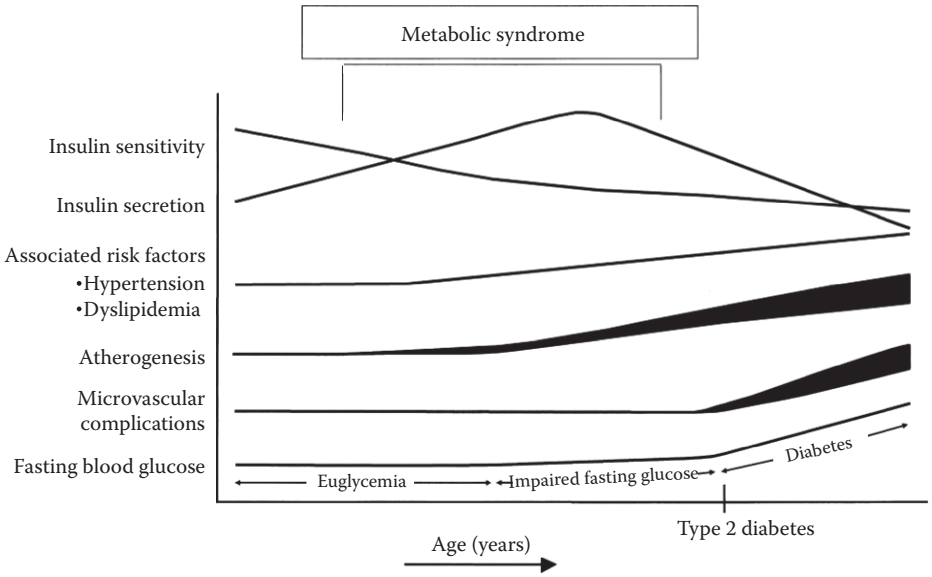

FIGURE 36.1 Schematic demonstrating the development of metabolic syndrome in the natural history of type 2 diabetes. As shown, with the development of metabolic syndrome, there is an increasing prevalence of the associated risk factors that are observed many years before the diagnosis of type 2 diabetes is made. In addition, the CVD risk is greatly accelerated during this time. Therefore, CVD risk is elevated many years prior to the diagnosis of diabetes in large part owing to the presence of metabolic syndrome. When the pancreas fails to compensate for the insulin resistance, hyperglycemia ensues, which also contributes greatly to CVD risk. (From Cefalu, W.T., Insulin resistance, *The Medical Management of Diabetes Mellitus*, Leahy, J. et al., eds., Marcel Dekker, New York, 2000, pp. 57–75. Reproduced with permission.)

presence of the syndrome may significantly contribute to the increase in CVD risk observed years prior to the diagnosis of type 2 diabetes (Figure 36.1). As early as 15 years prior to the diagnosis of type 2 diabetes, the relative risk for CVD is significantly increased and continues to increase particularly in the years closer to the diagnosis of diabetes.[20] The pathogenesis of the metabolic syndrome is complex and thus far incompletely understood.[21] To date, a single, central underlying mechanism has not been identified, although insulin resistance and central obesity have both been proposed as integral components in this process.[15,22] The most important dimension of the metabolic syndrome is its association with the risk of developing type 2 diabetes and CVD. Understanding of this complex set of risk factors is limited and warrants further research.

METABOLIC SYNDROME: MANAGEMENT OF COMPONENTS

The primary strategy for prevention and treatment of the metabolic syndrome is lifestyle modification through changes in diet and physical activity with the goal of improving risk factors for CVD.[23] The AHA's goals and recommendations for achieving diet and lifestyle change are provided in Tables 36.2 and 36.3.[24] Even in patients with established diabetes, intensive management of the metabolic syndrome will reduce the higher risk of CVD. Most individuals affected by the metabolic syndrome are overweight or obese; hence, weight reduction represents the principal goal of most intervention studies.[22,25] Weight loss is associated with significant improvement in the clinical abnormalities of the metabolic syndrome, such as blood glucose, lipid profile, and blood pressure.[26] Even a moderate weight reduction of 7% in 4 weeks can improve the metabolic syndrome despite persistence of a high BMI.[27] The greater the weight reduction, the greater the improvement in CVD risk factors. Likewise, effective lifestyle interventions should also increase insulin sensitivity and HDL-C levels, and decrease triglyceride, glucose concentrations, and blood pressure.

TABLE 36.2
AHA 2006 Diet and Lifestyle Goals for Cardiovascular Disease Risk Reduction

- Eat an overall healthy diet
- Achieve a healthy body weight (body mass index 18.5–24.9 kg/m^2)
- Achieve recommended lipid levels:
  Low-density lipoprotein cholesterol <100 mg/dL
  High-density lipoprotein cholesterol >50 mg/dL in women, >40 mg/dL in men
- Triglycerides <150 mg/dL
- Achieve a normal blood glucose level (≤100 mg/dL)
- Engage in physical activity
- Avoid use of and exposure to tobacco products

Lifestyle Modification: Glucose Intolerance (Landmark Studies)

The effectiveness of lifestyle intervention in preventing the development of type 2 diabetes in high-risk individuals has

TABLE 36.3
AHA 2006 Diet and Lifestyle Recommendations for Cardiovascular Disease Risk Reduction

- Achieve or maintain a healthy body weight (balance calorie intake and physical activity)
- Eat a diet rich in vegetables and fruits
- Select whole-grain, high-fiber foods
- Eat fish, especially oily fish, at least two times a week
- Limit saturated fat intake to <7% of energy, *trans*-fat to < 1% of energy, and cholesterol to <300 mg per day
- Minimize intake of food and drinks with added sugar
- Select and prepare foods with little or no salt
- Consume alcohol only in moderation

Source: Modified from American Heart Association Nutrition Committee, Lichtenstein, A.H. et al., *Circulation*, 114, 88, 2006.

been demonstrated in three prominent studies: China Da Qing Diabetes Prevention Study,[28] Finnish Diabetes Prevention Study,[29] and Diabetes Prevention Program (DPP).[30] These studies targeted individuals with impaired glucose tolerance (IGT). Dietary modification (i.e., reduction in energy) and increased physical activity were the main lifestyle interventions, which resulted in subjects losing weight (approximately ≥5%). The progression from IGT to type 2 diabetes over a defined period (3–6 years) of observation in the intervention group versus a comparison group was the primary outcome for the studies.[28–30]

China Da Qing Diabetes Prevention Study

The Da Qing study is a major controlled trial that examined the effects of dietary modification, weight loss, and increased physical activity in preventing diabetes.[28] In this study, 577 Chinese adults with IGT were enrolled. The subjects were randomized to one of three treatment groups (diet only, exercise only, or diet plus exercise) or control group. The dietary group was encouraged to reduce their weight if BMI was ≥25 kg/m^2 (61% of all participants) aiming at a BMI of 23 kg/m^2. The exercise group had to increase their level of leisure-time activity by at least 1–2 units (i.e., 1 unit equaled 30 min slow walking, 10 min slow running, or 5 min swimming) per day. The subjects were evaluated every 2 years for 6 years. At year 6, the diet, exercise, and diet plus exercise groups had a reduction in developing type 2 diabetes (31%, 46%, and 42%, respectively). The Da Qing Study is important because it establishes the feasibility of implementing a successful lifestyle modification program in an outpatient clinic setting.

In 2006, a follow-up Da Qing Study was conducted in the subjects with IGT to assess the long-term effect of the lifestyle interventions on type 2 diabetes and other related health conditions.[31] Compared with control participants, those in the diet plus exercise lifestyle intervention group had a 43% lower incidence of type 2 diabetes up to 14 years after the 6 year (years 1986–1992) active intervention ceased. In addition, the diabetes onset was delayed an average of 3.6 years. There were no significant differences between the intervention and control groups for CVD incidence and mortality, and all-cause mortality. These results indicate that benefits from lifestyle intervention can be maintained long term after active intervention has been stopped.

Finnish Diabetes Prevention Study

Another key clinical trial is the Finnish Diabetes Prevention Study, which examined the effects of an intensive modification program in 522 middle-aged and overweight Finnish subjects with IGT.[29] Subjects were randomized to either intensive lifestyle intervention or a control group. The lifestyle intervention goals included reduction in weight of ≥5%, total fat intake <30% of energy, saturated fat intake <10% of energy, fiber intake ≥15 g/1000 kcal, and moderate exercise for ≥30 min/day (recommended aerobic and resistance training). After the first year, there were reductions in the clinical and metabolic variables from baseline for weight, waist circumference, glucose, insulin, triglycerides, and blood pressure in the intervention group. The body weight decreased on average 4 kg (5%) in the intervention group and 1 kg (1%) in the control group. At year 2, the lifestyle intervention group continued to have a greater weight loss than the control group. After 4 years, the cumulative incidence of diabetes was 11% in the intervention group and 23% in the control group. The risk of diabetes was significantly reduced by 58% in the lifestyle group. During the overall follow-up period of 7 years (4 years of active intervention), the incidence of diabetes rates were still lower in the intervention (4.3% per 100 person-years) versus control (7.4% per 100 person-years) groups.[32] This indicated a 43% reduction in the relative risk of diabetes. Most importantly, the beneficial effects of lifestyle intervention were maintained after discontinuation of the study.[32]

Diabetes Prevention Program

The DPP is the largest study in the United States that examined the efficiency of a lifestyle modification program to prevent or delay the development of type 2 diabetes in people with IGT.[30] This multicenter trial randomized 3234 subjects with IGT to one of three interventions (1082 to placebo, 1073 to metformin, and 1079 to the intensive lifestyle intervention). The goals of the intensive lifestyle intervention were at least a 7% weight loss (low-calorie and low-fat diet) and 150 min of physical activity per week (moderate intensity, such as brisk walking). The intensive lifestyle group received individual counseling and motivational support on an effective diet, exercise, and behavior modification. After an average follow-up of 2.8 years, the lifestyle intervention group reduced the incidence of diabetes by 58% when compared to the placebo group. DPP participants who took the oral diabetes medication also reduced their incidence of diabetes (31%), but not as much as those in the lifestyle intervention group. In addition, the lifestyle intervention group had a significantly greater average weight loss (5.6 kg) than the metformin (2.1 kg) and placebo (0.1 kg) groups. Thirty-eight percent of the lifestyle participants achieved at least a 7% weight loss and 58% met the physical activity goal.

Another important highlight of the DPP study was the impact of intensive lifestyle intervention, metformin, and

placebo on components of the metabolic syndrome which are risk factors for CVD.[33] When compared to metformin and placebo groups, the lifestyle intervention group had a reduction in the prevalence of dyslipidemia, LDL phenotype B (i.e., smaller, denser, and more atherogenic LDL particle), and hypertension. In addition, the intensive lifestyle group had decreased systolic and diastolic blood pressure (DBP) and triglyceride levels, and increased HDL-C when compared to the other groups. At the third year follow-up, there was a reduced need for antihypertensive and lipid-lowering medications among subjects assigned to the intensive lifestyle intervention.[33] This finding is in agreement with the well-known favorable effect of dietary modification and exercise on the regulation of the various components of the metabolic syndrome.

Ten years following the randomization in the DPP, the DPP Outcomes Study (DPPOS) found the diabetes incidence was reduced by 34% in the lifestyle intervention group and 18% in the metformin group compared with the placebo group.[34] The DPPOS's results indicated that high-risk individuals can delay or prevent developing type 2 diabetes by losing weight through regular physical activity and a diet low in fat and calories. The DPPOS's findings support other follow-up studies that found the beneficial health results from modifying lifestyle can be maintained long term.[31,32]

Lifestyle Modification: Obesity

Diet and Weight Loss

A weight loss of at least 7% can improve the metabolic syndrome.[27] Dansinger et al. compared four popular "fad" diets (i.e., Atkins, Ornish, Weight Watchers, and Zone) in a randomized trial of 160 overweight and obese participants with known hypertension, dyslipidemia, or fasting hyperglycemia.[35] The Akins diet restricted carbohydrates, the Ornish diet restricted fat, the Weight Watchers diet restricted calories, and the Zone diet had a macronutrient balance. CVD risk factor outcome measures were assessed at baseline, 2, 6, and 12 months. At 1 year, all four diets resulted in a moderate, statistically significant effect on weight loss, as well as other CVD risk factors such as total cholesterol (except Akins and Zone diets), low-density lipoprotein cholesterol (LDL-C; except Atkins diet), HDL-C (except Ornish diet), LDL-C/HDL-C ratio, insulin (except Atkins diet), and C-reactive protein (except Zone diet) (Table 36.4). Perhaps, this moderate effect was due to poor long-term compliance with the diets. The effect of a Mediterranean-style diet on body weight was evaluated by Esposito et al.[36] Seventy-five women who had a carbohydrate intake equal to or less than 50% (low-carbohydrate diet) were compared to 115 women who had a dietary intake of carbohydrate greater than 50% of energy (high-carbohydrate diet).[36] The women were followed for up to 2 years and those who consumed a low-carbohydrate diet significantly lost more weight and had a greater change in adiponectin and triglyceride levels than the women who consumed a high-carbohydrate diet.[36] Weight loss improves CVD risk factors; however, the benefits will not remain if the weight loss is not maintained. It is important to note that behavioral weight loss clinical trials, such as Trials of Hypertension Prevention Phase II (TOHP II),[37] STOP regain,[38]and Weight Loss Maintenance (WLM),[39] have been able to demonstrate the ability to maintain weight loss. Specifically, 30 months after the initial 6 month behavioral weight loss program, the WLM Randomized Controlled Trial found that 71% of the study participants remained at or below their entry level weight.[39] This weight loss was sustained by providing monthly brief personal contact sessions.

Physical Activity and Combination of Physical Activity and Diet

Independent of dietary changes, physical activity has been shown to decrease abdominal visceral and subcutaneous fat in healthy, overweight, and obese men and women.[40–44] Joseph et al. evaluated the effects of a 6 month weight loss (250–350 kcal/day caloric restriction) and low-intensity aerobic exercise (i.e., walking) program on body composition and metabolic parameters in obese postmenopausal women with and without the metabolic syndrome.[45]After the 6 month program, they found reductions in weight, fat mass, visceral and subcutaneous abdominal tissues, triglycerides, C-reactive protein, tumor necrosis factor α (TNF-α), and glucose concentrations in women with the metabolic syndrome. Resolution of the metabolic syndrome was best predicted by reductions in fat mass. Furthermore, the HERITAGE Family Study found that after 20 weeks of supervised aerobic exercise training (cycle ergometer), 30.5% of the obese subjects no longer had metabolic syndrome.[46] There were also decreases in their waist circumference and improvement in their metabolic profile (triglycerides, HDL-C, blood pressure, and fasting plasma glucose concentrations). Another significant study conducted by Lofgren in 70 overweight, obese premenopausal women found that 10 weeks of increased low-impact physical activity (walking) and consumption of a low-energy diet lead to significant reductions in weight, BMI, waist circumference, total fat mass, trunk fat mass, and insulin and leptin levels.[47] Importantly, after the intervention, some subjects with metabolic syndrome no longer had the syndrome.

Lifestyle Modification: Hypertension

Weight Loss

A small change of 2 mm Hg in DBP can have an impact on the risk of stroke (15% reduction) and coronary heart disease (6% reduction).[48] Weight gain has been reported to be strongly associated with the development of hypertension.[49] Multiple lifestyle modification, randomized trials have found that weight loss helps to lower blood pressure.[37,50–53] Particularly, a meta-analysis of 25 lifestyle intervention trials (n = 4874 subjects) found that a calorie-restricted diet, increased physical activity, or both resulted in a weight loss of 5.1 kg, which contributed to reduction in systolic blood pressure (SBP) and DBP of 4.44 and 3.57 mm Hg.[54]

Diet

A non-weight loss hypertension clinical trial reported a meta-analysis of 36 (n = 2635) randomized trials.[55] It concluded that

*$P < 0.01$ for difference from baseline within the group.

**$P < 0.05$ for difference from baseline within the group.

a low-sodium diet reduced blood pressure more in hypertensive (−4.8/−2.5 mm Hg; SBP/DBP) than non-hypertensive (−1.9/−1.1 mm Hg) patients. Further, a landmark trial of diet-based modification of blood pressure evaluated different levels of dietary sodium (high, 3.5 g/day; intermediate, 2.3 g/day; and low, 1.2 g/day) combined with the Dietary Approaches to Stop Hypertension (DASH) diet (fruits, vegetables, low-fat dairy products) versus a standard American diet (control) in 412 adults with prehypertension or stage 1 hypertension.[56] Compared to control, the DASH diet significantly lowered blood pressure at each sodium concentration. Likewise, in the PREMIER study, the addition of the DASH diet decreased SBP in metabolic syndrome individuals with prehypertension or stage 1 hypertension.[57] The Optimal Macronutrient Intake Trial to Prevent Heart Health (OmniHeart) compared three diets (diets rich in carbohydrates, protein, and unsaturated fat) in subjects with prehypertension and hypertension.[58] Relative to the carbohydrate group, the protein and fat diet groups exhibited a greater decrease in SBP and DBP, total cholesterol, and triglycerides despite no difference in weight loss among the three groups.

Physical Activity and Combination of Physical Activity and Diet

Like dietary treatment, increasing physical activity can also lower blood pressure. The beneficial effect of physical activity on blood pressure has been well documented.[59–61] Hypertension has a disproportionate effect on African Americans when compared to other ethnic groups. However, Rigsby found that 12 weeks of aerobic training (walking) resulted in improved control of blood pressure in African Americans.[62] Whelton et al. conducted a meta-analysis of 54 randomized clinical trials (n = 2419 subjects) that implemented aerobic exercises to treat blood pressure.[63] The results demonstrated a significant reduction in SBP and DBP (−3.84 and −2.58 mm Hg) in normotensive or hypertensive people who were normal weight or overweight. This blood pressure reduction was similar in trials that did not observe weight loss, thus suggesting that the effects of aerobic exercise on blood pressure may be independent of the change in body weight. A more profound reduction of SBP (14.83 mm Hg) and DBP (5.63 mm Hg) has been observed in a recent study among severe obese subjects after a 12-month moderate-intensity physical activity program (brisk walking) along with dietary changes.[64] In addition, physical activity (biking, walking, or jogging) along with dietary modifications has been shown to be associated with significantly greater reductions in both SBP (16.1 mm Hg) and DBP (9.9 mm Hg) when compared with only dietary adjustments among prehypertensive or stage 1 hypertensive patients.[65]

Lifestyle Modification: Lipids, and Inflammatory and Prothrombotic Markers

Diet

Low-carbohydrate diets have resulted in lower triglyceride concentrations and higher HDL-C levels than conventional

diets and the opposite effect has been documented with a high-carbohydrate diet.[66–70] Lipid effects with utilization of the DASH diet have yielded mixed results. The DASH diet has been reported to lower total cholesterol, LDL-C, and HDL-C with no effect on triglycerides and yet another randomized controlled trial resulted in higher HDL-C and lower triglycerides.[71,72] Besides the DASH diet, soy protein and the Mediterranean diet have also played a role in improving the lipid and inflammatory marker profiles. An increased consumption of soy protein (~47 g/day) has been shown to reduce total cholesterol (9.3%), LDL-C (12.9%), and triglycerides (10.5%) and increase HDL-C (2.4%).[73] A randomized trial using the Mediterranean-style diet or a regular control diet in 180 adults with metabolic syndrome was conducted by Esposito et al.[74] After 2 years, the intervention group had a lower body weight, highly sensitivity C-reactive protein, interleukin-6 (IL-6), IL-7, IL-18, and insulin resistance versus the control group. Furthermore, the intervention group had an improved endothelial function score.

Physical Activity and Combination of Physical Activity and Diet

Evaluation of the effect of daily aerobic exercise in combination with a diet low in fat and cholesterol while high in complex unrefined carbohydrates and fiber was reported by Beard et al.[75] This plan induced a reduction in LDL-C (20%), total cholesterol (20%), HDL-C (17%), triglycerides (26%), blood glucose (16%), and body weight (4%). Regarding HDL-C levels, a meta-analysis conducted by Leon and Sanchez found that ≥12 weeks of aerobic exercise increased HDL-C.[76] Reports by Ford and King et al. showed that after adjusting for several potential confounders, the time devoted to physical activity was inversely associated with C-reactive protein, plasma fibrinogen concentrations, and white blood cell count in adult participants in NHANES III (1988–1994).[77,78] Likewise, Abramson and Vaccarino reported that physical activity was associated with a lower probability of having elevated C-reactive protein levels, white blood cell count, and fibrinogen levels among healthy U.S. adults aged 40 years and older, independent of several confounding factors.[79]

Lifestyle Modification: Resistance Training

While there is considerable evidence on the effects of aerobic physical activity or training on individual CVD risk factors and metabolic syndrome as discussed earlier, less is known about the health effects of resistance training. Resistance training increases muscular strength and fat-free mass, and decreases fat mass and intra-abdominal adipose tissue.[80–82] In addition, resistance training can increase insulin sensitivity and decrease blood pressure, total cholesterol, LDL-C, and triglycerides in obese, hypertensive, and type 2 diabetic subjects.[83–87] Interestingly, studies have found that men with more muscular strength are less likely to develop the metabolic syndrome.[88,89]

ALTERNATIVE STRATEGIES FOR MANAGING METABOLIC SYNDROME

Smoking Cessation

Cigarette smoking is listed as one of the Framingham CVD risk factors.[90] Long-term prospective studies have clearly demonstrated the significant mortality risk reduction associated with smoking cessation.[91–94] Specifically, Critchley and Capewell conducted a meta-analysis of 20 smoking cessation studies that included 12,603 smokers with coronary heart disease at baseline. There was a 36% relative risk reduction of mortality in those patients with coronary heart disease who quit smoking versus those who continued to smoke.[91] Likewise, Gerber et al. have also shown that subjects with CVD improved their survival with smoking cessation. In this study, 1521 patients (≤65 years) with a first acute myocardial infarction were followed for a mean of 13.2 years. Relative to the persistent smokers, the odds of dying were lower for the never smokers (hazard ratio: 0.57), pre-acute myocardial infarction quitters (hazard ratio: 0.50), and post-acute myocardial infarction quitters (hazard ratio: 0.63). In addition, persistent smokers who reduced their number of daily cigarettes had an 18% decline in mortality risk for every five cigarettes decreased after being diagnosed with acute myocardial infarction.[94]

Botanicals

It is estimated that ~38% of adults use complementary and alternative medicine in pursuit of achieving good health and well-being.[95] Specifically, the most commonly used complementary and alternative medicine therapies are non-vitamin, non-mineral, and natural products (especially derived from botanicals) because they are perceived to be less toxic with fewer side effects than synthetic products.[95] Botanicals have been proposed as therapeutic agents for the treatment or prevention of the metabolic syndrome. These plant-derived therapeutics often contain many biologically active compounds with numerous mechanisms of action that are postulated to augment each other's activity synergistically, thus providing a greater benefit than a single chemical compound. Graf et al. reviewed a number of botanicals that have been commonly associated with treatment of the metabolic syndrome.[96] These botanicals consisted of cinnamon, Russian tarragon, bitter melon, fenugreek, blueberries, grape seed, hawthorn, and hoodia. These plant-derived therapeutics have been shown to exhibit antidiabetic, antihypertensive, antiobesity, and cholesterol-lowering effects in several reports (Table 36.5).[96] Specifically, Stull et al. found that 6 weeks of supplementation with blueberry smoothies improved insulin sensitivity when compared to consuming a placebo smoothie in obese and insulin-resistant (prediabetes) adults.[97] However, specific and precise validation for each botanical in prevention and treatment of the metabolic syndrome and the associated risk factors is still lacking and recommendations for general use for this purpose cannot be determined at this time.

Pharmaceutical

Lifestyle interventions are well-established strategies that improve the metabolic syndrome. However, it should be noted that although lifestyle changes can provide many benefits for the management of the syndrome, sometimes these changes are difficult to implement and maintain. When lifestyle modifications are unsuccessful, pharmacological interventions that are capable of reducing blood pressure, lipids, and glucose concentrations, weight, and other abnormalities related to the metabolic syndrome become pertinent. Therefore, pharmaceutical treatments including metformin and thiazolidinediones are able to increase insulin sensitivity.[98] A single or combination therapy using a statin and/or a fibrate can reduce atherogenic dyslipidemia and also angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers can effectively treat hypertension.[99,100] In addition, pharmacotherapy such as sibutramine, rimonabant, and orlistat have been documented to have weight loss and lipid-lowering effects in an overweight and obese population.[101–105] A more aggressive therapy for weight loss is bariatric surgery which includes gastric banding, gastric bypass, gastroplasty, and biliopancreatic diversion or duodenal switch.[106]

SUMMARY

Lifestyle modification plays a pivotal role in managing the metabolic syndrome. The syndrome is a complex condition that involves treatment of multiple CVD risk factors. The evidence briefly reviewed in this chapter demonstrates the efficacy of modifying diet and increasing physical activity to reduce CVD risk factors, primarily mediated through weight reduction. Incorporating dietary and physical activity changes to induce modest weight loss exerts beneficial effects on the CVD risk factors of the metabolic syndrome. However, the current challenge is the long-term maintenance of the lifestyle changes because only long-term changes can reduce the morbidity and mortality of the metabolic syndrome. In order to achieve successful interventions, physicians and health care professionals must be willing to incorporate lifestyle change as part of their medical practice and encourage their patients to adapt those lifestyle changes to prevent or treat the metabolic syndrome.

INTRODUCTION

No longer is there any doubt that human behavior is a factor in many health-related issues that mankind must endure. It is clear that smoking, diet, and physical activity all have a causal relationship to heart disease, still the number one cause of death in the United States. For more than 40 years, evidence has been accumulating that cancer, the number two cause of death in this country (soon to surpass heart disease in that regard), also has those same lifestyle factors as etiological factors for many diseases classified as "cancer." With cancer accounting for more than one-half million Americans dying each year, researchers have intensified efforts to identify which cancers are significantly influenced by lifestyle issues and what other controllable behaviors are responsible for adding to the risk of one succumbing to cancer.

Since diet and physical activity have such a bearing on one's weight, the accumulation of excess body fat is one lifestyle-related factor that has become of major significance in the development of certain cancers. In fact, it is predicted that as tobacco control measures continue to reduce the overall use of tobacco products that obesity will soon become the number one etiologic factor for most cancers.

In this chapter, five of the most common cancers which in one or another way are impacted by lifestyle are described and certain interventions that are either explicit or inferred that can alter either the incidence of the cancer or in some instances the severity or types of specific cancer are discussed.

In order of the magnitude of deaths in the United States, the following cancers are presented: lung, colon and rectal, breast, prostate, and skin (with special emphasis on malignant melanoma).

LUNG CANCER

Lung cancer is the leading cause of cancer-related death in the United States, comprising 31% of cancer deaths in men and 25% of cancer deaths in women. An estimated 215,020 new cases of lung cancer will have been diagnosed in this country in 2008 and 161,840 deaths will be attributed to lung cancer in the year 2008.[1] Approximately 85%–90% of lung cancers are related to tobacco use.[1] Furthermore, approximately half of all patients with lung cancer have quit smoking before their diagnosis.

Worldwide, nearly a billion men are cigarette smokers, including ~35% of men in developed countries and 50% of men in developing countries. Worldwide, ~250 million women are smokers, including 22% of women in developed countries and 9% of women in developing countries. Currently, in the United States ~25% of the adult population is smokers, or ~46 million adults.

There has been significant interest in evaluating risk of lung cancer in both smokers and nonsmokers. Approximately 1 in 10 lifelong smokers will develop lung cancer. The risk of lung cancer increases with duration of smoking and with the number of cigarettes smoked daily.?

Approximately 1.6% of lung cancer cases are attributable to secondhand smoke. Authors have found a relative risk of 1.14 to 5.20 in persons who never smoked but who resided with a smoker.[2,3] Furthermore, exposure to secondhand smoke in childhood has been found to carry a relative risk of lung cancer in adulthood of 2.6.[4]

A role for genetic susceptibility for the development of lung cancer includes data that show that only ~10% of smokers will develop lung cancer. Additionally, studies demonstrate clustering of lung cancer within certain families.

Li and Hemminki[5] reported a germ-line epidermal growth factor T790M sequence variation in a family with multiple cases of lung cancer. Bailey-Wilson et al.[6] reported the results of a genome-wide linkage study of 52 families demonstrated a new major susceptibility locus influencing lung cancer risk at 6q23-25p. Hung et al.[7] reported a locus at chromosome 15q25 associated with lung cancer. In this analysis of 3502 lung cancer case patients and 7377 controls, the risk of lung cancer was 30% higher for people with one copy of the marker at chromosome 15q25 and 70%–80% higher for persons with two copies of the marker. The region where the marker resides contains three genes that encode subunits of the nicotine acetylcholine receptor.

The field of molecular epidemiology focuses on evaluation of susceptibility to environmental carcinogens. Within this field, a number of investigators have evaluated the role of genetic variability in susceptibility to the carcinogenic effects of nicotine. One such gene is the *CYP2D6*, a gene in the cytochrome P450 family which plays an important role in the metabolism of many common drugs and activates tobacco smoke–derived nitrosamine.

Studies by Spitz et al. show that 90% of the U.S. population are extensive metabolizers, increasing their risk for lung cancer. This is related to the enzyme's high risk of activating tobacco carcinogens. The remaining 10% of the population are poor metabolizers, with a lower associated risk of lung cancer due to a lower ability to activate tobacco carcinogens.

Another gene that may affect genetic susceptibility to lung cancer is the glutathione *GSTM1* gene.[8] This gene belongs to a large family of genes that facilitate the detoxification of a variety of carcinogens, including polycyclic aromatic hydrocarbons present in tobacco smoke.

Individuals who have the GSTM1 enzyme are able to detoxify carcinogens using this metabolic pathway, while those individuals lacking this enzyme are less able to detoxify carcinogens and therefore have a higher lung cancer risk.

Diets that are rich in fruits and vegetables have been suggested to have a protective effect against the development of lung cancer, possibly due to their rich antioxidant content.[9,10] Researchers have hypothesized that micronutrients protect against oxidative damage to DNA, thereby conferring a protective effect against cancer.[11] Early studies by Bjelke suggested a protective effect of vitamin A against lung cancer.[12] However, randomized studies evaluating the effects of β-carotene and retinoids (vitamin A derivatives) have not demonstrated protective effects against lung cancer.[13–15]

At least 21 studies have demonstrated a protective effect of exercise against lung cancer risk.

A Norwegian study[16] demonstrated a 25%–29% reduction in the risk of lung cancer in men who engaged in moderate exercise (at least 4 h/week) compared to sedentary men; this effect was demonstrated after controlling for tobacco use. Another study[17] reported results from the Harvard Alumni Health Study which followed 13,905 men for up to 16 years. After accounting for tobacco use, men who engaged in light, moderate, and strenuous amounts of exercise on a regular basis were shown to have, respectively, a 13%, 24%, and 39% reduction in lung cancer risk.[17] It should be noted that many of these studies are cohort studies conducted in Caucasian populations of higher socioeconomic status.

Smoking prevention and cessation are of critical importance in the prevention of lung cancer and in improving outcomes of lung cancer patients. Evidence from the Copenhagen Health study demonstrated that smoking cessation reduces the risk of development of lung cancer by 50%. Primary prevention of tobacco use has also been demonstrated to be a successful strategy in reducing lung cancer incidence rates in states such as California which have strong antitobacco legislation.

Data also demonstrate that smoking cessation is associated with improved survival after a diagnosis of lung cancer and improved treatment efficacy.[18,19] Gritz et al. reported that in a population of 840 patients with diagnosis of stage I non-small cell lung cancer, 40% of patients who were smokers at the time of diagnosis subsequently quit smoking.[20]

Ongoing tobacco use can adversely affect outcomes of surgery, radiation, and chemotherapy.[18,19] The incidence of postoperative complications is increased in smokers; this rate is decreased in patients who have quit smoking prior to surgery.[18] Continued smoking may also decrease the efficacy of chemotherapy for lung cancer. There is evidence that nicotine increases the metabolism of multiple drugs via the induction of hepatic enzymes which may decrease the efficacy of certain chemotherapy agents.[21] Smoking cessation at the time of diagnosis furthermore decreases the rate of subsequent lung cancers.[22,23]

COLON AND RECTAL CANCER

The concepts of preventing colon cancer and upper gastrointestinal malignancies through lifestyle changes have evolved over time, with inconsistent recommendations. The data obtained were derived from the multitudes of prospective and retrospective trials, reanalyzed in a meta-analytical fashion.

Due to its high incidence, and its impact on human morbidity, mortality, and health dollar expenditure,[24] colon cancer prevention ranks high on the importance list of cancers to prevent. In a population, individuals also have a vested interest in preventing colon cancer due to its mostly sporadic incidence.

Dietary habits are known to contribute to or improve the risk of colon cancer[25–27]; thus, it would make sense to modify dietary behavior in order to reduce risk. In doing so, researchers have looked at intake of animal fat, red meat, fruits, vegetables, and fiber, as some of the many dietary factors may influence the risk of colon cancer.

Among the studies that have looked at the dietary content of red meat and the risk of colon cancer, a large European population study[28] looked at intake of red meat, poultry, and fish, and prospectively followed the incidence of cancer. There was an increased risk of colon cancer in the group that consumed more than 180 g/day of red meat compared to those who consumed less than 20 g/day (hazard ratio of 1.35). Interestingly, the hazard ratio for high fish intake

was 0.80, and the risk for poultry intake was not significantly different than that of the average population. In another case–control study,[29] red meat intake was associated with a near 85% increase in colorectal cancer in subjects who ate red meat seven times per week compared to three times per week. Several other studies,[30–32] at least one of which was a prospective,[33] have corroborated the relationship between red meat intake and colon cancer.

It is not clear whether the risk is due to the heme, animal fat, or carcinogens generated during the meat preparation.[34,35] It may very well be a combination of all three. To date, however, no studies have explored the impact of changing red meat content on colon cancer incidence. It is also unclear if the impact occurs at a young age or later in life.

Dietary fiber and the intake of fruits and vegetables have also been looked at extensively. No conclusive benefit can be drawn from the available data. A pooled analysis of 13 prospective cohort studies showed no advantage to increased dietary fiber intake when other dietary risk factors were taken into consideration.[36] Several other studies seem to corroborate these findings. Some smaller studies have shown a protective impact against colon cancer in people who consume more fruits. One large European study showed a reduction of the incidence of colon cancer when comparing the upper and lower quintile of fiber intake.[37] This benefit was limited to colon cancer but not to rectal cancer. Most of the studies evaluating the impact of dietary fiber on the incidence of adenomatous polyps showed no significant reduction in polyp formation.[38–40] There was, however, no disadvantage to the consumption of fruits, vegetables, and other fiber-rich foods on the incidence of colon cancer.

Dietary supplementation as a means of disease prevention is a widely used practice among the public, mainly due to a perceived benefit carried down over generations of folklore. Solid data behind such practices are nearly absent, more so in the cancer prevention arena. In order to make evidence-based recommendations, several studies, both retrospective and prospective, have been conducted looking at the effect of such supplements on the incidence of cancer. Calcium intake in the form of dairy products has been shown to reduce the risk of colon cancer.[40,41] But high calcium levels may be associated with increased risk of prostate cancer.[42–44] The benefit-to-risk ratio has been postulated to be optimal at lower rather than higher doses, but this is subject to dispute. It may be appropriate to take into consideration the individuals risk for either cancer when deciding on calcium supplementation. The benefit from calcium occurs at high doses that are usually unattainable with regular consumption of dairy products and thus require high dose supplements.

Vitamin D may have an effect on colonic mucosal cells,[45,46] and in turn a protective effect against colon cancer.[47,48] The data are inconclusive and in some studies no benefit was demonstrated except in very high dose supplementation.[49] It is important to note that the beneficial effect of sun exposure to improve vitamin D levels can be negated by the increased risk of skin cancer.[50]

Antioxidants have a very solid rational as protective agents against the mutagenic effect of free radicals, which can affect malignant transformation[51,52] although some investigators theorize that reactive oxygen species are part of the cellular signaling mechanisms, and thus, loss of such species may also lead to malignant transformation.[53] The evaluation of several antioxidants, including omega-3 fatty acids, vitamin C, and vitamin E did not conclusively demonstrate a protective effect against several cancers including colorectal cancers.[54,55] It is also not clear if supplemental multivitamins in general offer any benefit over a well-balanced diet.[56]

Moderate to intense exercise seems to have a favorable impact on the risk of developing colon cancer. In one systematic review of published literature,[57] a definite inverse relation was observed between increased physical activity and the risk of colon cancer. A near 50% reduction in incidence of colon cancer was observed in those undertaking the highest level of activity. This benefit was maintained even with multivariate analysis accounting for other variables such as diet and weight.[58] The benefit was evident in colon cancer more so than rectal cancer.[59,60]

In a recent study presented by McClain at the AACR 7th Annual International Conference on Frontiers in Cancer Prevention,[61] the investigators found that, at least in women, the beneficial impact of exercise was negated by the lack of sufficient sleep. In that trial, around 6000 women were queried regarding their exercise and rest patterns. Investigators assessed the physical activity energy expenditure (PAEE) and the duration of sleep. During a 10 year follow-up, the subjects were monitored for the incidence of breast and colon cancer. Of the 604 women with either breast or colon cancer, those who slept less than 7 h/day had a higher incidence of breast and colon cancer, negating most of the beneficial effect derived from vigorous physical activity.

Exercise was also found to prevent relapse of resected stage 3 colon cancer. This was found upon analysis of the data from a large randomized trial looking at two different chemotherapy regimens administered in the adjuvant setting. The benefit of exercise was found to be independent of sex, body mass index, number of positive lymph nodes, age, baseline performance status, or chemotherapy received.[62] The mechanism by which physical activity and rest affect a change in malignant transformation is not clear. The effect of exercise on hormonal, immune, and weight changes may impact the inflammatory and proliferative environment that could lead to abnormal and eventually malignant cell growth.

Chemoprevention, in the form of nonsteroidal anti-inflammatory agents (NSAIDs), and more specifically aspirin have been shown to reduce the incidence of colonic polyps and the risk of colon cancer.[63–65] In several large randomized and observational trials, there was a benefit to using aspirin; however, the data were not clear as to which dose was most beneficial. Some of the data implied a dose–response effect with higher doses resulting in less incidence of polyps and malignant lesions.[66] The duration of therapy was also very important. Most of the benefit became evident after 10 years of therapy. Some population-based

observational trials were analyzed after 5 years of NSAID therapy and were found to be negative.[63]

Due to the potential complications of NSAID therapy, including hemorrhagic gastritis, increased risk of bleeding, and renal complications, caution should be exercised when utilizing these agents to prevent colon cancer and should be limited to very specific high-risk groups such as patients with familial adenomatous polyposis (FAP). When evaluating the available data, the U.S. Preventative Services Task Force (USPSTF) concluded that the risks of using NSAIDs at the dose and for the durations required to prevent colon cancer outweigh their benefits and thus should not be used in the general population.[67]

BREAST CANCER

In 2008, about 180,000 new cases of breast cancer were diagnosed in the United States, and 40,000 women died due to advanced breast cancer. Five-year survival for early stage breast cancer is 98% and drops to 89% for all stages together.[68] There are an estimated 2 million breast cancer survivors in the United States today and thus the implications of lifestyle modifications are enormous.

Though diet and lifestyle have been associated and often implicated in the risk of developing breast cancer, there is very little known about its effect on breast cancer survival.

Understanding the consequences of diet and lifestyle on breast cancer survival is extremely important to breast cancer survivors who want to make appropriate choices to improve not only their lifespan but also the quality of life.

There are only two published studies that have looked at the relationship between diet after breast cancer diagnosis and long-term survival. Although the results are promising, it is too early to tell if these results will be confirmed over time. The Nurses Health Study[69] examined diet after breast cancer diagnosis and its impact on survival. In this study, 1982 women with breast cancer were followed for an average of 13 years. Of that total, 1237 of the women did not develop metastatic disease. Women in this group who ate the largest amounts of poultry, total protein, and omega-3 fatty acids had a statistically significant lower risk of death compared to women who ate the least amounts of these foods and nutrients. Women who ate more fiber, fish, and vegetables also had a lower risk of death than women who ate less of these. The association of diet with survival was different for the 745 women whose did develop metastasis. Women who ate the largest amounts of dairy products and had high levels of calcium in their diets had a significantly lower risk of death. In addition, women with metastasized tumors who ate more protein had a lower risk of death. There are no published studies that have examined the effect of eating soy products on breast cancer survival.[70,71] Studies of women eating soy products daily have shown that soy-containing foods can act like estrogen and can cause cell proliferation in the breast. This could have a negative effect on breast cancer survival. Phytoestrogens in soy have also been reported to both oppose and complement the effects of tamoxifen in breast cancer cells. More study is needed in this area. At this time, it is a good idea for breast cancer survivors to avoid soy supplements and use soy-containing foods in moderation.

Some foods or nutrients were associated with as much as a 50% decrease in the risk of death. If these results prove to be correct, they could be quite important, as diet after diagnosis is something over which cancer survivors have control. It is important to recognize that these studies report associations and are not to be considered as recommendations.

The foods may just be representative of the women's lifestyle in general. Poultry products, like chicken and turkey, are often viewed as healthier choices than red meat. Women who ate more poultry may also have been making other efforts toward a healthier lifestyle.

Likewise, eating more hydrogenated oils may have been something done by the women who ate more processed baked foods (where these oils are found) and who were less concerned with healthy lifestyles.

Currently, it is unclear if specific diets before diagnosis affect breast cancer survival. Twelve studies have examined the effect of diet before breast cancer diagnosis on various aspects of survival. Four studies reported no association of survival with dietary fat consumption before diagnosis, but five studies reported that eating high levels of dietary fat was associated with a statistically significant increase in the risk of death. Some of these studies also examined the intake of vitamins A, C, and E from dietary food, not supplements, and showed differing results. Thus, no conclusions regarding the use of vitamins can be made at this time.

Although obesity at the time of diagnosis has been associated with decreased survival, it is unclear if weight gain after breast cancer diagnosis affects survival.[72,73] Weight gain is common in breast cancer patients after diagnosis and in 50%–96% of all early stage breast cancer patients receiving chemotherapy.[74] Two studies did not show any association between weight gain and an increased risk of cancer recurrence, but two other studies did report a possible association. Several studies have reported that weight gain is psychologically troubling and reduces the quality of life of breast cancer patients and thus negatively impacts long-term outcome.[73,74]

The effect of low body weight at the time of diagnosis and weight loss following diagnosis has been studied less often. Three studies have reported poorer survival for women of low body weight at the time of diagnosis; two of these reports saw this effect only in women with advanced breast cancer. One study reported that the loss of 11 or more pounds in women of any body size was associated with poor survival.

The effect of exercise on breast cancer survival is not known.[75,76] It may improve the quality of life of breast cancer survivors but no studies have directly examined how exercise after cancer diagnosis affects survival. An Australian study that followed 412 women with breast cancer for an average of 7 years showed no association of recreational exercise before diagnosis and survival.

Increasing physical activity, even if started later in life, reduces overall risk of developing breast cancer by 20% across women of all risk categories, including those

considered to be high risk. Consistent physical activity is more important than how strenuous an activity is. Inducing a "negative energy balance"—where less energy is taken in than is spent—by eating a low-calorie diet or increasing exercise can decrease postmenopausal risk of breast cancer associated with obesity.

Several studies have reported associations between exercise and improvements in the quality of life of breast cancer survivors, including improved mood, self-esteem, and sleep patterns and less nausea and fatigue.[77] These studies differed greatly in their study design, so comparisons between the studies are difficult. The results, although currently early, show promise. A reasonable suggestion for exercise would be that recommended by the U.S. Surgeon General, who recommends that everyone participate in moderate physical activity for at least 30 min 5 days a week.

Although smoking has been associated with numerous health problems, its effect on breast cancer survival is, as yet, not resolved.[78] Well-conducted studies have demonstrated an association between smoking and an increase in the risk of death but others show no association with the risk of death from breast cancer. Smokers may be at increased risk for the spread of cancer.[79] Two studies have reported an increase in the metastasis of tumors from the breast to the lung in smokers. Survival of women who have stopped smoking has been examined in one study and found to be similar to that of women who never smoked.

Drinking alcoholic beverages is considered to be a risk factor for getting breast cancer. However, most but not all studies have reported no association between drinking alcoholic beverages and breast cancer survival.[80]

It currently appears that group psychological therapy does not affect the survival of women with metastatic breast cancer. A recent, well-designed study, along with two other studies, disagrees with an early study that found that group therapy increased the survival of women with metastatic cancer.[81] Studies examining group psychological therapy for patients with other types of cancer have also reported mixed results. Yet, the support of fellow survivors and the encouragement to express concerns and feelings during group psychological therapy have been shown to have positive effects on breast cancer survivors' quality of life.

Alternative medical practices have not been studied sufficiently to determine whether they can affect breast cancer survival.[82,83] Few epidemiological studies or clinical trials have examined alternative therapies for breast cancer survivors. Over 30% of the women diagnosed with breast cancer report using alternative treatments including relaxation methods and spiritual practices; alternative medicines such as megavitamins, herbal medicines, and homeopathy; and healing therapies such as massage, chiropractic, acupuncture, and energy healing. More study is needed of these practices. To this end, the National Institutes of Health has established a National Center for Complementary and Alternative Medicine (http://nccam.nih.gov/) to fund and encourage the study of alternative medicine in various areas including cancer treatment.

The preliminary studies looking at diet and lifestyle after breast cancer diagnosis are encouraging and support the concept that diet and lifestyle choices can make a difference for breast cancer survival, as well as help these women feel better. There is limited evidence on specific diet and lifestyle behaviors that women can use to increase survival, but living a healthy lifestyle is a sensible choice for breast cancer survivors.

PROSTATE CANCER

The effects of obesity, energy expenditure, and specific nutrients are being vigorously studied in both the development and the outcomes of prostate cancer. In fact, countries with historically lower incidences of prostate cancer are now beginning to recognize increases in its diagnosis as their lifestyles become more "Westernized."[84]

With one in three adults in the United States being considered obese,[85] it is clear this epidemic could have a very marked effect in the way we think about prostate cancer. Even though obesity by itself is not clearly associated with an increased risk of developing prostate cancer, it has been linked to the diagnosis of more advanced prostate cancer, higher risk of dying of prostate cancer, and progression after prostatectomy.[86–88] The mechanism for this is not clear, but difficulties in examining the prostate, inaccurate nodal staging during prostatectomy, lower PSA values in obese patients, a low testosterone–high estradiol environment, leptin, adiponectin, and insulin-like growth factor have all been implicated as potential contributors to these findings.

Obese patients have increased caloric and fat intake. The increased intake of calories has been prospectively linked to an increased prostate cancer mortality.[89] Conversely, increased physical activity does not appear to have either a positive or a negative correlation.[90] Preadulthood height and obesity may indeed be associated with the previously mentioned risk in mortality.[91]

This implies that efforts to control the effect of obesity on cancer mortality should start during childhood and adolescence.

The U.S. diet is rich in linoleic acid, a fatty acid commonly found in corn oil. In vitro studies show that androgen-sensitive prostate cancer cell lines exhibit increased growth when exposed to this ubiquitous fatty acid.[92] Again, there is no apparent relationship to fat intake in terms of prostate cancer incidence[93] yet one study linked the consumption of saturated fat to increased relapse rates after prostatectomy.[94]

The Western diet, in addition to being rich in calories and saturated fat, may lack certain specific nutrients. Particular attention has been paid to those that may have antioxidant properties, under the hypothesis that excessive oxidative damage to nucleic acids is likely to lead to carcinogenesis and cancer progression.

Particular attention has been paid to lycopene, an antioxidant commonly found in tomatoes.

Most of the U.S. intake of lycopene is derived from tomato sauce consumption. Results from a 2004 meta-analysis initially

showed a possible decrease in incidence of 10%–20%.[95] However, a recent analysis from the Prostate, Lung, Colorectal and Ovarian Screening trial shows no relationship between this nutrient and prostate cancer incidence. Moreover, consumption of β-carotenoids, a related group of antioxidants, was associated with an increased risk of aggressive prostate cancer in the same study.[96]

Selenium has received much attention as well. This stems from an initial trial of selenium supplementation in skin cancer patients residing in areas with low dietary selenium. As a secondary endpoint, it was noted that there were fewer prostate cancers in subjects assigned to selenium.[97,98] The possible preventive role of selenium has been recently investigated by the National Cancer Institute in the SELECT trial, where 35,533 subjects were given placebo, selenium, and/or vitamin E for up to 7 years. After a negative planned second interim analysis, the Data and Safety Monitoring Committee recommended the discontinuation of these supplements.[99]

High milk consumption has been associated with increased risk of prostate cancer. In order to test whether this was related to calcium intake and vitamin D levels, the Health Professionals Follow-up Study assessed 47,750 males. The results showed that high calcium intakes of more than 1500 mg/day were associated with the development of high-grade prostate cancer, but not of low-grade, organ-confined, prostate cancer. In addition, those patients with an intake of more than 1500 mg/day did indeed have lower levels of circulating vitamin D. This led to the hypothesis that lower levels of vitamin D may impair the differentiation of prostate cancer cells toward a less aggressive, more confined cancer.[100]

With respect to diet, review of the published evidence does not support the viewpoint that the development of prostate cancer is the direct result of increased caloric intake, fat intake, or nutritional deficiencies. However, the studies indicate that our dietary habits may modify the biological behavior of preexistent foci of less aggressive prostate cancers. The implications are that this impact will be noted mostly in terms of detection of aggressive cancers, rates of relapse after curative treatment, and ultimately, in the risk of death.

At this point, it is impossible to make evidence-based recommendations toward the ingestion or avoidance of any specific nutrient. But based on the information presented on caloric and fat intake, it would appear wise to support a dietary regimen that would avoid obesity and excess fat as early as possible in one's life.

SKIN CANCERS

Worldwide, the incidence of melanoma is increasing at a rate faster than any other malignancy.

One in five Americans will develop skin cancer during their lifetime. An estimated 1 in 63 Americans will develop melanoma and this risk is 1 in 33 if in situ melanomas are included.[101]

Melanoma incidence is increasing across all age groups. It is now the second most common cancer in women in their 20s and third most common cancer in men in their 20s.[101] More than 1 million new skin cancers will be diagnosed this year in the United States, but actual numbers are likely higher and underreported. It is estimated that $500 million is spent annually in the treatment of skin cancers in the United States.[101]

Ultraviolet (UV) radiation has been demonstrated to be both mutagenic and carcinogenic in in vitro and in vivo studies. Its damaging effects on molecules and cellular structures have been well demonstrated. Skin cancer develops because DNA is altered after exposure to UV radiation.[102] UVB radiation has a long-accepted role in the development of skin cancers. UVB radiation, by virtue of its short wavelength (<320 nm), is absorbed throughout the epidermis, including proteins and DNA.[103] The carcinogenic effects of UVB radiation occur through direct absorption of photons, but it is also known that UVB radiation damages proteins and cell membranes, in addition to generating oxidative stress.[104,105]

The role of UVA radiation in the development of malignancy and immunosuppression has recently become more clear.[105,106] UVA radiation, with its longer wavelength (320–400 nm) more easily penetrates the skin, even reaching the basal layer of the epidermis, including dermal fibroblasts. The integrity of the genetic code is maintained by DNA repair mechanisms, which allow damaged bases or altered gene sequences to be eliminated and replaced via base and nucleotide excision repair pathways.[103] If DNA damage gets to a certain point, and repair enzymes are saturated, and signaling pathways can be stimulated; hyperproliferation of abnormal cells and subsequent tumor development may occur.[103,107,108]

The more common skin cancers, basal cell carcinoma (BCC) and squamous cell carcinoma (SCC), most commonly occur on sun-exposed areas of skin. The risk is highest among those who burn easily.[109–111] Skin cancer risk is highest among those with fair skin. These individuals are more sensitive to exposure at wavelengths 290–320 nm.[112]

The incidence of skin cancer worldwide is highest in those areas with above average annual UV radiation.[113] Mortality rates from melanoma in the United States and Canada have also been shown to directly correlate with ambient UV exposure, and this correlation is even higher when ambient UVA (320–400 nm) radiation is included.[114,115]

There is a direct correlation with BCC and SCC incidence and latitude, as demonstrated by Scotto et al. There is a strong inverse correlation between latitude and incidence of BCC and SCC for both men and women.[116] Long-term chronic UV exposure seems to increase the risk of nonmelanoma skin cancer, where the opposite (acute intermittent UV exposure) increases the risk of melanoma.[117] The incidence of melanoma is also higher in high-altitude regions, possibly related to higher UV fluencies (measured in J/cm^2) in these areas.[118]

A complex study by Fears et al. demonstrated that when lifetime residential history was coupled with levels of mid-range UV radiation (UVB flux) to provide a measure of individual exposure to sunlight, a 10% increase in annual UVB flux was associated with a 19% increased risk of melanoma. Even in women who could tan easily, a 10% increase in

hours outdoors was associated with 5.8% increase in melanoma incidence.[119] The influence of sun exposure in early life appears to be greater than exposure at a later age. Migration studies of people born in Australia demonstrate an increased risk of skin cancer compared to native Northern Europeans who migrated to Australia at age 10 years or older.[120] Nevertheless, UV exposure at later age also contributes to the risk of developing skin cancer. In patients before and after age 15 years, investigators demonstrated a similar upward gradient of melanoma related to the frequency of sunburns. Importantly, more than five sunburns doubled the melanoma risk, regardless of age at which the sunburns occurred.[121]

In areas of the skin consistently exposed to UV, such as the head and neck, the density of skin cancer is highest. In rarely exposed areas such as the scalp and buttocks, skin cancer development is rare.[122] In women, melanoma is more common on the lower extremities, where there tends to be more UV exposure, than in men.[123] Individuals with higher number of nevi (personal nevus count) have a higher risk of melanoma.[124]

Protection from UV exposure can lower subsequent skin cancer risk.[125] Sunscreens offering broader spectrum protect skin better from UV-induced neoplasia. In fact, daily use of broad-spectrum sunscreens significantly reduces UV-induced skin damage.[126] In children who regularly used sunscreens, lower nevus counts were found than in children who used less sun protection, thus suggesting that sun protection during childhood does reduce subsequent melanoma risk.[127]

A meta-analysis of 11 studies of melanoma risk and sunscreen use showed only a small protective advantage.[128] However, when more recent studies are included where high sun-protection factor sunscreens were available, a protective effect is identified, and other inherent flaws associated with retrospective studies may be responsible for protection not being noted.[129] It is important that development of future sunscreens incorporate a full range of UV protection.[130]

In addition to sunscreen, patients are advised to wear protective clothing and avoiding sun exposure during peak (midday) hours when UV intensity is greatest. These interventions, coupled with regular sunscreen use, have the greatest impact in lowering skin cancer risk.[131]

According to the National Institutes of Health states, "exposure to sunlamps or sunbeds is known to be a human carcinogen."[132] In a case–control study, the incidence of SCC and BCC was significantly associated with the use of any tanning device.[133] In a prospective cohort study of over 100,000 Scandinavian women, a 55% increased melanoma risk was demonstrated in those who used tanning devices at least once a month between the ages of 10 and 39 years, compared to those who rarely or never used such devices.[134]

There are over 50,000 tanning facilities in the United States, generating revenue of approximately $5 billion.[135] Of the 1 million people who use tanning salons every day, 70% are females between the ages of 16 and 49 years.[136] Tanning beds emit both UVA radiation and UVB radiation.[137] In fact, the UVA irradiation emitted by some tanning beds may be 10–15 times higher than that of the midday sun. The idea that "controlled" salon tanning, while touted as being safer than "uncontrolled" beach tanning, is inaccurate.[137]

According to the International Agency for Research on Cancer, the use of tanning beds was positively associated with melanoma, particularly if first exposure occurred before the age of 35 years.[138] In a recent survey of non-Hispanic white teenagers (ages 13–19 years), 24% of respondents reported using a tanning facility at least once in their lives and 28% of American teenage girls report having used tanning salons three or more times during their lives.[136] Among children ages 11–18 years, 10% reported using indoor tanning sunlamps within the past year.[139] Twenty-eight states have regulations limiting teenagers' access to tanning facilities. In 2007, 16 more states introduced similar bills.[140] In some states, written parental consent is required for minors using commercial tanning beds. The Colorado House rejected a Senate-passed bill prohibiting anyone under the age of 18 years from using a tanning bed without a doctor's prescription, notarized parental consent, or parents present at the salon. In California, laws were recently passed prohibiting those ages 14–18 years from using any UV tanning device without written parental consent. In that state, tanning bed use under the age of 14 years is already banned.[141]

The Indoor Tanning Association, a vehement industry group, states that its mission is to "protect the freedom of individuals to acquire a suntan, via natural or artificial light. When it involves a suntan, the State has no business inserting itself between child and parent. This notion that government knows more about child rearing than parents is preposterous."[142,143] The International Agency for Research on Cancer,[137] American Academy of Pediatrics,[144] World Health Organization,[145] American Medical Association,[146] and American Academy of Dermatology[147] have all issued position statements against the use of tanning beds.

CONCLUSION

The main aim of the fight against cancer is to decrease mortality from the disease. This can be achieved by better treatments or by decreasing the incidence of cancer. Treatment of cancer has reached new horizons over the last two decades resulting in cure of several types of cancer, increase in survival of patients living with cancer, and improvement in quality of life. A universal cure for all types of cancer is still not in the foreseeable future.

Decreasing the incidence of cancer can be achieved by modulation of known causes of cancer. In this regard, changes in lifestyle, e.g., adhering to a healthy diet, regular exercise, and avoiding smoking and excessive exposure to UV radiation, can decrease the incidence of cancer.

Yet another way of controlling one's lifestyle that can lead to a decrease in the incidence of cancer is by following medical recommendations related to screening for cancer. That includes screening for breast cancer with mammograms, for cervical cancer with Papanicolaou smears, for prostate cancer with digital rectal examination and serum prostate-specific

antigen (PSA), and for colon cancer with colonoscopies.[148] Screening can lead to early detection of cancer or precancerous lesions. This is important, because early detection of cancer can lead to early medical intervention and a higher chance of cure. The detection of precancerous lesions can help in preventing the development of cancer by removing these lesions or by starting the affected individual on chemoprevention medications. There is clear evidence that if a breast precancerous lesion is detected, the use of chemoprevention medications may reduce the chance of breast cancer developing in that individual.[149,150]

Know your genes. Our lifestyle has to accommodate our genes. Over the last decade, many inherited gene mutations that may predispose one to cancer have been discovered. Testing for carrier status of susceptibility genes for breast and colon cancers is commercially available.[151]

Those tested and found to be carriers should focus their lifestyle around their susceptibility to that certain cancer and should seek counseling with regular physician visits and appropriate screening. Additional considerations for such an individual may include chemoprevention and an awareness of the impact of inherited genes on their personal family planning. The U.S. congress recently passed the genetic information nondiscrimination act (GINA law) which protects an individual carrier of an identified genetic mutation from work and insurance discrimination.[152] It is hoped that this legislation will result in a wider use of genetic testing for individuals with a strong family history of cancer.

While the molecular basis for most cancers is now well known, the inciting process for many has yet to be defined. However, what is clear is that certain controllable human behaviors often may be the trigger mechanism and changes in lifestyle may be one's best protection from becoming another victim of some very preventable diseases.

Cancer is a group of diseases that result from uncontrolled growth and spread of genetically altered cells. Cancers are caused by both external factors (tobacco, infectious organisms, radiation, chemicals) and internal factors (inherited mutations, hormones, immune conditions, metabolic abnormalities). Interactions among these causative factors are thought to lead to genetic changes that transform normal cells into those that no longer respond to the normal homeostatic mechanisms enjoyed by normal tissue. At least two external factors are controllable, and if they were to be eliminated, a large number of cancers could be prevented. The use of tobacco products and excessive body fat contributes greatly to the incidence of several of the most serious forms of cancer.

For more than half a century, it has been appreciated that a causal relationship between cigarette smoking and lung cancer exists [1]. Of interest, it was German scientists during the 1930s under Adolph Hitler who were the first to link smoking to lung cancer [2]. Beginning in the mid-twentieth century, investigators began identifying other malignancies that are associated with smoking [3], and medical professionals have become accustomed to advising their patients who smoke to discontinue that particular lifestyle. From those efforts and from a number of government [4] and nongovernmental initiatives, the number of Americans who continue to smoke has significantly decreased [5,6]. Between 1965 and 2004, cigarette smoking among adults aged 18 and older declined by half from 42% to 21%. By 2007, that rate diminished to 20%. Thus, a considerable reduction in the incidence of tobacco-related diseases, including several cancers, has occurred [7].

As numerous efforts to eliminate smoking appear to be effective, that lifestyle factor is declining [7], but unfortunately the other controllable lifestyle factor, being overweight or obese, is doing just the opposite. Many sources have substantiated the fact that there is a frightening rise in the number of Americans, including children, who are obese [8,9]. And while there has long been an association of obesity with heart disease and other noncancerous medical conditions, only during the past 10–20 years has the etiologic relationship between obesity and cancer been fully appreciated [10,11]. In fact, some authorities feel that obesity and lack of physical activity have or soon will surpass tobacco use as the leading cause of cancer [12,13]. Not rare cancers, but some of the more common and serious forms of cancer including colon, breast (postmenopausal), endometrial, renal, and esophagus [11]. In addition, some studies have also reported links between obesity and cancers of the gallbladder, ovaries, and pancreas [12].

This chapter will describe what is known about the relationship between obesity and cancer and examine the possible etiologic factors that research has uncovered in this most troubling, yet potentially controllable, situation. Since obesity and a sedentary lifestyle have, for all practical purposes, a cause and effect relationship, much of the reported evidence relating obesity and cancer refers as much to the lack of physical activity as to body weight or body mass index (BMI).

The National Health and Nutrition Examination Survey (NHANES), a program within the Centers for Disease Control and Prevention, reported that in the year 2008, approximately 34% of U.S. adults over the age of 20 were overweight and more than one-third (33.8%) were classified as obese [9]. In 2008, 16.9% of children, 2–19 years of age, were overweight, more than triple the number two decades earlier [8]. A startling statistic reported by NHANES is that since 1976, the percentage of adult Americans with BMI values above 30.0 (“obese”) has doubled. Studies have shown that being overweight or obese directly relates to both a lack of physical activity and the ingestion of a high caloric and/or fatty diet.

In 2001, the International Agency for Research on Cancer of the World Health Organization convened a group

of experts to evaluate the evidence for the role of physical activity and weight control in cancer prevention. The group concluded that being overweight or obese increases the risk of breast cancer (postmenopausal) and cancers of the colon, endometrium, kidney (renal cell), and esophagus (adenocarcinoma) and possibly thyroid cancer. And, by losing weight, one may reduce his or her risk of developing these cancers, but there is insufficient evidence to definitively conclude that such is the case. These experts determined that physical activity plays a significant role in preventing cancers of the colon and breast. Taken together, they concluded that excess body weight and physical inactivity account for approximately a quarter to one-third of cancers of the colon, breast, endometrium, kidney (renal cell), and esophagus (adenocarcinoma). Thus, lack of physical activity and being overweight or obese appear to be the most important lifestyle factors causing these cancers [12].

More than 150 epidemiologic studies of physical activity and cancer risk have been carried out. Several possible biological mechanisms relating physical activity and cancer have been proposed, including changes in androgen, estrogen, and metabolic hormone levels and various growth factors, decreased BMI, and possibly changes in immune function. Excess weight and central adiposity have been implicated in promoting metabolic conditions that relate to carcinogenesis [13,14].

One of the most in-depth studies to estimate the number of obesity-related cancers in the United States was reported in 2008 [10]. Using published meta-analyses and/or large cohort studies, it was estimated that 33,966 new cancers (4% of all cancers) in males and 50,535 (7% of all cancers) in females, diagnosed in 2007, or 6% of all cancers, may be attributable to obesity.

Regarding mortality, if the correlation between obesity and cancer is indeed causal, it was estimated that in 2004, obesity accounted for one in seven (14%) cancer deaths in American men and one in five (20%) cancer deaths in American women, or a total of 17% of all cancer deaths in the United States [11]. More recent data would suggest that as many as one-third of the 562,340 cancer deaths in 2009 were related to overweight or obesity, physical inactivity, and poor nutrition. Reflecting on the relationship between tobacco use and cancer, the American Cancer Society reported that in 2009, approximately 30% of all cancer deaths in the United States were related to the use of tobacco [15]. If these numbers are factual, then obesity may have passed tobacco use as the number one cause of cancer in the United States.

What follows is a more in-depth narrative of the relationship between being overweight or obese and certain cancers that are causally linked to this lifestyle factor.

BREAST CANCER

There is rather irrefutable evidence that obesity increases the risk of a woman developing breast cancer and depends upon a woman's menopausal status. Premenopausal women who are obese actually have a lower risk of developing breast cancer than nonobese premenopausal women [16–19]. Women who are postmenopausal and obese are those who have an increased risk of developing breast cancer, as much as 1.5 times that of women with healthy weights [16,17,20].

While the evidence is not conclusive, studies suggest that the distribution of the adipose tissue in obese women may have significance. Women with abdominal distribution of fat are at greater risk of developing breast cancer than those whose fat is predominantly deposited over the hips, buttocks, and thighs [21,22].

It is believed that the increased risk of breast cancer in obese women is due to their having higher levels of estrogen. While the main source of estrogen is the ovaries, adipose tissue is also a producer of this female hormone and becomes the main source of estrogen in the postmenopausal state. Obese postmenopausal women produce nearly twice the level of estrogen as postmenopausal women with healthy weights [18]; therefore, estrogen-sensitive tissues such as estrogen-responsive breast cancers are more apt to be stimulated to grow.

An additional statistic related to obesity and breast cancer is the observation that death rates for this disease are higher in overweight women. Experts believe that this can be attributed to a delay in detecting a palpable tumor mass in the obese breast, thus leading to a later stage of disease at diagnosis [19].

While being overweight does not seem to confer a greater risk of developing the disease in African American women, these women, obese or not, have a greater likelihood of having a more advanced stage of disease at diagnosis [23]. Hispanic women who are overweight have a higher risk of breast cancer, irrespective of menopausal status [24].

COLON CANCER

While there is strong evidence for a relationship between obesity and the risk of developing colon cancer, this has been consistently reported for men [25–28], but not for women [25,28,29].

Just as with breast cancer, the distribution of adipose tissue appears to be a factor in those who are obese and at risk for developing colon cancer. Since men with high BMI are generally obese with an increase in abdominal fat, and women with high BMI are more likely to have their adipose tissue distributed around hips, buttocks, and thighs, the risk of colon cancer appears to relate to abdominal fat [27,28].

The mechanism responsible for the increased risk of colon cancer, especially in obese males, is not determined; however, there is some evidence that high levels of insulin or insulin-related growth factors may enhance adenomatous growth in the colon and thereby lead to the evolution of a cancerous tumor [30].

An additional comparison to breast cancer and obesity is the possible causative factor of estrogen. Unlike for breast cancer and uterine cancer (see the following), the presence of estrogen appears to be protective for colon cancer in women [31]. However, obese women who also take estrogenic

hormone replacement therapy, regardless of menopausal status, increase their risk of developing colon cancer not dissimilar to the risk seen in obese men [32].

ENDOMETRIAL (UTERINE) CANCER

Obesity accounts for more than a third of all cases of endometrial (uterine) cancers [33]; and, obese women have nearly a four times greater risk of developing uterine cancer than women with healthy weights, irrespective of menopausal status [34–37].

Evidence suggests that high levels of estrogen and higher than normal levels of insulin in overweight or obese women may account for this increased risk [34–36].

ESOPHAGEAL AND GASTRIC CANCER

There is an increase in esophageal and gastric cancer of a particular histology, specifically adenocarcinoma, and location (distal esophagus and gastric cardia at the esophageal–gastric juncture) in obese individuals [38–42]. Obesity confers two times greater risk of developing one of these cancers than for individuals who have healthy weights [38–40].

Since it is known that gastric reflux may lead to the development of Barrett's esophagus, a precancerous condition affecting the distal esophagus, reflux has been postulated to be the mechanism that is responsible for the increased risk of adenocarcinoma of the esophagus. However, the evidence is inconclusive, and a precise mechanism has not been determined [41].

KIDNEY CANCER

Obese women are at increased risk of developing kidney cancer (renal-cell carcinoma) [43–47]. This risk may be as high as four times that for women who are not overweight. For men, there does not seem to be this association between obesity and renal cell carcinoma [43]. Like other cancers associated with obesity, the exact mechanism is uncertain, but estrogen exposure certainly has been considered an etiologic factor since the risk is gender related.

PROSTATE CANCER

While the overall risk for obese men developing prostate cancer appears to be no greater, perhaps even slightly less, than for men with healthy weights, obese men appear to be at greater risk of developing the more aggressive forms of prostate cancer [48–51].

The observation that obese men may have lower rates of prostate cancer than thinner men may not reflect an actual lower risk, but a lower rate of early detection through prostate cancer screening. Using data from three U.S. government health surveys, researchers found that among men who underwent prostate cancer screening with a prostate-specific antigen (PSA) blood test, obese men generally had lower PSA levels than thinner men. They were also less likely to have their PSA test followed up with a biopsy to rule out or confirm prostate cancer. Of obese men who had ever had PSA screening, 4.6% had undergone a biopsy versus 5.8% of normal-weight men [52].

Furthermore, mortality studies have yielded conflicting data, at least one such study suggesting that obese men may in fact have a better prognosis than nonobese men with prostate cancer [53].

OTHER CANCERS

An association between obesity and ovarian cancer has not been delineated [54,55]; however, one study described an increased incidence of this cancer in women who were overweight or obese during adolescence or young adulthood [56].

Obesity as a risk factor for pancreatic cancer has been reported in one study [57], but such an association was not confirmed in other reports [58]. It has been suggested that persons who exhibit physical inactivity are at increased risk of developing pancreatic cancer [59].

Women who are obese are at increased risk of developing cancer of the gall bladder [60,61]. Obesity is associated with a high frequency of gallstones, and the relationship between gall bladder cancer and gallstones is a recognized phenomenon.

PHYSICAL ACTIVITY

While caloric intake is the most important determinant of BMI, not to be overlooked in the variables that contribute to one's BMI is the amount of physical activity that an individual undertakes. Clearly, when there is a high intake of calories accompanied by a sedentary lifestyle, the chance of one becoming overweight or obese is greatly increased. Therefore, one may conclude that those cancers that are associated with obesity as a causative factor might become less common in a population that exhibits regular physical activity.

In fact, with colon cancer, such has been observed. Even with moderate levels of physical activity, the risk of developing colon cancer was reduced by 50% [62,63].

With respect to breast cancer, most studies have looked at the effects of physical activity in postmenopausal women where it has been shown that moderate levels of physical activity (e.g., walking approximately 30 min each day) reduced the risk of developing breast cancer by nearly 20%, the greatest benefit experienced by women who were not overweight, with no benefit seen in obese women [64].

The beneficial effects of increased physical activity as it relates to other cancers with a known association with overweight and obesity are unknown. Virtually no controlled studies to examine this question have been undertaken.

A summary of the foregoing information relating to the causality of obesity and certain cancers and data relating to proposed mechanisms and the relationship of physical activity to the respective cancer is shown in Table 38.1.

TABLE 38.1
Obesity: A Causality Factor for Certain Cancers and Related Data

Cancer	Overweight/ Obesity Related	Population at Risk	Proposed Mechanism of Relationship	Physical Activity Related
Breast	+++++	• Obese postmenopausal • Obese Hispanic women	• Estrogen	++ • Postmenopausal women • Women with healthy weight
Colon	+++++	• Obese men • Obese women on hormone replacement therapy	• Abdominal fat • Insulin • Insulin-related growth factors	+++
Uterine	++++	• Obese pre- and postmenopausal	• Estrogen • Insulin	Not studied
Kidney	+++	• Obese women	• Estrogen	Not studied
Esophageal	++	• Obese men and women • Distal esophagus	• Gastric reflux	Not studied
Gastric	++	• Gastric cardia	• Gastric reflux	Not studied
Gall bladder	++	• Obese women	• Gall stones	Not studied
Ovarian	+	• Obesity during youth or early adulthood	• Unknown	Not studied
Pancreatic	+	• Obese men and women	• Decreased physical inactivity	Not studied
Prostate	+	• Obese men with aggressive form	• Unknown	Not studied

+++++, Conclusive evidence; ++++, strong evidence; +++, moderate evidence; ++, inconclusive evidence; +, weak evidence.

DIET

Evidence is rather compelling that dietary patterns and dietary elements are etiologic factors for several types of cancer. As many as 35% of cancer deaths may be related to dietary factors [65]. Research shows that diets low in fat and high in fiber, fruits, vegetables, and grains are associated with reduced risks for certain cancers.

Diets high in fat have been linked to breast, colon, and prostate cancers and possibly to pancreas, ovary, and endometrial cancers [66]. The average U.S. diet is estimated to contain nearly 40% of calories from fat, which is significantly higher than that needed to meet the physiological needs for energy and essential fatty acids. The major sources of fat in the American diet are added fats and oils used as spreads, cooking fats, and salad oils as well as the fat in meats and whole milk dairy products.

Because dietary fat intake is highly correlated with calorie intake, there is the issue as to whether fat intake or caloric intake is the major dietary factor affecting cancer risk. Several studies have looked at the importance of fat intake versus caloric intake and suggest that both have independent effects. Since dietary fat is the most concentrated source of energy of all the nutrients and supplies (9 cal/g compared to 4 cal/g from either carbohydrate or protein), a reduction in dietary fat intake is accompanied by a decrease in total calorie intake and body weight [67,68].

Evidence suggests that diets high in fiber are associated with a reduced risk for cancer, especially cancer of the colon [69]. This may also be true for cancers of the breast, rectum, oral cavity, pharynx, and stomach [70].

With respect to fruits and vegetables, it has been observed that populations whose diets are rich in fruits and vegetables have a lower risk for cancers of the lung, colon and rectum, breast, oral cavity, esophagus, stomach, pancreas, uterine cervix, and ovary. Fruits, vegetables, and grains contain a number of nutrients, including carotenoids, vitamin A, and vitamin C. For most cancer sites, especially those of the respiratory and digestive tracts, persons with low fruit and vegetable intake had about twice the risk of cancer as those with high intake [71].

The current dietary recommendation is for five servings of fruit and vegetables a day, and Americans fall somewhat short of this goal. Only approximately 20% of the population is achieving this goal with the average daily intake of only three and a half daily servings of fruits and vegetables [72].

In addition to vitamins A and C and the carotenoids, fruits, vegetables, and grains contain other vitamins and minerals associated with a protective effect against cancer.

Vitamin E has inhibited tumors in experimental animals and been linked to reduced risks of oral, stomach, and other cancer in epidemiologic studies. Selenium also may have a protective effect. In a recent randomized large-population trial testing the effectiveness of vitamin/mineral supplementation among persons in high-risk areas of China, those who received daily supplements with a combination of beta-carotene, vitamin E, and selenium for 5 years had

a significantly lower cancer death rate [73]. The findings do not automatically translate to Western populations—in that the Chinese population studied was chronically deficient in a number of nutrients—but offer a hopeful sign that certain vitamins and minerals may lower risk of some cancers. However, two other recent large randomized trials of supplements, one testing the effect of supplemental beta-carotene or alpha-tocopherol in the prevention of lung cancer among smokers and the other testing the effect of supplemental beta-carotene and vitamins C and E in the prevention of adenomatous polyps (a precursor lesion for colorectal cancer), suggest that supplemental use of these nutrients does not reduce the risk of either lung or colorectal cancer [74,75]. In the study of the effect of beta-carotene or alpha-tocopherol on lung cancer among smokers, dietary intake of these nutrients from foods was associated with a reduced risk for lung cancer [74]. Some studies suggest that calcium may play a protective role in colon cancer. A 19 year prospective study in men showed that the risk for colon cancer was lower in those with the highest calcium intake [75]. In addition to dairy products, certain vegetables are good sources of calcium, notably roots, okra, and dark green leafy vegetables such as collard greens.

OVERVIEW OF CANCER

In the United States alone, over 1.6 million new cases of cancer (excluding skin cancer) are expected to be diagnosed in 2012, and just over 577,000 Americans are expected to die from the disease [1]. Cancer is the second most common cause of death in the United States after heart disease. The four most common cancers—prostate, breast, colorectal, and lung—account for over 55% of all new cancer cases and over 50% of all new cancer deaths each year [1]. The population of cancer survivors is growing as there are approximately 12 million individuals with a history of cancer alive today in the United States [1].

It is estimated that the overall cost of cancer in the United States in 2007 was just over $227 billion [1]. Cancer is now viewed as a major public health burden not just in the United States but worldwide. The 5-year relative survival rate in the United States across all cancers and disease stages is 67% [1], although this survival rate varies substantially by cancer type and stage. For example, the 5-year relative survival rate for breast cancer is now 90% (99% if the cancer is local and has not spread to other parts of the body outside the breast). In contrast, the 5-year relative survival rate for lung cancer that is localized (i.e., early stage) is 52%, but only 16% when all stages are considered. Despite the high death rates, for certain cancers, more individuals are surviving their cancer.

DEFINITION OF A CANCER SURVIVOR

There are several definitions used to describe a cancer survivor. For some, an individual receiving their first diagnosis of cancer may be considered a survivor, instead of "survivorship" starts from diagnosis. Alternatively, an individual may not be labeled "survivor" until the completion of primary and systemic treatments (including but not limited to surgery, chemotherapy, and radiotherapy). Others define survivors as those with a cancer history who live 5 or more years beyond their diagnosis [2]. The National Cancer Institute (NCI) maintains that an individual is a cancer survivor from the time of diagnosis through the balance of his or her life [3]. In support of this definition, a cancer control continuum was developed that defines six phases of the cancer trajectory ranging from prevention and early detection to diagnosis, treatment, survivorship, and end-of-life [2]. Individuals in each phase of the continuum have unique needs related to their cancer that affect their overall health and quality of life. One mechanism known to help improve many aspects of health and quality of life across the cancer control continuum is physical activity (PA).

PA is a well-documented strategy that can be effective in improving physical, biological, and psychosocial health during cancer survivorship. Courneya and Friedenreich [4] extended the cancer continuum and developed the Physical Activity and Cancer Control (PACC) framework for understanding

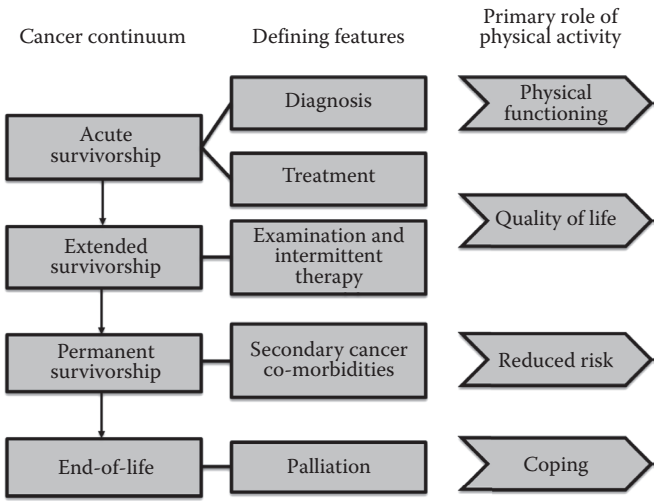

FIGURE 39.1 Cancer Survivorship and Physical Activity (CSPA) Schema.

PA as a facilitator of cancer prevention and cancer recovery. The PACC framework has been used as a template to help organize, focus, and stimulate research and initiatives related to PA and cancer [4], as well as the development of PA guidelines for cancer survivors [5]. Synergizing PA and the cancer continuum has helped foster public health efforts aimed at helping more individuals with a history of cancer initiate and maintain PA. These efforts have also helped guide research on the determinants and outcomes of PA among cancer survivors. In Figure 39.1, we provide a modified model that adapts the PACC framework and the NCI cancer continuum and summarizes the literature to provide an overview of the association between PA and cancer survivorship.

The Cancer Survivorship and Physical Activity schema (CSPA; Figure 39.1) details different stages of cancer survivorship, which spans diagnosis to end-of-life. The CSPA defines features of each phase drawing on Mullan [6]: acute survival (a period dominated by diagnosis, diagnostics, and treatments), extended survival (postsystemic treatment, dominated by constant examination and intermittent therapy), and permanent survival (a period following the "cure," dominated by potential for secondary effects of cancer treatment and long-term risk). We also include an end-of-life phase in the model as consistent with cancer survivor definitions and frameworks. Although regular PA is important during each of these stages of survivorship for a number of reasons, the most important role for each phase is illustrated in Figure 39.1. For acute survivorship, PA can help improve physical functioning and reduce treatment side effects. In the period of extended survivorship, PA can help improve quality of life, which is defined broadly as having physical (e.g., body composition, fatigue), psychological (e.g., mood, stress and anxiety), and social (e.g., social support and connectedness) dimensions [7,8]. For the period of permanent survivorship, PA is likely to help reduce the risk of recurrence of some cancers such as breast and colon [e.g., 9–12], and to help protect against comorbidities such as cardiovascular disease, hypertension, diabetes, overweight, and obesity [13]. Finally, the primary role of PA in the end-of-life stage is to help individuals manage their emotions and cope with the predominant symptoms associated with persistent fatigue, low energy, and anorexia–cachexia conditions [14,15].

As illustrated in Figure 39.1 and in this chapter, we focus on the effects of PA during the extended and permanent survival periods of cancer survivorship (the period that spans posttreatment to end-of-life). We also present research examining PA promotion strategies for cancer survivors. Based on the research presented, we provide health care practitioners with some strategies that can be discussed with survivors to facilitate PA.

PHYSICAL ACTIVITY AND CANCER SURVIVORSHIP

Researchers and clinicians are increasingly interested in understanding the role PA in promoting the health of cancer survivors. This has yielded a large body of evidence linking various aspects of PA to biopsychosocial outcomes [16]. Evidence of the growing body of literature is reflected in the several reviews and meta-analyses synthesizing evidence from observational and experimental studies that have now been published [5,16–20]. These reviews have varied in regards to the search terms used, inclusion/exclusion criteria applied, types of studies reviewed, and health-related outcomes examined. For example, some reviews focused on certain cancer types (e.g., breast), whereas others reviewed studies where various tumor groups were included. Some reviews summarized studies with individuals at various phases of the cancer continuum and others chose a specific phase. One recent systematic review identified 64 randomized controlled trials (RCTs) postdiagnosis (i.e., both during and after treatments) across various cancer groups [16]. Properly conducted and well-designed RCTs provide the best evidence of the efficacy of a treatment or health care intervention [21]. This review of RCTs, and other meta-analyses and systematic reviews, provides mounting evidence suggesting that PA both during and after cancer treatments may improve multiple health outcomes. Table 39.1 presents an overview of existing review articles examining associations between

PA and cancer survivorship [5,16–20,22–28]. Given the outcomes identified from the reviews presented in Table 39.1, and the overview of benefits in Table 39.2, PA is associated with numerous physical, biological, and psychosocial health outcomes among cancer survivors. This evidence supports the potential value of interventions and public health programs aimed at increasing PA.

BENEFITS OF PHYSICAL ACTIVITY FOR CANCER SURVIVORS

Physical Activity and Bio-Physiological Health

The evidence presented in Table 39.1 (i.e., outcomes examined in the studies reviewed in the meta-analyses and review articles) and benefits summarized in Table 39.2 show the breadth of biophysiological benefits associated with PA among cancer survivors. Many of these benefits are important for improved health and may help in the prevention of secondary cancers and comorbidities such as cardiovascular disease, hypertension, diabetes, and osteoporosis. The biophysiological benefits span immune function adaptations and protective effects for chronic inflammation, improvements in markers of cardiovascular disease and risk, and prevention of bone loss and improved bone mineral density. Also, reduced cancer-related fatigue may be a positive outcome of a physically active lifestyle [29]. Brown et al. [22] reported that PA may be effective in reducing fatigue during survivorship for individuals diagnosed with various cancer types, cancer stages, and treatments endured. Similarly, Speck et al. [16] suggest there is a moderate relationship between PA and fatigue across various cancer types posttreatment. Additional benefits of PA may include

TABLE 39.2
Summary of Physical Activity Benefits for Cancer Survivors

Improvements	Reductions
• Survival rates	• Rates of all-cause mortality
• Natural killer cell cytotoxic activity	• Rates of cancer-related mortality
• Physical, functional, and mental health	• Cancer recurrence
• Cardio-respiratory fitness	• C-reactive protein
• Muscle strength/mass	• [3H] thymidine uptake by peripheral blood lymphocytes
• Flexibility	• Cancer-related fatigue
• Immune function	• Body weight
• Body composition	• Fat mass
• Sexual functioning	• Bone loss
• Sleep quality	• Incontinence
• Balance	• Pain
• Healthy hemoglobin levels	• Systolic blood pressure
• Diastolic blood pressure	• Resting heart rate
• Quality of life	• Depression
• Mood and happiness	• Anxiety
• Body image	• Stress
• Self-esteem	• Tension
• Perceptions of sexual attractiveness	• Cognitive disorganization
• Posttraumatic growth	• Emotional irritability
• Personality functioning	• Confusion
• Locus of control	
• Perceptions of social support	
• Feelings of connectedness	

improved sexual functioning, reduced incontinence, improved sleep, reduced pain, improved balance, and healthy hemoglobin levels, blood pressure, and resting heart rate [5,16,30]. Related to these latter benefits, PA has been clearly linked to improved cardiorespiratory fitness, muscular strength, and flexibility [5,16,17,31,32].

The evidence presented in a variety of cohort studies also suggests that PA may protect cancer survivors from premature death and/or death due to their cancer [10–12,33,34]. Furthermore, it appears that PA postdiagnosis plays a more important role in reducing risk of mortality than lifetime PA prediagnosis [11]. That is, PA started after a survivor is diagnosed may exert a greater influence on mortality than PA engaged in prior to being diagnosed, even if the survivor was previously inactive.

Physical Activity and Psychosocial Health

Table 39.1 provides a detailed description of systematic reviews and meta-analyses exploring the associations between PA and psychosocial health among cancer survivors. To summarize, several reviews provide strong support for the role of PA in facilitating psychosocial health among cancer survivors [16–18,23,35]. For controlled studies conducted posttreatment, significant weighted effect sizes were observed for overall quality of life, physical condition, mood disturbance, confusion, body image, and fatigue [16]. Given the expanding evidence-base, systematic reviews and meta-analyses are beginning to target specific psychosocial outcomes. For example, the first systematic review and meta-analysis exploring the effects of PA specifically on depression symptoms among cancer survivors has recently been published [23]. Overall, 15 RCTs comparing PA with usual care and assessing depressive symptoms both pre- and post-intervention were reviewed. PA was significantly associated with reduced depression symptoms. In light of these reviews, clinically relevant and exciting evidence continue to emerge that supports the role of PA as a safe and effective intervention to facilitate favorable physical and psychosocial health outcomes among various cancer survivor groups. Furthermore, while most of the evidence to date has focused on the more adverse or negative psychosocial effects of cancer and the association with PA, it is expected that studies and reviews on the promotion of positive effects (e.g., posttraumatic growth [36]) through PA will be introduced in the literature shortly.

Finally, cancer survivors continue to have needs for social support beyond the active treatment phase, and these support needs change as survivors move along the cancer continuum [37]. The association between PA and social support is an overlooked area of research among cancer survivors. Thus far, the studies exploring the role of PA in fostering social support among cancer survivors have mostly been focused on dragon boating for breast cancer survivors [36,38]. The evidence suggests that group-based PA is beneficial in helping these women gain support by providing them with a forum to discuss cancer (and noncancer) related concerns. More work is needed to ascertain the role of PA in improving social benefits during cancer survivorship.

PHYSICAL ACTIVITY GUIDELINES FOR CANCER SURVIVORS

The biological, physiological, psychological, social, and recurrence and survival benefits of PA for cancer survivors are summarized in Table 39.2, and are discussed in detail by Sabiston and Brunet [39]. De Backer and Colleagues [40] also provide a review of the specific benefits associated with resistance training. With the variety of health benefits observed following PA programs or participation, one must ask the questions "Do all cancer survivors who lead physically active lifestyles experience these benefits?" As part of an effort to improve cancer survivors' health and well-being, guidelines have been formulated for cancer survivors based on existing evidence drawn mostly from studies with survivors of breast, prostate, colorectal, hematologic, and gynecologic cancers. Regularly cited guidelines in the literature include those from the American Cancer Society [41,42] and the American College of Sports Medicine [5]. The most recent American Cancer Society guidelines suggest that cancer survivors should engage in at least 30 min of moderate-to-vigorous PA, above usual activities (i.e., those that are done regularly as part of one's daily routine), on 5 or more days of the week, although 45–60 min of PA is preferable. The type of PA being recommended is not specified.

There are three main modes of PA. These include aerobic activity, strength training, and flexibility training [41,43]. Aerobic (or endurance) activity refers to any activity that uses large muscle groups, can be maintained continuously for a long period of time, and is rhythmic in nature. Examples include walking, jogging, running, cycling, dancing, skating, swimming, aerobics classes, and household chores (e.g., vacuuming, sweeping, mopping, raking). Resistance (or strength) training refers to any activity that uses resistance methods (e.g., free weights, an individual's own weight, machines, elastic bands) to increase one's ability to exert or resist force. These activities involve concentric (i.e., lifting and pushing/pulling) and eccentric (i.e., controlled lowering/returning) muscle contractions and are done for each major muscle group (i.e., quadriceps, hamstrings, hip adducters/abductors, upper/lower back, abdomen, chest, shoulders, biceps/triceps, and neck). Flexibility training refers to activities that lengthen muscles to increase range of motion around the joints. These activities can be static (i.e., stretch is held for a period of time), dynamic (i.e., fluid motion such as tai chi), or active (i.e., hold stretch while balancing such as yoga) [41,43].

More recently, the importance of delineating the different types of PA has been recognized. Consequently, guidelines have been modified to specify that all three types of PA should be undertaken [5,43]. The American College of Sports Medicine convened an expert committee consisting of clinical and research experts in the field to review existing evidence on the safety and efficacy of PA during and after adjuvant cancer therapy [5]. This panel of experts developed PA guidelines for cancer survivors to include engaging in aerobic activity, musculoskeletal or strength training, and flexibility training [5]. These guidelines recommend that cancer survivors engage in: (a) aerobic activities at a *moderate* intensity (i.e., heart rate and sweating increases, can still maintain a conversation) for a total of 150 min/week, (b) *vigorous/strenuous* intensity activity (i.e., fast and hard breathing, heart rate increases considerably, cannot maintain a lengthy conversation) for 75 min/week, or (c) some combination of moderate and vigorous activities. Recommendations for strength training suggest cancer survivors should perform activities that work the major muscle groups of the lower and upper body two or three times per week. Finally, guidelines suggest stretching major muscle groups when aerobic and strength training activities are performed. There are insufficient data available to conclude what the optimal intensity and volume for each type of activity is for cancer survivors. The guidelines indicate that these are the minimum amounts of PA cancer survivors should strive to meet and that additional benefits will likely result if frequency and duration is increased.

PHYSICAL ACTIVITY PREVALENCE ACROSS TUMOR GROUPS

The overwhelming majority of cancer survivors do not achieve the dose of PA suggested in the guidelines [44–47]. These data suggest that from the time an individual is diagnosed with cancer, PA substantially decreases. The most substantial change occurs from prediagnosis to the treatment phase in the cancer continuum. While PA rates improve after treatment is completed, PA rates after treatment remain significantly lower than prediagnosis rates [48–51]. Total PA, moderate and vigorous PA, and sports or recreational PA substantially decrease from prediagnosis, to during treatment, and through to postdiagnosis phases.

Evidence comparing rates of PA between cancer survivors and individuals who have never received a cancer diagnosis is equivocal [52–54]. Some studies have documented that cancer survivors are less active than noncancer controls [44,55], whereas other have found no differences [45,56–58]. Regardless, large population-based studies have documented the low PA behavior rates among cancer survivors such as in the American Cancer Society's Study of Cancer Survivors-II (ACS SCS-II) [44]. The ACS SCS-II is a United States national cross-sectional survey that includes over 9000 survivors from six different cancers. Data from this survey show that the minority of breast (37.1%), prostate (43.2%), colorectal (35.0%), bladder (36%), and uterine (29.6%) cancer survivors were meeting the American Cancer Society's recommendations for PA (i.e., accumulate at least 150 min of moderate to strenuous PA or 60 min of strenuous PA per week). Studies with large Canadian and Australian samples of cancer survivors have yielded similar results. For example, the Canadian Community Health Survey data from cancer survivors demonstrated the minority of prostate (23.9%), breast (16.6%), and colorectal (17.1%) cancer survivors were achieving PA levels that were consistent with public health recommendations [46]. From the Australian National Health Survey, only 28% of the 968 cancer survivors were meeting Australian PA guidelines (i.e., accruing 150 or more minutes of PA over at least five sessions per week) [56]. Taken together, there may be small differences in the rates of PA across cancer sites but more research is needed to understand the mechanisms associated with these differences. For example, Blanchard et al. [44] demonstrated that survivors of uterine cancer were least likely and survivors of skin melanoma and prostate cancer were most likely to meet the PA guidelines. Bellizi et al. [59] reported that survivors of prostate cancer were most likely to meet PA guidelines whereas survivors of lung, larynx, and pharynx cancer were among the least likely to meet PA guidelines. Given these PA rates, increasing PA levels among all cancer survivors should remain a high research and public health priority worldwide.

Until now, most research pertaining to the PA behavior levels of cancer survivors has utilized self-report measures. Recently, two studies have implemented PA data using accelerometers [60,61]. Accelerometers are small devices providing objective, gold standard PA information and provide the researcher with individuals' activity counts, vector magnitude, energy expenditure, steps taken, and activity intensity level. The data examined in these studies are drawn from two waves of the National Health and Nutrition Examination Survey (2003–2004 and 2005–2006), where

accelerometer data were available for a heterogeneous sample of self-reported cancer survivors. Among 111 breast cancer survivors from the NHANES database, Lynch et al. [60] reported that survivors were engaging in an average of only 3.7 min of moderate-to-vigorous intensity PA (MVPA) per day. Similarly, among 103 prostate cancer survivors, the average time per day spent engaging in MVPA was 6.0 min [61]. These NHANES studies indicate PA behavior rates of cancer survivors derived from self-reported measures may be substantially inflated.

Regardless of how the PA estimate is obtained, the prevalence of PA among cancer survivors is very low, and it is important to better understand the reasons for these low rates of participation. One way to understand the prevalence of PA is to examine the cancer-related barriers that may impede participation among survivors.

POTENTIAL CANCER-SPECIFIC BARRIERS TO PA

Survivors likely report the common PA barriers identified by researchers studying individuals of all ages (e.g., lack of time, motivation, money, knowledge or information, competence and skill, and/or social support, among many others [64,65]). However, there are unique cancer-specific barriers to PA an individual may experience as they go through diagnostic steps and treatments compared to when he or she has finished treatments and are returning to work or various life roles. This is another reason why it is beneficial to distinguish survivorship phases (see Figure 39.1) as this may help inform targeted efforts aimed at understanding and reducing the PA barriers. Table 39.3 identifies main cancer-specific barriers to PA across the cancer continuum.

TABLE 39.3
Potential Cancer-Related Barriers to Physical Activity across the Cancer Continuum

Cancer Continuum Phase	Potential Barriers to Physical Activity
Acute survivorship	
Diagnosis	Other life priorities, time management, negative affect and emotions, anxiety, fear of exacerbating condition
Treatment (early effects)	Seroma, ascites, peripheral edema, short-term pain after treatment, dry and sore skin, mouth and throat sores, swelling, and lymphedema, fatigue, hair loss, nausea and vomiting, immunosuppression and fear of compromising immunity to postpone treatment, myelosuppression, body image disturbance, depression
Extended survivorship	
Treatment (late effects)	Fibrosis, cardiovascular and pulmonary toxicities, hypertension, atherosclerosis, lymphedema, hematologic abnormalities, avascular necrosis, thrombocytopenia, neuropathy, dyspnea, fatigue, joint pain, body image disturbance, depression
Permanent survivorship	Recurrence of another type of cancer, second cancers, cardiac dysfunction, weight gain or loss, bone loss, lymphedema, arthralgias, cognitive dysfunction, menopausal symptoms, reduced health-related quality of life, fatigue, joint pain, body image disturbance, lack of social support, lack of PA knowledge, and psychosocial distress
End-of-life	Weight loss (e.g., cachexia), motivation, pain, fatigue, cognitive deficits, decreased balance, impaired fine and gross motor skills, shortness of breath, lowered aerobic capacity, deconditioning, muscle atrophy

EVIDENCE-BASED BEHAVIOR CHANGE STRATEGIES

Identifying and understanding the cancer-specific barriers that may impede PA participation is one step in helping to optimize PA opportunities among cancer survivors. Additionally, evidence-based initiatives focused on PA among cancer survivors can be used to help advance research and clinical practice. Approximately 12 million cancer survivors may possibly benefit from evidence-based, well-designed PA programs [5]. Moreover, many cancer survivors are interested and opportunistic in pursuing PA programs and receiving PA counseling [52]. Few interventions, however, have been developed and evaluated to facilitate PA initiation and maintenance among cancer survivors. Physician counseling on PA may be one targeted strategy to increase PA among cancer survivors [66,67]. Yet, the limited guidelines put forward to assist practitioners and PA programmers in providing PA recommendations to cancer survivors have resulted in PA counseling being done on a sporadic and infrequent basis [43,68]. The Oncologist Recommendation to Exercise (ONCORE) Trial was one trial that examined the effects of two oncologist-centered interventions on self-reported PA behavior in breast cancer survivors beginning treatment using an RCT design [67]. During their initial treatment consultation, participants were randomized to receive either (a) an oncologist's recommendation for PA, (b) an oncologist's recommendation for PA plus a referral to a Kinesiologist, or (c) usual care (i.e., no recommendation). Results of this study indicated that participants receiving one of the exercise recommendations reported total PA amounts that were significantly higher than those receiving usual care (i.e., approximately 30 min/week).

However, given the amount of information that is given during an initial treatment consultation, and not to mention the distress an individual might experience during their treatment consultation, it is unclear whether the treatment consultation represents the opportune time to recommend PA. As the authors indicated, participants may have only been concerned with critical information regarding prognosis and treatment. This contention is supported in that only 59% of individuals correctly recalled the group they were randomly

assigned to. Nonetheless, this trial suggests that advocating a physically active lifestyle via an oncologist's recommendation may be an easy and efficient form of promoting PA among breast cancer survivors.

Researchers are also starting to engage in PA promotion efforts by exploring targeted tools and resources that can facilitate PA adoption and maintenance in this population. To provide an example, Vallance et al. [69] evaluated the role of PA print resources and step pedometers in facilitating PA behavior among breast cancer survivors. *Exercise for Health: An Exercise Guide for Breast Cancer Survivors* was a 62-page PA resource designed for breast cancer survivors. Developed within the Theory of Planned Behavior framework [21], the development of this resource along with evidence supporting the suitability, appropriate readability, and theoretical merit of the resource has been documented [69]. Messages within this resource were based on theoretical beliefs (e.g., attitudes, norms) and PA programming preferences previously elicited from breast cancer survivors [70,71]. The *Exercise for Health* resource consisted of 10 chapters and included activities that were designed to facilitate positive attitudes (i.e., instrumental and affective attitudes), subjective norms (i.e., injunctive and descriptive norms), perceived behavioral control (i.e., self-efficacy and controllability), and implementation intentions (e.g., goal-setting, planning) related to PA.

The *Act*ivity Promot*ion* (ACTION) trial was a four-group RCT designed to determine the effects of the *Exercise for Health* resource, a step pedometer, or their combination, on PA behavior, health-related quality-of-life (HRQoL), and fatigue in breast cancer survivors compared to survivors receiving a verbal recommendation for PA that was consistent with current PA guidelines [72]. At the 3-month postintervention assessment, the *Exercise for Health* resource and the step pedometers were effective strategies for increasing PA behavior (both independently and in combination), HRQoL, and reducing fatigue symptoms in breast cancer survivors. Overall, PA increased by about 40–60 min/week (equivalent to one or two extra PA sessions) in the three intervention groups compared to the verbal PA recommendation group. A significant change was also observed for brisk walking across all intervention groups when compared to the recommendation group. Brisk walking was increased by 60–90 min/week, which is equivalent to 2–3 more days of PA per week. Finally, the intervention group receiving both the print resource and pedometer also reported significantly improved HRQoL and reduced fatigue symptoms compared to the verbal PA recommendation group.

The usefulness and effectiveness of telephone counseling for facilitating PA behavior change among cancer survivors has also been examined. In one of the largest experimental studies, Morey et al. [73] randomized 641 older, overweight, long-term cancer survivors to receive either telephone counseling or mailed print materials based on PA and diet or to a wait-list control group. Results from this study suggested that receiving telephone counseling and mailed print resources facilitated overall HRQoL including physical and mental health, pain, vitality, and social functioning when compared to survivors in the control group. Survivors in the intervention group also reported significant increases in the duration and frequency of strength and endurance training. Significant reductions in body weight and body mass index were also reported in the intervention group. In Australia, Eakin et al. [74] conducted an RCT with newly diagnosed breast cancer survivors (receiving treatment at baseline) evaluating an 8-month PA intervention delivered by exercise physiologists over the telephone. In this trial, survivors receiving telephone counseling were two times more likely to be engaging in at least 180 min/week of PA 6 months after surgery and two times more likely 12 months after surgery compared to baseline. Also, survivors were over eight times more likely to be engaging in resistance training 6 months after surgery and over three times more likely 12 months after surgery. Continued development and evaluation of modes in which to communicate and potentially facilitate PA behavior among cancer survivors is critical. Such programs and opportunities may facilitate longer survival and better quality of life for millions of cancer survivors.

LIMITATIONS AND FUTURE DIRECTIONS

The evidence linking PA to health outcomes in cancer survivors is mounting, and there are important considerations for advancing this line of inquiry. Based on the reviews and meta-analyses outlined in this chapter, one of the common criticisms is that much of the information available derives from studies that have been conducted with breast cancer survivors. Survivors of certain cancer types are underrepresented (e.g., lung, testicular, head/neck, colorectal, gynecologic, hematological), which reduces opportunities for determining the effects of PA in these sub-populations. Homogeneous samples of survivors drawn from underrepresented cancer types are needed to better understand cancer-specific responses to PA. Similarly, homogeneous samples within specific phases of the cancer continuum should be used to understand unique needs and effects of PA to better target intervention and clinical practice guidelines. Currently, some investigations have included solely cancer survivors as defined in this chapter (i.e., individuals who completed primary treatment) and other studies and reviews have included both patients and survivors.

There is also a lack of comparability in the methods used to assess PA and the health-related outcomes between studies that prevent researchers from being able to make comparisons across studies. Furthermore, there are few studies aimed at understanding the mechanisms that link PA to health-related outcomes. Identifying the pathways through which PA influences cancer survivors' health represents one area of future research needed to better understand how PA can promote health. In addition to understanding mechanisms, there are also limited studies looking at the long-term effects of PA. The majority of studies reviewed in this chapter implemented short-term interventions (i.e., <6 months) and few included

long-term follow-up measures, which makes it difficult to ascertain the long-term or delayed effects of PA.

Further, the mode of delivery differs greatly across studies. Some investigations have used unsupervised/home-based or supervised/facility-based protocols for the delivery of interventions, with some studies utilizing both approaches. Despite the fact that unsupervised/home-based interventions may be more sustainable long-term, monitoring whether participants follow the prescribed intensity and volume of PA is more difficult when the intervention is unsupervised, unless monitoring devices are used to assess adherence. Also, there are inconsistent PA parameters included in the tested interventions across the different studies. For instance, different types (i.e., aerobic, resistance, flexibility), intensities (i.e., lifestyle, light, moderate, vigorous), frequencies (i.e., times per week), and durations (i.e., session length) of PA have been prescribed; however, the types, intensities, and volume of PA that are most beneficial for cancer survivors are unknown since most studies have examined the links between PA and health-related outcomes rather than the dose–response effects of PA on short- and long-term outcomes. Finally, given new objective PA data suggesting the PA prevalence among cancer survivors is much lower than previously thought [60,61], researchers should rely on more objective assessments of PA (e.g., accelerometers, step pedometers). Such efforts will provide a more accurate and precise estimate of how much PA cancer survivors are engaging in.

PRACTICAL STRATEGIES FOR PRACTITIONERS

All practitioners working with cancer survivors are encouraged to refer to the *American College of Sports Medicine Roundtable on Exercise Guidelines for Cancer Survivors* [5]. Overall, this panel concluded that there appears to be consistent evidence that PA is safe during and after cancer treatment. The panel recommended that cancer survivors should engage in an overall volume of weekly PA equivalent to 150 min of at least moderate intensity PA. If the survivor is engaging in vigorous intensity PA, the recommendation can be achieved by accruing 75 min per weak. The 150 min should include 2–3 days of strength training as well as stretching activities.

It is difficult to provide guidelines that are individually tailored since there is considerable variation in cancer survivors' pathophysiology and treatment(s) received. Many cancer survivors experience adverse effects months and/or years after treatment(s) are completed (e.g., cardiovascular and pulmonary toxicities, hypertension, atherosclerosis, lymphedema, hematologic abnormalities, neuropathy) that can decrease their capacity to engage in certain types of PA. These negative side effects can result in fatigue, pain, decreased balance, impaired motor skills, shortness of breath, lowered aerobic capacity, deconditioning, muscle atrophy, and general performance limitations. For example, cancer survivors experiencing shortness of breath may find it difficult to engage in certain aerobic activities, whereas survivors experiencing pain may find it difficult to engage in weight bearing activities. In addition, since cancer is an advancing age disease there are likely other aging health concerns (e.g., chronic obstructive pulmonary disease, osteoporosis) that may occur alongside cancer-related comorbidities and interfere with PA.

Accordingly, the presence of these medical comorbidities and/or negative side effects of treatment may be significantly debilitating and affect cancer survivors' ability to tolerate and/or engage in PA. This highlights the need for practitioners to be attentive of these issues and help survivors chose activities that are appropriate, safe, and feasible (e.g., seated activities for survivors reporting loss of balance). Thus, although the guidelines discussed above are useful, PA prescriptions should be tailored for survivors based on their PA levels prediagnosis and current health status. Programs for survivors who have always been inactive and experience negative treatment side effects will differ from programs for survivors who have always been active and are without encumbering side effects. Nevertheless, all cancer survivors should be encouraged to resume activity gradually and should see the PA guidelines presented above as a long-term goal.

The first step in facilitating PA behavior change is to communicate to and educate cancer survivors about benefits of regular and sustained PA and provide them with clear guidelines. To support PA behavior change among patients, practitioners may also want to encourage survivors to engage in intermittent bouts of activity throughout the day until they are able to complete a continuous longer bout of activity [43]. Participating in shorter bouts of PA (i.e., at least 10 min in duration) has been shown to facilitate adherence to PA [75]. For survivors that are unfamiliar with how to initiate and maintain a PA program, practitioners could promote *lifestyle-based* physical activities. These activities are planned or unplanned activities that are part of everyday life such as leisure, occupational, household, and/or care-giving/childcare activities. Practitioners could encourage their patients to at least perform these lifestyle-based activities at a moderate intensity. During moderate intensity PA, there should be an increase in heart rate, light sweating, and the individual may need to catch their breath if they are talking during the activity. If the individual is going for a walk, walking as if one was late for an appointment is one example of moderate intensity PA. The lifestyle approach may be particularly beneficial for survivors who are reluctant to begin a traditional PA program because they fear that intense activity may exacerbate their cancer-related symptoms (e.g., fatigue, pain, nausea).

Additionally, practitioners must recognize the unique disease and treatment-related PA barriers that survivors may face (see Table 39.3) in addition to the "traditional" barriers that healthy adults report (e.g., lack of time, lack of motivation, financial burden) [43]. One common suggestion practitioners can provide is for their patients to engage in PA when fatigue levels are lowest (e.g., morning), for shorter durations, lower intensities, and perform interval training (i.e., alternate activity and rest bouts). While the majority of cancer survivors are able to safely participate in regular PA, practitioners should still consider individual factors (e.g., body size, functional limitations, treatment received) and provide PA recommendations that are suitable, appropriate, and allow the survivor the

highest likelihood to experience success. Practitioners should involve and engage their patients in the discussion regarding PA and ways PA guidelines can be achieved. There is good evidence that providing individuals choices for PA is indeed associated with greater participation [76]. This is an important consideration when discussing PA among cancer survivors.

For practitioners who are unfamiliar or uncomfortable with discussing PA with their patients, there are several avenues where patients can seek assistance. The practitioners may refer the patient to a local Certified Exercise Specialist or fitness trainer. There are a number of exercise specialists also now achieving the ACSM Cancer Exercise Trainer certification [5], and there are published tips for proper training for some cancer survivor groups, such as breast cancer [77]. Practitioners can also refer their patients to a local Young Men's Christian Association (YMCA) or other local wellness centers offering appropriate PA programs delivered by qualified instructors. Several cancer centers and hospitals now offer PA and/or rehabilitation programs for cancer survivors. As the evidence-base continues to grow and support the role of PA across the cancer survivor context, practitioners should be prepared to discuss PA and refer their patients to available PA opportunities and pursuits.

CONCLUDING REMARKS

There is now unquestionable merit in encouraging and fostering PA throughout the cancer continuum. Overall, the data suggest there are many biopsychosocial benefits associated with regular and sustained PA participation, and these benefits are observed among cancer survivors as defined in this chapter. Unfortunately, most cancer survivors fail to meet established PA guidelines, and their long-term health and well-being may be at risk. It is important that survivors realize that PA is beneficial. With the assistance and guidance from physicians, health professionals, and qualified PA personnel, more cancer survivors may realize the benefits associated with PA.

Among the several lifestyle activities affecting cancer risk that humans have within their control, such as the use of tobacco products, overexposure to cosmic irradiation, physical activity and diet, one would think that the most easily controlled is the one that relates to what one eats and how much one eats. The National Cancer Institute estimates that at least 35% of all cancers have a nutritional connection.

As reflected in Chapter 38, the subject of the relationship between being overweight or obese and one's risk of developing cancer is addressed. Strong evidence exists that obesity is a causal factor for certain cancers, including breast cancer, colon cancer, uterine cancer, and others. In that chapter, there is a brief reference to diet and how the intake of dietary components are or may be related to the reason those cancers may evolve. This chapter will inform the reader of more detail about how nutrition has a bearing on these and other cancers and which dietary nutrients may have a significant role in that process.

EPIDEMIOLOGY

Epidemiologic evidence that nutrition plays a role as an etiologic factor for several cancers is compelling. There is considerable evidence that nutrition significantly affects the development of certain cancers, including cancers of the colon, pancreas, kidney, breast, ovary, endometrium, and prostate [1].

Both epidemiologic studies and laboratory experiments have provided evidences that dietary factors have a role in carcinogenesis. In 1982, the Committee on Diet, Nutrition, and Cancer of the National Research Council conducted a comprehensive evaluation of this evidence. That assessment suggested that a high fat diet is associated with increased susceptibility to cancer of different sites, particularly the breast and colon, and to a lesser extent, the prostate, and that dietary fiber may have a protective effect against colon cancer.

In epidemiologic studies, consumption of certain fruits and vegetables, especially citrus fruits and carotene-rich and cruciferous vegetables, is associated with a lower incidence of some cancers. It is not clear which specific components of these foods are responsible for these effects, although the epidemiologic evidence appears to be most consistent for an effect of beta-carotene on lung cancer and less so for vitamins A and C and various cancer sites [2].

With respect to geography, studies on migrant populations have supported the concept that diet and nutrition as risk factors for human cancers relate to dietary habits. Reduction in gastric cancer and an increase in colon cancer incidences have been observed in immigrants moving from Japan to the United States via Hawaii with concurrent change in dietary habits. In this population, high fat consumption has been linked to increased incidence of breast and colon cancer, and increased intake of dietary fiber (or some specific component of it) may be associated with diminished risk of colorectal cancer [3].

FRUITS, VEGETABLES, AND CANCER

Epidemiologic evidence of a protective role for fruits and vegetables in cancer prevention is substantial. Current U.S. fruit and vegetable intake averages about 3½ servings per day.

The strength of the scientific evidence guides U.S. policy-making in diet and health issues and facilitates community and local programs that address national dietary goals to increase fruit and vegetable consumption.

The types of vegetables or fruit that appear to be protective against cancer are raw vegetables, followed by allium vegetables, carrots, green vegetables, cruciferous vegetables, and tomatoes. Substances present in fruits and vegetables that may help protect against cancer include the group of phytochemicals such as dithiolethiones, isothiocyanates, indole-3-carbinol, allium compounds, isoflavones, protease inhibitors, saponins, phytosterols, inositol hexaphosphate, lutein, beta-carotene, lycopene, flavonoids, D-limonene, and other nutrients that have been known for some time such as vitamin C, folic acid, selenium, vitamin E, and dietary fiber [4].

While most studies have shown a protective effect of high consumption of fruits and vegetables, one large study of more than 142,000 men and 335,000 women, conducted by the European Prospective Investigation into Cancer and Nutrition (EPIC), during 1992–2000, revealed only a very small inverse association between intake of total fruits and vegetables and cancer risk, and the reduced risk was restricted to women [5].

ANTIOXIDANTS AND CANCER

Antioxidants are substances that may protect cells from the damage caused by unstable molecules known as free radicals. Due to their highly chemical reactivity, free radical damage may lead to cancer. Antioxidants interact with and stabilize free radicals and may prevent some of the damage free radicals might otherwise cause. Examples of antioxidants include beta-carotene; lycopene; resveratrol; vitamins C, E, and A; and selenium. Considerable laboratory evidence from chemical, cell culture, and animal studies indicates that antioxidants may slow or possibly prevent the development of cancer.

In the 1990s, several large randomized trials examining the effect of antioxidants on cancer were reported, with inconsistent conclusions. One large study examining the effect of beta-carotene, vitamin E, and selenium on cancer in Chinese men and women at high risk for gastric cancer showed a significantly reduced incidence of both gastric and cancer and cancer overall [6].

Examining the effects of beta-carotene and vitamin E on the incidence of lung cancer, the Alpha-Tocopherol (vitamin E)/Beta-Carotene Cancer (ATBC) Prevention Study, reported in 1994,demonstrated that lung cancer rates of Finnish male smokers increased significantly with beta-carotene supplements and were not affected by vitamin E [7]. Another 1994 study, the Beta-Carotene and Retinol (vitamin A) Efficacy Trial (CARET), also demonstrated a possible increase in lung cancer associated with antioxidants supplements [8]. The 1996 Physicians' Health Study I (PHS) found no change in cancer rates associated with beta-carotene and aspirin taken by U.S. male physicians [9]. Taken together, these results suggest there is no convincing evidence of a benefit of antioxidants for overall cancer risk.

CALCIUM AND CANCER

Some studies have suggested that high calcium intake may decrease the risk of one or more types of cancer, whereas other studies suggest that a high calcium intake may actually increase the risk of prostate cancer.

In one study, a randomized trial that included nearly 1200 healthy, postmenopausal Nebraska women, participants in the study were randomized to receive daily calcium supplementation alone (300–600 mg elemental calcium), calcium supplementation (300–600 mg elemental calcium) combined with vitamin D supplementation (1000 IU), or a placebo for 4 years [10]. The incidence of all cancers combined was approximately 60% lower for women who took the calcium plus vitamin D supplements compared with women who took the placebo. A lower risk of all cancers combined was also observed for women who took calcium supplements alone, but this finding was not statistically significant.

Several studies have suggested that a high intake of calcium may increase the risk of prostate cancer. In 2008, The European Prospective Investigation into Cancer and Nutrition reported an increased prostate cancer risk among more than 142,000 men consuming a high intake of protein or calcium from dairy products. Calcium from nondairy sources, however, was not associated with increased risk [11]. Another study, a prospective analysis of dairy product and calcium intakes among more than 29,000 men participating in the National Cancer Institute's (NCI) Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial showed increased risks for prostate cancer associated with high dietary intakes of calcium and dairy products, but not from calcium supplements [12]. In contrast, results from the NIH-AARP Diet and Health Study showed no increased risk of prostate cancer associated with total calcium, dietary calcium, or supplemental calcium intakes [13].

Ovarian cancer may be less frequent in women consuming calcium from dairy products [14]. The Nurses' Health Study found that higher intakes of calcium reduced the risk of breast cancer among premenopausal, but not postmenopausal women [15,16]. This was seen only with calcium-containing dairy products as nondairy sources were not associated with the reduction in risk [15].

There is also evidence that high calcium intake may confer protection from developing colorectal cancer, and while the exact mechanism by which calcium may reduce the risk of colorectal cancer is unclear, it is known that calcium binds to bile acids and fatty acids in the gastrointestinal tract to form insoluble complexes known as calcium soaps. It is speculated that this process may reduce the ability of the acids (or their metabolites) to damage cells in the lining of the colon. Calcium also may improve signaling within cells and cause cancer cells to differentiate and/or die [17].

SOY, GARLIC, TEA, AND CANCER

"Soy" comes from the soybean, a legume native to Northern China. It is often called a complete protein because it is the most complete protein source from vegetables comparable in that regard to animal protein derived from meat products. Soy protein contains many essential nutrients, and human populations that regularly include soy in their diets and decrease meat protein intake are generally healthier. In a meta-analysis of 8 studies among Asian women and 11 studies among low soy consuming Western women, a reduction in risk of breast cancer was observed among Asian women with high (≥20 mg/day) versus low (<5 mg/day) soy consumption. In contrast, no such benefit was observed among Western women whose range of soy consumption was significantly lower (from 0.8 to 0.15 mg/day). A meta-analysis of eight prostate cancer cohort and case control studies examining the effect of dietary soy consumption revealed a reduction in prostate cancer risk with increased soy consumption [18]. In addition to these very common cancers, colorectal cancer and lung cancer also seem to be less frequent in these populations. In a case control study examining lung cancer risk and phytoestrogen intake, a 46% risk reduction was observed among those in the highest quartile of phytoestrogen consumption from food sources [19]. These benefits were observed both in nonsmokers and current smokers. The effectiveness of soy appears to be due to the presence of phytochemicals, chemicals derived from plant products. One such chemical, phytate is an organic acid that is the storage form of phosphorus, a substance that binds iron and calcium in the intestines. Other constituents of soy include saponins that protect DNA from damage, a process known to result in cancer transformation, and protease inhibitors, which are important in their property of inhibiting protein digestion. Finally, isoflavones, natural estrogenic-like chemicals unique to soybeans, have been shown to impede cell proliferation and cancer growth in vitro. However, because these specific compounds are plant estrogens, more research is needed to end the controversy regarding the safety of soy foods for women with breast cancer.

Garlic is a vegetable (*Allium sativum*) that belongs to the allium class of bulb-shaped plants. Other vegetables in this class include onions, chives, leeks, and scallions. Garlic is used for flavoring in cooking and is unique because of its high sulfur content, the source of its characteristic odor and flavor, created when allicin is formed when garlic bulbs are chopped, crushed, or damaged [20]. Garlic also contains arginine, oligosaccharides, flavonoids, and selenium, all of which may be beneficial to health [21].

Several population studies have shown an association between increased intake of garlic and reduced risk of certain cancers, including cancers of the stomach, colon, esophagus, pancreas, and breast. An analysis of data from several studies showed that the higher the amount of raw and cooked garlic consumed, the lower the risk of stomach and colorectal cancer [22].

In another large prospective study investigating whether diet, distribution of body fat, and other risk factors are related to cancer incidence, findings showed a strong association between garlic consumption and colon cancer risk. Women in that study who consumed the highest amounts of garlic had a 50% lower risk of cancer of the distal colon compared with women who had the lowest level of garlic consumption [23].

Other population studies have found that frequent consumption of garlic and various types of onions and chives was associated with reduced risk of esophageal and stomach cancers [24].

Evidence also suggests that increased garlic consumption may reduce pancreatic cancer risk. A study conducted in the San Francisco Bay area found that pancreatic cancer risk was one-half that for people who ate larger amounts of garlic compared with those who ate lower amounts [25].

Tea, among the oldest and most popular beverages in the world, is composed of polyphenols, alkaloids (caffeine, theophylline, and theobromine), amino acids, carbohydrates, proteins, chlorophyll, volatile organic compounds (chemicals that readily produce vapors and contribute to the odor of tea), fluoride, aluminum, minerals, and trace elements [26]. The polyphenols, a large group of plant chemicals that includes the catechins, are thought to be responsible for the health benefits that have traditionally been attributed to tea, especially green tea [27]. The most active and abundant catechin in green tea is epigallocatechin-3-gallate (EGCG).

Among their many biological activities, the predominant polyphenols in green tea, EGCG, and others, and the theaflavins and thearubigins in black teas have antioxidant activity [28]. These chemicals have substantial free radical scavenging activity and may protect cells from DNA damage caused by reactive oxygen species [29]. Tea polyphenols have also been shown to inhibit tumor cell proliferation and induce apoptosis in laboratory and animal studies [30]. In other laboratory and animal studies, tea catechins have been shown to inhibit tumor cell invasiveness [30]. In addition, tea polyphenols may protect against damage caused by ultraviolet (UV) B radiation [31], and they may modulate immune system function [32]. Green teas have been shown to activate certain enzymes such as glutathione S-transferase and quinone reductase that may help protect against tumor development [32]. Although many of the potential beneficial effects of tea have been attributed to the strong antioxidant activity of tea polyphenols, the precise mechanism by which tea might help prevent cancer has not been established [30].

More than 50 epidemiologic studies of the association between tea consumption and cancer risk have been published since 2006. While inconclusive and inconsistent, the results of these studies have linked tea consumption to reduced risks of cancers of the colon, breast, ovary, prostate, and lung [33–37]. The inconsistent results may be due to variables such as differences in tea preparation and consumption, the types of tea studied (green, black, or both), the methods of tea production, the bioavailability of tea compounds, genetic variation in how people respond to tea consumption, the concomitant use of tobacco and

alcohol, and other lifestyle factors that may influence a person's risk of developing cancer, such as physical activity or weight status.

NUTRITION AND BREAST CANCER

Many studies indicate that a diet high in vegetables and fruits may protect against breast cancer and, given the observed variations in incidence rates with this disease among geographically differing populations, it has been strongly considered that diet is a risk factor for breast cancer.

In one large study of premenopausal women 40 years of age or older, identified through pathology records from hospitals in Western New York, it was shown that intake of vegetables appeared to decrease premenopausal breast cancer risk. Fruits were weakly associated with a reduction in risk. In this study, intake of vitamins C and E and folic acid taken as supplements did not influence risk and no single dietary factor explained the favorable effect [38].

Data on intake of specific carotenoids and breast cancer risk are limited. Furthermore, studies of vitamins A, C, and E in relation to breast cancer risk, not limited to premenopausal status, are inconclusive. In a cohort of more than 80,000 women (aged 33–60 years in 1980) who were participating in the Nurses' Health Study, 2697 incident cases of invasive breast cancer (784 premenopausal and 1913 postmenopausal) were identified. In this large analysis, intakes of beta-carotene from food and supplements, lutein/zeaxanthin, and vitamin A from foods were weakly associated with a reduction in breast cancer risk, but only in premenopausal women and in those premenopausal women who consumed five or more servings per day of fruits and vegetables. Moreover, this association was stronger among those who had a positive family history of breast cancer [39].

Most of the foregoing evidence that an intake of vegetables and fruits protects against developing breast cancer comes from case control studies. A more recent analysis in which a prospective study was employed casts some doubt that there truly is a protective effect from consuming these nutrients. This study included 285,526 women between the ages of 25 and 70 years, participating in the European Prospective Investigation Into Cancer and Nutrition (EPIC) study, in which each participant completed a dietary questionnaire in 1992–1998 and subsequently followed for incidence of cancer until 2002. During 1,486,402 person-years (median duration of follow-up, 5.4 years), 3659 invasive incident breast cancer cases were reported. No significant associations between vegetable or fruit intake and breast cancer risk were observed. Although the period of follow-up, at the time of publishing the results was limited, the results suggested that total or specific vegetable and fruit intake is not associated with risk for breast cancer [40].

There is no clear association between the intake of red meat and breast cancer. In the Nurses' Health Study II, red meat intake in premenopausal women between ages 26 and 46 was assessed with subjects being questioned regarding intake in 1991, 1995, and 1999 with follow-up in 2003. During the 12 years of follow-up of 90,659 premenopausal women, greater red meat intake was strongly related to elevated risk of breast cancers that were estrogen and progesterone receptor positive, but not to those that were estrogen and progesterone receptor negative. Thus, higher red meat intake may be a risk factor for premenopausal women who develop estrogen and/or progesterone positive breast cancer [41].

NUTRITION AND COLORECTAL CANCER

While there is clear evidence of genetic predisposition to colon cancer, dietary habits also appear to be a significant risk factor. Some data suggest that vegetables are associated with a lower risk of colon cancer; and, fiber content in the diet does not alone seem to account for this association. In both men and women, red meat consumption appears to be associated with increased risk; however, evidence would suggest that this is not explained solely by its fat content. Mutagenic compounds, particularly heterocyclic amines, produced when meat protein is cooked, may explain the meat association. On the contrary, certain microconstituents of the diet, including folate and calcium may be associated with reduced risk. Rectal cancer is less well studied than colon cancer but, at present, there are few data to suggest that the dietary risk factors are markedly different [42].

With respect to dietary fiber, this nutrient has received considerable attention as a factor that may reduce the risk of colorectal cancer. Potential mechanisms for a protective effect include dilution of fecal carcinogens, reduction of transit time of feces through the bowel, production of short chain fatty acids, which promote anticarcinogenic action, and binding of carcinogenic bile acids [43]. Inconsistent findings from observational studies have continued the controversy over the effects of dietary fiber on these cancers. One large meta-analysis, in which 13 prospective cohort studies were examined, over 700,000 men and women were followed for 6–20 years. In this pooled analysis, dietary fiber intake was inversely associated with risk of colorectal cancer. However, after accounting for other dietary risk factors, high dietary fiber intake as an independent variable did not appear to be solely responsible for the reduced risk of colorectal cancer [43]. In yet another large meta-analysis of 25 reported studies, it did appear that a high intake of dietary fiber, in particular cereal fiber and whole grains, was associated with a reduced risk of colorectal cancer [44].

With respect to fish consumption and colorectal cancer, epidemiologic studies have been inconsistent. Animal studies

have shown favorable effects of n-3 fatty acids (omega-3) on inflammation and cancer, thus the potential that this nutrient, abundant in certain fish, may reduce the risk of colorectal cancer has been studied in a very limited manner. In one large analysis of cohort studies, fish consumption was shown to slightly reduce colorectal cancer risk, but as noted, few data are available addressing this association [45].

NUTRITION AND PROSTATE CANCER

There is considerable evidence that prostate cancer is the result of both inherited as well as environment influences. African American men have the highest incidence of prostate cancer in the world, while Asian men have the lowest. As men from the Far East migrate to the United States and as Western cultural influences, such as diet, are being adopted in that part of the globe, those who immigrate and those who more frequently consume a Western diet appear to be at greater risk of developing prostate cancer [46].

Such epidemiologic studies combined with animal model and in vitro experiments indicate that natural components of the diet, including n-3 PUFA, the carotenoid lycopene, and the trace element selenium, may serve as chemopreventive agents that suppress the growth and dissemination of neoplastic prostate cells [47].

Soyfoods are a unique dietary source of isoflavones, which have both hormonal and nonhormonal effects relevant to prostate cancer prevention. The in vitro studies have shown that the main soybean isoflavone protein, genistein, inhibits prostate cancer cell growth; in animals, some studies show isoflavone-rich soy protein and isolated isoflavones inhibit prostate tumor growth. Although limited epidemiologic data indicate soy intake reduces prostate cancer risk, results from one trial suggest isoflavones may be beneficial to prostate cancer patients [48].

Several case control and large prospective studies have suggested that the intake of tomatoes and tomato products may reduce one's risk of having prostate cancer and that lycopene, one of the compounds in tomato products, may confer that protection. Other carotenoids and phytochemicals in tomato products may also contribute to the proposed health benefits. Since only randomized controlled studies would provide a definitive answer to this hypothesis, such studies are unlikely due to the fact that tomato products are such a common part of the American diet and the duration of these trials would make them very difficult. As noted, numerous other potentially beneficial compounds are present in tomatoes, and, conceivably, complex interactions among multiple components may contribute to the anticancer properties of tomatoes [49–50].

NUTRITION AND ENDOMETRIAL CANCER

Endometrial cancer is the most common gynecologic cancer in the United States. While the relationship between obesity and endometrial cancer is quite well established, there is limited evidence that nutritional factors influence the incidence of this cancer. Case control studies have suggested an inverse association between fruit and vegetable consumption and endometrial cancer [51]; however, cohort studies have failed to substantiate this relationship [51,52]. Essentially, the same conclusion has been reached for dietary fiber, red meat, and antioxidant intakes [53,54].

NUTRITION AND OVARIAN CANCER

For ovarian cancer, the second most common gynecologic cancer in the United States, there are no recognized nutritional risk factors [55]. A somewhat detrimental relationship exists for obesity and limited physical activity [56]; however, additional controlled studies are needed to confirm such associations.

NUTRITION AND PANCREATIC CANCER

Pancreatic cancer is the fourth leading cause of cancer mortality in the United States and while there is substantial evidence that tobacco smoking and type 2 diabetes increase the risk of developing pancreatic cancer, there is limited evidence that dietary factors such as increased red meat and decreased intake of fruit and vegetables affect the incidence of this cancer [57,58].

NUTRITION AND GASTRIC CANCER

While somewhat uncommon in the United States, cancer of the stomach is the second leading cause of death from cancer worldwide [59]. Even though a relatively rare cancer in the United States, the overall incidence of this cancer appears to be increasing, an observation that may be related to gastric reflux into the lower esophagus due to abdominal obesity [60]. Numerous studies have shown that a diet of increased fruit and vegetables reduces the risk of developing gastric cancer, whereas a diet of increased salt and salt-preserved foods is associated with an increased risk [61,62].

SUMMARY

"The scientific study of nutrition and cancer is highly complex, and many important questions remain unanswered (Table 40.1). It is not presently clear how single nutrients, combinations of nutrients, over-nutrition, and energy imbalance, or the amount and distribution of body fat at particular stages of life affect a person's risk of specific cancers. Until more is known about the specific components of diet that influence cancer risk, the best advice is to consume a mostly plant-based diet that limits red and processed meats and emphasizes a variety of vegetables, fruits, and whole grains, legumes, nuts, seeds, herbs, and spices. A special emphasis should be placed on controlling total caloric intake to help achieve and maintain a healthy weight" [63].

TABLE 40.1
Relationships between Nutritional Factors and Certain Cancers

Cancer Site	Dietary Influences
Breast	• High dietary fat consumption has been linked to an increased incidence [3] • Higher intakes of calcium-containing dairy products reduced the risk in premenopausal, but not postmenopausal women [15,16] • High consumption of soy (≥20 mg/day) has been associated with a reduction of risk in Asian women. More research is needed to end the controversy regarding the safety of soy foods for women with breast cancer [18] • Increased intake of raw or cooked garlic is associated with a reduced risk [22] • While inconclusive and inconsistent, the results of studies have linked tea consumption to a reduced risk [33–37] • Total or specific vegetable and fruit intake is not associated with risk for breast cancer [40]. Intake of vegetables may decrease risk in premenopausal women; fruits are weakly associated with a decreased risk [38] • Studies of vitamins A, C, and E, not limited to premenopausal women, are inconclusive in relation to risk. Beta-carotene from food and supplements, lutein/zeaxanthin, and vitamin A from foods were weakly associated with a reduction in risk, but only in premenopausal women who consumed five or more servings per day of fruits and vegetables [39] • No clear association with red meat consumption; however, higher red meat intake may be a risk factor for premenopausal women who develop estrogen and/or progesterone positive breast cancer [41]
Esophagus	• Increased intake of garlic and various types of onions and chives is associated with a reduced risk [24]
Lung	• A reduced risk was observed among those with increased phytoestrogen consumption from food sources, both in nonsmokers and current smokers [19] • While inconclusive and inconsistent, the results of studies have linked tea consumption to a reduced risk [33–37] • Possible increase associated with antioxidant supplements (beta-carotene); no effect with vitamin E [2,7,8]
Gastric	• Beta-carotene, vitamin E, selenium showed a significantly reduced incidence in Chinese men and women [6] • Increased intake of raw and cooked garlic and various types of onions and chives is associated with a reduced risk [22,24] • Increased fruit and vegetable intake reduces risk [61,62] • Increased salt and salt-preserved foods increases risk [61,62]
Pancreatic	• Limited evidence that dietary factors such as increased red meat and decreased intake of fruit and vegetables affect the incidence [57,58] • Increased intake of garlic is associated with a reduced risk [25]
Prostate	• High intakes of calcium and dairy products may be associated with an increased risk [11,12] • Increased consumption of dietary soy revealed a reduction in risk [18] • While inconclusive and inconsistent, the results of studies have linked tea consumption to a reduced risk [33–37] • In animal and in vitro studies, n-3 PUFA, lycopene, and selenium may serve as chemopreventive agents [47] • There are limited epidemiologic data, however one trial suggests isoflavones may be beneficial to prostate cancer patients [48] • Intake of tomatoes and tomato products may reduce risk [49–50]
Ovarian	• No recognized nutritional risk factors [55] • May be less frequent in women consuming calcium from dairy products [14] • While inconclusive and inconsistent, the results of studies have linked tea consumption to a reduced risk [33–37]
Endometrial	• Limited evidence that nutritional factors influence the incidence; cohort studies have failed to substantiate the relationship with fruit and vegetable consumption, dietary fiber, red meat, and antioxidant intakes [51–54]
Colorectal	• After accounting for other dietary risk factors, high dietary fiber intake as an independent variable does not appear to be solely responsible for a reduced risk [43]. However, intake of particularly cereal fiber and whole grains was associated with a reduced risk [3,44] • High dietary fat consumption has been linked to an increased incidence [3] • High calcium intake may confer protection [17] • Higher consumption of raw and cooked garlic is associated with a lower risk [22,23] • While inconclusive and inconsistent, the results of studies have linked tea consumption to a reduced risk [33–37] • Red meat appears to be associated with increased risk [42] • Inconsistent results in regards to fish consumption and risk [45]
Overall Cancer Risk	• Very small inverse association between intake of total fruits and vegetables and cancer risk which was restricted to women [5] • Beta-carotene, vitamin E, and selenium showed a significantly reduced incidence in Chinese men and women [6] • No convincing evidence of a benefit of antioxidants [9] • 300–600 mg elemental calcium plus 1000 IU vitamin D supplementation reduced the risk of all cancers combined by approximately 60% in women [10]

EPIDEMIOLOGY OF ADULT OBESITY

Obesity represents one of the most significant public health issues for the world in recent history. Obesity increases the risk for numerous chronic diseases and significantly contributes to worldwide morbidity and mortality. Obesity results in an excess mortality of approximately 300,000 deaths annually in America [1], and the estimated health care costs associated with obesity morbidity are approaching the $100 billion mark. Indeed, obesity is one of the leading preventable causes of death and disease globally.

Obesity and Adiposity

Clinically, obesity is a condition characterized by the accumulation of excess adipose tissue. Therefore, standards to define and classify obesity require the assessment of total body adiposity. However, the quantitative determination of body fat composition remains difficult and costly to obtain. Techniques such as dual-energy x-ray absorptiometry (DEXA) and bioelectrical impedance possess the ability to quantify total body fat. However, these techniques require the use of specialized equipment by qualified technicians. Thus, these methods

remain largely restricted to small-scale research purposes because the high cost and burden of data collection make their use in large-scale research or clinical practice unrealistic. For practical reasons, researchers and clinicians often rely on proxy measurements to approximate adiposity.

MEASUREMENT OF ADIPOSITY

There are numerous accepted adiposity measurement systems used for indirectly measuring total body fat and for screening nutritional and health status. Those measurements include hydrodensitometry, DEXA, anthropometry, bioelectrical impedance analysis (BIA), computed tomography (CT), and ultrasonic technique. Often more than one method of body fat measurement is used to assess body composition in order to address the clinical or research goal appropriate for the individual and population. All methods that estimate body fat are interpreted using the same cut point for obesity (% body fat > 25.0 for men and > 30.0 for women; Table 41.1) [2].

Hydrodensitometry

Hydrodensitometry or underwater weighing (UWW) has long been considered one of the "gold standards" for measuring body composition and estimating body fat [3]. It is one of the classic two-compartment (2-C) models. In the 2-C model, the body is divided into two components, fat mass and fat-free mass (water, protein, and mineral). Therefore, by subtracting fat-free mass from body weight, fat mass can be defined. The UWW applies Archimedes' principle to determine total body volume or body density by measuring the difference of body's weight in water and in air after correction for the volume of air in the respiratory system and in the gastrointestinal tract [4]. In this model, it assumes that fat-free mass contents are fixed for all ages [3,5]. Using Siri's formula [6], fat mass can be determined and percent body fat can be indirectly estimated using Equation 41.1:

$$\%\,\text{Body fat} = \left(\frac{495}{\text{Body density}}\right) - 450 \qquad (41.1)$$

Although UWW has been widely accepted and frequently referred as a gold standard for body density measurement, there are several limitations associated with this method. It is time and labor consuming, requires special training, and often creates individual discomfort [5,7,8]. In addition, the fat-free mass component normally varies by individuals due to gender, ethnicity, age, and/or physical activity [9,10]; hence, estimates must be corrected for variation from these factors. Furthermore, this technique is particularly challenging with heterogeneous populations such as children, pregnant women, and elderly or disabled individuals.

An air-displacement plethysmography was developed to be an alternative to hydrodensitometry. This method determines body volume by measuring the changes of chamber volume caused by placing an individual in a closed air-filled chamber [7]. Adequate corrections for temperature and gas composition as well as lung volume are required before calculating body volume. Several studies reported that the plethysmographic method demonstrated good agreement with the UWW techniques [11,12]. However, since both of these methods are 2-C models neither is more accurate that the other, making conclusions difficult. The absolute differences between the Bod Pod, the commercially available method of air-displacement plethysmography, and UWW were about 1% body fat and were not consistent in any direction [13]. Studies have demonstrated high agreement (0.91–0.94) [13,14] between the Bod Pod and DEXA, which uses a 3-C model for estimating body fat. In one study of 160 men, the mean difference in body fatness (2.2%) between methods was significant and increased as body fat increased [13]. An advantage of the air-displacement plethysmography technique is that it is less stressful for the individual because they are not immersed in water; however, it may be a problem for those who are claustrophobic.

Dual-Energy X-Ray Absorptiometry

DEXA has been developed to assess body composition in order to improve accuracy over the 2-C model. It uses four-compartment (4-C) models examining regional and whole body composition, including body fat, lean soft tissue, water volume, and bone mineral mass [5,15]. This technique requires participants to remove all metal accessories and lay in a supine position on a bed while the collimated low intensity x-ray source passes below the bed synchronized with the movement of a detector array above the body [16]. DEXA is quick and easy to perform on all types of individuals regardless of their disability and often is used as the gold standard reference method for body composition analysis in clinical settings [17]. Limitations include its expense and moderate validity [15,18]. DEXA's accuracy is affected by varying fat distributions, but it is superior to UWW weighing because it lacks sensitivity to a person's residual volume of unexpelled air or hydration status [15,19]. DEXA measures of central adiposity also correlate well with measures of intra-abdominal fat measured by magnetic resonance imaging (MRI) in nonobese women ($r = 0.88$) and men ($r = 0.87$) [20].

TABLE 41.1
Classification of Overweight and Obesity by BMI Levels and Public Health Action Points

WHO Classification	BMI (kg/m²)	Public Health Action Points, BMI (kg/m²)
Underweight	<18.5	—
Normal	18.5–24.9	23.0
Overweight/preobese	25.0–29.9	27.5
Obese Class I	30.0–34.9	32.5
Obese Class II	35.0–39.9	37.5
Obese Class III	≥40.0	—

Anthropometric Measurements

Body Mass Index

BMI is the most popular and practical indicator for overweight and obesity classification because it is inexpensive, simple to calculate, and easy to gather weight and height via measurements or self-report [21,22]. Equation 41.2 indicates the calculation of BMI:

$$\text{BMI} = \frac{\text{Body weight (kg)}}{\text{Height (m)}^2} \tag{41.2}$$

Although BMI is the most frequently used measure of adiposity, it does not directly assess fat mass; instead, it is a measure of weight controlling for height. BMI correlates with percent body fat for the majority of the population. The use of BMI in adults allows for the categorization of adiposity estimates independent of gender and age. Therefore, agencies such as the World Health Organization (WHO) and International Obesity Task Force (IOTF) recommend the use of BMI to define and classify obesity. International standards to classify BMI consider an individual with a BMI between 25 and 29.9 kg/m^2 overweight and any person with a BMI ≥ 30.0 kg/m^2 obese [22–27] (Table 41.1). These BMI guidelines are based on numerous longitudinal cohort studies showing increased mortality risk as BMI increases beyond 25 kg/m^2. The BMI guidelines are based on the assumption that body fatness is increased as weight increases in relation to height [28], they do not consider fat content, and inadequately distinguish between lean and fat tissues [29,30] nor does BMI provide information on the distribution of fat mass [27]. Thus, BMI may overestimate fat mass in individuals with high levels of lean (muscle) mass (e.g., athletes, some military) [2,31] and underestimate fat mass in individuals with low levels of lean mass such as the elderly.

The correlation between BMI and percent body fat can vary between gender, age, and ethnic groups. For example, non-Hispanic blacks generally have a lower percentage of body fat for a given BMI compared to other ethnic groups [32,33]. Therefore, the health risk corresponding to a given BMI category may differ among gender, age, and ethnic groups [27,34]. An expert consultation by WHO amended the guidance in 2004 and identified potential public health action points (Table 41.1) to further aid countries' identification of individuals at increased risk for obesity-related comorbidities [27].

Waist Circumference

Waist circumference (WC) is used for measuring the fat located in the central region of the body (intra-abdominal fat). WC is more strongly associated with visceral adipose tissue and central adiposity than are BMI and waist-to-hip ratio [35–37]. In addition, WC is highly correlated with cardiovascular and diabetes risk factors and all-cause mortality and is considered to be a stronger predictor of obesity-related risk factors than BMI [2,38,39]. WC is measured with a nonelastic tape at the superior border of iliac crest [2], the mid-abdomen or midpoint between iliac crest and lowest rib [2], umbilicus level [40], or at the narrowest point of the waist [41], to the nearest 0.1 cm. A WC of >102 cm (or >40 in.) in men and >88 cm (or >35 in.) in women is considered as abdominal obesity, while men with a WC 94–102 cm and women with a WC 80–88 cm are classified as overweight (Table 41.2) [42]. The combination of classification of overweight or obese and a large WC is proposed to carry additional risk [2,43]. WC correlates with MRI measures of intra-abdominal fat in nonobese women ranging from r = 0.49 to 0.77 and among men from r = 0.77 to 0.90 [20]. WC is a comparable measure of abdominal fat mass to DEXA for men, but not for women [20].

TABLE 41.2
Classification of Overweight and Obesity by Anthropometric Measures

	Overweight		Obese	
Anthropometric Measure	**Male**	**Female**	**Male**	**Female**
WC [42]	94–102 cm	80–88 cm	102 cm	88 cm
Waist-to-hip ratio [22]	0.9–1.0	0.8–0.85	>1.0	>0.85
Skinfolds (sum of biceps, triceps, subscapular, and suprailiac) [2]	—	—	>25.0	>30.0

Waist-to-Hip Ratio

WHR is an alternative anthropometric measure for abdominal obesity additional to WC. WHR is obtained by dividing the WC by the hip circumference. For hip measuring, the tape is placed at the maximum extension of the buttocks [22]. Classification of obesity is as follows: men with a WHR > 1.00 and women with a WHR > 0.85, and classification of overweight is as follows: men with a WHR = 0.90–1.00 and women with WHR = 0.80–0.85 (Table 41.2) [22]. Because WHR provides additional information related to hip circumference, gluteofemoral muscle mass, and bone structure, it might be a better predictor of risk factors for cardiovascular disease as hip circumference is inversely related to the development of insulin resistance, dyslipidaemia, cardiovascular disease, hypertension, and death [22,44,45]. WHR and DEXA measures of abdominal visceral fat had the same correlation with MRI measures in men (r = 0.80) but WHR was not as good a measure among women as DEXA when using the MRI as the standard measure (r = 0.19) [20].

Skinfolds

Skinfold thickness measurement has been used as a body composition measurement to estimate percentage of body fat (%BF) since the 1970s [46]. It is still considered the most practical method used to estimate body fat and fat-free mass. This technique is simple, quick, inexpensive, but does require training [47]. According to Durnin and Womersley [46], skinfold thickness is measured to the nearest 0.1 mm on the right side of the body, at the biceps, triceps, subscapular, and suprailiac areas, using a Harpenden caliper (British Indicators Ltd., Luton, United Kingdom). The sum of skinfold thickness

at these four sites is used to predict %BF (Table 41.2). The correlation between body fat measures from skinfolds and DEXA was $r = 0.74$ and for fat-free mass was $r = 0.85$ among 50 chronic kidney disease patients [18]. Studies have shown agreement between skinfold measures and DEXA measures of body fat decline as %BF increases and the measures are lower among females than males. Women consistently have a low agreement with the gold standard possibly due to their ratio of subcutaneous and visceral fat and the ability of the skinfold measures to assess these parameters [48].

Bioelectrical Impedance

Compared to anthropometry methods, BIA is a more sophisticated technique to assess body fatness and %BF. It is noninvasive, simple to use, and has reproducible results. BIA is based on the principle that electrical current is more impeded through fat mass than fat-free mass or lean tissue (mostly water and electrolytes), resulting in differences in electrical resistance between fat mass and fat-free mass [49,50]. Two BIA measurements, whole body BIA and segmental BIA, have been developed for body composition assessment. For whole body BIA, surface electrodes are placed on a hand and a foot, or foot-to-foot or hand-to-hand, sending single or multiple frequencies measuring whole body resistance [51–53]. Because whole body BIA measures use multiple body segments, its results are likely to be influenced by a number of factors such as hydration and fat fraction [51]. In addition, as Lukaski and Scheltinga [54] noted, the trunk, which contains a large volume of conductors, only contributes a small amount to whole body resistance, which might be a problem in overweight and obese individuals [55,56]. Therefore, segmental BIA has been developed to minimize this effect. Segmental BIA focuses on body segment measurements of resistance derived by applying either two additional electrodes on the wrist and foot on the opposite side, the wrist, shoulder, upper iliac spine and ankle, or the forearm, lower leg and trunk [57–59]. Fat-free mass, fat mass, and total body water are estimated using predictive equations including impedance or resistance values [51]. BIA in elderly Finnish women has an agreement with DEXA for fat-free mass of $r = 0.7$ and fat mass of $r = 0.93$ as compared to skinfold measures with DEXA, which were $r = 0.62$ and 0.89, respectively [60]. Results by gender indicate BIA estimates of %BF in males had less error (6.8%) than that among females (8.8%) when compared to DEXA estimates of body fat [48]. General consensus suggests the equations used to calculate %BF from BIA can explain some variation between studies [48,60].

Computed Tomography

CT is an imaging technique widely used for body composition measurement. This technique uses x-ray as a source to detect body fat distribution. During CT scanning, the x-ray rotates around the body or body segments covering 360° while the photodetectors send the information regarding visceral and subcutaneous adipose tissue at each degree of rotation to yield CT images [61,62]. The main advantage of CT is that the images can be used to identify and visualize body adipose tissue mass, providing highly accurate body fat estimation [63,64]. Limitations of CT scanning include high costs and the need for radiation for imaging, which cannot be applied outside clinical or laboratory settings [65].

Ultrasound Technique

Ultrasonography was proposed by Armellini et al. [66] to be an alternative method to CT for visceral adiposity estimation. It is clinically accepted as the best technique for quantifying intra-abdominal fat because it directly measures fat thickness between the muscle and the skin [66,67]. The UT uses an ultrasound wave as a source to determine the thickness of subcutaneous fat [68]. The use of UT in intra-abdominal fat assessment was shown to be strongly correlated with %BF measured by DEXA [68], and CT [65]. UT is considered as a noninvasive and accurate technique of body fat measurement and is cheaper and more convenient to use than CT [69].

PREVALENCE OF OBESITY

BMI remains the most popular proxy measurement for obesity surveillance and monitoring due to its affordability and simplicity. Despite its limitations, BMI allows for the standardized tracking and comparison of obesity within and among populations.

U.S. Obesity Trends

The prevalence of obesity has been increasing for almost 100 years in the United States [70]. Since the 1960s, the National Health and Nutrition Examination Survey (NHANES) has taken an active role in tracking the prevalence of obesity in the United States. The prevalence of obesity remained fairly constant between 1960 and 1980 [71]. However, between 1976–1980 and 1988–1994, the overall prevalence of adult obesity increased by 8% points [72]. Moreover, all age, gender, and ethnic groups experienced a statistically significant increase in obesity prevalence [72]. From 1988–1994 to 1999–2000 the prevalence of adult obesity significantly increased in all age and gender categories except 40- to 59-year-old males [73]. Most recently, the prevalence of obesity increased significantly in men and nonsignificantly in women between 1999–2000 and 2007–2008 [74] (Figures 41.1 and 41.2). Although the recent data suggest obesity trends may be approaching a plateau, the prevalence of adult obesity remains high. The current prevalence of obesity is approximately double that of 1970 with 33.8% of the population considered obese and another 34% considered overweight [24,74].

Significant variations exist in the geographic and demographic distribution of obesity. Geographically, the states of the southeastern and midwestern United States have the highest rates of obesity, although the prevalence has increased in every state over the last 30 years [75]. Demographically, the distribution of obesity varies across gender, age, ethnic and socioeconomic groups. Minority

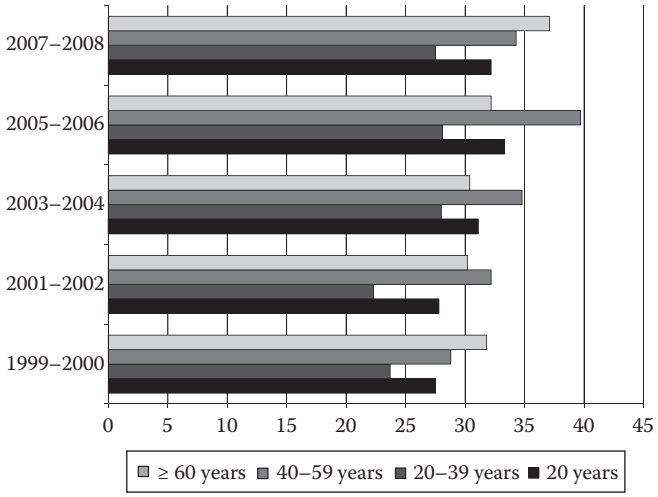

FIGURE 41.1 Trends in male prevalence (%) of obesity (BMI > 30 kg/m^2) by age. (Data from Flegal, K. M., et al. *JAMA* 303, 235–241, 2010.)

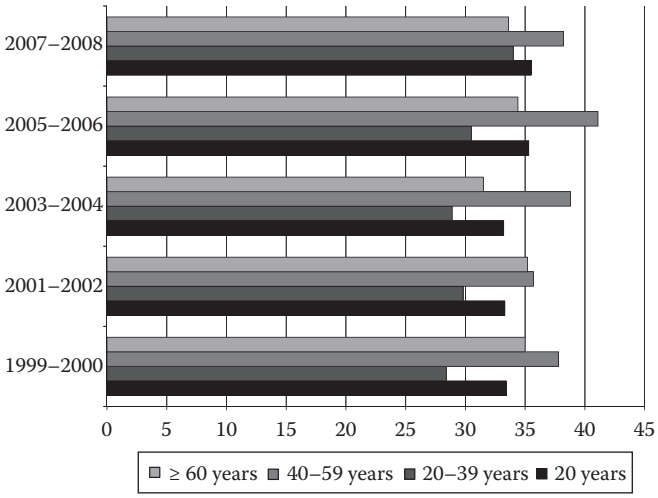

FIGURE 41.2 Trends in female prevalence (%) of obesity (BMI > 30 kg/m^2) by age. (Data from Flegal, K. M., et al. *JAMA* 303, 235–241, 2010.)

populations generally have higher rates of obesity compared to non-Hispanic whites [74]. Additionally, gender differences in the prevalence of obesity often exist within ethnic groups; however, the direction and magnitude of the disparity depends on the population of interest [74]. Finally, the prevalence of obesity is 50% higher among women of low socioeconomic status (SES) compared to women of higher socioeconomic status, whereas the prevalence of obesity is approximately equal among men regardless of socioeconomic status [76].

Every age, sex, race, and smoking status group is experiencing the obesity epidemic; thus distributional changes in these factors cannot fully explain the rapid changes seen in the last three decades. The increasing positive skew of the obesity distribution is worrisome because it indicates the most obese are even more obese than those in previous years [77].

Global Obesity Trends

Obesogenic environments currently exist in almost every country. Meta-analyses of data from 9.1 million participants indicate the mean worldwide BMI increased 0.4 kg/m^2 per decade for men and 0.5 kg/m^2 for women since 1980 [78]. Obesity has indeed reached the pandemic level. It is no longer a crisis only for developed countries as it is increasingly being seen in developing countries [22,78–80]. The onset of a rise in obesity began almost simultaneously in developed countries in the 1970s and 1980s [22,78–80]. While comprehensive data are not available from every country; evidence gathered by the International Association for the Study of Obesity supports the notion that the epidemic has spread globally [80]. Figure 41.3 rank orders a selection of developed and developing countries by the prevalence of obesity among males. Worldwide male prevalence of obesity ranges from 1.3% in India to 55.7% in Nauru. The females in Figure 41.4 are in the male ranked order. Comparison of these two figures clearly indicates the gender discrepancies in prevalence of obesity within countries [80]. The range of obesity prevalence is wider among females than males ranging from 2.8% in India to 70.3% in Tonga. Several large gender differences in the prevalence of obesity among both developed and developing countries are evident in Pakistan, Fiji, Algeria, Barbados, Bahamas, France, Egypt, Wales, Saudi Arabia, Samoa, and Tonga. Obesity is most common in the low socioeconomic status groups and in rural areas in countries with a low gross domestic product, whereas the high socioeconomic groups in urban areas have been the first to have increased obesity prevalence in low- to middle-income countries [79]. Evaluation of women in 37 developing countries suggests lower SES women have had a faster increase in overweight than that among higher SES women [81].

POTENTIAL CAUSES OF OBESITY

Determining the causes of obesity is not a straightforward issue. Many believe it is largely a problem of energy imbalance and the solutions are to reduce energy intake and increase physical activity. Body weight is determined by a combination of metabolic, genetic, environmental, behavioral, cultural, and socioeconomic factors [24]. These factors affect energy balance asymmetrically [79,82]. The proximal role energy imbalance plays in the obesity epidemic is evident [83]. However, the distal factors affecting energy consumption, energy expenditure, and metabolic performance are complicated and their roles are not well understood. The influence of other risk factors for obesity has remained in the shadows of the two big factors: over consumption and inactivity. This section provides a brief overview of energy imbalance issues as well as numerous other risk factors for obesity describing how each could affect weight gain. Future obesity researchers will benefit from a systems approach utilizing all identifiable risk factors to decipher the pandemic etiology.

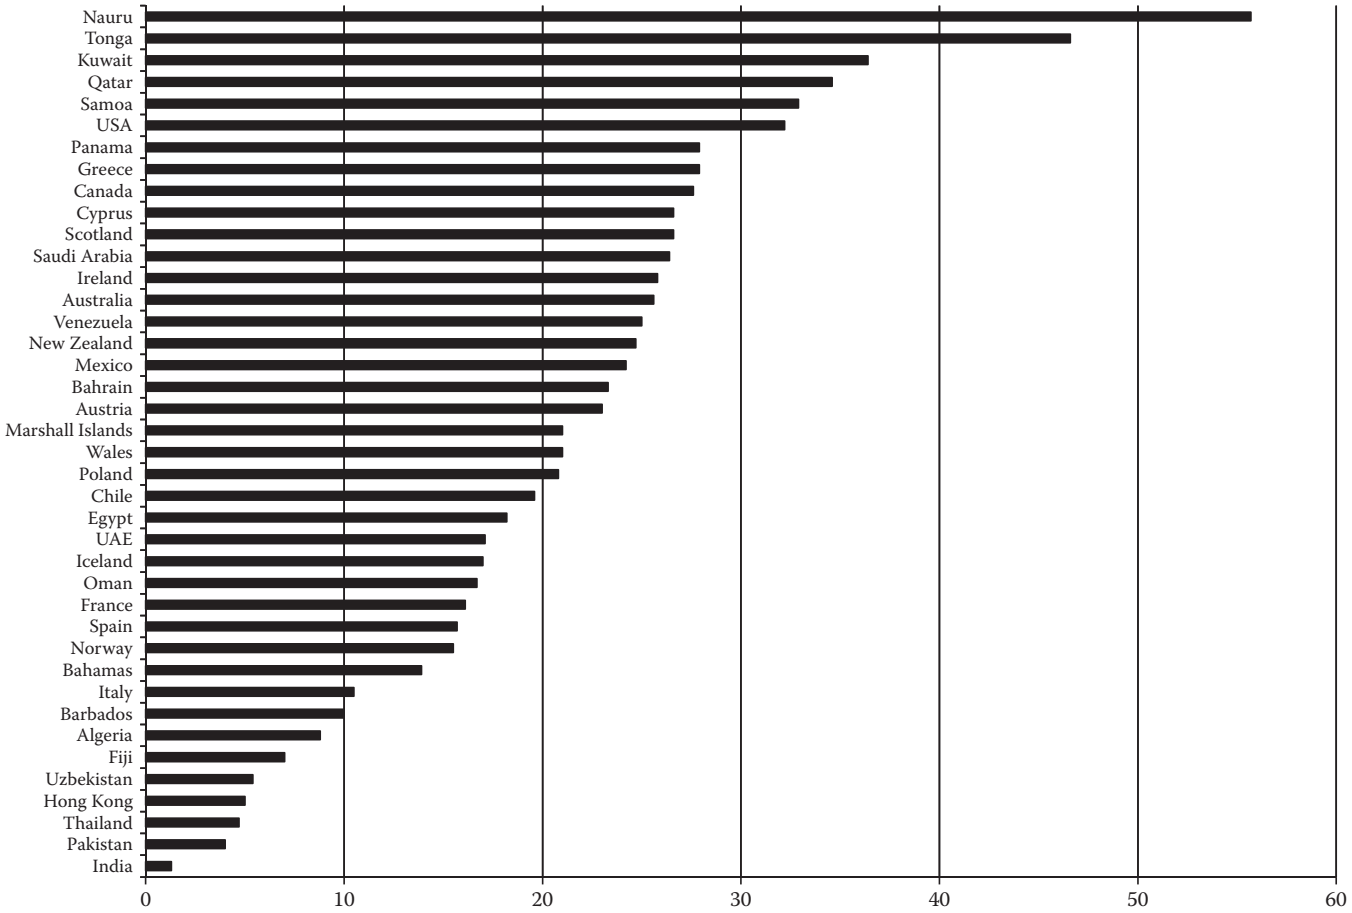

FIGURE 41.3 Adult male prevalence (%) of obesity (BMI > 30 kg/m^2). (Data from International Association for the Study of Obesity. Global prevalence of adult obesity. [database online] 2011.)

Energy Imbalance

Weight change is associated with an imbalance between energy intake and energy expenditure. When energy intake exceeds energy expenditure, the excess is stored as fat, leading to increased adiposity. The effect of energy imbalance on bodyweight has been quantified and models indicate gaining weight is indeed easier to do than losing weight [84,85]. Simply reducing energy intake to tip the balance in favor of weight loss may not result in steady weight loss because of physiologic adaptations of metabolic rate and energy burn from physical activity [2,84,86,87]. This phenomenon is frequently seen in practice and helps explain results from interventions to reduce obesity showing mixed effects and low sustainability [85].

Energy intake changes to support the rise in obesity are attributed to portion size increases [88] and increased availability of inexpensive, energy-dense, nutrient-poor foods and beverages. Portion sizes of many foods did increase from 1977 to 1996 [88]. The portion sizes of salty snacks, desserts, soft drinks, fruit drinks, French fries, hamburgers, cheeseburgers, and Mexican foods increased regardless of whether they were consumed in the home or not. Increased portions resulted in energy increases ranging from 49 to 133 kcal per food [88]. Between 1977 and 2006, changes in portion size accounted for an average 10 kcal/day increase in energy intake [89].

Energy density per eating occasion increased steadily over the last 30 years according to nationally representative data [89]. Inexpensive, convenient, energy-dense food is readily available throughout the day for most people. Much of our food preparation is now done at a mass production level and not by individuals. The available food is inexpensive, highly processed, and contains added sugar (or high-fructose corn syrup), fat, salt, and flavor enhancers enhancing the taste of food and encouraging consumption [79,90]. Overall energy intake in the U.S. population has shifted upward since the 1976–1980 NHANES survey; however, the increase has not been as steep as the rise in obesity [83]. An area of active investigation focuses on the macronutrient mix of the energy component of diet. Weight change can differ by the macronutrient content of the diet even if energy levels remain constant. The energy stored from equal amounts of protein, fat and carbohydrate differs markedly. In addition, the body employs a complex regulation of fuel sources, which varies by macronutrient. And although short-term energy restricted diets of all macronutrient combinations can lead to weight loss, little is known about the long-term efficacy of diets by macronutrient content [84,85,87]. Changes over time in the energy sources of the diet may be an important aspect of understanding the obesity epidemic.

Energy expenditure occurs for metabolism, thermoregulation, and daily physical activity. Metabolism and thermoregulation

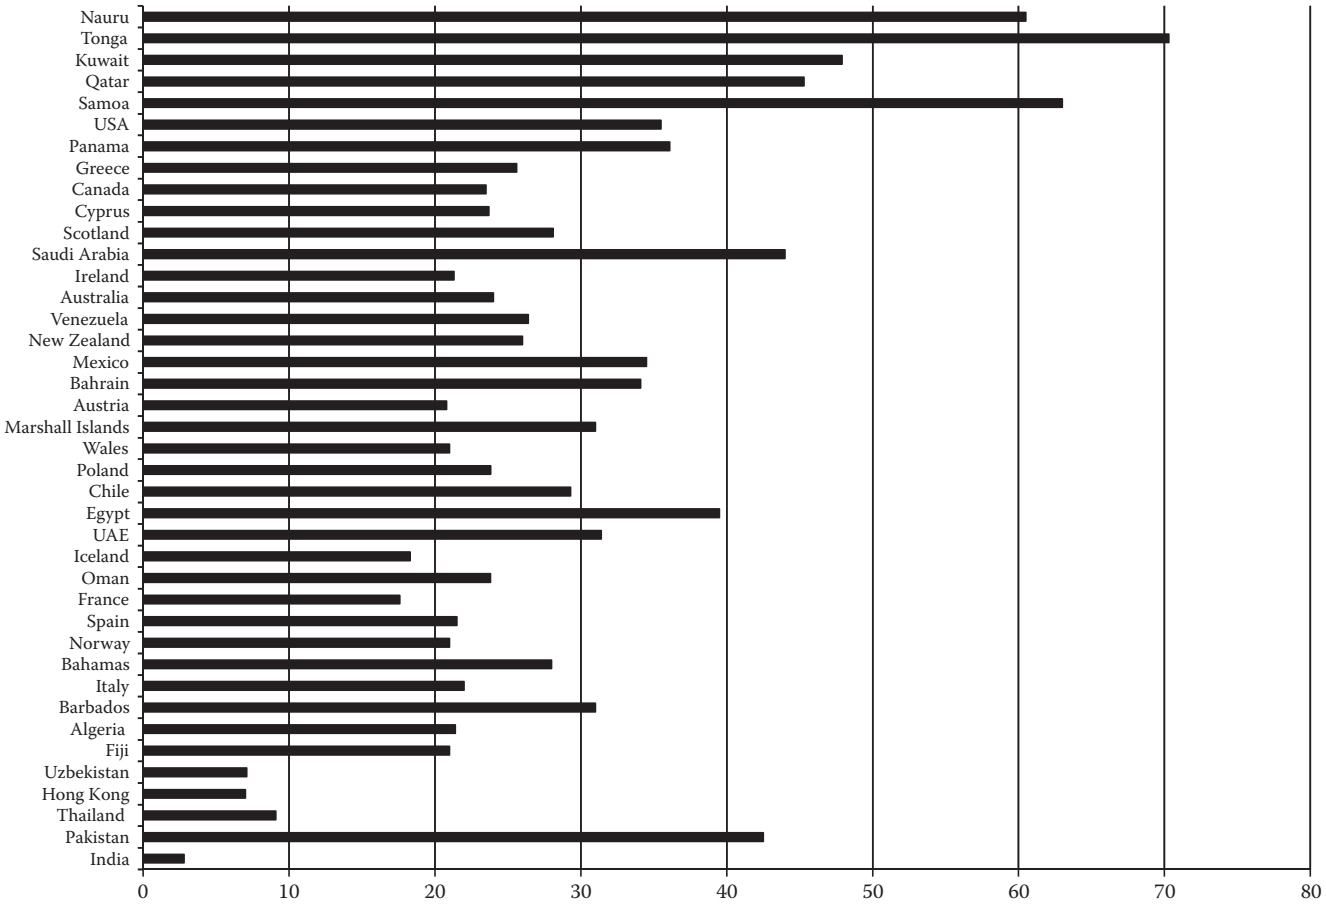

FIGURE 41.4 Adult female prevalence (%) of obesity (BMI > 30 kg/m^2). (Data from International Association for the Study of Obesity. Global prevalence of adult obesity. [database online] 2011.)

account for 60%–70% of energy expenditure and daily physical activity among predominately sedentary individuals about 20%–30% [83]. The energy expenditure concepts thought to influence the rise in obesity include reduced physical activity resulting from the "built environment" and reduced physical activity in schools. Technologic conveniences and labor-saving devices continually make life easier diminishing the energy required for completion of previously labor intensive tasks. Sedentary jobs are prevalent and energy expenditure from transportation decreased. Television, videos, and computers occupy increasingly more of peoples' time. Television viewing has increased steadily from 10.4 h/week in 1965 to 15.1 h in 1985, and 25.2 h/week in 1992–1994 [83]. In 2008, 25.4% of the U.S. population did not engage in any leisure time physical activity [91]. Data to support the impact of reductions in physical activity are scant, thus the impact of changes in these behaviors is difficult to quantify. However, available data suggest this component of energy balance has indeed declined, which could result in increased weight [70,79,84,85,87].

Genetics and Epigenetics

Enormous efforts have provided extensive information about genetic variation associated with obesity summarized in 12 annual reports through 2005 [92]. From this report, 11 different genes with single mutations have been reported from 176 human obesity cases. A total of 50 loci related to Mendelian syndromes commonly associated with obesity have been mapped and candidate genes identified for many of these syndromes. Through 2005, there have been 426 reports of positive associations between DNA sequence variation and obesity with 127 candidate genes [92]. Epigenetic influences include environmental exposures causing alterations or dysregulation of molecular processes leading to weight change. Studies in both animals and humans indicate genes associated with energy balance could be altered by environmental influences influencing susceptibility to obesity [93].

Infections

The etiologic role of infections in the development of obesity is novel. There are possibly interactions between the similar function of the immune system and adipose tissue. There are 10 microbes reported to cause obesity in different experimental models, however Adenovirus-36 (Ad36) is the most studied [93]. Although the adipogenicity action of Ad36 is not well understood, the in vitro and in vivo studies collectively suggest the virus infects preadipocytes and stem cells. Ad36 increases adipogenic commitment in stem cells, preadipocyte replication, adipogenic differentiation,

and lipid accumulation in rodent and human cells [94–96]. Ad36 strongly upregulates glucose uptake by adipocytes and adipose tissue [95,97]. Thus, it appears Ad36 increases not only adipocyte cell number but glucose and lipid uptake by these cells, which may collectively contribute to increased adiposity. Infections can affect metabolism and adipose tissue can impact inflammation, a factor associated with obesity. Ad36, first identified in 1980, coincided with the early recognition of the rising prevalence of obesity.

Smoking

Smokers consistently have been shown to weigh less than nonsmokers. The physiologic response to nicotine includes appetite suppression and alteration in thermogenic responses [77]. Smoking cessation studies provide evidence of weight gain following cessation, but the molecular mechanism for this change is still not well described [98,99]. Smoking prevalence during 1997–2004 was lower than in 1987–1994 for all occupational groups in the National Health Interview Survey [98]. Thus, a lowering prevalence of smokers over time could be associated with the rising prevalence of overweight and obesity.

Sleep

Evidence from animal and human studies supports an inverse relationship between amount of sleep and obesity. Several endocrine changes associated with lack of sleep include decreased glucose tolerance, leptin, and thyroid-stimulating hormone and increased ghrelin levels [77]. Each of these has a role in obesity development stimulating food intake and energy storage [100–109]. As much as 30% of adults and 69% of teens do not get the recommended hours of sleep [110]. Reports suggest hours of sleep have declined in adults and children over the last 20 years [111,112]. Sleep deprivation as a risk factor for obesity should be considered in the systems approach to curbing the obesity epidemic.

Other Factors

Other putative factors are being explored as associated with the rise in obesity such as endocrine disruptors, pharmaceuticals, and ambient temperature control [77,93]. Each of these requires more investigation to establish mechanisms and experimental evidence in animals and humans.

HEALTH CONSEQUENCES OF OBESITY

Obesity is associated with increased overall mortality and is a significant risk factor for developing numerous comorbidities [22,113–116]. Obesity is associated with increased risk of type 2 diabetes, cardiovascular diseases, numerous cancers, asthma, chronic back pain, sleep apnea, gout, osteoarthritis, pulmonary embolism, breathing problems, gallbladder disease, pregnancy complications, menstrual irregularities, stress incontinence, and psychological disorders [24,117–120]. There is a positive trend associated with weight gain and disease risk with even small weight gains of 10–12 lb associated with increased risk [24]. Certain comorbidities have a higher prevalence among different racial groups; however, the increased risks associated with being obese appear to be consistent globally.

ECONOMIC COSTS OF OBESITY IN THE UNITED STATES

The economic costs associated with obesity in the workplace have continued to increase over the last several decades in the United States [74] and worldwide. The economic costs related to obesity have been estimated based on the direct health care costs associated with treating comorbid diseases (e.g., hypertension, diabetes, osteoarthritis) and the indirect costs, which comprised of different indicators of lost productivity and include presenteeism, absenteeism, disability and worker's compensation claims, and premature mortality.

Direct Costs

Obesity direct costs are defined typically as the expenses (both out-of-pocket and insurance covered) related to treatment or services provided by a health care provider (e.g., physician, nurse practitioner) for office-based, outpatient, inpatient hospital, or emergency room care and pharmaceuticals or procedures [121]. However, because obesity as a condition is usually not treated directly, the direct costs of obesity usually are estimated based on the costs associated with treating related comorbid conditions such as hypertension, diabetes, heart and other cardiovascular-related diseases, osteoarthritis, sleep apnea, etc., all conditions for which obesity has been demonstrated to substantially increase risk. Thus, the proportion for each disease condition that can be attributed to obesity and the prevalence of that condition and the medical expenditures associated with each condition are used to estimate the direct costs of obesity with aggregate data [122,123]. If individual data are available, then actual medical expenditures for comorbid conditions can be compared for obese and nonobese individuals [122,123]. A number of studies calculated the direct medical and health care costs attributable to obesity, but their estimates vary based on a number of factors including how many comorbid conditions were included that are linked to obesity [121]. Thus, there is no definitive estimate of health care costs associated with obesity.

The substantial direct costs of obesity in the United States have been estimated in a number of studies [121]. For example, Wolf and Colditz [124] conducted the first study in this area and estimated the direct costs of obesity to be 45.8 billion dollars in 1990 dollars among all Americans. However, more recent studies such as Finkelstein et al. [125] estimated the direct costs attributable to obesity among full-time workers to be 73.1 billion dollars (in 2006 dollars). In addition, they found that individuals with BMI > 35 were culpable for 61% of excess costs. They estimated the per person direct medical expenditures attributable to obesity to be $2568 for men and $6201 for women and found that the costs increased for

each class of obesity, that is, costs per person were higher for workers who were Class III obese when compared to those that were Class II or I obese.

Dor et al. [121] reviewed a large number of studies conducted in the United States over the last 20+ years and adjusted all of their estimates to 2009 dollars. They concluded that the direct costs attributable to obesity have increased substantially over time due to the growing prevalence of obesity. Withrow and Alter [123] also reviewed direct cost estimation studies conducted in a number of mostly industrialized nations including the United States, Canada, Italy, Sweden, France, China, Japan, Australia, New Zealand, and Brazil and concluded the direct costs attributable to obesity accounted for between 0.7% and 2.8% of a country's total health care costs. While the estimates vary based on how the study was conducted and what obesity comorbid conditions were included, it should be clear that obesity results in significant individual and societal direct health care costs diminishing the resources of national economies and employers.

Indirect Costs

Indirect costs are those nondirect medical expenditures representing lost productivity in the workforce. They include presenteeism, absenteeism, disability and worker's compensation claims, and premature mortality [121].

Presenteeism and Absenteeism

Presenteeism is defined as time and productivity lost due to workers who are at work but are unable to perform at their full capacity as a result of obesity-related health problems [121,126]. Absenteeism refers to the loss of productivity associated with missed work days or sick leave [121,126]. A number of studies have examined the relationship between obesity and the primary indicators of lost productivity in the U.S. workplace [126]. For example, Tucker and Friedman [127] found that obese workers were 70% more likely to experience absenteeism categorized as "high level" (i.e., seven or more absences due to illness in the past 6 months) than lean employees. Pronk et al. [128] found that obesity was associated with more work loss days and greater difficulty getting along with coworkers while greater levels of physical activity and cardiorespiratory fitness were associated with better work quality, job performance, and greater work quantity and effort in a diverse sample of workers.

In addition to documenting an association between obesity and losses in work productivity, several studies estimated the economic losses to employers. In a very early study on this topic, Robbins et al. [129] found male military service personnel who exceeded their maximum allowable weights accrued 17,117 lost work days over 12 months totaling to $2.2 million annually, resulting in excess weight attributable costs of approximately $2,809 per male service member. Ricci and Chee [130] conducted a national telephone survey of 7472 adult workers in the United States estimating obesity-attributable costs for both presenteeism and absenteeism combined totaling $42.3 billion (in 2002 dollars).

In a large study of more than 500,000 American workers in a variety of job classifications (e.g., professional, managers, sales, service, office, and equipment and transportation operators), workers who were obese were found to experience a significantly higher probability of missing any work when compared to workers in the normal weight range [131]. In addition, their absences were associated with greater incremental per worker costs when compared to normal weight employees and their aggregated costs to employers were estimated to be nearly $4.3 billion (in 2004 dollars).

Gates et al. [132] evaluated lost productivity in a sample of manufacturing employees and found that workers who were Classes II and III obese reported more work limitations with regard to time needed to complete work tasks and ability to perform physical job demands. They also found that both Class I and Classes II and III obese workers had significantly higher absenteeism than normal weight workers. The resultant loss in overall productivity was estimated to cost the employer $506.00 for presenteeism and $433.00 for absenteeism per each Classes II and III obese worker annually [132].

Poston et al. [133] examined the relationship between obesity and missed work days due to injury in a large group of male, career firefighters in the Midwestern United States. Obese firefighters missed between 2.7 and 5 times (depending on obesity class) the number of days due to injury when compared to normal weight firefighters, even after adjustments for potential confounders. They also computed the economic costs of absenteeism for firefighters who were at increasing levels of overweight and obesity compared to normal weight firefighters. When compared to normal weight firefighters, the additional costs to fire departments because of the greater missed days of work after injury in firefighters who were overweight, Class I obese, and Classes II and III obese combined were estimated to be $74.41, $254.00, and $1682.90 per firefighter, respectively [133].

Finkelstein et al. [125] evaluated the costs associated with presenteeism and absenteeism both at the level of the individual worker and then extrapolated aggregate costs for all workers in a sample of over 32,000 full-time workers. Average incremental annual costs per worker for absenteeism and presenteeism associated with obesity were estimated to be $1960 and $5193 for obese male workers and $1736 and $5393 for obese female workers, respectively. Extrapolated to all workers, obesity was estimated to cost employers 12.8 and 30.0 billion dollars for productivity losses associated with absenteeism and presenteeism [125].

Disability and Premature Mortality

Disability costs, for both short and long term, result from salary continuation benefits, insurance policies, and government programs (e.g., workers' compensation claims) allowing employees time away from work due to illness or injury for periods of time longer than allowed for typical sick leave [121,126]. Premature mortality refers to the lower projected life expectancy experienced by obese workers when compared to nonobese individuals

leading to lost productivity during working years and increased life insurance premiums and payouts [121,126].

Several studies have focused on estimating costs associated with disability and premature mortality. Disability studies usually focus on evaluating costs associated with time away from work that involved disability claims or payments while premature mortality studies estimate the value of years of life lost related to obesity [121,126]. For example, both Dor et al. [121] and Trogdon et al. [126] reviewed several studies and concluded that obesity was consistently a significant predictor of disability, and for studies in the United States, the costs associated with disability for obese individuals were substantial. For example, Soteriades et al. [134] prospectively evaluated risk of any type of short-term or permanent disability in a group of male firefighters over more than 6 years. They found that obesity predicted which firefighters would receive disability; each BMI unit increase was associated with a 5% increase in the likelihood a firefighters would be disabled. Annual costs of short-term disability for a number of studies were computed by Dor et al. [121] and they estimated that when compared to normal weight employees, obese employees' disability costs were $349 per employee.

Other investigators examined the relationship between obesity and Workers' Compensation claims and found that there was significant association between increasing BMI and number of claims [135]. For example, Classes I–III obese individuals had 8.8, 10.8, and 11.7 claims per 100 fulltime equivalents (FTEs) compared to only 5.8 for normal weight workers, respectively. Not surprisingly, this greater number of claims resulted in greater medical and indemnity (i.e., income replacement) claims costs. For example, the total estimated medical and indemnity claims costs for obese workers totaled to $94,125 and $117,107 per 100 FTEs, respectively. The same claims costs for normal weight workers were only $7503 and $5396; thus the excess cost due to obesity was substantial.

Premature mortality, as years of life lost, has been quantified by Fontaine et al. [136] using national data, which were then converted into cost estimates by Dor et al. [121]. For example, they estimated that obesity resulted in a total loss of income of $468,333 and $376,667 for white men and women, respectively, and that the gender difference is partly a function of the fact that obese men have a lower life expectancy than obese women. Other studies estimate the costs of lost earnings in the United States due to obesity to be approximately $30 billion dollars [126].

SUMMARY

The prevalence of obesity is alarmingly high and the trajectory of this epidemic is uncertain. The drivers of the proposed causal factors are complicated; thus, interventions to curb this epidemic are not in place. The economic and health implications of a continued rise in this obesity epidemic are staggering. An immediate global effort is needed with systematic approaches involving governments, businesses, and individuals.

INTRODUCTION

Overweight and obesity are significant public health problems in the United States and other countries throughout the world. Within the United States, the age-adjusted mean body mass index (BMI) was 27.8 kg/m^2 in men and women ≥20 years of age in 2009–2010 based on data from the National Health and Nutrition Examination Survey (NHANES) [1]. Based on the NHANES data [1], the age-adjusted prevalence rates for overweight (BMI ≥ 25.0 kg/m^2) and obesity (BMI ≥ 30.0 kg/m^2) are 68.8% and 35.7%, respectively. Moreover, the age-adjusted percentage of adults with a BMI ≥ 35.0 kg/m^2 or BMI ≥ 40.0 kg/m^2 is 15.4% and 6.3%, respectively. These prevalence rates are of significant public health concern because of the association between many chronic diseases and excess body weight [2]. Thus, interventions are needed to reduce body weight in overweight and obese patients, and the cornerstone of these interventions is behavioral programs that focus on reducing energy intake and/or increasing energy expenditure.

EFFECT OF PHYSICAL ACTIVITY ON WEIGHT LOSS

Cardiovascular (Aerobic) Activity

Physical activity has been recommended as a key behavior within interventions that target overweight and obesity [2]. However, the effects of physical activity on weight loss, when not coupled with a concurrent reduction in energy intake, appears to be modest. For example, average weight loss of 2% at 6 months and 1% at 18 months was reported in a study of overweight adults who were prescribed home-based physical activity without a prescribed reduction in energy intake [3]. Others have reported a similar magnitude of weight loss for interventions lasting 3–6 months that also focused on physical activity without prescribing a reduction in energy intake [4,5]. This is also consistent with the 0.5–3.0 kg weight loss in response to 180–270 min/week of physical activity that was reported in the 2008 Physical Activity Guidelines Advisory Committee Report [6]. However, there may be a dose–response effect, with

the magnitude of weight loss increasing as dose of physical activity increases. For example, a systematic review of the literature conducted for the 2009 Position Stand of the American College of Sports Medicine (ACSM) [7] concluded that there was no significant change in body weight in response to <150 min/week of physical activity, whereas 2.0–3.0 and 5.0–7.5 kg are observed with >150 and 225–420 min/week of physical activity, respectively.

Resistance Exercise

While the majority of research related to the effect of physical activity, in the absence of restrictions in energy intake, has focused on cardiovascular (aerobic) forms of physical activity, there is a body of literature on the effects of resistance exercise on weight loss. It has been proposed that resistance exercise may influence body weight by increasing lean mass that will results in an increase in resting metabolic rate (RMR), increase strength that will result in an increase in free-living physical activity, and increase total daily energy expenditure from performing the resistance exercise [7]. However, numerous systematic reviews have concluded that resistance exercise has a modest influence on weight loss when performed in the absence of reductions in energy intake [7,8]. While it is possible that the resulting increase in lean mass that is proposed to occur with resistance exercise may offset the reductions in fat mass causing absolute weight to remain relatively unchanged [9–12], it should not be expected that energy expenditure from resistance exercise will be sufficient to result in significant reductions in body weight over a period of 3–6 months, with limited data available from longer-term studies to determine if this pattern would change with a longer intervention period [7,8]. Despite the lack of evidence that resistance exercise will result in significant reductions in total body fatness, resistance exercise may reduce subcutaneous abdominal adiposity [13]. Thus, the benefits of resistance exercise in the treatment of obesity may not be in reductions in total body fatness, but rather improvements in lean mass and strength, and the reductions in abdominal adiposity.

Lifestyle Activity

It has been recommended that nonstructured forms of physical activity can also contribute to increases in energy expenditure and should be a component of interventions for obesity. The term nonexercise activity thermogenesis (NEAT) is used to describe energy expenditure that does not result from sleeping, eating, or structured exercise [14]. A common methodology to increase NEAT is through the use of pedometers, with patients recommended to increase the number of steps walked. When this methodology has been used to promote an increase in physical activity, it has been shown that this results in an increase of 2100 steps/day, and this results in a modest decrease in BMI of 0.38 units [7], which is the equivalent of approximately 2.0–3.0 kg of weight loss. However, others have reported that a 12 week pedometer intervention increased steps by 3000/day; however, there was no association between steps walked and change in BMI, but there was an association between steps walked and change in waist circumference [15]. Thus, it may be necessary to combine the increase in energy expenditure resulting from NEAT with the increased energy expenditure resulting from structured forms of activity (exercise) to maximize increases in total energy expenditure, which can contribute to weight loss in overweight and obese adults.

Physical Activity Combined with Reductions in Energy Intake

It is commonly recommended that physical activity be combined with a reduction in energy intake for the treatment of obesity [2]. Examination of the evidence suggests that the addition of physical activity to an energy-restricted diet will result in an additional 2.0–3.0 kg beyond what is achieved with an energy-restricted diet alone. For example, [16,5] reported that the addition of physical activity to an energy-restricted diet increased weight loss at 6 months by 2.7 and 1.2 kg, respectively, above what was achieved with an energy-restricted diet that did not include physical activity. These results are similar to results reported by [4]. While this magnitude of additional weight loss appears to be modest, [17] have suggested that the combination of physical activity and an energy-restricted diet results in 20% greater weight loss than the weight loss achieved with an energy-restricted diet alone.

Physical activity may also be important for enhancing weight loss beyond the initial 6 months of treatment, improving long-term weight loss maintenance, and minimizing weight regain. An important observation is that relatively high levels of physical activity may be necessary to improve long-term weight loss [18–20]. We have contributed to the scientific literature supporting the need for physical activity to improve long-term weight loss. Results of a 24 month intervention in overweight and obese women showed that an increase in physical activity of 1500 kcal/week above baseline levels was associated with weight loss of 14.2 kg (16.8% of initial body weight), whereas significantly less weight loss was observed at 24 months with lower amounts of physical activity [21]. We estimated that the 1500 kcal/week of physical activity above baseline levels was reflective of approximately 275 min/week of brisk walking above what was being performed prior to the start of the 24 month intervention. Additional analysis of the data showed that physical activity was an important behavior in the ability to achieve an initial weight loss of ≥10% and to sustain this magnitude of weight loss at the conclusion of the 24 month intervention period [22]. This magnitude of physical activity is similar to what we have reported in other studies. For example, we

have reported 18 month weight loss of 13.1 kg in women who reported participating in an average of 280–300 min/week of physical activity throughout the entire intervention period, and this weight loss was significantly greater than the weight loss achieved when participating in lower amount of physical activity [23].

Role of Physical Activity in Surgically Induced Weight Loss

Bariatric surgery has become a popular, and effective, method in the treatment of obesity. However, unpublished data from our laboratory have suggested that many patients who have undergone bariatric surgery are not provided information to participate in physical activity, and when provided information related to physical activity, it is not consistent with public health recommendations for physical activity. This is of concern because there is a growing body of literature to support the need for physical activity in patients who have undergone bariatric surgery. For example, greater weight loss has been observed in bariatric surgery patients who participate in ≥150 min/week of physical activity compared to patients participating in <150 min/week [24]. This is consistent with other research showing improvements in weight loss at 6–24 months following bariatric surgery with the inclusion of physical activity [24–26]. Thus, health care professionals are encouraged to include physical activity as a component of a comprehensive treatment plan for patients undergoing bariatric surgery.

WEIGHT LOSS VARIABILITY IN RESPONSE TO PHYSICAL ACTIVITY

As described earlier, on average, modest weight loss on the magnitude of 0.5–3.0 kg is observed with physical activity. However, as reported by [27], there is significant interindividual variability observed in weight loss in response to physical activity. Thus, there is a possibility that physical activity may result in greater weight loss for some individuals than what is commonly reported in the literature. Moreover, it is possible that there will be differences in weight loss between individuals in response to participation in similar doses of physical activity. Bouchard et al. [28] reported that weight loss in response to 4 months of highly controlled exercise resulted in a range of weight loss equivalent to approximately 3.0–12.0 kg. Thus, it is important to consider factors that may contribute to this variability in weight in response to physical activity.

Biological Factors

Bouchard et al. [29] have suggested that there may be biological factors that contribute to the weight loss observed in response to physical activity. These investigators studied seven pairs of identical male twins examined over a period of 93 days in which energy intake was held constant and physical activity performed twice daily. Subjects were also monitored 24 h/day to minimize any variability in energy intake or physical activity. The results from this study showed that weight loss was similar within each pair of twins; however, weight loss was highly variable between pairs of twins. Thus, the variability in weight loss observed between individuals may have biological underpinnings.

Influence of Physical Activity on Other Components of Energy Expenditure

A state of negative energy balance in which energy expenditure exceeds energy intake is necessary to induce weight loss. It has been stated that physical activity is the most variable component of total energy expenditure, and therefore this component of energy expenditure may have the greatest influence on the ability to create this state of negative energy balance [30]. However, it has been suggested that physical activity may also influence other components of energy expenditure, namely RMR, which can further affect total energy expenditure. There appears to be an acute increase in RMR in response to physical activity, and chronic physical activity participation may be associated with a higher RMR [31]. This may be of importance for overweight and obese individuals because RMR tends to decrease in the presence of weight loss, which can decrease total energy expenditure and possibly affect weight loss and weight loss maintenance. However, even when physical activity is included as a component of the intervention, RMR has been shown to decline in response to significant weight loss [32]. Thus, health care and health-fitness professionals should refrain from promoting that physical activity will increase or at least prevent the decline observed in RMR with weight loss.

Influence of Physical Activity on Energy Intake

There is evidence of interindividual variability in energy intake in response to physical activity, and this may provide some evidence of why physical activity results in greater weight loss in some individuals compared to others. For example, in response to 50 min of physical activity, Finlayson et al. [33] reported a positive increase in energy balance in 50% of study participants. This is very similar to the findings of a study conducted in our laboratory in which 58% of participants consumed more calories following a 35–45 min period of activity compared to following a seated rest period [34]. This may suggest that for some overweight and obese adults, physical activity increases hunger and appetite, whereas in others physical activity may enhance satiety, which can influence energy intake.

Factors Influencing Adherence to Physical Activity

The variability in weight loss observed in response to free-living physical activity may also be a reflection of one's ability

to adopt and adhere to an adequate dose of physical activity to promote weight loss. It has been suggested that there may be genetic factors that contribute to physical activity participation [35–37]. However, there is also evidence of more traditional behavioral factors contributing to physical activity participation in overweight and obese adults. For example, we have previously reported that higher levels of physical activity self-efficacy are associated with higher levels of physical activity in response to a 6 month behavioral weight loss intervention [38], and recent unpublished data support the continued association between long-term physical activity participation and physical activity self-efficacy. Moreover, identifying and overcoming barriers to physical activity contribute to physical activity participation in overweight and obese adults [38,39]. This appears to suggest that overweight and obese adults need to engage in interventions to increase self-efficacy and to reduce barriers for physical activity. Thus, simply instructing overweight and obese adults to engage in physical activity without addressing the behavioral factors that are associated with physical activity may not be effective. This may require that health care and health-fitness professionals receive additional training in these areas of behavior change when treating overweight and obese adults and recommending physical activity as a component of the intervention plan.

PHYSICAL ACTIVITY, FITNESS, AND HEALTH OUTCOMES

In addition to the potential benefits of physical activity on weight loss, overweight and obese adults also realize significant improvements in cardiorespiratory fitness in response to engaging in sufficient amounts of physical activity. Numerous studies have shown that cardiorespiratory fitness improves only when physical activity is included as a component of the intervention program, and these improvements are present regardless of whether or not the intervention results in weight loss [40]. However, fitness does not improve significantly when weight loss is induced by energy restriction alone [40,41]. Thus, physical activity is an important component of interventions for overweight and obese adults that results in improved cardiorespiratory fitness. However, the magnitude of improvement in fitness depends on the dose of physical activity performed. For example, a dose–response relationship has been reported between the improvement in cardiorespiratory fitness and prescribed dose of physical activity in overweight adults across an 18 month intervention [3]. Church et al. [42] reported similar findings in response to 6 months of supervised physical activity in overweight and obese postmenopausal women [42]. Thus, these data support the need for clinicians to recommend physical activity to overweight and obese adults.

Effects on Mortality

An interesting observation is that the association between higher levels of cardiorespiratory fitness and reduced risk of mortality is present even when data are adjusted for level of adiposity. The findings reported by Blair et al. [43] showed an association between fitness and mortality, and this association remained even after controlling for level of BMI. Additional findings from the Aerobics Center Longitudinal Study have consistently supported the finding that a higher level of fitness remains an important factor in reducing the risk of mortality, and this effect appears to be independent of the influence of BMI [44–47] or body fatness [48,49].

Despite these findings, not all data support the contention that fitness will completely ameliorate the risk of a higher level of BMI or body fatness on these outcomes. A prospective examination of data from older men in the Veterans Exercise Testing Study found that both higher levels of cardiorespiratory fitness and a higher BMI were protective of all-cause mortality [50]. Data from the Lipid Research Clinics Study also suggest that both fitness and fatness contribute to risk of mortality [51]. These findings appear to suggest that interventions for overweight and obese adults should focus on both weight loss and improving fitness to elicit reduced risk of all-cause and cardiovascular disease mortality.

Effects on Risk Factors for Cardiovascular Disease

Cardiovascular disease is a leading cause of death, and results in significant health care costs, in the United States. As described earlier, cardiorespiratory fitness appears to at least partially contribute to reduction in cardiovascular disease mortality in overweight and obese adults. This may be a result of the influence of cardiorespiratory fitness on risk factors known to be associated with cardiovascular disease such as blood pressure, lipids, inflammatory biomarkers, and diabetes. However, as described in detail later, fitness may not completely eliminate the association between adiposity and these risk factors for cardiovascular disease.

Blood Pressure

It is commonly accepted that hypertension is a primary risk factor for cardiovascular disease. However, the combined influence of fitness and fatness on blood pressure appears to have mixed findings. For example, Rankinen et al. [52] have reported a significant association between BMI and risk of developing hypertension; however, this association was attenuated with cardiorespiratory fitness. Conversely, Chen et al. [53] reported that both BMI and cardiorespiratory fitness are associated with systolic blood pressure, yet when both variables were considered concurrently, BMI but not fitness continued to be associated with systolic blood pressure. Wing et al. [54] reported that both BMI and cardiorespiratory fitness were significantly associated with systolic blood pressure in women regardless of whether medication was being taken for blood pressure control. However, in men not taking medication for blood pressure control, BMI but not fitness was associated with systolic blood pressure. Thus, these findings appear to suggest that both BMI and fitness may be important for blood pressure control in overweight and obese adults, and both should be targets of clinical interventions.

Lipids

An abnormal blood lipid profile is considered a primary risk for cardiovascular disease. Because of the association between obesity and blood lipids [2] interventions that target obesity may also have a favorable influence on blood lipids. However, physical activity appears to have a modest influence on blood lipids in overweight and obese adults. For example, the results of a meta-analysis of studies that included overweight and obese adults concluded that total cholesterol was reduced by 3.4 mg/dL, LDL was reduced by 3.0 mg/dL, and HDL was increased by 1.6 mg/dL in response to physical activity interventions that did not include dietary restriction or result in significant weight loss [55]. This same meta-analysis reported that physical activity interventions significantly reduced triglycerides by 16.1 mg/dL in overweight and obese adults [55]. Church et al. [56] reported no influence of 4 months of exercise without concurrent caloric restriction on blood lipid parameters compared to a control condition.

When combined with caloric restriction, there are mixed results for the effect of physical activity on blood lipids. For example, Goodpaster et al. [16] reported that the addition of physical activity to an energy-restricted diet did not improve blood lipids when compared to the improvements observed with an energy-restricted diet without exercise in severely obese adults (BMI $\geq$ 35.0 kg/m^2) [16]. However, results from the CALERIE Study showed that when physical activity was added to calorie restriction, there were significant reductions in both total cholesterol and LDL-C, and these improvements were not observed with calorie restriction that did not include physical activity as part of the intervention [57].

Inflammatory Markers

It has been suggested that biomarkers of inflammation such as C-reactive protein (CRP), interleukin-6 (IL-6), tissue necrosis factor-α (TNFα), and the anti-inflammatory molecule adiponectin contribute to the prothrombotic processes of atherosclerosis [58]. Because of the impact of physical activity and cardiorespiratory fitness on other cardiovascular disease risk factors, one could hypothesize that physical activity and cardiorespiratory fitness would also have an influence on inflammatory markers that may contribute to cardiovascular disease. However, both Church et al. [56] and Nicklas et al. [59] have reported that physical activity does not improve the markers of inflammation. Moreover, Hamer and Steptoe [60] reported no association between cardiorespiratory fitness and measures of inflammation. Thus, physical activity may not be the optimal therapy for improving measures of inflammation that can reduce cardiovascular disease risk in overweight and obese adults.

SUMMARY

Physical activity is recommended as a component of comprehensive interventions for weight loss in overweight and obese adults. Physical activity can contribute to modest short-term weight loss of approximately 0.5–3.0 kg and can also enhance weight loss when combined with a reduction in energy intake. Moreover, physical activity appears to be important for enhancing long-term weight loss and prevention of weight regain following initial weight loss. Of interest, physical activity also appears to be an important intervention component for individuals who have undergone bariatric surgery. Physical activity has also been shown to improve health outcomes beyond the effect that it has on weight loss, which further supports the need to promote physical activity in overweight and obese adults. However, there is significant interindividual response to physical activity with regard to weight loss that may be influenced by biological factors, the effects on other component of energy expenditure, the effects on energy intake, and factors that influence the adoption and adherence to a physically active lifestyle. Thus, health care and health-fitness professionals need to consider these factors when developing weight loss interventions and when recommending the physical activity for overweight and obese adults.

The dietary management of overweight (BMI of 25–29.9) and obese (BMI > 30) individuals is one of the greatest health care challenges today. During the past 20 years, there has been a dramatic increase in the rates of obesity with no state in America having a prevalence rate of obesity <20% [1]. Health consequences of obesity and medical costs associated with obesity continue to rise and have a significant economic impact on health care [2,3]. The growing global epidemic of obesity calls attention to its serious nature and treatment limitations as a continuing worldwide public health threat [4]. Obesity is now well-recognized as a disease that is rarely, if ever, cured [5,6]. Weight reductions of as little as 5%–10% of initial body weight produce significant benefits to health and are recognized as successful outcome measures [5].

There remains no doubt that weight management and maintenance of overall health are both related to the quantity and quality of food intake. The role of the diet in producing successful outcomes for the treatment and prevention of obesity are to: (1) provide essential nutrients to achieve and maintain optimal nutritional status; (2) produce an energy deficit to yield a reasonable weight loss or to provide sufficient energy to prevent further weight gain; and (3) provide enjoyment of eating while supporting healthy and sustainable eating patterns. Dietary management is essential for any treatment for obesity to succeed.

The most current treatment guidelines from the National Heart, Lung, and Blood Institute (NHLBI) categorize treatment strategies based on body mass index (BMI) and comorbidities [5]. For a BMI of 25–29.9 with comorbidities, weight loss is best achieved through diet, physical activity, and behavior change. Pharmacotherapy can be considered for BMI $\geq$ 30 kg/m^2 or with a lower BMI $\geq$ 27 kg/m^2 with a comorbidity. Bariatric surgery can be considered at a BMI $\geq$ 40 kg/m^2 or BMI $\geq$ 35 kg/m^2 with a comorbidity. Surgical interventions are reserved for patients who have failed less invasive interventions and are at high risk for obesity-related morbidity and mortality.

TRADITIONAL DIETS: DEFINITIONS

The major classification of diets for weight management has been based on the total level of energy in kilocalories (kcal) per day provided. Low-calorie diets (LCDs) are those which provide a caloric deficit of 500–1000 kcal/day aimed at achieving a weight loss of 1–2 lb/week and produce an average weight loss of 8%–10% of body weight over a period of 3–12 months. Balanced deficit diets (BDDs) have been defined as LCDs generally above 1200 kcal/day and are nutritionally adequate; they provide the essential nutrients by using a variety of well-chosen foods [5]. LCDs above 1200 kcal/day are generally safe. LCDs less than 1200 kcal/day may have different nutrient composition and should be used with caution since they may not provide the essential nutrients needed. It should be recognized that the majority of dieting individuals will embark on weight reduction regimens without professional advice and will engage in self-help forms of treatment, including books and/or organized commercial groups. Generally, these are safe for individuals without medical complications over the short-term and involve using a variety of individual approaches and diet fads currently in vogue.

Very low-calorie diets (VLCDs) are those that usually provide approximately 800 kcal/day (or 6–10 kcal/kg) and are considered to induce a modified fast [5]. Regular foods are replaced with specially formulated foods and/or drinks and supplements. Emphasis is placed on the provision of 40–100 g (or 0.8–1.5 g/kg of ideal body weight) of high biological value protein to meet minimum protein requirements. Up to 100 g of carbohydrates and 100% of the daily value of essential vitamins and minerals are also provided. Weight loss averages 20 kg over 12 weeks or approximately 3 lb/week [3,4]. Although initial weight loss is greater on VLCDs, overall long-term weight loss (>1 year) is not different from LCDs. In 1998, the NHLBI expert panel recommended against the use of the VLCD based on studies showing no differences in long-term success and greater weight regain. VLCDs are sometimes prescribed before bariatric surgery to reduce overall surgical risk due to higher compliance and results over the short-term. There may be other circumstances where VLCDs are recommended, but the duration of treatment is usually limited to 12–16 weeks and patients are carefully monitored. Recognizing LCDs as the dietary treatment of choice, this chapter will primarily focus on dietary intervention utilizing an LCD.

MEDICAL ASSESSMENT FOR WEIGHT LOSS TREATMENT

Before interventions are implemented, a medical history and examination along with a nutrition assessment should be performed. First, the patient should be categorized as overweight or obese and then matched with the treatment recommended for that level of BMI category, as shown in Table 43.1 [5]. It is important to note that diet, physical activity, and behavior change are recommended for all levels of BMI > 25. The medical history should query conditions associated with obesity such as symptoms of diabetes, cardiovascular disease, sleep apnea, and gallstones, in particular. Gathering family and social history is important to identify the patient's support networks and to identify other members of the household who are overweight and might also be targeted for intervention and/or support or assessed for behaviors that might be detrimental to success. Further, social pressures, environmental conditions, and situational factors that may impact the ability for the patient to lose weight should be identified and discussed with regard to how they might be barriers to success.

Acquiring medication history is also helpful because certain drugs can cause weight gain and should be identified. Medications for diabetes such as insulin, sulfonylureas, and thiazolidinediones can cause weight gain. Additionally, several psychiatric medications can also cause weight gain such as the antidepressants paroxetine (Paxil), fluoxetine (Prozac), and atypical antipsychotics such as clozapine (Clozaril), olanzapine (Zyprexa), and risperidone (Resperdal) [7]. Alternatively, the antidepressant bupropion (Wellbutrin) can cause weight loss [8].

It is critical to offer an appropriate office environment to accommodate overweight and obese patients. Some simple but important measures are to have larger chairs or chairs without arms, step stools near examination tables, large sized examination gowns, and larger sized blood pressure cuffs. The physical examination should be performed with attention paid to findings that are conditions associated with obesity. During the examination, the patient should be warned that rapid weight loss can increase the incidence of symptomatic gallstones and the area of the gallbladder should be pointed out to the patient. He or she should be warned to notify the physician if pain occurs in that area during the weight management treatment. Also, sensitivity to possible causes of weight gain (such as water retention) should be explained to the patient and assessed with them so that temporary incidents of weight gain will not be discouraging.

Medical causes for obesity should be carefully ruled out. If a patient has fatigue, weight gain, constipation, and cold intolerance, a TSH and Free T4 can be measured to rule out hypothyroidism. Cushing's disease is rare and is suggested by the physical examination findings of moon face or buffalo

The practical guide to the identification, evaluation, and treatment of overweight and obesity in adults, National Institutes of Health, Bethesda, MD, Publication No. 00-4084, 2000.

hump. This can be assessed with a 24 h urine cortisol test, if suspected. In addition, a routine CBC to screen for anemia should be done. Importantly, for women, pregnancy should be ruled out before recommending a weight management regimen. For women who are pregnant, the Institute of Medicine has set guidelines for total and rate of weight gain during pregnancy by prepregnancy BMI. Any recommendations for weight gain during pregnancy should be individualized based on prepregnancy BMI to improve pregnancy outcome, avoid excessive maternal postpartum weight retention, and reduce risk of the child acquiring chronic disease later in life [9].

Other medical, psychological and/or physical conditions that may impair success for weight loss (i.e., terminal illness, severe psychiatric disorders, orthopedic problems, etc.) should be evaluated and documented and patient motivation should be considered. It is also helpful to establish the patient's readiness for current recommendations by assessing past dieting history, current physical activity limitations, and weight gain, particularly in the past 3, 6, and 12 months. Drastic changes from current lifestyle patterns without patient education and realistic commitment are typically unsuccessful. It may also be advantageous to assess the patient's weight history; in particular, highest adult body weight (HABW), lowest adult body weight (LABW), usual body weight (UBW) (within the last 6 months) and, finally preferred body weight (PBW). This information can help determine individualized goals for weight loss over time.

Nutrition and Diet Assessments for Weight Loss Treatment

The nutrition assessment begins with a measurement of BMI and waist circumference. First, height should be assessed using a wall-mounted stadiometer to obtain an accurate measurement. Next, weight should be assessed on a balance beam scale or a medical grade electronic scale with the patient wearing light clothing or a gown and without shoes. BMI is calculated as weight (kg)/height $(m)^2$ or if pounds and inches are used [weight(pounds)/height$(inches)^2$] × 703 or through the use of a BMI Calculator. For waist circumference, use a nonstretchable tape (7–12 mm wide) and measure the waist at the top of the iliac crest while the patient is standing with the tape placed in a horizontal plane around the abdomen parallel to the floor [10].

A personalized, patient-centered nutrition assessment also includes determining the appropriate energy level for maintenance of current weight. To calculate the patient's baseline total energy intake (TEI) or kcal/day needed to maintain their current weight, the total energy expenditure (TEE) for that individual must be estimated.

$$\text{TEI} = \text{TEE}$$

The TEE consists of three components including: basal energy expenditure (BEE), thermic effect of food (TEF) and an adjustment factor for the physical activity level (PAL).

$$\text{TEI} = \text{TEE} \quad \text{or}$$

$$\text{TEI} = (\text{BEE} + \text{TEF} + \text{PAL})$$

In practice, the resting energy expenditure (REE) is used in lieu of the BEE because it is impractical to measure energy expended in the basal state. The REE is considered to be ~10% above the basal state and is substituted for the more difficult to measure TEF, which is also approximately 10% of TEE.

$$\text{TEI} = \text{TEE} \quad \text{or}$$

$$\text{TEI} = (\text{REF} + \text{PAL})$$

To complete an estimation of TEE, the PAL must be estimated. Assess the patient's current activity level and apply the appropriate activity factor of REE × 1.2 (sedentary), × 1.4 (low active to moderate), and × 1.6 (active) (or 20%, 40%, and 60% above REE, respectively). Subsequent adjustments for intentional activity or exercise (such as walking, biking, dancing, or exercise routines, etc.) are added as individuals engage in these activities and can be adjusted per day or averaged per week. Evidence-based medicine (EBM) guidelines recommended by the Academy of Nutrition and Dietetics (AND) prioritize the estimation of energy needs based on resting metabolic rate or RMR (same as REE). It is recommended that RMR should be measured (e.g., indirect calorimetry) [11] whenever possible. New hand-held, medical devices for practical measurement of RMR/REE in the primary care setting have become available at reasonable cost. These devices measure inspired and expired airflow and use the Weir formula to estimate RMR/REE mainly from the oxygen consumed over time under standard pretest conditions at rest. These new devices have been demonstrated to correlate well ($r = 0.91$) with the more sophisticated, expensive instruments such as the standard Douglas Bag technique [12]. However, if measurement is not possible, RMR should be estimated using the most accurate formula found to predict RMR within ±10% of measured in most individuals, the Mifflin-St. Jeor Equation (MSJE) [11,13,14].

$$\text{Females}: 10\,\text{Wt (Kg)} + 6.25\,\text{Ht (cm)} - 5\,\text{age (years)} - 161$$

$$\text{Males}: 10\,\text{Wt (Kg)} + 6.25\,\text{Ht (cm)} - 5\,\text{age (years)} + 5.$$

The MSJE has been made available in computerized handheld devices for convenient access along with other tools including charts and wheels, which facilitate practical and user-friendly applications in the office setting (Table 43.2) [15].

Because TEI from food and beverages is difficult to assess in the office setting, patients can be instructed to bring in a food diary (1–7 days or a typical day) and TEI can be estimated with a quick review and focused

discussion [16]. It has been determined that a 7 day food record is a representative of intake over 28 days ($r = 0.89$) [6] and can be combined with an activity record to serve as a baseline assessment on which to measure changes. Many obese individuals underestimate their intake and do not adequately describe their consumption on a recall basis. Thus, a 7 day prospective food record is recommended to be kept by all patients in as much detail as possible. This record should reflect the patient's "usual" diet prior to intervention and should also be sensitive to the pattern of eating (time, place, and occasion), portion size, and method of preparation. Patients should be instructed in detail how to keep the food record and counseled with regard to why it is important to establish a true baseline before any interventions. The 7 day food record should then reflect a good pattern on which to base any dietary interventions or recommendations for change.

Because food and nutrient intake are generally compromised in dieting individuals, a well-formulated multivitamin to provide 100% of the recommended daily allowance (RDA) should be considered, especially for those individuals at the lower intake levels (≤1200 kcal/day).

Access to food, food selection, and functional capacities for food preparation are key considerations to assess before outlining a treatment plan. Observing a patient's verbal and nonverbal cues is also important to assess as they may provide clues to confidence and self-efficacy in making changes. Furthermore, weight maintenance (±5 lb between any two points in time or ~3% of body weight) [31] should be considered when patients are resistant to weight loss and calorie deficit diets.

DIETARY INTERVENTION

Close collaboration with the patient will help to create a realistic diet plan that takes into consideration weight loss and adequate nutrition. The total energy intake is of central importance; however, reductions in intake are too often accompanied by a decline in essential nutrients and overall quality of the diet. A major outcome of dietary treatment should be a notable improvement in diet as evidenced by adherence to the dietary guidelines the majority of the time (or at least 4 days of the week) [17]. The adequacy of low-calorie diets that are not carefully selected poses particular concern for intakes of calcium, folic acid, and vitamin B-12. In addition, even overweight Americans not dieting have diets inadequate in calcium, potassium, vitamin D, and fiber [18].

The dietary intervention should begin with the patient's usual pattern in mind. The first goal is either to achieve caloric balance to maintain weight or to achieve a caloric deficit to accomplish a desired weight loss. The diet plan should build on the strengths of the patient's current diet and incorporate modifications necessary to manage comorbid conditions. An intervention plan can be made using the plate method (choosemyplate.gov), as outlined in Figure 43.1 or by examples of the 1200- and 1600-cal meal plans found in the Clinical Guidelines document [5]. Foods eaten that are out of proportion to the recommendations from the plate are then targeted for evaluation jointly with the patient. It is important to be realistic about what can be achieved and what weight loss can be expected. Thus, the usual food pattern derived from the 7 day food record can be used to begin recommendations for

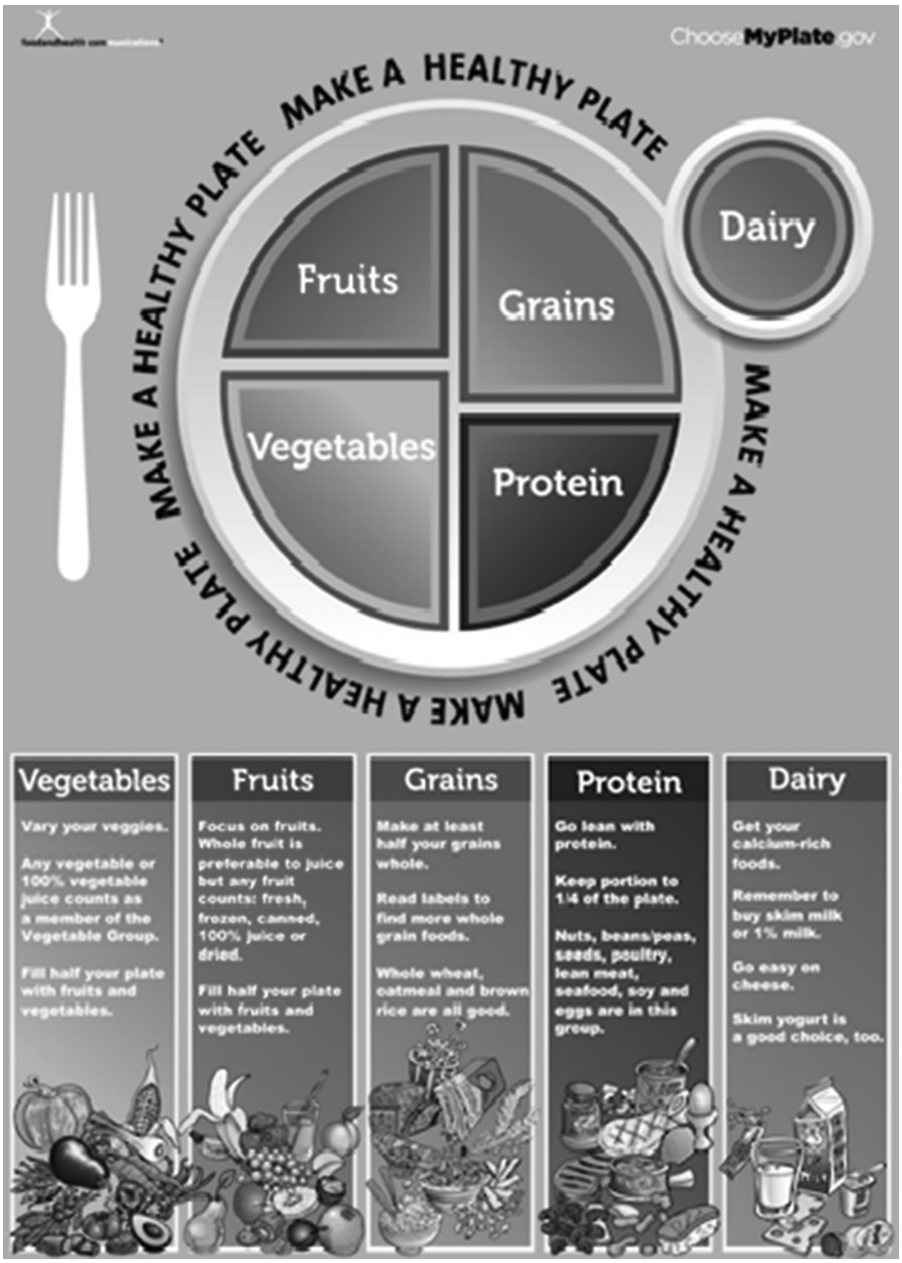

FIGURE 43.1 Foods and portions making up a healthy diet.

change (increasing or decreasing food groups, assessing portion sizes, changing or substituting foods especially of high caloric and/or high fat value, and changing eating patterns where feasible) in order to impose a practical deficit (250–1000 kcal/day in general) to attain a 0.5–2 lb weight loss/week using the approximation of −500 kcal/day = −1 lb/week.

In the past, it has been difficult for patients to monitor their daily caloric intake and diet composition. However, the ease and availability of online programs that can be used with smart telephones to record both caloric intake and nutrition composition may be very useful in achieving weight loss. These web-based programs allow the user to monitor progress toward goals for weight, food intake, and physical activity. Self-monitoring can also be achieved through traditional paper monitoring. Self-monitoring with these tools can be used to reinforce behavioral changes and to encourage adherence to prescribed dietary and activity changes. By simply asking a patient to record daily food and beverage intake or weekly weights or weight changes, simple changes can be encouraged, monitored, and assessed. The goal is to encourage small, incremental changes in behaviors toward a prescribed balanced deficit diet with increases in physical activity monitored by activity type and time or by counting steps through the use of a pedometer.

DIET COMPOSITION

Although consensus was seemingly established around the efficacy of prescribing diets low in fat, the increasing incidence of obesity despite lower fat intakes in the United States has raised many questions regarding associated trends in low-fat diets and has shifted attention to total caloric intake [18]. In actuality, the ideal composition of the diet for weight loss and weight maintenance has not been established. Additionally, the advantages of different diets such as the Mediterranean diet, Asian diets, European diets, and American diets are currently being compared and published, leaving many health professionals confused regarding the diet composition to recommend. During weight reduction, it appears that the greatest impact of diet is from its total energy deficit, and the diet composition has little effect on the rate or magnitude of weight loss over the short-term [19].

The effect of diet composition on total energy balance through increased intake and/or increases in energy expenditure through the TEI need further study. Further, the role of fat intake on fat stores through selective oxidative processes and the genetic predisposition to gain fat and deposit fat centrally are important issues still to be addressed. Behavioral, psychological, and environmental factors also affect eating patterns and food intake, thus ultimately affecting diet composition. Additionally, physiologic stimulators as well as genetic factors may predispose the selection of foods higher in carbohydrates and/or fat. Thus, dietary patterns are highly individual and highly variable, resulting in unpredictable outcomes. Importantly, long-term compliance to dietary interventions is affected by how well the diet composition meets the most important of these established needs.

Studies have demonstrated the efficacy of meal replacements (liquids, bars, frozen entrees) in improving compliance with low-calorie diets and enhancing long-term successful weight management [20,21]. Meal replacements, which are generally formulated products such as shakes or portion controlled entrees, have value because they provide a regulated amount of calories per serving, are usually fortified with essential nutrients and fiber, and are economical, safe, and convenient to use. They also provide a departure from normal eating patterns and can serve as a venue for reeducation about and/or reformulation of what foods can be substituted or reintroduced.

EVIDENCE RELATED TO DIET AND BODY WEIGHT

Although not conclusive, the USDA Nutrition Evidence Library along with the Academy of Nutrition and Dietetics Evidence Analysis Library provide many clues to successful outcomes in the management of obesity [20,22]. In addition, the National Weight Control Registry (NWCR) provides insights on indicators of weight management success [23]. Current recommendations supporting successful weight loss outcomes include the following.

1. Meal replacements can be an effective tool because they are portion controlled, lower in calories, convenient and include foods of lower energy density.
2. Eating breakfast can be effective in controlling appetite, lowering the chances of overeating later in

the day. Breakfast eating is a key strategy for people who are able to maintain weight loss.
3. Three to four servings of low-fat dairy foods should be included to meet nutritional needs.
4. Total caloric intake should be distributed throughout the day, with the consumption of four to five meals, including breakfast.
5. Portion control should be included as part of a comprehensive weight management program.
6. Limited television screen time should be encouraged along with recommendations to increase physical activity overall.
7. Self-monitoring of intake, physical activity, and weight should be encouraged as an important part of a weight management program.

BEYOND DIET

Fat and sugar substitutes have a role in the dietary management of overweight and obese individuals primarily because they can potentially lower fat and caloric intake overall. However, it is important that they are used in the context of a regular diet, used in moderation and balance with other foods, are appreciated for total energy and nutrient value, and do not replace other nutritious foods [24,25]. Dietary supplements should be considered when eating patterns are compromised, erratic, limited in choices, or <1200 kcal/day [6]. Vitamin and mineral supplements should never be used in lieu of a healthy diet, and their use should be evaluated on a case-by-case basis. Meal patterns and food portion sizes are also deemed important in regulating dietary intake overall and should be evaluated as part of the dietary history and 7 day food records. Interventions should be focused on the total diet, eating patterns rather than specific foods, and obtaining nutrient adequacy through a variety of foods. Finally, the enjoyment of eating should not be overlooked, and flexibility in a meal plan must be included to maximize the potential for long-term adherence rather than short-term compliance.

THE FUTURE OF DIETARY TREATMENT

Diet fads come and go. There will always be a popular diet or dietary strategy that will seemingly monopolize the current marketplace. Education of consumers toward realistic goals, maintenance of a diet that complies with the dietary guidelines, and the rationale that there is no one food, nutrient, or strategy that will be uniquely successful will always be a major challenge. Fad diets usually emphasize: (1) large weight losses in short amounts of time; (2) the best or ideal macronutrient composition of the diet (fat, carbohydrate, or protein); (3) special attributes of a ingredient, food, or substance; (4) a rationale for a specific mechanism of a food or food combination that is preferred: (5) featured and/or structured meal plans and recipes; (6) foods or food combinations with special actions; and/or (7) a focus on why other diets do not work. Diet recommendations should be seriously evaluated with regard to efficacy, safety, and long-term effects. Although there can usually be some "half-truth" imbedded in any claims, the best way to evaluate a diet fad is by asking the following questions (all of which should be answered affirmatively) [26].

1. Is the diet well-balanced and does it include a variety of foods? Are all the major food groups included?
2. Does the diet impose a consistent caloric deficit or balance? Are the weight loss expectations reasonable? Is a safe weight: loss (0.5–3 lb/week) consistent?
3. Is a minimum of 50 g protein provided daily?
4. Is a minimum of l00 g of carbohydrate provided daily?
5. Are the meal plans practical, flexible, and individualized? Does the plan allow for special foods and preferences?
6. Is increased energy expenditure or physical activity emphasized without compensation by foods?
7. Are total kilocalories emphasized along with other aspect of the diet (fat, carbohydrate, protein, alcohol) in a totally integrated lifestyle change approach?
8. Are reasonable dietary goals established?
9. Is nutrition education provided?
10. Is positive behavior change for both diet and activity incorporated into the program?

Practical approaches that emphasize normalized eating patterns and a variety of foods as part of a long-term, integrated lifestyle should form the foundation of a solid dietary approach. Special efforts to maximize individual treatment considerations should be given when the dietary management includes attention to adjunctive therapies, such as pharmacotherapy or pre- or postsurgical interventions for weight loss and/or special dietary needs for the management of obesity-related conditions, such as diabetes, hypertension, and cardiovascular diseases. Caution should be taken to ensure adequate intake because some patients may compromise their intake because of increased motivation to new treatments, such as pharmacotherapy, and lose weight more rapidly than anticipated.

Weight loss of 5%–10% of body weight is significant and yet low-calorie diets are not appropriate for everyone. Pregnant and lactating women, those with eating disorders, and patients who have illnesses that can be negatively impacted by a caloric reduction require further evaluation before undertaking weight loss. In addition, caution and expertise is needed when reducing caloric intake of children. Implications for the treatment of obesity for people over the age of 65 is controversial and requires careful assessment and follow-up for protein adequacy and changes in body composition to prevent muscle loss and its consequences [27].

The future of dietary treatment for obesity includes innovation to meet these new challenges and emphasis on

maintenance of weight lost or the prevention of weight gain/regain. A seven-step process is recommended before initiating any dietary treatment for obesity [28].

1. Establish and assess BMI and related risks (waist measurements for men >40 in. and women >35 in.)
2. Assess weight-related comorbidities (diabetes, hypertension, cardiovascular diseases), medications, readiness to diet, and any contraindication to a low-calorie diet (pregnancy, cancerous cachexia, and other debilitating diseases) or Asian male >35 in. and women >31 in.
3. Calculate and evaluate REE from BMI
4. Estimate level of activity and usual activity
5. Estimate dietary intake and/or establish a dietary intake pattern
6. Project energy balance and prescribe a level of energy deficit and other dietary parameters
7. Develop long-term, practical dietary strategies, and individual goals with individuals to prevent weight gain or regain utilizing ±5 lb (or 3% of BW) as an indicator of significant change [29,30].

Thus, as we begin to better assess the needs and future directions for the dietary management of the obese, as well as overweight individuals, we can project important successful outcomes that take time and effort. Short-lived, unhealthy diet fads should be avoided, and emphasis should be placed on practical interventions that support health and the enjoyment of eating.

INTRODUCTION

Obesity: A Serious Condition

The prevalence of obesity continues to rise globally. Based on the body mass index (BMI) calculated from measured heights and weights, the 2007–2008 National Health and Nutrition Examination Survey (NHANES) noted a high prevalence of overweight (BMI 25.0–29.9 kg/m^2), obesity (BMI 30.0 kg/m^2 or greater), and extreme obesity (BMI 40.0 kg/m^2 or greater) to be 34.0%, 33.8%, and 5.7%, respectively [1].* Previous NHANES surveys were conducted about every 4 years with at least 1 year between survey periods. Beginning in 1999, NHANES became a continuous survey. There is an increase in obesity between the late 1980s and today, with an estimated age-adjusted prevalence moving from a previous level of 23% in NHANES III (1988–1994) to approximately 34% in 2007–2008. The World Health Organization (WHO) estimates that over one billion people are overweight globally, and that if current trends continue, that number will increase to 1.5 billion by 2015.† It is estimated that there are more than 475 million obese people worldwide.‡

Obesity promotes numerous medically significant comorbidities such as diabetes mellitus, hypertension, dyslipidemia, sleep apnea, several cancers, and gall bladder disease, all of which contribute to the increase in morbidity and mortality, particularly in younger individuals [2–5]. It has been estimated that more than 300,000 people die each year from obesity-related diseases in the United States [6,7]. Therefore, measures to prevent and treat obesity are urgently needed.

Obesity Treatment

Historically, clinical treatment of obesity has focused on calories and macronutrient intake, and lifestyle modification, but has recently evolved to include drug therapy and bariatric surgery. Although each component claims efficacy, a successful treatment of obesity often needs more than just a single approach. Combinations of some of these components are recommended for maximum weight loss and successful maintenance.

Physicians have often been reluctant to prescribe antiobesity drugs. In the past, this was due to the addictive potential of amphetamines (which are no longer used as obesity drugs) and the belief that obesity drugs do not work in the long term. Currently available obesity drugs approved for short-time use can be effective, and drugs approved for long-term weight loss usage usually produce less impressive, but medically effective, weight loss in the long run. Some people, including some physicians and health care professionals, seem to believe that obese people have little or no personal control over their eating and behavior patterns and attitudes about their weight control. This leads to a misconception that a simple change in patient's attitude and behavior is all that is necessary to achieve medically needed weight loss. Furthermore, since obesity is perceived to be a self-imposed issue, drug side effects of any degree are considered unacceptable for treating this "behavioral" condition. It is hard to achieve successful weight management for the majority of the obese population if the option of drug therapy is underutilized due to misconceptions.

* National Health and Nutrition Examination Survey 2007–2008. http://www.cdc.gov/nchs/nhanes.htm
† http://www.who.int/mediacentre/news/releases/2005/pr44/en/
‡ International Obesity Task Force, http://www.iaso.org/iotf/obesity/obesitytheglobalepidemic.

This environment has created reluctance on the part of some physicians to use obesity drugs. Research from past several decades has revealed that lifestyle modification alone as a treatment for obesity may help some individuals, but is inadequate to bring about the changes at the community level or to stop the global obesity epidemic. Concerted efforts are required from various angles to prevent or treat obesity and this includes the use of pharmacological agents to supplement the weight loss efforts of individuals. New discoveries on the genetic and chemical basis for obesity [8–12] have led to a rapid expansion of research on obesity drugs. Obesity experts and primary care physicians have a renewed and intensified interest in the drug industry, together with the support of the Food and Drug Administration (FDA), to develop new and more effective obesity medications for the acute and long-term management of obesity and weight maintenance. Many obese adults will have tried several self-help approaches available through advertisements, social media, and on the advice of friends and family before consulting with their physicians for advice about their unhealthy weight. Some patients feel that their doctors are both too busy, and lack the expertise and perhaps the compassion to help them [13]. The public awareness is increasing about the medical and lifestyle consequences of being an obese individual. There is no obvious cure in sight. The medical profession needs to be at the forefront to treat patients with obesity. This chapter will discuss mechanisms of action of obesity drugs, theories of altered body defense of body weight, FDA-approved drugs, off-label use, over-the-counter (OTC) medications and diet supplements, fat substitutes, drugs awaiting FDA approval, compounds under development, drug combinations, approaches to the drug management, and the role of the FDA.

MECHANISMS OF ACTION AND CATEGORIES FOR OBESITY DRUGS

In obesity, body stores excess energy in the form of fat. A period of negative energy balance is required to reduce this excess body fat. This can be accomplished either by a reduction of food intake or an increase in energy expenditure (EE). Pharmacologic agents act by various mechanisms on this energy balance equation but mainly focus on reducing energy intake. Maintenance of energy balance is so critical to survival that there are many redundant mechanisms that influence food intake and EE [14]. Numerous areas of the brain, participate in the regulation of energy balance and they respond to different neurotransmitters. Most of the drugs currently approved for the treatment of obesity in the United States act on two of the more important neurotransmitters systems to regulate energy balance: the centrally acting serotonergic and adrenergic systems. Some other drugs reduce energy intake by reducing the digestibility and absorption of macronutrients.

Reduction of Energy Intake

Energy intake may be reduced in several ways. All currently FDA-approved obesity drugs except orlistat are thought to reduce appetite or hunger, increase satiety, and modify food-seeking behavior [15–17]. There is some evidence that obesity drugs may alter dietary preference for fat or carbohydrates but this evidence is limited. By using obesity drugs selectively, patients may be better equipped to regain control over eating behaviors and possibly more compliant with behavior and lifestyle changes that are needed for a long-term change in body weight.

Centrally Active Serotonergic Agents

Centrally active serotonergic agents are DEA class IV drugs that prevent the reuptake of serotonin in the neural clefts. Studies suggested [18] that serotonin may reduce cravings for carbohydrates. Sibutramine (Meridia) is a serotonin agonist drug that was FDA approved in 1997 and withdrawn in 2010 after an FDA review. Currently there are no drugs available in this class that are FDA approved for obesity. There are however, serotonin reuptake inhibitors approved by the FDA as antidepressants (fluoxetine [Prozac] and sertraline [Zoloft]), which have some potential to produce weight loss [19]. These drugs are not FDA approved for obesity management.

Centrally Active Adrenergic Agents

Centrally active adrenergic agents are DEA schedule class IV drugs that includes phentermine, diethylpropion, and mazindol. The schedule IV obesity drugs have minimal addiction or abuse potential and are the most prescribed adrenergic drugs for obesity in America [20]. These adrenergic agents either stimulate the secretion of norepinephrine from the central nerve terminals (phentermine and diethylpropion) or inhibit its uptake (mazindol), thus leading to actions on food intake and EE.

Schedule III drugs include benzphetamine, chlorphentermine, clortermine, and phendimetrazine. They are rarely used by most physicians to treat obesity, since their abuse potential is higher than the more favored and low-risk schedule IV drugs. Schedule II drugs are only used in extremely rare circumstances due to their significant abuse potential. They do not produce more weight loss than the schedule III or IV agents and should be used only with extreme caution. These drugs include dexamphetamine, methamphetamine, and phenmetrazine.

Enzyme Inhibitors

As a class they act by reducing the intestinal absorption of nutrients. Prescription orlistat (Xenical) and OTC orlistat (Alli) are the only FDA-approved drugs for obesity management in this class.

Increase in Energy Expenditure

Animal and human studies suggest some obesity drugs may act by increasing energy consumption, by increasing the resting metabolic rate (RMR), or through increased thermogenesis

induced by diet, cold, or exercise. Another mechanism is to stimulate physical activity through tremors or spontaneous physical activity but this literature is controversial [16,21]. Anecdotally, patients on obesity drugs report an increase in willingness to exercise and are comfortable when active but there have been no studies to clearly document this phenomenon or to attribute it to drug action. The FDA-approved drugs phentermine, diethylpropion, and mazindol fall in this category. The drug combination of ephedrine and caffeine with or without aspirin increases RMR probably by stimulating β-adrenergic receptors [22,23].

Most clinical trials that use obesity drugs also include behavioral therapy including a focus on increasing activity. The independent contribution of medications on increasing EE is difficult to determine in these trials.

Altering the Set Point/Settling Point

Since the 1980s, researchers have theorized that obesity drugs may reduce the level at which body weight is defended. This has raised the question of a "set point" theory. The set point theory holds that the body has a complicated homeostatic feedback system for controlling body fat stores [24–26]. There is also the concept of a "settling point," a defense of body weight, which is a confluence of many factors that have an effect body weight [27]. Weight loss lowers the metabolic rate [26]. Weight regain appears to be caused by additional factors besides variations in metabolic rate [28]. It has been argued that treatment with obesity drugs reduces body weight and this reduction is maintained despite the lower metabolic rate [16].

FOOD AND DRUG ADMINISTRATION-APPROVED OBESITY DRUGS

The majority of obesity drugs currently on the market are centrally active adrenergic drugs and were FDA approved when the FDA only required short study periods for approvals. Reviews in 1976 and in 1992 of over 200 studies of antiobesity drugs concluded that all of the antiobesity agents produced similar results [17,29]. The average weight lost in these reviews was about one-half pound per week greater than placebo [17,29]. The centrally acting serotonergic drug sibutramine was approved in 1997 as a long-acting antiobesity treatment but was removed from market by the manufacturer after FDA review in 2010. In 2001, the FDA approved the enzyme inhibitor orlistat for long-term use and was approved for OTC use at a lower dose in 2007. This was the last time the FDA has granted approval for a new drug for the pharmacological management of obesity.

Orlistat (Xenical)

Orlistat (Xenical) is a gastrointestinal (GI) lipase inhibitor acting through inactivating intestinal enzymes and partially inhibiting the digestion of fat. This action results in a decrease in fat absorption and energy intake, and the promotion of malabsorption [30–33]. Fat absorption can be reduced by approximately a third, in subjects eating a meal containing 30% fat. Less than 1% of this peripherally acting drug is absorbed. GI side effects can occur in up to 40% of patients. Malabsorption can result in diarrhea, fecal incontinence, or urgency, oily stool, anal leakage, bloating abdominal pain, and gas. There may be the need for fat-soluble vitamin replacement. Higher dietary fat content increases the likeliness of GI adverse events [34]. In a 2 year Orlistat study, drug-treated subjects lost nearly 10% body weight in the first year compared to 5%–6% weight loss in the placebo group [34]. Study dose of orlistat was 120 mg three times a day (TID). There was about a 4 lb weight regain during the second year in the treatment group versus 8 lb in the placebo group. This signified a sustained weight reduction in study year 2. Orlistat also partially inhibits the digestion of triglycerides. During the study fasting low-density lipoprotein cholesterol and insulin levels improved. Some lipid values improved more than can be explained with weight reduction alone. Lipid-soluble vitamins A, D, and E and β-carotene concentrations may be slightly reduced after treatment orlistat. Some nutrients and some medications might have decreased absorption. The antihypertensive agents, warfarin, and oral contraceptives concentrations are not affected by orlistat [34–36].

In studies of obese subjects with or without type 2 diabetes, orlistat demonstrated an improvement in glucose metabolism and a reduction in high blood pressure [37,38]. In a 3 year orlistat weight maintenance study, there was no change in eating behavior, except in a subgroup that selectively decreased their intake of fatty foods. The subgroup had an enhanced weight maintenance, which the study authors ascribed to a change in fat consumption behavior [39]. Education on lowering dietary fat consumption is needed for maximizing weight loss with the help of orlistat.

A 3 year Orlistat study involved 383 adults who had abdominal obesity and metabolic risk factors, including dyslipidemia, impaired fasting glucose, and diet-treated type 2 diabetes. The study aim was to investigate the effect of orlistat on weight regain and cardiovascular risk factors following a very-low-energy diet (VLED). Subjects who lost at least 5% of their body weight (309 of 383 subjects) were then randomized to receive lifestyle counseling together with a placebo or orlistat 120 mg TID for 3 years. Study results identified that compared to the placebo group, orlistat plus lifestyle intervention resulted in an additional 2.4 kg weight loss after VLED and a reduced occurrence of type 2 diabetes for up to 3 years. The study authors concluded that orlistat may be a useful adjunct to conventional dietary and lifestyle treatment of high-risk obese subjects [40].

Another study examined the effect of orlistat on eating behavior in a 3 year weight maintenance trial. Three hundred and six obese women and men (19–45 years old), were a part of the Scandinavian Multicenter study of obese subjects with the metabolic syndrome. Subjects were treated with orlistat after a VLED-induced weight loss and followed for the next 3 years in a maintenance program. Results

showed that dietary restraint increased and disinhibition, hunger, and binge eating decreased in orlistat and placebo groups in a similar fashion. The authors pointed out that these changes in eating behaviors are needed for successful weight maintenance [39].

In 2007, FDA approved orlistat as an OTC obesity drug for adults. The commercial name is Alli. The dose is 60 mg TID and should be taken in conjunction with a reduced calorie and low-fat diet. Exercise and a multivitamin are also recommended. Side effects of the OTC orlistat are similar to prescription orlistat. See OTC obesity drug section for further details. The FDA has received reports of rare cases of severe liver injury in the use of orlistat by prescription or the OTC use. In response, the FDA has added a drug label.*

Drugs Approved for Short-Time Use

Phentermine

Phentermine is the most commonly prescribed obesity drug in the United States. The FDA approved phentermine for short-term treatment of obesity in 1959. It is a centrally active adrenergic drug, a sympathomimetic amine that stimulates norepinephrine release in synaptic terminals. With phentermine usage, patients can experience increased satiety and less of hunger, craving, binging, and nighttime eating. There are no recent studies with phentermine, but earlier studies show effectiveness and safety [41,42] including studies in combination with fenfluramine [43–46].

The popularity of phentermine over the other schedule IV drugs is most likely due to the long-term medical research and the subsequent clinical experience gathered with the drug combination of phentermine and fenfluramine [43–45]. Also, phentermine is associated with a rapid onset of appetite control and the improvement in patient attitude and weight management program adherence [43–45].

The most common side effects of phentermine include decreased appetite, dry mouth, headache, insomnia, irritability, nervousness, euphoria, palpitations, tachycardia, and an elevated blood pressure. Phentermine should be avoided in patients with active cardiovascular disease, moderate to severe hypertension, hyperthyroidism, agitated states, glaucoma, and a history of drug abuse. Drug abuse potential and addiction is reported as minimal [47]. There have been a few case reports of primary pulmonary hypertension in patients taking phentermine alone [48].

Phentermine is available as a 37.5 mg scored tablet and a 30 mg nonscored tablet or capsule form. These are also the maximum approved doses. Due to a possible association with valvular heart disease, fenfluramine was removed from the market by the FDA in 1997. Phentermine was not shown to contribute to valvular heart disease and was not withdrawn.

Diethylpropion

Diethylpropion is a centrally active adrenergic sympathomimetic agent with an action similar to phentermine. Diethylpropion is structurally similar to the FDA-approved antidepressant drug bupropion. Bupropion has been studied for its weight loss effect but is not FDA approved for weight loss and will be discussed in a later section [49]. Short-term studies [50] have compared diethylpropion to placebo in a 6 month trial where the diethylpropion-treated group lost 12.3% of initial body weight compared to 2.8% loss in the placebo group. In a 24 week study comparing continuous diethylpropion daily or every other month, the continuous therapy group was the most successful. Blood pressure reduction occurred in proportion to the weight lost [42]. Adverse effects included dry mouth, euphoria, asthenia, nervousness, decreased appetite, insomnia, and sleeplessness with frequent awakening. There was a delay of rapid eye movement (REM) sleep and increased time in stage 1 sleep [42]. In this study, the dropout rate was a high 82%. Diethylpropion is not recommended for patients with heart disease, high blood pressure, hyperthyroidism, or glaucoma. The recommended dose is 75 mg/day.

Mazindol

Mazindol is an FDA-approved drug for weight loss. It is a norepinephrine and serotonin reuptake inhibitor that has been withdrawn by the manufacturer from the U.S. market. There are no long-term double-blind placebo-controlled studies using mazindol but open-labeled long-term studies show significantly greater weight loss with mazindol, compared to the placebo group [51]. Side effects are similar to that of phentermine.

Drug Combinations

Currently, there are no FDA-approved combination drugs for obesity treatment. The FDA has disallowed three new drug requests for drug approval between November 2009 and January 2011, two of which are drug combinations. Historically, the only successful drug combination for obesity treatment was the combination of phentermine with the now-withdrawn drug fenfluramine. Fenfluramine, a serotonin agonist, and phentermine, an adrenergic agonist, were first reported in combination for obesity management in 1984, and then in 1992, a 4 year study was published [43,45]. Treatment in these studies included behavior modification, nutrition education, and exercise. Weight loss plateaued at 6 months with a 15.8 kg weight loss at the end of study year 1 [45]. After 3.5 years of treatment, the phentermine and fenfluramine (phen-fen) combination was discontinued, and at a 6 month follow-up, body weight returned to near-baseline levels, demonstrating the requirement of these drugs in maintaining weight loss. Side effects included dry mouth, fatigue, sweating, and insomnia. There were few dropouts due to side effects. A large phen-fen combination study included over 1300 subjects treated up to 2 years [43]. Weight losses of about 16 kg persisted for 2 years in subjects who continued on drugs.

Fenfluramine and dexfenfluramine were removed from the market by the FDA in 1997 due to a suspected association

* NIH Publication No. 07-4191 November 2004, Updated December 2010.

with fibrosis of the mitral and/or aortic heart valves resulting in regurgitation. It was initially suggested that the mechanism responsible was an increased level of circulating serotonin.

However, fenfluramine was not shown to increase the circulating serotonin and the exact mechanism responsible for the heart valve problems is unclear. No clear cases of heart valve problems due to phentermine alone have been reported and phentermine remains an FDA-approved drug, without valvular heart implications, for the short-time treatment of obesity.

When prescribing antiobesity medication, an echocardiogram may be indicated if a heart murmur or symptoms of dyspnea on exertion, easy fatigue, fainting, or chest pain are present, especially if a patient has previously been on the combination of phentermine and fenfluramine.

OFF-LABEL DRUG USE

The off-label and the investigational use of marketed drugs is defined by the FDA as follows; "Good medical practice and the best interests of the patient require that physicians use legally available drugs, biologics and devices according to their best knowledge and judgment. If physicians use a product for an indication not in the approved labeling, they have the responsibility to be well informed about the product, to base its use on firm scientific rationale and on sound medical evidence, and to maintain records of the product's use and effects. Use of a marketed product in this manner *when the intent is the "practice of medicine"* does not require the submission of an Investigational New Drug (IND) Application, Investigational Device Exemption (IDE), or review by an Institutional Review Board (IRB). However, the institution at which the product will be used may, under its own authority, require IRB review or other institutional oversight.*

The FDA also regulates how an approved medication can be promoted and advertised. There is no FDA restriction on physicians relying on their clinical experience in using an FDA-approved medicine for a condition, or a dose or duration that is different than that approved by the FDA. The National Institutes of Health document entitled "Prescription Medications for the Treatment of Obesity" reminds prescriber that for off-label determinations, there need to be a balance between a drug's known and unknown side effects and the potential added benefit of off-label use.† The medical needs of a patient in conjunction with a physician's knowledge of the complexity of obesity, should guide the decision for an off-label drug use. It is recommended that a careful and detailed review of the rationale for an off-label drug use should be documented in patient records. Each patient should be informed and educated as to why this drug is being prescribed and the patient's agreement to the treatment should be documented. It is recommended that such a document be signed and maintained in the patient's record.

Clinical evidence for the off-label use for obesity treatment is reported for the following medications.

Antidepressants

Fluoxetine

Fluoxetine (Prozac) is a highly selective serotonin reuptake inhibitor (SSRI) approved by the FDA as an antidepressant. It has been investigated for its weight loss effect. Weight loss has not been consistent in all clinical trials and patients who lost weight in the initial 6 months of the trial tend to regain weight despite the ongoing fluoxetine therapy [19,52,53]. In trials that contained a behavior modification component, significant weight loss at 1 year was reported [52,53]. The weight loss mechanism for fluoxetine is not well understood. The most common side effects of fluoxetine include anxiety nervousness, weakness, asthenia, decreased sexual desire or ability, loss of appetite, nausea, diarrhea, dizziness, drowsiness, dry mouth, flu-like symptoms, increased sweating, or trouble sleeping. Fluoxetine dosage for obesity treatment varied from 20 to 80 mg in clinical trials [19,52–54]. A 1 year study of fluoxetine for depression showed that weight loss occurs early in the fluoxetine group (20 mg) compared to no weight loss in the placebo group. Later in the study, both groups increased their weight, but the weight gain in the fluoxetine treated group was slower [55].

Interestingly, the study authors concluded that after depressive symptoms went into remission, weight gain in patients taking fluoxetine for long periods is not different from the placebo group and is most likely related to recovery from depression. A 6 month weight loss trial of obese subjects prescribed with fluoxetine (20–60 mg/day) and phentermine hydrochloride (from 18.75 to 37.5 mg/day) produced significant weight loss [56]. A phen-flu combination had been proposed as an alternative obesity treatment for the phen-fen combination. A retrospective chart review study compared the use of phen-flu in 97 subjects with those treated with phen-fen. They were all compared to obese subjects never treated with drug therapy. This was a 6 month open-label trial and all patients were seen at a university nutrition clinic. Results showed that the phen-flu group lost 9% weight loss, compared to 12.6% in the phen-fen-treated group. Echocardiograph assessments identified eight of 38 phen-fen subjects with cardiac valve lesions and none in the 15 phen-flu subjects or in the 25 non-drug-treated control subjects [57]. These results suggested that a fluoxetine combination therapy may be an alternative for phen-fen combination for obesity management.

Bupropion (Wellbutrin)

Bupropion (Wellbutrin) is FDA approved and indicated for the treatment of depression and smoking cessation. Bupropion is not related to the tricyclic antidepressants and is not an SSRI

* "Off-label" and investigational use of marketed drugs, biologics, and medical devices—Information sheet guidance for institutional review boards and clinical investigators: http://www.fda.gov/RegulatoryInformation/Guidances/ucm126486.htm

† Prescription medications for the treatment of obesity. NIDDK. Weight Control Information Network. U.S. Department of Health and Human Services. National Institutes of Health NIH Publication No. 07-4191. November 2004. Updated December 2010.

but a norepinephrine, serotonin, and dopamine uptake inhibitor. It is effective in promoting weight loss in patients with or without depression [58,59]. Like fluoxetine, bupropion-treated subjects had varied weight loss results and the weight lost was maintained for as long as 1 year [58,59]. Bupropion dosage in clinical trials varied from 300 to 400 mg/day for a period of 26–48 weeks [58,59]. Side effects were reported as minimal. Most common side effects include agitation, weight loss, dry mouth, nausea, headache, constipation, dizziness, tremors, and tachycardia.

Antiseizure Drugs

Topiramate (Topamax)

Topiramate (Topamax) is an antiepilepsy drug that blocks sodium channels and enhances the neuroinhibition of γ-aminobutyric acid (GABA). Common side effects of topiramate include fatigue, sedation, concentration and focus issues, slow thinking, memory problems, psychomotor slowing, diplopia, nystagmus, dizziness, ataxia, paresthesia, anorexia, headache, and speech problems [60].

There have been observational reports of weight loss associated with topiramate treatment of bipolar disorders. A retrospective study reviewed the treatment of five patients with bipolar disease and schizoaffective disorders treated with topiramate that was gradually titrated to a maximum dose of 125 mg in the morning and 150 mg at bedtime. Treatment produced good psychiatric response. Weight was monitored up to 3 months and all patients lost an average of 22 lbs with a range of 8–56 lb [60].

In a 6 month clinical trial for weight loss, the topiramate groups lost significantly more weight than placebo patients at all doses of topiramate [61]. The dropout rate was greater for the drug group (21%), compared with that for the placebo patients (11%), which was attributed to the side effects of cognitive dysfunction and paresthesia.

Another clinical trial of obese subjects evaluated weight loss maintenance [62]. Subjects were first treated for 8 weeks with a low-calorie diet followed by topiramate or placebo therapy for weight maintenance for 44 weeks. Study dose varied from a placebo to 96–192 mg/day of topiramate. The weight loss phase resulted in clinically significant reduction in body weight and visceral fat. During the 44 week maintenance period, weight loss was maintained and an additional 6% weight loss occurred for the topiramate group [62]. Topiramate was generally well tolerated.

A 2 year study of 1289 healthy obese adults explored the long-term efficacy and safety of topiramate at various doses [63]. All study subjects received behavior modification training, and were randomized to doses of topiramate that were titrated to the following final doses: 0 (placebo), 96, 192, or 256 mg/day. The study sponsor elected to discontinue the study at the end of the first treatment year in order to commence development of a new controlled-release drug formulation. At 60 weeks, subjects in the placebo group lost 1.7% of their baseline body weight. In the topiramate groups, weight loss was 7.0%, 9.1%, and 9.7%. There were improvements in glucose tolerance and in blood pressure. Side effects mostly occurred during upward drug titration and included difficulty with concentration/attention, depression, difficulty with memory and concentration, language problems, nervousness, and psychomotor slowing and paresthesia.

Zonisamide (Zonegran)

Zonisamide (Zonegran) was approved by the FDA in 2000 for the treatment of partial focal seizures in adults with epilepsy. Zonisamide also has serotonergic and dopaminergic actions and weight loss was identified during clinical trials for epilepsy. It has since been studied for weight loss [64]. In a 16 week study with an additional 16 week extension that included a 500 kcal deficit diet, zonisamide-treated subjects lost considerably more weight compared with placebo. The study doses of zonisamide were gradually increased from 100 to 400 mg/day. In subjects who had lost less than 5% body weight at 12 weeks of therapy, the dose was titrated to 600 mg/day. Zonisamide-treated subjects had a mean weight loss of 9.2 kg at 32 weeks compared to 1.5 kg for the placebo group. Waist circumference and systolic and diastolic blood pressure reduced significantly in the treatment group. There was also an associated improvement in mobility, occupational functioning, and activities of daily living. Fatigue was the only drug-related side effect reported. However, in clinical trials of zonisamide as an antiepileptic drug, cognitive impairment, dizziness, and somnolence were frequently noted. Zonisamide is a sulfonamide and there is a potential for hypersensitivity reactions.

A combination of zonisamide and bupropion was compared to zonisamide alone in a 12 week weight loss study of 18 obese women. The initial zonisamide dose was 100 mg/day, with a gradual increase to 400 mg/day in both groups and given as a nighttime dose. Bupropion was titrated up from 100 to 200 mg/day and given as a morning dose [65]. The combination produced more weight loss (8.1 kg) than zonisamide alone (3.0 kg).

Atomoxetine

Atomoxetine is FDA approved for treating attention deficit/hyperactive disorder (ADHD). It is a central norepinephrine uptake inhibitor. A 12 week study of atomoxetine for weight loss included 30 healthy but obese women. The study dose of atomoxetine was titrated from 25 to 100 mg/day. Modest weight loss (5% of body weight) was recorded with 3 of the 12 completers compared to placebo in this preliminary study [66]. The most common side effect reported was a decrease in appetite.

Antidiabetic Drugs

Metformin

Metformin (Glucophage) is an FDA-approved antidiabetic drug. Studies with metformin have shown it to be either weight neutral or promoting weight loss compared to sulfonylureas, thiazolidinediones, and insulin, which are more associated with weight gain. In a clinical trial to assess weight

changes associated with antihyperglycemic agents in type 2 diabetes mellitus, the study authors concluded that a case can be made for the early use of metformin as a treatment of choice in the management of type 2 diabetes to prevent weight gain or to promote weight loss [67,68]. In some metformin obesity trials, hunger and calorie intake were reduced [69,70]. Metformin for weight loss has also been studied in obese children [71].

A 1 year study of 100 severely obese children aged 6–12 years was designed to determine whether metformin promoted weight loss and improved obesity-related comorbidities in obese insulin-resistant children. The metformin dose was titrated from 500 mg twice daily to a maximum dose of 1000 mg twice daily over a 3 week period. Results demonstrated modest weight loss and improved measures of body fatness. Body circumference and skinfold thickness measurements decreased in the treatment group. There were no significant liver function abnormalities. Side effects included nausea and loose stools, and fatigue [72].

Acarbose

Acarbose (Precose) is FDA approved for the treatment of diabetes. It is an alpha-glucosidase inhibitor, which blocks the digestion of complex carbohydrates [73,74]. Studies of acarbose for obesity treatment in diabetic patients and in polycystic ovary syndrome patients have demonstrated only small changes in body weight [74–77].

Side effects of acarbose are due to undigested complex carbohydrates in the colon and include increased intestinal gas, flatulence, diarrhea, and abdominal pain. In an NIH publication, it was reported that there is not sufficient efficacy or safety evidence to consider prescribing acarbose in nondiabetics as an off-label treatment for obesity.*

Exenatide

Exenatide is FDA approved for type 2 diabetes. It is part of the incretin family of type 2 diabetes drugs, a glucagon-like peptide-1 (GLP-1) receptor agonist. It suppresses appetite and promotes weight loss in obese diabetic patients [78]. Studies to investigate exenatide as a weight loss drug for nondiabetics are ongoing and are discussed further in this section.

Amylin

Amylin is a peptide hormone that is secreted from pancreatic β cells in response to eating a meal and is part of a complex neurohormonal feedback system. It slows gastric emptying and stimulates satiety after a meal [79]. It acts within the brain to reduce food intake and body weight [80].

Pramlintide

Pramlintide is a subcutaneous injectable synthetic analog of human amylin. It is FDA approved for type 1 diabetes and used for patients with type 1 or type 2 diabetes who are taking insulin and need diabetes control. In studies of obese type 2 diabetic adults, pramlintide has produced sustained reductions in food intake, body weight, and total daily insulin usage [81]. The addition of pramlintide to preexisting insulin treatment of type 2 diabetes results in reductions in HbA1c and body weight [82]. Pramlintide appears to have a therapeutic role in type 2 diabetics with obesity. It also produces weight loss in nonobese diabetics [83]. A 24 week human weight loss study using a combination of pramlintide and metreleptin (leptin) resulted in about 13% weight loss. This weight loss was significantly greater than pramlintide or metreleptin treatment alone [84]. The study authors suggested that while previous trials using metreleptin as single therapy failed to show significant weight loss with doses up to twice as much as those used in this study, amylin and leptin together may have therapeutic use as a neurohormonal combination treatment for obesity. In a study, 204 obese men and women (30–70 years old), with or without type 2 diabetes, were treated with pramlintide. Almost 90% of treated subjects were able to escalate to the highest dose of 240 μg TID. Weight loss in pramlintide-treated subject was accompanied by a reduction in waist circumference [85,86]. In a 20 week study of 139 nondiabetic obese subjects, pramlintide (360 μg b.i.d.) was compared to pramlintide/metreleptin (360 μg/5 mg b.i.d.) and metreleptin group (5 mg b.i.d.). Subjects treated with the pramlintide/metreleptin combination had a significantly greater weight loss (13% vs. about 8% in subjects receiving either pramlintide or metreleptin). This weight loss was continuous through the study time frame while weight plateaued at approximately week 12 in the metreleptin and pramlintide monotherapy groups. Nausea was the main side effect in this study [87]. In a 12 month study, 411 obese subjects were treated to assess weight loss, efficacy, and safety of various doses of pramlintide. Subjects were randomized to one of six subcutaneous (sc) dosage arms, from 120, 240, or 360 μg sc injected either BID or TID versus placebo. Clinically significant weight loss (greater than 5%) was reached in the treated groups and maintained in 44%–47% of drug-treated versus 28% of the placebo-treated groups, over the course of the study year. Nausea was the main side effect [85].

Ephedrine with Caffeine and/or Aspirin

The FDA has banned ephedrine from OTC products. Clinical trials with ephedrine in combination with caffeine and aspirin have demonstrated an increase in lean body mass and a decrease in fat mass with mild and transient side effects [22,23,88–90]. The combination possesses anorectic and thermogenic properties, resulting in a prolonged norepinephrine activity. Ephedrine increases the synaptic release of norepinephrine, modulating food intake and the heart rate and blood pressure. It enhances thermogenesis through its sympathomimetic effect. Caffeine appears to potentiate the effect of ephedrine through delaying the degradation of norepinephrine and inhibiting phosphodiesterase in the postsynaptic neurons. Aspirin inhibits the activity of prostaglandins that degrade norepinephrine in the neural cleft [22,23,88,89].

* Diabetes prescription medications for the treatment of obesity. NIDDK. Weight Control Information Network. U.S. Department of Health and Human Services, National Institutes of Health NIH Publication No. 07-4191. November 2004. Updated December 2010.

A placebo-controlled 50 week study evaluated the combination of ephedrine and caffeine without aspirin in 180 subjects taking doses of ephedrine 20 mg TID and caffeine 200 mg TID, or ephedrine alone 20 mg TID, or caffeine alone at 200 mg TID, versus the placebo. A weight loss of about 16 kg was demonstrated in the ephedrine and caffeine group [89]. Another study assessed the safety and efficacy of the combination of ephedrine, caffeine, and aspirin. Study doses were as follows: ephedrine 75–150 mg TID, caffeine 150 mg TID, and aspirin 330 mg TID as premeal doses. Calories were not restricted. Weight loss at 5 months for the treatment group was 5.2 kg compared to a slight weight gain for the placebo group. From months 7 to 26, there was weight regain in the treatment group, but overall modest weight loss from the beginning of the study was maintained [88]. Similar results were also reported by Greenway et al. [91]. Adverse effects from the use of an ephedrine/caffeine combination in these studies were minimal and included tremor, insomnia and dizziness, and increased heart rate and blood pressure. If occurring, symptoms happened early in treatment and resolved within 1–2 months. Elevated serum insulin levels and occasional worsening of glucose intolerance or diabetic control were observed [22,23].

NONPRESCRIPTION MEDICATIONS FOR OBESITY TREATMENT

Food and Drug Administration Approved

Alli was introduced as an OTC drug in 2007 as a low-dose version of the FDA-approved obesity drug orlistat. This GI lipase inhibitor that partially blocks the absorption of dietary fat is the only FDA-approved OTC product for weight loss. A 16 week study of 391 mild to moderately overweight individuals assessed the efficacy and safety of a low dose of orlistat (60 mg TID) in subjects on a lifestyle management plan [92]. After the initial 2 weeks of treatment, the orlistat-treated subjects lost significantly more weight than placebo-treated subjects (3.05 vs. 1.90 kg). GI events were more common in the orlistat-treated group [92].

In a 2 year orlistat obesity trial involving 1187 subjects, orlistat dosage in the first year was 120 mg TID [34]. The second year focused on preventing weight regain and the orlistat dosage was decreased to 60 mg TID (equivalent to the OTC dose) or placebo. In the orlistat group, body weight was maintained within two-thirds of the maximum loss in year 1. Study subjects who were initially taking orlistat but then switched to placebo in year 2 regained most of the lost weight [34]. A 3 month-long pharmacy-based OTC study tested how consumers would use the dosing of orlistat in a nonsupervised environment. A total of 237 patients purchased and used orlistat and completed at least one post-use interview. About 80% successfully used the educational materials and lost approximately 5% body weight. Most took 2–3 capsules per day with meals throughout the study. GI side effects were noted, but there were no dropouts as a result of side effects [93].

Ephedra

In 2004, the FDA banned Ephedra from all OTC products. Ephedra was commonly used in dietary supplements, OTC sinus and cold preparations, and stimulants. The FDA ban was due to reports of palpitations, hypertension, strokes, and deaths.*

Laxatives

Laxatives have been included in selective OTC weight loss products. There are no data to support their use in weight management.

Phenylpropanolamine

The FDA has removed phenylpropanolamine (PPA) from OTC weight loss and cold and sinus preparations. In some states, nonprescription products containing PPA can be purchased with a personal ID card directly from the pharmacist.

Dietary Supplements

The U.S. Congress defined the term "dietary supplement" in the Dietary Supplement Health and Education Act (DSHEA) of 1994 as follows: "A dietary supplement is a product taken by mouth that contains a 'dietary ingredient' intended to supplement the diet. The 'dietary ingredients' in these products may include: vitamins, minerals, herbs or other botanicals, amino acids, and substances such as enzymes, organ tissues, glandulars, and metabolites. Dietary supplements can also be extracts or concentrates, and may be found in many forms such as tablets, capsules, softgels, gelcaps, liquids, or powders. They can also be in other forms, such as a bar, but if they are, information on their label must not represent the product as a conventional food or a sole item of a meal or diet. Whatever their form may be, DSHEA places dietary supplements in a special category under the general umbrella of 'foods,' not drugs, and requires that every supplement be labeled a dietary supplement."†

The FDA does not analyze dietary supplements before they are sold to consumers. It is the manufacturer's and not FDA's responsibility for ensuring that a dietary supplement or ingredient is safe before it is placed on the market. Manufacturers and their distributors do not need FDA approval to sell dietary supplements. It is only after a dietary supplement is on the market that the FDA becomes responsible for taking action against any reported unsafe dietary supplement. The reporting of all serious adverse events to the FDA falls upon the party whose name appears on the label. Except for the dietary ingredients, manufactures are not obligated to document to the FDA or to consumers any data on product safety or what claims they are making about their product. The FDA's Center for Food Safety and

* http://www.fda.gov/NewsEvents/Newsroom/PressAnnouncements/2004/ucm108379.htm

† http://www.cfsan.fda.gov

Applied Nutrition (CFSAN) is responsible for the agency's oversight of these products.*

Many of the popular dietary supplements used for weight loss contain some of the following ingredients: chromium picolinate, guar gum, chitosan, *Citrus aurantium*, *Camellia sinensis*, conjugated linoleic acid, and calcium [94]. Dietary supplement use by the overweight population is common. It has been estimated that as many as 20.6% of women and 9.7% of men have at one time used a weight-loss supplement and many of these patients do not share their use of supplements with their doctor [95].

Most of the weight-loss supplements contain stimulants and the majority of users have no idea that the safety and efficacy of the product they are about to purchase, lacks FDA regulation [96]. Some physicians also misunderstand the dietary supplement regulations [97].

Intake of supplements for weight loss should be asked of all patients and charted. It should be the responsibility of treating physicians to dispel common misconceptions about weight-loss supplements, as needed. The evidence against their use, if any, should be presented in a nonjudgmental fashion. Issues surrounding safety and efficacy of some dietary supplement warrant caution in recommending dietary supplements as part of a weight-loss program [95].

Fat Substitutes for Weight Loss

Fat substitutes are nonprescription food additives. They were developed by the commercial food industry to provide, amongst other benefits, a more pleasing taste, while providing a lower fat content for prepackaged grocery store foods.

Olestra (Olean) is a long fatty acid chained sucrose polyester that is too big a molecule to be digested or absorbed. It is a food additive, fat substitute developed to replace the fat content of prepackaged foods such as potato chips and crackers [51]. An early study used a sucrose polymer as a substitute for dietary fat (30 g/day) in a hypocaloric diet and demonstrated a 3.7 kg mean weight loss and a 23% reduction in low-density lipoprotein cholesterol (LDLC) in the familial hypercholesterolemia population of five subjects [98]. Side effects of olestra-containing products are similar to orlistat and include flatulence, diarrhea or loose stools, bloating, and anal leakage. Manufacturers are required to include vitamins A, D, and E in the food product containing olestra substitutes [99].

DRUGS AWAITING FDA APPROVAL

Lorcaserin

Lorcaserin is a selective serotonin receptor agonist influencing hunger [100]. A 12 week weight loss study used different doses of lorcaserin versus placebo in 469 adults. Compared to the placebo group, there was more weight loss in the lorcaserin groups proportionate to the dose. Side effects included headache, dizziness, and nausea [101]. In a 1 year lorcaserin study, 4008 obese and overweight adults received either lorcaserin 10 mg once or twice daily. All subjects received a lifestyle intervention program. Weight loss (in the 5%–10% range) was statistically significant in the lorcaserin groups than in the placebo group and was dose dependent. No increase in valvulopathy was seen in serial echocardiograms [102].

A 2 year clinical trial involved 3182 obese or overweight adults, who received placebo or lorcaserin 10 mg twice a day plus counseling. The treatment group showed significant weight loss at 1 year and maintenance of weight loss at 2 years. First year weight loss in the lorcaserin-treated group averaged 5.8 kg compared to 2.2 kg in the placebo group. Weight loss was maintained in year 2 in almost 70% of the lorcaserin group compared to 50% for those on placebo. The most common side effects were headache, nausea, and dizziness. There were no increased cardiac valvulopathy findings [100]. In a December 2010, an FDA review of lorcaserin did not receive approval. The manufacturer has agreed to work closely with the FDA to address the various concerns and will present new data about its use in type 2 diabetics.

Contrave

Contrave is an off-label combination of drugs bupropion and naltrexone. Both drugs have been approved by the FDA for almost 25 years. Bupropion is a dopamine and norepinephrine reuptake inhibitor approved for depression and smoking cessation. Naltrexone is an opioid receptor antagonist approved for alcohol and opioid dependence. The drug combination appears to suppress appetite. A 56 week study involving 1742 patients studied the drug combination for weight loss [103]. The two study doses included sustained-release bupropion 360 mg/day plus either sustained-release naltrexone 16 or 32 mg. The third group received placebo. Weight losses were 6.1% and 5.0% at the higher and lower doses of drugs, respectively. The placebo group lost 1.3% of body weight. Side effects included a transient rise in systolic and diastolic blood pressure of 1.5 mmHg, followed by a 1 mmHg reduction below baseline. There was no increase in depression or suicidal events compared with placebo, whereas headache, constipation, dizziness, vomiting, and dry mouth were experienced more frequently in the drug groups.

In December 2010, the FDA Advisory Committee approved Contrave but on January 30, 2011, the FDA turned down their approval recommendation, stating that the side effect of hypertension was worrisome enough to the FDA to refuse approval. A new 2 year study for Contrave is planned to further assess effectiveness and cardiac side effects.

Qnexa

This drug is a combination of the appetite suppressant phentermine together with the anticonvulsant topiramate. This drug combination was initially rejected by the FDA in December 2010 but will be reconsidered. The FDA has requested the

* http://www.cfsan.fda.gov

assessment of potential teratogenic risk and cardiovascular risk and a review of additional long-term data.*

A 56 week phase 3 study of phentermine plus topiramate assessed the efficacy and safety of the drug combination on body weight and comorbidities in 2487 overweight and obese adults, who had two or more of the following comorbidities: hypertension, dyslipidemia, type 2 diabetes, prediabetes, or abdominal obesity [104]. The drug doses were a once-daily phentermine 7.5 mg plus topiramate 46.0 mg or phentermine 15.0 mg plus topiramate 92.0 mg. All subjects received counseling for lifestyle management. The change in body weight was minimal in the placebo group (−1.4 kg) but significant and dose dependent in the drug groups (−8.1 kg and −10.2 kg, respectively). The most common side effects in the treatment groups were also dose related. At the higher dose, they included dry mouth and paresthesia (21%); constipation (17%); insomnia, dizziness, and dysgeusia (10%); anxiety-related adverse events (8%); and depression-related adverse events (7%).

CANDIDATES FOR DEVELOPING OBESITY DRUGS

Cannabinoid Antagonists

The endocannabinoid system, through its CB-1 receptors, has its effects on energy homeostasis through both central and peripheral effects on food intake and body weight. CB-1 receptor blockers decrease both central and peripheral effects of the endocannabinoid system and increase satiety and promote weight loss [105]. Rimonabant is a selective CB-1 receptor. It is a ciliary neurotrophic factor (CNTF) described in the next section. The original 12 week study of 173 obese human adults treated with a recombinant human variant ciliary neurotrophic factor (rhvCNTF) demonstrated greater weight loss in the treatment group compared to that in the placebo group [106].

A series of studies called RIO-Europe, RIO-North America, RIO-Lipid, and RIO-Diabetic used similar formats—all subjects received diet, behavior modification, and rimonabant at 5 or 20 mg/day or placebo. The RIO-Europe study showed that rimonabant 20 mg dose produced greater reduction in body weight, waist circumference, and triglycerides levels, and an increase in HDL-cholesterol, and improved plasma glucose–insulin homeostasis compared with the 5 mg dose. Both drug doses were significantly better than placebo. The 20 mg dose resulted in 6.6 kg weight loss versus 1.8 kg in the placebo group [107].

In the RIO-Lipid study, body weight and waist circumference reductions were similar to that in the RIO-Europe study. A focus of this study was on improvement in metabolic risk factors in overweight dyslipidemic patients. Improvement was documented in LDL particle size, adiponectin levels, glucose tolerance, fasting and post-challenge insulin levels, and plasma C-reactive protein levels. Side effects were also similar to that of the RIO-Europe study. The most frequent adverse events resulting in discontinuation of study drug were depression, anxiety, or nausea [108].

RIO-North America was a 2 year study to test the effect of rimonabant on weight and cardiometabolic risk factors in 3045 overweight or obese subjects [109]. After 1 year of rimonabant treatment (5 or 20 mg/day), subjects were re-randomized to receive placebo or continued to receive the same rimonabant dose in the second year. The placebo group continued to receive placebo during year 2. Compared to the placebo weight loss of 2.3 kg, the subjects who received 20 mg drug for two uninterrupted years had a mean weight loss of 7.4 kg and the weight loss was well maintained during the second year. There were improved waist circumference measures and risk factors. Patients treated with 5 or 20 mg of rimonabant at year 1 and re-randomized to placebo in year 2 regained a substantial amount of the weight lost. Final body weight in this group was slightly lower than that in the placebo group at 2 years.

RIO-Diabetes was a 1 year study of 692 obese subjects who had uncontrolled diabetes despite metformin or a sulfonylurea as single drug antidiabetes therapy [110]. Weight loss was greater in both rimonabant groups (−2.3 and −5.3 kg) in contrast to the placebo group (−1.4 kg). The HbA1c levels decreased by −0.6% in the 20 mg drug dose group, but increased by 0.1% in the placebo group. A trial of drug-naïve type 2 diabetic subjects studied the effects of 20 mg rimonabant on body weight, glycemic control, and lipid profile [111]. The baseline HbA1c (7.0%–10.0%) was reduced by −0.8% and −0.3% in the rimonabant and the placebo groups, respectively. Hemoglobin A1C was less than 7.0% at the end of the study in 51% of the drug-treated group and in 35% of the placebo group. Rimonabant also improved fasting blood glucose. Weight loss was 6.7 kg for the drug group versus 2.8 kg with placebo. Adverse events that led to discontinuation of study drug were mainly due to depressed mood disorders, nausea, and dizziness. The study authors felt that the data indicated that Rimonabant, in combination with diet and exercise, may produce a clinically meaningful weight loss and improve HbA1c in overweight or obese patients with type 2 diabetes inadequately controlled by metformin or sulfonylureas.

The FDA denied approval for rimonabant at the end of 2010. Further studies were discontinued because of disappointing weight loss results. This class of drugs may still have the potential to produce an antiobesity drug.

Ciliary Neurotrophic Factor

CNTF is a member of a cytokine family related in structure and action to a number of other metabolically active proteins and peptides including leukemia inhibitory factor (LIF), interleukin-6 (IL6), interleukin-1 (IL-1), and oncostatin M (OSM) that play some role in the regulation of EE [112]. In a study of amyotrophic lateral sclerosis (ALS), recombinant human CNTF (rHCNTF) was used as treatment. rHCNTF was not effective in altering ALS progression, but a marked

* http://ir.vivus.com/releasedetail.cfm?ReleaseID=524576

weight loss occurred in these nonobese study subjects. Side effects of anorexia, weight loss, and cough seemed to be dose related [113]. In mice, CNTF suppressed food intake without triggering hunger signals, and when CNTF treatment was stopped, the expected overeating and immediate rebound weight gain did not occur [114].

Leptin

It was shown in the 1990s in a mouse model that the regulation of energy balance could be controlled through the interactions of an obesity gene (ob gene) and that a defect in this gene causes massive obesity in these mice [12]. This gene product called leptin helped to strengthen claims for a genetic basis for obesity. Leptin is secreted by adipocytes, circulates in the blood and acts in the brain to regulate food intake and EE. Leptin functions as part of a signaling pathway from adipose tissue to the brain and plays a pivotal role in long-term body weight regulation [8,10–12]. To date, attempts to use recombinant leptin (metreleptin) for the treatment of obesity have not been very successful [84]. A leptin receptor (OB-Rb) is active in the parts of the brain associated with food intake and EE [8,10,11]. Researchers have been assessing the role leptin plays in homeostasis after either weight loss or weight gain. With a loss of body fat, leptin levels fall, appetite increases, and EE decreases. With an increase in body fat, leptin levels rise, appetite is suppressed until body fat mass is restored [115–118]. The role that leptin plays as a central regulator of homeostasis of body fat mass in human is under investigation [119].

Globally, there are only a few known cases of congenital leptin-deficient individuals. In a 19 week study of three genetically leptin-deficient patients, fat oxidation and EE were studied in response to weight loss, and the results were compared to values attained by typical obese adults after weight loss [120]. The three leptin-deficient patients received subcutaneous daily doses of recombinant methionyl human leptin and easily lost weight. Control obese individuals lost a similar amount of weight. However, after weight loss, the obese control subjects, but not the genetic leptin-deficient individuals, had EE lower than that expected for their new body weight. Also, the fat oxidation, which was similar at baseline for both groups, increased significantly upon weight loss for the genetic leptin-deficient individuals [120]. This study further confirmed what other studies have also shown: that leptin-deficient subjects who have undergone leptin replacement lose weight but do not manifest a reduction in EE and increased fat oxidation. The authors reported that their data suggest that leptin may have a thermogenic effect in humans [120].

A study testing recombinant leptin for weight loss in obese and lean adults included 54 lean and 73 obese adults. Leptin was given by a daily morning subcutaneous injection in varying doses. Lean subjects were treated for only 4 weeks and only obese subjects were allowed to continue for an additional 20 weeks. Lean subjects were on a eucaloric diet to maintain body weight and obese subjects on a calorie reduction of 500 kcal/day. Weight loss increased with the dose of leptin in both, lean and obese adults. In the highest dose of leptin, more than 95% of the weight loss was due to fat loss. There was considerable variability in the amount of weight lost by individuals. Baseline serum leptin concentrations were not related to weight lost. No significant side effects were reported during the study [121].

A study of five males and five females was designed to assess the role of leptin in the maintenance of weight loss. Leptin administration was continued in the post-weight loss phase in doses to restore circulating leptin concentrations to baseline levels present prior to weight loss. Results showed a reversal of the suspected decline in EE and the changes in skeletal muscle energetics that usually accompany weight loss [122], which may help in weight maintenance.

Neuropeptide Y

Neuropeptide Y (NPY) is a neuropeptide neuromodulator found in the brain and whose receptor may be involved in the regulation of food intake and body weight in humans [123]. The NPY stimulatory effect is primarily on carbohydrate intake [124,125]. In mice with diet-induced obesity, an NPY antagonist decreased body weight and body fat [126]. Human clinical trials have not yet shown NPY antagonists to have a significant effect on body weight or food intake [127].

Human Growth Hormone

Early studies suggested that growth hormone (GH) treatment in subjects who were obese and deficient in GH, would mobilize fat, reduce body fat stimulate oxygen consumption, and decrease protein loss [128]. A 6 month study recruited adult female patients who had laparoscopic-adjustable silicone gastric banding (LASGB) bariatric surgery in the past and had a functional severe GH deficiency. The subjects received either a placebo or recombinant human GH daily for 6 months [129]. Results demonstrated a decrease in fat mass (8.8%) and a reduction in visceral adiposity and lean body mass in the GH group. Insulin resistance increased during the GH therapy. The effects of GH on weight, fat mass, visceral adiposity, and lean body mass disappeared shortly after GH withdrawal.

A 12 month study of 40 postmenopausal women with abdominal obesity evaluated the effect of GH on visceral fat. The women received GH (0.67 mg) in a randomized, double-blind, placebo-controlled fashion. The GH treatment group reduced abdominal visceral fat, increased thigh muscle area and improved insulin sensitivity and lipid values. The improvement in insulin sensitivity was associated with reduced hepatic fat content [130]. In another 12 month study, 30 men with visceral obesity who did not have GH deficiency were tested for the effects of GH treatment on reducing visceral adiposity [131]. Subjects received GH or placebo in a double-blind fashion for the first 6 months followed by a 6 month washout period. After 6 months, the GH group had an increase in body weight and in lean body mass

(2.5 kg), yet an 8.8% reduction in visceral adiposity compared to placebo. Resting EE was increased, as was fasting insulin, glucose, and insulin resistance. Shortly after drug discontinuation, there was an increase in body fatness and visceral adiposity and a decrease in lean body mass. Total body weight remained the same after drug withdrawal. Waist circumference did not change during GH therapy, and at the 1 year assessment, the waist circumference was greater in the GH-treated subjects. The study authors concluded that although there was a small but statistically significant decrease in visceral adiposity, due to an increase in lean body mass and body weight and the worsening of metabolic parameters, the supra physiological dose of GH used was not an effective treatment approach.

Dehydroepiandrosterone

The role of the hormone DHEA in the treatment of human obesity remains unclear. In a 20 week randomized double-blind crossover study involving 14 subjects, there was significantly more loss of weight and body fat during treatment with etiocholanedione (ED), an oral steroid derivative of DHEA. During ED administration, the mean weight loss was 2.8 kg and a 5% loss in body fat, whereas, no weight change during the placebo phase. Three of the obese subjects had fat losses of 18%, 19%, and 25%. No significant side effects were reported [132]. A 10 week study involving 13 morbidly obese adolescents measured the effect of DHEA administration on body weight, body composition, lipids, and insulin resistance. DHEA was given as a 40 mg sublingual dose. Results documented an increase in DHEA and testosterone concentrations but there were no effects on body weight, sense of well-being, or any other measured variables [133].

DHEA has been used as a performance enhancing drug for athletes due to the supposition that it decreases central fat deposit and increases lean body mass. A 28 day study of the acute effects DHEA on body composition and serum steroids hormones was performed on 20 young competitive soccer players ages 19–22 years. DHEA dose was 100 mg daily or placebo. The drug group increased DHEA and testosterone levels but no significant change in body fat, total muscle mass or BMI, or waist-to-hip ratio was noted [134].

Many of the actions of DHEA in humans are thought to be mediated through its conversion to sex hormones, which are modulators of adiposity, muscularity, and insulin sensitivity. A 12 month study determined the effect of restoring DHEA level in 120 older men and women aged 60–88 years. DHEA 50 mg/day or placebo was given as an oral dose. Abdominal fat, thigh muscle, and fat were measured by computed tomography and trunk mass by DXA measurement. DHEA serum levels were restored to normal during the study. By the end of the study, central adiposity was not reduced nor was insulin action improved. Triglycerides were decreased but HDL-cholesterol was also decreased. Study authors concluded that restoring of DHEA serum levels to that of a young adult does not appear to reduce central adiposity or improve insulin action in older adults [135].

DHEA can be purchased OTC in drug stores or health food stores and online as a dietary supplement and can be labeled DHEA. DHEA component of a dietary supplement can be an extracted plant sterol derived from wild yams. It is called diosgenin (*Dioscorea villosa*). As an extract, it could even be labeled and sold as a "natural" DHEA without FDA approval. DHEA and testosterone are widely promoted as antiaging supplements, but the potential harm or long-term benefits are unknown. To test this, another 2 year study of 144 elderly men and women was conducted to restore low levels of DHEA or testosterone. Replacement therapy showed increases in plasma levels of both DHEA and testosterone. No significant effect on body composition of DHEA in men and women was documented. Fat-free mass was slightly increased in men who received testosterone, and men and women had an increase in bone density. Measured outcomes of physical performance, and quality of life showed no improvement. No major side effects were reported [136].

Testosterone/Dehydrotestosterone

Testosterone is the principal androgen product of the testis and is responsible for body masculinization. Testosterone is converted peripherally to DHT. Serum testosterone concentrations are associated with the severity of prostate cancer, metabolic syndrome, and type 2 diabetes. The well-recognized regional fat deposition pattern of men and women is considered a secondary sex characteristic involving sex steroids including testosterone [137,138]. Changes in fat deposition from puberty are an ongoing process [139,140]. Testosterone studies in humans have been mostly in older men and women and have documented that low testosterone is associated with increased body fat and fat distribution and increased waist circumference. As the level of obesity increases, testosterone levels drops [141]. Effects of low testosterone have been investigated during clinical trials of metastatic prostate cancer therapy where the mainstay treatment is androgen deprivation [142]. One such study showed that that when serum gonadal steroid concentrations were lowered to castration levels there was an increase in subcutaneous abdominal fat area without significantly changing the intra-abdominal fat [142].

An 18 month study involved 36 adult men aged 22–69 years with acquired hypogonadism [143]. Prestudy values showed that percent body fat in these men with low testosterone was significantly greater compared to normal controls. In this study testosterone treatment was initiated at a dose of 100 mg/week and resulted in a decrease in subcutaneous fat and an increase in lean muscle mass. Serum testosterone concentrations correlated directly with muscle mass and negatively with fat mass. Testosterone treatment also reduced bone remodeling and increased trabecular bone density [143]. A study of six healthy lean young men (mean age 23.2 years) evaluated changes in muscle strength and adiposity before and after gonadal suppression [144]. Testosterone suppression lasted 10 weeks. All subjects showed a decrease

in fat-free mass, an increase in fat mass, a decreased lean body mass, and increased adiposity. Leg muscle strength also decreased as did EE. The rates of lipid oxidation and whole body protein synthesis also decreased [144].

Overall, an increase in lean body mass, but not a particularly significant impact of testosterone on body fat is reported in young or older subjects [144–147]. The findings by Bhasin et al. [147] suggested that a short-term administration of androgens may have beneficial effects in patients who are immobilized; those with cancer or human immunodeficiency virus-related cachexia, or other chronic wasting disorders; or in space travel. The authors, however, acknowledged that anabolic steroids are used and abused by some athletes, recreational body builders, and others wishing to increase muscle mass and/or to lose weight and further emphasized that their results "in no way justify the use of anabolic–androgenic steroids in sports because with extended use such drugs have potentially serious adverse effects on the cardiovascular system, prostate, lipid metabolism, and insulin sensitivity" [147].

Gastrointestinal Pathway Drugs

The GI pathway is among the most active of endocrine organs. Food intake may be influenced by neural and hormonal actions of the GI tract. These peptides appear to have a function on eating behavior and the regulation of energy balance and body fat accumulation [148]. Meal anticipation and the presence of food in the upper GI tract stimulate the release of gut hormones and neurotransmitters that are then relayed to the central nervous system [149]. The mechanisms involved in sustaining weight loss following bariatric surgery are being investigated. Since gut hormones are thought to play a role in the sustained weight loss following the gastric bypass surgery, there may be a potential role for selective GI hormones as a direct treatment for obesity [149].

Cholecystokinins

CCK is a GI peptide produced in the stomach, gallbladder, and pancreas. It is secreted postprandially into the circulation and effects energy balance by decreasing food intake. Plasma CCK levels rise within 15 min after meals [149]. In response to a dietary fat load, CCK action results in a slowing of gastric emptying and satiety [150].

Glucagon-Like Peptide

Glucagon-like peptide (GLP-1) is a hormone produced in the distal ileum and colon. It inhibits glucagon secretion, stimulates insulin secretion following carbohydrate ingestion, delays gastric emptying, and increases satiety [149,151–153]. It improves blood glucose levels in diabetic subjects. In obese individuals, GLP-1 secretion is likely to be decreased and may contribute to the development of obesity [154]. GLP-1 is significantly elevated post-intestinal bypass surgery and may be a factor in influencing weight loss after bypass surgery by reducing appetite and food intake.

Liraglutide

Liraglutide is a human GLP-1 analog approved by the FDA in 2010 for the treatment of adults type 2 diabetes. It is prescribed together with diet and exercise in diabetic patients who have not responded to initial diabetes therapy. A 2 year clinical trial with liraglutide involved 564 individuals aged 18–65 years [155]. The trial evaluated the safety, tolerability, and sustained weight loss using liraglutide treatment for obesity for over 2 years. A report of the initial 20 weeks of the trial compared subcutaneous liraglutide treatment with orlistat and a placebo arm [156]. Liraglutide was initially given once daily subcutaneously at doses from 1.2 to 3.0 mg. The other treatment groups received orlistat 120 mg TID or placebo. The liraglutide patients treated at the 3.0 mg during the initial 20 weeks lost more weight than the other study groups and body fat decreased by 15.4% and lean tissue by 2.0%. All liraglutide groups lost more weight than the other two groups. There was an 84%–96% reduction in the prevalence of prediabetes in the 1.8–3.0 mg dose range and a reduction of blood pressure at all liraglutide doses. Side effects included nausea and vomiting that rarely lead to study discontinuation. In the report on the 84 week extension of the study, the liraglutide group maintained a 7.8 kg weight loss, which was also much greater than the other groups [155]. The study authors also reported that the 2 year prevalence of prediabetes and metabolic syndrome decreased by 52% and 59%. There were improvements in blood pressure and lipid values. The most frequent drug-related side effects were mild to moderate, transient nausea and vomiting.

Ghrelin

Ghrelin is a peptide hormone discovered in 1999. It is produced in the stomach and secreted into the circulation. It stimulates food intake and it is elevated in the fasting state and is suppressed in the postprandial state [157]. Obese subjects however exhibit a less marked drop in plasma ghrelin after a meal [149]. A study investigated the effects of intravenous ghrelin or saline infusion on appetite and food intake in nine nonobese adults [158]. Calorie consumption at a single free-choice buffet meal increased by 28% in ghrelin-treated subjects. Study authors suggested that a drug that inhibits ghrelin action may potentially be a target for obesity treatment [158]. A study measured ghrelin levels after Roux-en-Y gastric bypass surgery (RYGB) [159]. This study included nonobese subjects and obese subjects who were either postsurgery or who had lost weight with diet treatment. In subjects with diet-induced weight loss, ghrelin levels were higher than those for nonobese subjects. In the postsurgery subjects, plasma ghrelin levels were markedly lower than those of the lean and obese controls, and the surgery group did not have pre- and postprandial variations of ghrelin. The authors raise the possibility that suppression of ghrelin is one mechanism by which the gastric bypass surgery reduces body weight.

A study investigated the effects of a low- or high-dose intravenous ghrelin on food intake in 12 lean and 12 obese adults [160]. The low-dose ghrelin administration increased

energy intake (36.6%) only in the obese group, measured at a single buffet meal. High-dose ghrelin infusion increased energy intake in lean (20.1%) and obese (70.1%) groups. The authors concluded that inhibiting circulating ghrelin may be a useful therapeutic target in the treatment of obesity. Other GI peptides can affect the stimulatory action of ghrelin on food intake. New treatments for obesity drugs may result from such a research focus [161].

Peptide Y Y

Peptide Y Y (PYY) is a GI tract hormone that is secreted postprandially and appears to result in a decrease in postprandial hunger and calorie intake in both obese and nonobese individuals. PYY inhibits GI motility [162]. A greater release of PYY is observed with the ingestion of fat, compared to that of a carbohydrate or protein meal of similar calories. PYY may regulate EE, delay gastric emptying, and reduce acid secretion [149]. An 8 week weight loss study evaluated the effects of low-fat or low-carbohydrate energy-restricted diets on serum PYY levels. Results demonstrated that greater weight loss was associated with lower PYY levels, regardless of the diet plan. Study authors concluded that reduced PYY levels after weight loss likely represent a compensatory response to maintain energy homeostasis and that PYY contributes to the difficulty patients have losing weight while on a calorie-restricted diet [163].

A study compared the effects of medical or surgical weight loss of similar magnitude on PYY levels. RYGB and sleeve gastrectomy (SG) patients had increased PYY levels, increased satiety, and a decrease in appetite. In the medically treated group PYY levels did not decrease and appetite was unchanged [162,164,165]. The study authors suggest that the weight loss effects of RYGB and SG are enhanced by an increase in PYY and satiety.

WHO SHOULD RECEIVE PHARMACOTHERAPY FOR OBESITY?

BMI guidelines for identifying overweight and obesity, evaluation, and treatment are developed for physicians and health care professionals by the National Heart, Lung, and Blood Institute (NHLBI), in cooperation with the National Institute of Diabetes and Digestive and Kidney Diseases.* However, the pharmacological treatment of obesity has no established and proven algorithm, although this has been attempted on a limited scale [166]. The ideal obesity pharmacotherapy has yet to be developed. There is no proven and assured course of action to prevent obesity. The following sections provide one view about how pharmacotherapy of obesity may be managed. Several considerations are offered based on clinical experience. Clearly, other meritorious approaches are also possible.

Obesity experts emphasize the importance of early identification of overweight and obesity as an important first step for both, prevention and treatment. Primary care physicians see 11.3% of the U.S. population monthly and obese patients represent a high proportion of those visits [167,168]. In the most recent National Ambulatory Medical Care Survey (2005 and 2006 data) in medical practices where BMI was routinely captured, 27% of the patients seen in a doctor's office had a normal BMI, 31% were overweight, and 37% were obese. Only 30% of the obese patient visits included a recorded diagnosis of obesity [167]. Physician awareness and use of an electronic medical record may help in the documentation of obesity [169]. Primary care practices do not carry the entire burden of early detection of overweight and obesity. There is a wider spectrum of medical subspecialists and surgeons who see these patients for their comorbidities associated with obesity. These referral doctors could be educated to discuss and guide patients about their obesity risks. The prescribing of antiobesity drugs however should be the responsibility of physicians who have specific knowledge of the pharmacology of obesity medication, their side effects, and safety profile and access to health care professionals that can provide the important behavior modification and dietary components of overweight and obesity management to their patients.

When weight management options including pharmacotherapy should be discussed with patients is not well defined. Physicians who have an expertise and comfort level in their ability to treat obesity are more likely to have an early discussion with overweight or obese patients. For the majority of physicians, therefore, the trigger points to initiate a medical conversation about body weight are quite broad. Some clinicians wait until a patient requests help; others use the BMI or associated comorbidity as their triggers. There are variations amongst primary care physicians as to their specific BMI threshold for initiating the dialogue. Physicians match their medical expertise with the needs of individual patients in choosing a course of action and pharmacotherapy options [170]. A decision not to discuss obesity or not to treat obesity may be based on a patient's readiness to commit to a weight management program. For a patient to get maximum benefit from pharmacotherapy, a physician needs to gauge patient's compliance, ability, and willingness to follow medical directions. This information significantly improves a physician's ability to pick the right time to initiate successful pharmacotherapy. There are screening questionnaires that could provide such information [171].

If weight loss is medically necessary, patients may be self-motivated to follow a weight management plan but health is usually not a compelling motivator from a patient's standpoint and if used as the only argument by a physician, it may be unsuccessful. Patients who claim cosmetic reasons for wanting to lose weight and who qualify for obesity pharmacotherapy should not be turned away. Vanity can be a motivating force for success and is not a reason to deny drug treatment if the patient fulfills the medical criteria. A patient's request for pharmacotherapy during initial obesity consultations is

* National Heart, Lung, and Blood Institute, National Institutes of Health. Clinical guidelines on the identification, evaluation, and treatment of overweight and obesity in adults: The evidence report. Bethesda, MD: National Institutes of Health; September 1998 NIH publication No. 98-4083.

not unusual and is not necessarily a sign of a patient looking for a "short cut." A patient who insists on a pill to lose weight, could likely be one of your least successful patients, now seeking a different approach. Failed previous weight loss attempts or even yo-yo dieting are not contraindications to drug treatment.

Decisions to use FDA-approved drugs to treat conditions beyond the recommended guidelines are up to the physician. This is considered "off-label" use of the FDA-approved drugs. A decision to use pharmacotherapy beyond FDA guidelines is not prohibited by the FDA. The comorbidities of obesity can severely limit lifestyle and may shorten life. More progressive or chronic obesity, presence of comorbidities, and impaired quality of life contribute to the decision to initiate pharmacotherapy for weight loss. It is not uncommon that an obesity management program includes pharmacotherapy sooner rather than later. This may mean including drug therapy at the onset of a comprehensive program [172].

Guidelines suggest that pharmacotherapy for adults with obesity may be appropriate for those with BMI 27–29.9 kg/m^2 if comorbidities are present or for those with a BMI $\geq$ 30 kg/m^2 with or without comorbidities. It is also suggested that pharmacotherapy be considered after a patient has tried behavior therapy including diet, exercise, and lifestyle change and has had limited or no response. In reality, most patients have had some exposure to nonpharmacological approaches before seeking medical help for weight loss, since various establishments and online programs offer a variety of nonmedically supervised diet and exercise programs.

As with any pharmacological agent, the risk and benefit possibilities must be weighed before prescribing an obesity drug. Treating obesity in patients older than 65 years should be done with caution [43]. It is important to recognize that at present, obesity can be controlled, but cannot be cured. Therefore, a relapse is possible if an obesity drug is discontinued. If a patient loses and/or maintains weight loss on an obesity drug and no serious side effects have been identified, the drug may be continued and the drug efficacy and safety should be monitored for the duration of its use [173].

WHICH DRUG TO CHOOSE

In addition to the merits, limitations, adverse effects, and the mechanism of action of various drugs, selection of an obesity drug should be personalized to accommodate considerations for a patient's past medical and social history, current medical and mental health issues, and current medications including OTC drugs.

Clinical Considerations for FDA-Approved Obesity Drugs

Many obesity researchers and clinicians believe that long-term and possibly lifelong use of obesity drugs may be necessary for significantly obese individuals [174]. Studies suggest that a pharmacological agent that produces a weight loss of less than 4 lb in first month is unlikely to promote clinically effective weight loss in the long term. Initial weight loss, obtained during the first 2–4 weeks of treatment, is reported as predictive of subsequent weight loss response [175]. Before deciding to discontinue an obesity drug for inadequate effect, the dosage may be reassessed. If the current dose is below the recommended maximum dose then a dose increase may be appropriate. Patient compliance with the medication should also be considered.

Perhaps, changing the time of drug administration may be needed to promote better compliance. The possibility should be considered that other prescription or nonprescription drugs may interfere with drug effectiveness or may cause side effects that the patient may wrongly attribute to an obesity drug. Another consideration is the patient's compliance with dietary changes and physical activity. As the daily need of energy decreases with decreasing weight, consider if the calorie goals need to be redefined for continued weight loss. Is the rate and amount of weight loss appropriate for the patient's medical needs? Should the drug be now used to maintain the weight lost? As far as possible, the class of drug chosen should consider the eating behaviors of each patient. Information about hunger, cravings, eating between meals, binging, and nighttime eating issues should be obtained by using validated questionnaires or through questioning of all patients by physician or staff. With the exception of orlistat, all drugs currently on the market are centrally acting adrenergic antiobesity drugs and may control many of the eating-related issues. A written questionnaire detailing eating habits may help patients better focus on their eating issues, if any. Food preferences and types of foods frequently overeaten may influence the type and timing of obesity drug administration.

How to Use Phentermine and Orlistat: An Opinion

Phentermine is supplied by generic manufactures as phentermine–HCl in a 37.5 mg scored dose. It can be prescribed under the brand name *Ionamin* in a 15 or 30 mg capsule, as *Fastin* in a 30 mg capsule, and as *Adipex*, which is available either as a scored 37.5 mg tablet or capsule. Because this sympathomimetic drug is associated with side effects early in treatment, a stepped dose approach is an option, but not a requirement [7,176]. Starting with a half dose of phentermine (½ of a 37.5 mg tablet or a 15 mg capsule) and increasing it as needed may be quite effective at the onset of treatment. This approach can prolong the active weight-loss period [43]. The onset of action of phentermine is within a few days to a week, allowing a physician to increase the dose depending on patient response at each office visit. It can be given as a single daily dose or a split between morning and before dinner, depending on which helps the most with hunger control, with minimal side effects. Phentermine has also been shown to be effective even on an alternate day and even on an intermittent schedule [41,177]. A dose higher than 37.5 mg for tablets and 30 mg for the capsule is not approved nor is shown to be more effective. Side effects can be dose related, but are usually short lived and resolve with dose

lowering or drug discontinuation. If the occurrence of side effects is related to a specific time of the day, such as at bed time, it may be blunted or eliminated by taking that dose earlier. Insomnia and nighttime agitation may be an issue with an evening dose. If phentermine had been discontinued for reasons other than side effects, it could be reintroduced and may again be effective. If an alternative antiobesity medication is chosen, it could be started within a week of stopping phentermine. A patient who had been on phentermine and switches medications should be instructed that unlike phentermine, the onset of action of noncentrally acting weight loss drugs is slower and the almost immediate effectiveness experienced with phentermine will not occur with other currently approved medications. If not so instructed, patients may wrongly assume that the new medication is ineffective

After about 6 months, lost weight usually reaches a plateau [41,43,177]. There are no long-term studies of phentermine, and future studies are unlikely, since it is a generic drug. However, a study of long-term management of eight adults on continuous phentermine treatment for more than 10 years for weight loss and maintenance is reported [178] (see the section "How Are Drugs Being Used Differently in Various Clinical Settings").

Orlistat decreases dietary fat digestion and absorption. To maximize weight loss with orlistat, reduction in dietary fat intake should be encouraged. A high-fat intake may accentuate side effects of orlistat and may force patients to discontinue the drug. To preempt this, the negative effects of orlistat should be described to patients. However, the GI side effects must be presented in a manner so as not to prejudice a patient away from taking the drug. The conversation should be focused on minimizing the side effects, and an emphasis on their transient nature. The drug works best if taken with every meal. However, the drug may be skipped when a particularly low- or no-fat meal is taken. If a patient is unsure of dietary fat content, the drug should be taken. If a meal is skipped, orlistat could be skipped. A patient can monitor their fat intake by observing their stool texture and the presence of undigested floating fat in the commode. Physicians could use this information as a dietary teaching tool. The occasional GI event should be used as a teaching tool for food selection advice for future meals. Patients should be discouraged from abusing orlistat to counter intentional high fat consumption, which may not only lead to a significant GI event but may also undermine long-term weight loss efforts.

Weight Regain and Pharmacotherapy

Obese patients will regain some if not all of their lost weight, but the degree of weight loss and weight regain will vary. If a patient returns for care after some weight regain, mention the possibilities that in addition to behavioral factors, weight regain can also occur due to hitherto unclear reasons, outside of the patient's control. Weight regain may be due in part to self-regulatory mechanisms of energy balance, attempting to restore the body weight to a steady state [179]. Any situational life events that may contribute to recidivism should be identified and addressed. Some of these factors may be modifiable. Until the biochemical factors of weight gain or regain are better understood, counseling should be provided to prevent a lapse from progressing to relapse and eventually to collapse of the entire treatment for the individual. A decision needs to be made about restarting the original weight management plan including drug therapy. A variation of that plan may be more appropriate, or a completely different approach including bariatric surgery should be considered, if the criteria are met. Current guidelines to qualify for bariatric surgeries in the United States and Canada are a minimum BMI of 40, or a BMI of 35 with one or more severe comorbidities. The minimum BMI for a laparoscopic insertion of a Lap-Band device is a 35, or 30 with one or more severe comorbidities [180].

OBESITY DRUGS USE: VARIOUS APPROACHES

Between 2002 and 2005, 86,804 patient records of a large health care insurance company were reviewed to evaluate trends and patterns of obesity drug treatment. The results showed that a decreasing number of obese patients were prescribed obesity drugs during this time frame [170]. In this medical record review, orlistat was the most commonly used medications (39.4%), followed by phentermine (39.1%) and sibutramine (32.2%, but no longer available). Other older sympathomimetic medications were little used (8%). The trend was toward a decrease in orlistat and sibutramine use, while the use of phentermine remained stable. The study authors suggested that, the increased use of bariatric surgery, the hesitancy of both physicians and patients to use obesity medications due to their efficacy and safety concerns were among the reasons for the decrease in obesity drug use. High cost of the newer medications was also an issue [170]. Along with the obesity medications, 57% patients were also taking narcotics and 38% were taking antidepressants. An additional 8% of subjects were taking more than one obesity medication at the same time. These findings highlight the importance of physician awareness, preparedness, and experience when prescribing medications. Physicians need to be familiar with the concomitant medications taken by their patients. The authors pointed out that prescribers should be aware of FDA-approved drug durations of treatment and potential contraindications. Screening for depression and substance abuse should occur before starting obesity treatment, and asking about prescription and nonprescription medications is necessary.

Physician specialists may have a prescribing approach that is different from nonspecialists. In 2009 a report described the obesity drug prescribing approach of some physician members of a professional bariatric society [181]. Two hundred sixty-six physicians (35% of the membership) anonymously responded to a questionnaire about their approach to prescribing obesity drugs. All responders prescribed antiobesity drugs. Results identified varied approaches to drug management of obesity that included choice of drug, drug dosage, duration of treatment, and the use of drug

combinations. Phentermine was prescribed by 97% of these physicians and for various lengths of time beyond the FDA-approved 3 months of therapy. Of these, 56% prescribed phentermine for as long as they and their patients felt it was helpful in achieving weight loss or weight maintenance goals. Diethylpropion (48%) and phendimetrazine (29%) were other sympathomimetics used long term by these physicians. Sibutramine (no longer available) and orlistat approved by the FDA for long-term use were used less often by these physicians (32% and 33%, respectively). The study authors commented that, with the generic drugs being considerably less expensive, cost of the medications may have played a factor in their choice. The prescribing of more than one FDA-approved obesity drugs was practiced frequently or occasionally, by 83% of those surveyed. About 65% prescribed combinations of medications that are not approved for obesity treatment by the FDA, but are reported in medical literature to induce weight loss. About 14% used the combination of orlistat with sibutramine while another 1.4% prescribed the combination of caffeine with ephedrine. There were an additional 20% of physicians who used some drug combinations that had no scientific reports recorded in the medical literature.

A report from a single medical practice was published in 2004 [178]. It was an extensive review of the records of eight patients who received comprehensive obesity management that included 19 years of continuous antiobesity drug treatment. Six of the eight patients used phentermine as the primary therapeutic agent. A seventh initially used diethylpropion or mazindol and was ultimately prescribed phentermine. Occasionally other FDA-approved obesity drugs were prescribed to assess their effectiveness and tolerability, but all of the patients returned to the one medication that they have found to be most helpful. Only one patient used diethylpropion exclusively. No drug tolerance, or adverse events, addiction, or misuse related to phentermine occurred. Weight lost during the active weight-loss phase was maintained within 1 kg. The author emphasized that this was a small patient population, and that the experience of these eight individuals may not be generalizable. It did suggest that there are some patients who respond well to obesity medications and that consideration should be given to the chronic use of medications for the continuing management of obesity. The author recommended that efforts should be made to identify such responders so that a long-term pharmacological treatment of obesity could be pursued.

These studies are described here to demonstrate the variety of approaches in drug selection, length of treatment, and the variation in the prescribing habits of physicians. No single approach presented in this section is an endorsement by the authors of this chapter.

OBESITY DRUG NEEDS AND THE FDA: AN UNEASY RELATIONSHIP

Obesity is the second leading cause of preventable deaths in the United States. The U.S. Senate Committee on Appropriations at their September 8, 2011, meeting highlighted obesity as "a disease linked to cancer, high blood pressure, heart disease, diabetes, and stroke." The committee expressed a concern with the "absence of novel medicines to treat obesity" and called the lack of obesity drugs "a significant unmet medical need." This was recorded in a report accompanying a year 2012 appropriations bill for agriculture and rural development.* The committee noted that obesity treatment options include diet, exercise, and obesity surgery, but there is a lack of obesity pharmacotherapy options. The committee report included a section entitled "Obesity Therapeutics." In this section of the report, the FDA was instructed to provide steps it will take to support the development of new treatments for obesity. The FDA report is due March 30, 2012. The FDA was to use its "Risk Evaluation and Mitigation Strategy" to help especially with issues of drug safety. Drug safety has been a major reason for the FDA's nonapproval of all new drugs they have evaluated since the approval of orlistat in 1999.

The disapproval rate of all new antiobesity medications since 1999 has had an impact on physicians and their patients involved in obesity management. Why FDA disapproval has seemingly occurred so frequently in pharmacotherapy for obesity compared to that for other diseases has been questioned. Some experts however disagree on whether the FDA is too tough or on weight-loss medications.

Sibutramine had been an FDA-approved drug for the treatment of obesity since its introduction in 1998 and was a mainstay treatment of obesity management until October 2010 when it was voluntarily withdrawn by the manufacturer at the request of the FDA following a review. The antiobesity drugs lorcaserin, Qnexa (phentermine and topiramate), and Contrave (bupropion and naltrexone) failed to receive FDA approval. In March 2011, a meeting was held between the FDA officials and the obesity experts representing the Obesity Society, the Obesity Action Coalition, the American Society for Metabolic and Bariatric Surgery, and the American Dietetic Association. The meeting was with the director of the FDA's Center for Drug Evaluation and Research (CDER) and members of her staff. The goal was to help clarify the direction and future approaches to meaningful drug approval endpoints. Approval of obesity drugs by the FDA is vital to provide encouragement to research and commercial development of newer obesity drugs. It is hard to expect a continuous stream of obesity drug development, if the FDA is not likely to grant approvals. On the other hand, it is the responsibility of the FDA to ensure safety and efficacy of drugs and to approve only the meritorious drugs.

SUMMARY AND CONCLUSIONS

Obesity is a chronic disease that requires lifelong treatment. There is currently no cure for obesity. Experience with long-term use of obesity drugs is limited. However, current evidence suggests that pharmacotherapy in conjunction with lifestyle changes, improves the outcome and patient outlook.

* http://appropriations.senate.gov/sc-agriculture.cfm

There is insufficient data to assume that obesity drugs are totally safe, but the literature does seem to reinforce the benefits. Weight loss usually is modest with obesity drugs, but there are significant improvements in comorbidities of obesity. Obesity drugs must be used with caution and only in patients with medically significant obesity. Careful selection of a drug, its dose, and duration; follow-up and continuous assessment of efficacy; and due diligence on recognizing side effects are mandatory. For treating obesity, physicians should have the knowledge and expertise to successfully use FDA-approved obesity drugs. Also, they should familiarize themselves with the off-label use of other FDA-approved medication for managing obesity.

Few patients treated for their obesity will reach their goal weight and almost no one reaches the "ideal" weight with or without drug therapy. This, however, is not a reason to withhold pharmacotherapy. Obesity *drugs are not substitutes, but supplements, to other lifestyle interventions for weight loss*. Obesity drugs are expected to empower a person to adhere to a reduced calorie intake, in some cases provide better control over aberrant eating behaviors, increase compliance, and consequentially, increase weight loss and maintenance, and may also alleviate comorbidities of obesity. Obesity is a serious medical condition and not a moral failure or a character flaw. Behavioral treatment of obesity has marginal success, and pharmacotherapy should be given a serious consideration as an adjunct to lifestyle management.

INTRODUCTION

Various expert panels have endorsed bariatric surgery as an acceptable weight-loss option for patients with a BMI of $\geq$40 kg/m^2 or those with a BMI of $\geq$35 kg/m^2 who have comorbid conditions [1–7]. An international survey of 36 nations or national groups estimated that over 344,000 bariatric surgery operations were performed in 2008; 220,000 of these operations were performed in the United States or Canada [8]. The exponential growth in procedures is due to several factors including improved surgical techniques, reduction in the postoperative mortality rate, significant improvement in obesity-related comorbid conditions [9], increased media attention, and profitability. The upsurge in surgical procedures also reflects the increasing prevalence of severe obesity in the United States. Between 1986 and 2000, the prevalence of severe obesity (BMI $\geq$ 40 kg/m^2) quadrupled from about 1 in 200 adult Americans to 1 in 50; the prevalence of a BMI of $\geq$ 50 increased by a factor of 5, from about 1 in 2000 to 1 in 400 [10]. Nearly 6% of adult Americans are considered severely obese with prevalence figures reaching 14% for African-American women [11]. It is therefore likely that health care professionals from all disciplines will encounter patients who have undergone a bariatric surgical procedure. Similarly, primary care physicians will be expected to monitor and manage their patients on a long-term basis. Many of the weight-loss surgeries, most notably the combined restrictive–malabsorptive surgical procedure—Roux-en-Y gastric bypass (RYGB)—and the malabsorptive biliopancreatic diversion (BPD) and biliopancreatic diversion with duodenal switch (BPDDS), place patients at high risk for development of both macro- and micronutrient deficiencies unless they are properly counseled and supplemented. Since most of the deficiencies can be identified early at a preclinical stage, early treatment will prevent or reduce symptoms and deficiency syndromes. Although bariatric surgery does not cure obesity, it is considered a significant tool for weight loss and maintenance of weight loss. As such, patients are at risk to experience weight regain several years following surgery. This chapter will review the most commonly performed weight-loss procedures, the importance of preoperative and postoperative management, identification and management of nutritional deficiencies that may occur following bariatric surgery, and factors associated with weight regain.

BARIATRIC SURGICAL PROCEDURES

Weight-loss surgeries fall into one of three categories—restrictive, restrictive malabsorptive, and malabsorptive (Figure 45.1). Restrictive surgeries limit the amount of food the stomach can hold and slow the rate of gastric emptying. The vertical banded gastroplasty (VBG) is the prototype of this category but is no longer performed due to limited effectiveness in long-term trials. Laparoscopic adjustable gastric banding (LAGB) has replaced the VBG as the most commonly performed restrictive operation. The first banding device, the LAP-BAND™, was approved for use in the United States in 2001. A second device, the REALIZE™ band, was approved in the United States in 2007. In contrast to previous devices, the diameter of these bands is adjustable by way of its connection to a reservoir that is implanted under the skin. Injection or removal of saline into the reservoir tightens or loosens the band's internal diameter, respectively, thus changing the size of the gastric opening. Since there is no rerouting of the intestine with LAGB, the risk for developing nutritional deficiencies is entirely dependent on the patient's diet and eating habits. The third and most recently described restrictive procedure is the laparoscopic sleeve gastrectomy (LSG). In this procedure, the stomach is restricted by stapling and dividing it vertically and removing approximately 80% of the greater curvature, leaving a slim "banana shaped" remnant stomach along the lesser curvature.

The restrictive–malabsorptive bypass procedure combines the elements of gastric restriction and selective malabsorption. The RYGB is the most commonly performed procedure. It involves formation of a 10–30 mL proximal gastric pouch by either surgically separating or stapling the stomach across the fundus. Outflow from the pouch is created by performing a narrow (10 mm) gastrojejunostomy. The distal end of jejunum is then anastomosed 50–150 cm below the gastrojejunostomy. "Roux-en-Y" refers to the Y-shaped section of small intestine created by the surgery; the Y is created at the point where the pancreo-biliary conduit (afferent limb) and the roux (efferent) limb are connected. "Bypass" refers to the exclusion or bypassing of the distal stomach, duodenum, and proximal jejunum. RYGB may be performed with an open incision or laparoscopically.

There are two malabsorptive procedures. In the BPD a subtotal gastrectomy is performed, leaving a much larger gastric pouch compared with the RYGB. The small bowel is divided 250 cm proximal to the ileocecal valve and connected directly to the gastric pouch, producing a gastroileostomy. The remaining proximal limb (bilio-pancreatic conduit) is then anastomosed to the side of the distal ileum 50 cm proximal to the ileocecal valve. In this procedure, the distal stomach, duodenum, and entire jejunum are bypassed, leaving only a 50 cm

distal ileum common channel for nutrients to mix with pancreatic and biliary secretions. The BPDDS is a variation of the BPD, which preserves the first portion of the duodenum. In this procedure, a vertical subtotal gastrectomy is performed and the duodenum is divided just beyond the pylorus. The distal small bowel is connected to the short stump of the duodenum, producing a 75–100 cm ileal–duodenal "common channel" for absorption of nutrients. The other end of the duodenum is closed, and the remaining small bowel connected onto the enteral limb at about 75–100 cm from the ileocecal valve.

IMPORTANCE OF LIFESTYLE INTERVENTION

Since obesity is fundamentally a disorder of energy balance, all treatments must include attention to caloric intake (energy in) and physical activity (energy out). By altering gastrointestinal anatomy and physiology, weight-loss surgery is a powerful tool to reduce caloric intake. Nonetheless, patients need counseling on diet and nutrition that is consistent with the specific surgical procedure (restrictive versus malabsorptive) and with optimal health. They also need guidance on implementing dietary changes within the structure of their daily life. Similarly, patients benefit from education and advice about increasing daily physical activity and implementing an exercise routine.

PREPARING THE PATIENT FOR SURGERY

All patients who are considering weight-loss surgery should undergo a comprehensive assessment by a multidisciplinary team of health care providers that includes a physician, registered dietitian, and mental health care professional [1,5]. Preparation for surgery commonly spans 3–12 months depending on the patient's medical condition and criteria for insurance approval. During the preoperative process, patients are typically instructed on healthy eating and physical activity patterns, behavioral strategies to implement the lifestyle changes, and the importance of stress reduction and social support for long-term success. Specific dietary and nutritional recommendations pertinent to the surgical procedures include use of protein supplements, consumption of multiple meals and snacks, and slowing the rate of eating. Patients are seen either individually or in small groups. Many centers offer panel discussions between candidate patients and patients who have already undergone a procedure to provide a peer-to-peer discussion of risks, benefits, and challenges of life after bariatric surgery.

Although it is reasonable to encourage weight loss prior to surgery, the literature is conflicting regarding the benefit of mandating preoperative weight loss as a criterion to undergo surgery. The primary rationale for requiring routine preoperative weight loss is to decrease the short-term operative morbidity and mortality. Furthermore, the patient's motivation for and ability to adhere to the dietary restrictions considered essential for a successful surgical outcome can be assessed. While 5%–10% preoperative weight loss has been shown in some studies to reduce postoperative complications [12], hospital length of stay [13], operating room time [14], and improved 1 year weight loss [15], other studies have not shown a benefit in longer-term weight-loss outcomes [16–18]. An additional compelling reason to endorse preoperative weight loss is to optimize the operative field by reducing liver volume and visceral adipose tissue (VAT). Two prospective studies have confirmed the benefit of prescribing a very low calorie liquid diet (VLCD) for 9–12 weeks on preoperative loss of body weight, VAT and subcutaneous adipose tissue (SAT), liver volume and comorbid risk factors [19,20]. Based on the existing literature, it is reasonable to include preoperative weight loss as an expectation during the preoperative period [21].

WEIGHT-LOSS OUTCOMES AND IMPROVEMENT IN OBESITY-RELATED MEDICAL CONDITIONS

Several meta-analyses and systematic reviews of bariatric surgery outcomes have been conducted [9,22,23]. In general, weight loss is greatest with the malabsorptive procedures (BPD, BPDDS), followed by the restrictive–malabsorptive procedure (RYGB), and least with the restrictive procedures (LAGB, LSG). Percent excess weight loss at 3–6 years ranges from 62% to 81%, 53% to 77%, and 45% to 72% for each surgical type, respectively [24]. Significant improvement in multiple obesity-related comorbid conditions have been reported including type 2 diabetes, hypertension, dyslipidemia, and obstructive sleep apnea [24,25]. Readers are referred to a recent comprehensive guideline for further information on perioperative medical care and outcomes from bariatric surgery [24].

LIFESTYLE INTERVENTIONS IN THE POSTOPERATIVE CARE OF BARIATRIC SURGICAL PATIENTS

National guidelines suggest that continued attention to diet, physical activity, and emotional health after bariatric surgery is essential to ensure optimal outcomes [1]. Accordingly, patients are encouraged to participate in postoperative programs that support lifestyle modification.

NUTRITIONAL CARE

Dietary Changes after Bariatric Surgery

A variety of dietary changes occur after bariatric surgery. Most importantly, there is a significant and sustained reduction in caloric intake. Although portion sizes tend to increase gradually over time in postoperative patients, caloric intake is typically still reduced by 25% or more for years after surgery [26–28].

Food intolerances may occur and can lead to alterations in dietary patterns after bariatric surgery. Lactose intolerance can develop in patients who have undergone gastric bypass; as a result, nearly one-third of patients report avoiding milk after this procedure [29]. Dumping syndrome

occurs in up to 76% of patients after RYGB and may lead patients to reduce their intake of concentrated sweets and fatty foods to avoid associated postprandial symptoms, such as abdominal cramping, nausea, diarrhea, lightheadedness, sweating, and tachycardia [30]. In fact, over 60% of patients report avoiding sweets and nearly 30% avoid fatty foods after gastric bypass surgery [29,31]. Other food intolerances may occur as well. Among patients who have undergone VBG, for example, nearly two-thirds avoid consuming whole meats, one-third eschew bread, and one-third avoid fresh fruits and raw vegetables, presumably to avoid the phenomenon referred to as "plugging," when a food becomes lodged in the gastric pouch [31,32]. Similar eating patterns have been seen among patients who have undergone LAGB [33]. On the other hand, only around 10% or less of gastric bypass patients report avoidance of meats, fruits, and vegetables [31]. As a result, patients who have had RYGB may consume fewer fatty foods and sweets and more fruits and vegetables than patients who have had purely restrictive procedures, such as LAGB or VBG [27,31,33,34].

Regardless of the types of foods consumed, regurgitation or vomiting can occur when patients eat too quickly, fail to chew food thoroughly, or eat in excess of what the gastric pouch will hold. However, it should be noted that vomiting is not an intended consequence of bariatric surgery and it should not be viewed as normal, particularly in the late postoperative period. Patients who have persistent vomiting or regurgitation after surgery should be evaluated for the presence of maladaptive eating behaviors, as well as anatomical or functional issues such as stomal stenosis or ulceration, reflux, and gastric dysmotility [24,35].

Patients with symptoms of dumping syndrome can usually be managed by dietary modification, including avoidance of concentrated sweets and simple sugars, consumption of small frequent meals, and inclusion of protein at every meal. Patients with symptoms suggestive of postprandial hypoglycemia that are not ameliorated by dietary modification should undergo evaluation for the presence of endogenous (or "post-bypass") hyperinsulinemic hypoglycemia [24,36]. Patients with more severe neuroglycopenic symptoms (such as confusion or loss of consciousness) should also undergo evaluation for this condition, which can occur after gastric bypass.

Recommended Dietary Patterns and Eating Behaviors

As a result of the reductions in gastric capacity and caloric intake after surgery, patients must take care to ensure that nutritional needs are met. Postoperative patients should be advised to consume small portions, have—four to six small meals daily, and ensure an adequate intake of lean protein (60–120 g/day), fruits and vegetables (more than five servings per day), and whole grains [24,37]. Patients should also eat slowly, chew thoroughly, avoid fatty foods, sweets, and sugar-sweetened beverages, and avoid ingestion of liquids within 30 min of meals. Unfortunately, many postoperative patients fail to follow the recommended guidelines, particularly regarding fruit and vegetable consumption and avoidance of sweets and caloric beverages [37]. For this reason, clinicians should routinely assess patients' dietary intake during postoperative visits and reinforce recommended dietary goals.

Prevention of Micronutrient Deficiencies after Bariatric Surgery

Patients who have undergone bariatric surgery should be counseled that they are at risk for the development of micronutrient deficiencies after surgery. After RYGB, the most common micronutrient deficiencies include those of vitamin B_{12}, vitamin D, calcium, and iron [38,39]. Folic acid deficiency has also been reported but is largely preventable with regular use of a standard multivitamin preparation [38]. Sleeve gastrectomy has been reported to produce similar deficiencies as gastric bypass but at a somewhat lower frequency [39]. As compared to gastric bypass, the BPDDS is much more likely to produce deficiencies of the fat-soluble vitamins, including vitamin A [40]. Purely restrictive procedures such as LAGB are infrequently associated with specific nutritional deficiencies [41].

In many cases, micronutrient deficiencies can be prevented by regular vitamin and mineral supplementation along with appropriate clinical follow up and routine biochemical surveillance. Expert guidelines are available regarding recommended vitamin and mineral supplementation after surgery and the frequency of laboratory screening for deficiency states [24]. Tables 45.1 and 45.2 summarize these recommendations. Patients who are found to have evidence of specific micronutrient deficiencies will need additional vitamin or mineral supplementation, as indicated.

PHYSICAL ACTIVITY

Among individuals who have lost weight with nonsurgical treatment approaches, physical activity clearly plays a vital role in long-term maintenance of weight loss [42,43]. Much less is known about the role of physical activity in weight control after bariatric surgery, but it may be an important factor.

Physical Activity Levels after Bariatric Surgery

Numerous studies suggest that self-reported levels of physical activity increase significantly after bariatric surgery [44,45]. However, there is little objective data regarding changes in physical activity levels in the postoperative period. In one surprising study, patients reported a large increase in moderate to vigorous intensity activity after surgery, but accelerometer data suggested that such an increase did not actually occur in most individuals [46]. In fact, data suggest that only 10%–24% of postbariatric surgery patients

TABLE 45.1
Recommended Micronutrient Supplementation after Bariatric Surgery

Supplement	Dose and Frequency
Multivitamin	1–2 daily
Calcium citrate (after RYGB, SG, or BPD/DS)	1200–2000 mg/day in 2 or 3 divided doses
Calcium citrate or carbonate (after LAGB only)	1200 mg/day in 2 divided doses
Vitamin D (in calcium supplement or separate)	400–800 IU/day
Elemental iron (for menstruating women)	40–65 mg/day
Vitamin B_{12} (after RYGB, SG, or BPD/DS only)	≥350 mcg/day oral Or 500 mcg every week intranasally Or 1000 mcg/month intramuscularly Or 3000 mcg every 6 months intramuscularly

Note: Patients with micronutrient deficiency states will require additional supplementation as indicated.

LAGB, laparoscopic adjustable gastric banding; RYGB, Roux-en-Y gastric bypass; SG, sleeve gastrectomy; BPD/DS, bilipancreatic diversion with duodenal switch.

meet national guidelines regarding minimal physical activity levels for general health promotion (i.e., ≥150 min/week or moderate-to-vigorous physical activity in bouts of 10 min or more) [37,47]. Data from the National Weight Control Registry indicate that patients who have lost weight through bariatric surgery tend to be less physically active than individuals who have lost similar amounts of weight through nonsurgical approaches [48].

Benefits of Physical Activity in Postoperative Bariatric Surgery Patients

In epidemiologic studies of postoperative patients, increased self-reported physical activity has been repeatedly associated with improved weight loss, mood, and psychosocial functioning [44,49,50]. Similarly, in a cross-sectional study that used armband accelerometers to measure activity in patients who had undergone gastric bypass 2–5 years earlier, higher levels of moderate-to-vigorous physical activity were associated with greater postoperative weight loss [47].

However, data from intervention studies are lacking. In one small, nonrandomized, prospective study, participation in a postoperative exercise program (including 75 min of supervised aerobic exercise and resistance training three times a week) for 3 months did not significantly increase weight loss after RYGB surgery [51]. However, the intervention did prevent the observed decrease in dynamic muscle strength that was seen in postoperative patients who did not exercise, and it was also associated with an increase in functional and aerobic capacity. In a small, randomized, controlled trial, Shah and colleagues randomly assigned 33 obese (BMI ≥ 35.5 kg/m^2) postoperative patients to either high-volume exercise (with a goal of expending ≥2000 kcal/week in moderate intensity aerobic exercise) or a usual activity control for 12 weeks [52]. Subjects assigned to the exercise intervention reported a greater than threefold increase in time spent in moderate physical activity and a nearly twofold increase in recorded step counts. In this small study, intervention group subjects did not have greater weight loss or greater improvements in body composition, fasting glucose, or insulin levels, lipids, or blood pressure, as compared to controls. However, they did have significantly greater improvements in physical fitness and glucose levels after an oral glucose challenge. Additional data are needed to further characterize the benefits of exercise in postoperative bariatric surgery patients and to determine the optimal physical activity levels in this group.

TABLE 45.2
Recommended Laboratory Tests and Frequency of Routine Biochemical Surveillance

Procedure	Recommended Frequency of Biochemical Surveillance	Recommended Laboratory Tests
LAGB, RYGB, and SG	*First year*: every 3–6 months *Thereafter*: annually	CBC, electrolytes, glucose, iron studies, ferritin, vitamin B_{12}, liver function, lipids, 25-hydroxyvitamin D *As needed*: intact PTH, thiamine, RBC folate, MMA, HCy
BPD/DS	*First year*: every 3 months *Thereafter*: every 3–6 months	*Every 3–6 months*: CBC, electrolytes, glucose, iron studies, ferritin, vitamin B_{12}, RBC folate, liver function, albumin, prealbumin, lipids *Every 6–12 months*: 25-hydroxyvitamin D, vitamin A, vitamin E, vitamin K, INR, intact PTH *Every 12 months*: urine N-telopeptide, metabolic stone evaluation (24 h urine calcium, citrate, uric acid and oxalate), zinc and selenium *As needed*: osteocalcin, carnitine, essential fatty acid chromatography

LAGB, laparoscopic adjustable gastric banding; RYGB, Roux-en-Y gastric bypass; SG, sleeve gastrectomy; BPD/DS, bilipancreatic diversion with duodenal switch; CBC, complete blood count; PTH, parathyroid hormone; RBC, red blood cell; MMA, methylmalonic acid; HCy, homocysteine; INR, international normalized ratio.

Barriers to Physical Activity after Bariatric Surgery

Significant weight loss, such as that achieved after bariatric surgery, may enable severely obese patients to become more active. However, cognitive barriers to physical activity may persist after bariatric surgery and may influence patients' activity levels [45]. These barriers include reduced awareness of the health benefits of exercise, fear of injury, a lack of confidence in the ability to participate in physical activity, and self-consciousness, or embarrassment. Treatment strategies that address these barriers may help patients become more physically active.

Recommendations for Physical Activity after Bariatric Surgery

National guidelines suggest that, for optimal weight control, most overweight individuals will need to accumulate at least 150–300 min of moderate physical activity per week, or 30–60 min most days of the week [53]. In one recent study of subjects who have successfully maintained large weight losses over time after surgical or nonsurgical treatments, nearly 70% engage in 150 min or more of moderate to vigorous physical activity per week, and over 30% are physically active for at least 300 min/week [43]. Other data from the National Weight Control Registry indicate that walking is the preferred form of physical activity in this group of individuals [54]. In randomized controlled trials as well as epidemiologic studies, individuals who use pedometers to reach a specific step-count goal (such as >10,000 steps/day) increase their activity levels more and lose slightly more weight than those who do not use pedometers [55]. Regular pedometer use may therefore be a practical and helpful strategy for patients who have had bariatric surgery.

BEHAVIORAL/PSYCHOLOGICAL CARE

Bariatric surgical patients experience a variety of psychosocial challenges in the postoperative period. Initially, patients must adjust to the postoperative diet and to their altered relationship with food. As weight loss progresses, patients must adapt to changes in their appearance and their interactions with others. Dramatic weight loss, however desirable to the patient, can lead to unexpected consequences, such as body image issues related to excess skin, unwanted sexual attention from others, and jealousy from friends and loved ones. As a result of these many challenges, mood disorders, disordered eating patterns, and substance abuse are common among postoperative patients.

Mood Disorders

Mood disorders are prevalent among candidates for bariatric surgery. For example, in one prospective study utilizing structured clinical interviews to assess mood pre- and postoperatively, clinical depression was present in approximately one-third and anxiety was present in almost 20% of preoperative patients [56]. In this population, the prevalence of clinical depression decreased by over 50% in the 3 years following surgery, but the prevalence of anxiety remained relatively stable. Other studies have reported significant improvements in depressive symptoms that persist for up to 5 years postoperatively [57–59]. Data from the large Swedish Obese Subjects (SOS) study suggest that after dramatic improvements in both depression and anxiety in the first postoperative year, there may be some deterioration of mood over time [60]. However, even 10 years postoperatively, the prevalence of mood disorders did not return to baseline levels in this cohort.

It is important to note that some studies have yielded less encouraging findings. In one small cohort, levels of depression and anxiety did not change significantly after surgery [28]. In another cohort, improvements in mood seen in the first postoperative year eroded after 2 years [61]. Other reports suggest that clinical depression may occur for the first time in some postoperative patients, despite good weight-loss outcomes [62]. Furthermore, patients who have undergone bariatric surgery may be at an increased risk of suicide, particularly in the first 3 years after surgery [62–64]. In one large retrospective cohort study, individuals who had undergone gastric bypass surgery were twice as likely to commit suicide as obese control subjects matched for sex, age, and baseline BMI [64]. Case studies suggest that patients who commit suicide after bariatric surgery often have a history of recurrent major depression, both before and after surgery, and that their depression persists even if they have excellent weight-loss results [65]. These reports highlight the importance of continued attention to psychosocial health in the postoperative period, regardless of weight-loss outcomes.

Disordered Eating

The prevalence of disordered eating appears to be high after bariatric surgery. In fact, studies suggest that half of all postoperative patients experience recurrent episodes of loss of control over eating [28,66,67]. Patients who have disordered eating patterns before surgery often continue to exhibit similar behaviors after surgery. In one prospective study, two-thirds of patients with preoperative binge eating disorder reported persistent eating pathology after surgery [68]. In many cases, patients may no longer be able to consume large amounts of food in a short period of time, due to the restriction in gastric capacity after surgery. However, emotional eating and grazing, which is defined as repeated episodes of consumption of small amounts of food, along with a perceived lack of control, are common in this population [69]. Patients may not report these behaviors unless they are prompted by a clinician.

Alcohol Misuse

As a result of media attention in recent years, there has been heightened concern about the potential for development of

alcohol dependence or abuse in postoperative patients [70]. There is a lack of published studies that have evaluated this issue prospectively with an appropriate control group. However, in one small cross-sectional study, structured clinical interviews were employed to determine the rates of current and lifetime alcohol use disorders in a group of 51 postoperative patients [71]. In this study, 35.3% of individuals met DSM-IV criteria for a lifetime history of alcohol use disorder, and 11.8% had a current alcohol use disorder, comparable to published rates in the general population (30.3% and 8.5%, for lifetime and current disorders, respectively). Patients with a prior history of alcohol use disorders (in remission at the time of surgery) appear to be at risk for recurrence after surgery [71]. Fortunately, anecdotal reports suggest that only a very small number (<3%) of patients significantly increase their alcohol intake after surgery [72].

The absorption and metabolism of alcohol may be altered after bariatric surgery, and as a result, postoperative patients may be more susceptible to the intoxicating effects of alcohol [73–76]. Patients should therefore be counseled to exercise caution when consuming alcohol after surgery. In addition, clinicians who care for bariatric surgery patients should ask patients about alcohol intake after surgery and remain alert to the possible presence of alcohol use disorders in this population.

Psychological Counseling and Peer Support in the Postoperative Period

Data suggest that patients with postoperative depression experience poorer weight loss than those who are not depressed [56]. Similarly, postoperative patients who exhibit disordered eating patterns, such as grazing and loss of control over eating, have poorer weight loss and greater weight regain [67,68]. Clearly, patients who are found to have mood disorders, disordered eating behavior, or substance abuse after bariatric surgery should be offered expert psychological counseling and support. It is not known, however, whether such treatment improves weight loss or other outcomes.

In epidemiologic studies, attendance at postoperative support groups is associated with improved weight-loss outcomes [77–79]. There is a lack of data regarding the effects of other types of postoperative psychological support, such as group or individual therapy, on weight loss and other outcomes.

Interestingly, patients who exhibit disordered eating patterns may be more receptive to a behavioral intervention after surgery than before surgery. In one small nonrandomized prospective study, pre- and postoperative bariatric surgical patients with binge eating or other disordered eating patterns were referred to a 10 week cognitive behavioral therapy program designed to address and improve the maladaptive eating patterns [80]. Patients who were referred to the program postoperatively were much more likely to attend the initial session and to complete the program than patients referred preoperatively.

COMPREHENSIVE LIFESTYLE INTERVENTIONS AFTER BARIATRIC SURGERY

There is limited data regarding the benefits of comprehensive lifestyle interventions in the postoperative period. However, in one small, randomized controlled trial, subjects who were assigned to a multifaceted lifestyle intervention after vertically banded gastroplasty reported improved dietary habits, increased physical activity levels, and reduced television viewing, as compared to subjects assigned to usual care [81]. Furthermore, subjects in the lifestyle intervention group lost significantly more weight at 1, 2, and 3 years after surgery than subjects in the usual care group.

The timing of the intervention may be important. Kalarchian and colleagues recently reported the results of a small randomized, controlled study (n = 36) involving patients who had undergone bariatric surgery at least 3 years earlier but who had failed to lose 50% or more of their excess weight [82]. Participants were randomly assigned to a comprehensive lifestyle intervention, including 12 weekly group education sessions and 5 individual telephone coaching sessions over 6 months, or a waitlisted control group. Subjects randomized to the intervention group lost slightly more weight (3.3 ± 8.1 kg) than those in the control group (1.3 ± 6.8 kg), but the difference was not statistically significant. Interestingly, in this study, the presence of depressive symptoms at the beginning

TABLE 45.3
Etiological Factors for Weight Regain Following Bariatric Surgery

Anatomical
LAGB malfunction or mismanagement
Band or port breakage, band to lose
RYGB
Pouch enlargement
Gastrojejunal anastomosis dilation
Gastro-gastro fistula
Physiological
Pregnancy
Menopause
Weight gaining medications
Smoking Cessation
Endocrine disorder: hypothyroidism, Cushing's disease
Intestinal or hormonal adaptation
Behavioral
Dietary
Unhealthy eating patterns, grazing, nibbling, mindless eating
Consumption of high energy foods and beverages
Loss of dumping syndrome symptoms
Loss of control over urges, binges
Reduced vigilance
Physical Activity
Reduced leisure time activity
Increased sedentary behaviors
Insufficient moderately and vigorously intensity exercise
Development of physical limitations to exercise

of the study was associated with greater weight loss in the intervention group but not the control group, suggesting that the behavioral component of the intervention may have been helpful for patients with depression.

WEIGHT REGAIN FOLLOWING BARIATRIC SURGERY

Although clinicians commonly see bariatric surgery patients regain some weight postoperatively, the prevalence and incidence of weight regain has not been well characterized. Using cross-sectional data, weight regain has been estimated to occur in 20%–35% of patients, depending upon the procedure performed and duration of time following surgery [23,35,38,83]. The causes of weight regain are likely to be multifactorial, similar to patients who regain weight after nonsurgical approaches. Table 45.3 provides a categorical list of potential etiologies that should be explored with all patients who present with weight regain. The physiological and behavioral (diet and physical activity) causes are common to surgical and nonsurgical patients. Depending on the patient's age and gender, a through history should be performed that reviews all of these reasons followed by appropriate counseling. In contrast, the anatomical factors for weight regain result directly from either malfunction or disruption of the surgical procedure. These causes need to be evaluated by an imaging procedure or upper endoscopy. Additional studies are needed to better understand the frequency, etiology, and treatment for weight regain.

CONCLUSION

Bariatric surgery is an effective and acceptable treatment for individuals with severe obesity who are at risk for or have complications associated with obesity. Several surgical procedures are available with variable risk and weight-loss outcomes. However, regardless of the procedure performed, surgery is considered a tool that is adjunctive to choosing a healthy, calorie-controlled diet and engaging in daily physical activity. For patients who undergo restrictive-malabsorptive or malabsorptive operations, dietary supplementation is necessary to avoid nutritional deficiencies. Patients are at risk for weight regain following surgery due to several biopsychosocial factors. In order to maximize successful outcomes, all patients should be monitored and managed by a multidisciplinary team of health care providers knowledgeable in bariatric surgical care.

The numbers are clear and the trajectory has been obvious for years: Overweight and obesity are rampant in the United States and obesity-related diseases are at epidemic levels. Prior to the launch of the Food Guide Pyramid in the mid-1970s, the weight status of the U.S. population was relatively stable and the prevalence of obesity was relatively low. Subsequent to the 1970s, in the 1980s and 1990s the rate of obesity increased by 50% per decade [1]. Between 1980 and 1994, the prevalence of obesity among U.S. children grew by 100% [2]. The NHANES results from 2007 to 2008 demonstrated that out of U.S. citizens 20 years and older, over 34% were overweight, 33% were obese, and close to 6% were extremely obese [1]. From 2007 to 2009 alone, the number of obese U.S. residents grew by 2.5 million. Despite presidential backing, as of 2010 no state had met the *Healthy People 2010* goals of obesity rates at or below 15%. In fact, from 2009 to 2010, the number of states with an obesity prevalence of 30% or more increased from 9 to 12 [3]. If current trends continue, by 2023 it is estimated that 80% of Americans will be overweight or obese [4].

As the rates of overweight and obesity continue to increase so does the prevalence of diseases associated with excess adiposity. In the United States, obesity constitutes a leading cause of mortality, second only to smoking [5]. Of the host of disease states associated with obesity are the components of metabolic syndrome, cardiovascular disease (CVD), and the growth and proliferation of certain types of cancer cells. Obesity also affects an individual's quality of life by negatively impacting their social and occupation functioning along with their mental health. If the problems of obesity and overweight cannot be controlled, particularly among children, the current U.S. generation may actually experience decreased longevity compared to their parents. Rather than a singular focus on weight reduction for the purpose of improved health, future obesity treatments should be developed, which positively impact the cluster of disorders accompanying weight gain.

Despite concern over the obesity epidemic and immense effort and investment in developing weight-loss interventions over the past 40 years, the impact of obesity treatments have been largely disappointing. Regardless, Jeffrey et al. [6] report 47% and 75% lifetime prevalence rates for dieting among men and women, respectively, and it is reasonable to believe that as overweight and obesity rates climbed over the subsequent 20 years that these numbers would have commensurately increased. Optimistic reports suggest that the majority of weight-loss interventions demonstrate some success in the short-term [7] and approximately 20% of overweight individuals are successful at maintaining at least a fraction of weight lost. On the other hand, numerous reports have also suggested that weight lost is usually regained within a few years of treatment, with perhaps as many as 30%–64% of weight-loss intervention participants gaining back weight in excess of what they had initially lost [8]. In general, the more time between cessation of intervention and follow-up, the more weight is regained [8].

Additional evidence for the lack of practical success of weight-loss interventions come from the methodology typically employed in weight-loss trials. Most weight-loss studies have compared a low-fat diet group to a control group. Despite the control groups receiving no intervention and the low-fat diet groups receiving intensive intervention typically consisting of food diaries, food weighing, group and individual counseling, the intervention groups do not fare significantly better than the control groups [7]. In studies where low-fat diet protocols are compared to other diet types of similar intensity, the low-fat diets generally perform worse [7]. As a result of the lack of long-term success

experienced by many individuals on low-fat diet regimens, and the frequency with which many individuals engage in dieting, the development of any new dietary approach should carefully consider the potentially very negative ramifications of weight cycling [8].

Although long-term outcomes are generally poor, the typical low-fat caloric-restriction weight-loss prescription is still widely endorsed. Interestingly, this continued allegiance persists without respect to outcome or complaints from participants in such programs of feeling unsatisfied and hungry. Even on low-fat diet plans that do not encourage strict energy restriction, participants often report feelings of hunger, which may be a result of declines in blood glucose subsequent to the metabolism of a high glycemic meal. Unfortunately, such feelings of hunger have been associated with the development of adverse mood states. Cheatham et al. [9] found that over the course of a 6 month study, a group of participants following a high glycemic diet reported significant consistent worsening of mood. Wells et al. [10] also found that after just 1 month, individuals following a low-fat diet reported increasing scores on a measure of anger and hostility. An increasingly negative mood, particularly with regard to the development of worsening depressive symptoms as is frequently noted in those following low-fat, high-carbohydrate diet protocols, have been shown to adversely impact the long-term commitment to such weight-loss programs [9]. Six of the seven studies and meta-analyses included in the Nutrition Evidence Library indicate greater attrition rates for low-fat diets as compared to low- or very-low carbohydrate diets [11]. On average, studies reporting attrition in nonpharmacological behavioral weight-loss interventions report rates ranging from 22% at 6 months [12] to 70% at 12 weeks in a commercial weight-loss program [13]. As an aside, outcomes for weight-loss medications are often no better due to 1 and 2 year adherence rates of less than 10% and 2%, respectively [14].

To move forward in addressing the challenges of overweight and obesity in the coming decades will require reexamination of the approaches most heavily relied upon for weight control. Since weight loss over time is negligible, negative mood states are increased, attrition is high, and participants report a lack of satisfaction with energy restriction and low-fat diets, the investigation and development of alternative approaches is imperative. Moreover, since obesity is so strongly correlated with a plethora of metabolic dysfunctions, trends in diet and contributions to understanding metabolism from anthropology and biochemistry are warranted. This chapter will address emerging lines of research that incorporate interdisciplinary approaches to the development of unifying theories of overweight, obesity, and modern diseases of civilization.

CHANGES IN DIETARY PATTERNS OVER TIME

Prior to the introduction of agriculture and animal husbandry (~10,000 years ago), hominins largely relied on animal meat (including internal organs), fish, fruit, vegetables, and nuts for sustenance [15,16]. Although for years it was thought that hunter gatherers (HG) subsisted primarily upon vegetation, this inference was a result of limited study by Lee [17], whose data were misrepresented and misinterpreted over the years [18]. More recent ethnographic and quantitative analyses of archaeological data in addition to studies of modern foraging populations indicate that animal products comprised the majority of the HG diet [18]. Richards and colleagues analyzed isotopic evidence from Neanderthal skeletons [19] and Paleolithic humans [20] and found strong evidence of a diet predicated heavily on animal products. Moreover, contrary to popular belief that HG lead short difficult lives riddled with disease, archaeological evidence suggests that our HG ancestors were fit, strong, lean, and tall with healthy teeth and bones [21]. In fact, it was the assimilation to a carnivore diet that throughout evolution facilitated the development of a larger brain, a smaller jaw, a faster metabolism, and a reduction of gut size [22–24]. However, there simply has not been a sufficient amount of time for the human genome to adapt to a diet based on the genetically manipulated monocrops of modern agriculture (e.g., wheat, soy, etc.), factory farming, and processed foods since the past 10,000 years constitutes only about 1% of our evolutionary history [15,25,26].

While patterns of macronutrient consumption varied by region, culture, season, and other factors, HG, and the animals consumed by HG, foraged on native and natural foods. Current protein intake estimates for modern worldwide HG cultures range from 19% to 35% [27] well above the current estimates for protein consumption in the United States (~15% of total energy intake) and at the upper end of government recommended levels for adults (10%–35%; [28]). This rate of intake has been relatively stable since 1970, with the average intake of meat, eggs, and nuts having increased over time by only 70 cal [29].

The primary macronutrient difference, however, between the HG diet and modern Western diets is centered on the consumption of carbohydrates. While current estimates of the percentage of total caloric intake from carbohydrates ranges from 49% to 52% [28] for men and women in the United States, well-aligned with the government recommended level of 45%–65%, HG diets likely ranged from 22% to 40% carbohydrate [27]. Moreover, important qualitative differences should be noted. Carbohydrates consumed by HG consisted primarily of low-glycemic high-fiber wild vegetables with honey on occasion when seasonally available [30]. In contrast, an examination of the top 25 sources for calories among adult Americans, reveals an inherent reliance on high-glycemic carbohydrates in the form of (in descending order) grain-based desserts, yeast breads, soda/energy/sports drinks, alcohol drinks, pizza, tortillas/burrito/tacos, pasta, potato/corn/other chips, fried white potatoes, ready-to-eat cereals, candy, rice, quickbreads, and fruit drinks. These types of foods comprise approximately 72% of the total daily caloric intake by people in the United States [31] and contributed to the

131.9 lb/person/year consumption of refined sugar in the United States in 2010 [32]. Overall, of the calories consumed by most Americans, 75% come in the form of highly processed foods containing high levels of sugars and high glycemic carbohydrates [33].

In addition to the changing role of carbohydrates in the human diet, particularly the Western diet, a similar pattern, albeit in the opposite direction, is noted for fat intake. The majority of modern foraging cultures, much like our HG ancestors, consume a diet comprised of approximately 36%–43% of total caloric intake from fat with no adverse health effects [27]. These numbers are somewhat higher than the current fat intake of Westerners [28] and higher than government recommended levels for adults (20%–35%; [31]. During the late 1960–early 1970s, the government began advising the American public to replace saturated fats with polyunsaturated fat. Then during the 1980s that message shifted to one advising the elimination of all fats. By 1990, the American Heart Association was calling for the use of nonfat dietary products [7]. Among nutrition and diet researchers, virtually sole emphasis has been placed on reducing fat intake as a method to promote weight loss and improve health parameters. The American public has dutifully responded to advice to reduce fat intake and from 1971 to 2000 reduced the percent of energy from fat from approximately 37% to 33% [28]. The consumption of saturated fat also declined from approximately 13.5% to 11% during this time period as the U.S. government began making recommendations to keep saturated fat below 10% of total daily caloric intake [28]. Unfortunately, according to Willett ([7]: p. 30), "we probably have collectively as a nutrition community contributed to the overweight problem" as a result of this line of thinking since the American public has been led to believe that so long as they avoid fats they can consume as much carbohydrate as they wish.

Despite the widespread belief that fat is "bad," the claim has never received empirical support and a large body of evidence suggests just the opposite. In fact, Zelman [34], stated in the *Journal of the American Dietetic Association* that targeting dietary fat as a cause of obesity and harm to health was misguided. Over the past 30 years numerous high-profile, large longitudinal studies failed to support the lipid-hypothesis in relation to obesity and indicators of poor health. These include the Framingham Heart Study [35], the Multiple Risk Factors Intervention Trial [36], and the Women's Health Initiative [37]. Hoenselaar ([38]: p. 122), in his review of the discrepancies between scientific evidence and dietary advice, summarized that "(t)he results and conclusions about saturated fat intake in relation to CVD, from leading advisory committees, do not reflect the available scientific literature."

In the Nurse's Health Study, which investigated the relationship between intake of various types of fats and the subsequent development of CVD, women with a high-consumption of trans fats in relation to polyunsaturated fats ran a three times greater risk of developing CVD. Overall, though, level of dietary fat was not associated with risk of CVD [7,16], in their review of the relationship between various fats and coronary heart disease (CHD) prevention called for the reduction or elimination of trans fats, while suggesting that the elimination of saturated fats and monounsaturated fats will have negligible to no impact on CHD risk, and the increased consumption of polyunsaturated fats may be cardioprotective.

In addition to addressing the lipid hypothesis, any effort to influence a change in the eating behavior of the American public will need to be accompanied by a clear explanation of macronutrient metabolism. It simply is not the case that all calories are created equal and continued advocacy for energy restriction with disregard for this evidence will perpetuate failure in attempts to reduce obesity. Although the government continues to call for the reduction of excessive caloric intake through the *Dietary Guidelines for Americans* [31] even the DGA committee recognized that caloric intake has remained relatively stable over time and within recommended guideline levels.

It has long been accepted, although not entirely among weight-loss researchers, that different macronutrients vary in their thermogenic properties. The rates of thermogenesis for carbohydrate are approximately 5% while protein is approximately 20% [39]. Hence, very low carbohydrate ketogenic diets (VLCKDs) due to protein driven gluconeogenesis provide metabolic conditions favorable for mass and fat loss. Under ketogenic conditions, established via low carbohydrate consumption, energy is provided through exogenous protein and fat sources. In instances where caloric-expenditure exceeds caloric intake, endogenous glycogen and fat stores are burned as well. In this state, similar to conditions of starvation, fatty acids and ketones are used as fuel [39]. However, unlike starvation, with adequate levels of protein and fat intake and restricted carbohydrate consumption, glucose levels are maintained and feelings of hunger are thwarted.

A relatively recent re-evaluation of the lipid hypothesis in conjunction with increased awareness of the role of carbohydrates in insulin production and weight gain has resulted in the proliferation of research examining the impact of fats vs. high-glycemic carbohydrates on weight status and health parameters. Such dietary comparisons are very instructive for the weight-loss practitioner and should be examined carefully given the relative lack of significant impact from the conventional weight-loss approaches focusing on thermodynamics and the lipid hypothesis [40,41].

INSULIN-SENSITIVITY HYPOTHESIS

In an effort to further elucidate the role of insulin in weight status and health, as well as investigate the applicability of the lipid hypothesis in comparison to the insulin-sensitivity hypothesis, comparisons of weight lost on low-fat diets (LFD) and low-carbohydrate diets (LCD) have received increasing consideration. Interventions in which the fidelity of each approach is maintained may expose potentially

constructive theoretical and pragmatic conceptualizations of the obesity epidemic. Although dietary protocols among LCD interventions are relatively inconsistent with regard to total kcal/day, percent of energy from fat and protein, and fat and protein sources, results indicate a clear trend. Volek et al. [42] found that among LFDs and LCDs with equivalent caloric intake, weight loss among individuals following an LCD was significantly greater than among participants in LFD groups (10.1 vs. 5.2 kg). Results from the A to Z Weight Loss Study [43] demonstrated that individuals adhering to the Atkins diet, which is low in carbohydrate, evidenced two times the weight loss in comparison to individuals on other diets. Hession et al. [44] reviewed the literature comparing LFDs to LCDs and reported that LCDs are more effective at 6 months and as, if not more, effective than LFDs at 1 year. Foster et al. [45], in the only 2 year randomized clinical control trial to date, reported greater 2 year weight loss on LCDs than LFDs despite a lower energy intake in the LFD.

In fact, studies comparing LFDs to LCDs often restrict the caloric intake of the LFD groups while allowing the LCD group to consume ad libitum. Despite caloric differences, weight loss is generally comparable if not greater in the LCD condition and the LCD groups report greater satiety and satisfaction with the diet [46–48]. Moreover, as is typical for LFD and low-calorie diets, any weight lost is only maintained for as long as the individual remains in a calorically deprived state.

A confound in many studies involving LCDs is the gradual reintroduction of carbohydrates. Evidence suggests that such a methodology compromises weight loss and results in weight regain over time. An additional source of bias involves studies including exclusively vegetarian sources of protein and fat, limited or no red meat, and high dairy protocols as part of LCDs. These aspects appear to mitigate weight loss as well.

The extent to which carbohydrates should be limited in an effort to impact health and weight status is not entirely clear; although, it now seems evident that any reduction of carbohydrates below 100 g/day is likely to yield positive results. The very low carbohydrate ketogenic diet (VLCKD), in which carbohydrate intake is sufficiently low to create the presence of detectable ketones, generally requires carbohydrate intake no greater than 10% of total energy. VLCKDs typically involve unrestricted intake of saturated and unsaturated fat, meat products, fish, eggs, heavy cream, and oil with limited amounts of hard cheeses and low-carbohydrate vegetables and a small amount of nuts and seeds. Restricted foods include fruits and juices, other dairy products, all grains and cereals, high-carbohydrate vegetables, and desserts.

Aside from absolute weight loss, distinct patterns of change are noted in comparing LFD to LCD weight loss. Percent of weight loss due to fat loss is significantly greater on LCDs than on LFDs. According to Garrow and Summerbell [49], a weight loss of 10 kg achieved through dieting alone should consist of 71% fat mass loss. However, studies examining fat loss patterns in individuals consuming an LCD suggest a preferential loss of fat mass [48,50]. Volek et al. [48] found that for obese males, LCDs ranging from 30 to 104 g of carbohydrate per day result in a corresponding weight loss comprised of 95%–75% fat mass, respectively. Moreover, individuals on LCD protocols evidence greater midsection and abdominal weight loss than is seen with those following an LFD regimen. Volek et al. [48] noted body fat loss in the trunk region three times greater in a very low-carbohydrate diet group than in a low-fat diet group. While the most significant differences occurred with men, within-group examination of women alternately consuming both a VLCKD and an LFD reveal slightly greater reductions in body mass, total fat mass, and trunk fat mass while consuming the VLCKD, as well. In fact, Volek et al. [48] demonstrated that many subjects regained fat subsequent to switching from a VLCKD to an LFD. However, no subjects regained weight or fat on the alternate protocol. This pattern of fat loss, likely a product of the five to seven times greater reactivity to insulin molecules of abdominal fat than more distally located subcutaneous adipocytes, should be of great interest to obesity researchers since abdominal adiposity is often mostly closely related to the health problems associated with metabolic syndrome [51].

In addition to frequently noted weight loss and higher than predicted percent fat loss, an LCD may constitute the most promising future direction in obesity for other reasons. First, free-living individuals on an LCD often naturally reduce their caloric intake as a result of decreased appetite and hunger resulting from higher consumption of fat and protein. In a controlled study, researchers found that hunger level on an LFD was equivalent to hunger level experienced on a 1000 kcal/day less LCD [52]. Increased ketones have been shown to inhibit appetite while low-glycemic intake prevents dips in blood glucose, which occur on higher carbohydrate diets and which may produce carbohydrate cravings, resulting in increased intake. While high-protein and fat diets reduce appetite and increase feelings of fullness, diets creating a high-insulin response (e.g., high-carbohydrate diets) are shown to increase food intake, are experienced as less satisfying, and may result in an overall higher energy intake. It is perhaps a result of decreased feelings of hunger on an LCD that also results in higher rates of compliance among participants on LCDs than on LFDs [39]. Furthermore, while many studies of weight loss are inherently problematic with regard to objective measurement of intake and relationship between intake and physiological measures, fidelity to a VLCKD is directly verifiable through daily urine testing with reagent strips for the presence of acetoacetic acid. During approximately 10 weeks of testing, Volek et al. [48] noted 85% compliance to a VLCKD through urine testing for ketones. The ability to objectively measure fidelity, in combination with decreased attrition rates and greater satiety, contributes to the demonstrated feasibility of implementing LCDs in output settings.

Fidelity to an LCD and decreased attrition may also be the result of improved mood promoted by these diets. Multiple

reports indicate that an LCD may be more protective of mood during weight loss than an LFD. Evidence suggests that consumption of a high-fat/low-carbohydrate meal results in greater feelings of relaxation and friendliness and decreased feelings of tension and antagonism as compared to consumption of a low-fat/high-carbohydrate meal [10,53,54] Cheatham et al. [9] also examined the impact of diet on subclinical depression among participants in a weight-loss study. Their results indicated lower levels of subclinical depression and negative mood among participants following an LCD as compared to those on an LFD.

Overall, it appears that an LCD may provide a potentially effective means for weight control over traditional calorie restriction and low-fat diets without concomitant hunger and decline in mood. Moreover, improvement in health parameters generally occurs rapidly and regardless of weight loss.

LCDs AND PHYSIOLOGICAL MARKERS

The emphasis, over the years, on reduction in overweight and obesity has primarily been driven by the relationship between weight loss and improved markers for health. Of primary concern to obesity researchers is the relationship between weight and CVD, the current leading cause of death in the United States. Coronary artery disease (CAD), a rarity in the early 1900s [55], is thought to have increased in prevalence due to dietary changes brought about through industrialization [56]. Since obesity rates began to climb the emphasis with regards to weight loss and health has rested almost exclusively on lipid profiles and cholesterol. The LDL of healthy newborns is between 30 and 70 mg/dL; however, as soon as infants are weaned and started on a modern diet LDL increases [33]. The average LDL of American adults is approximately 130 mg/dL, well above the physiologically normal range. Approximately 80% of CAD events occur within the 90–130 mg/dL range [57], and prognosis of CAD event improves as LDL levels approach the physiologically normal range [58]. However, as research into lipid profiles has proliferated, it has become clear that the atherogenic risk with regard to LDL comes almost entirely from the small, dense particles rather than the overall LDL cholesterol concentration [59–61]. Moreover, the small dense LDL particles are now considered to be an associated feature of metabolic syndrome [42].

Since it is now clear from epidemiological studies that there exists a positive, inverse, or at minimum, no relationship between saturated fat and CVD morbidity and mortality, the hypothesis that fats contribute to higher risk of CAD needs to be replaced with the greater likelihood that excess carbohydrate intake results in increased levels of small dense LDL particles [42]. Evidence from multiple studies points to improvement in lipid markers of CVD subsequent to a VLCKD, which is typically high in fat including saturated fat [59–61]. Small dense LDL particles are often converted to larger LDL and decreases in plasma saturated fatty acids are noted, despite higher saturated fat intake. While LFDs often produce reductions in LDL when participants lose weight, reductions in HDL-cholesterol (HDL-C, along with triglycerides, the lipid component most strongly associated with insulin resistance) are also generally noted [62,63]. Conversely, LCDs typically result in increased HDL-C levels [45]. Overall, Frassetto et al. [15] found consistent improvement in the physiology and metabolism of carbohydrate and lipids on LCDs. On VLCKDs reduction in CVD risk has been noted during weight loss and weight maintenance phases after only 8–12 weeks [64–67]. Overall Volek et al. ([42]: p. 307) conclude that "carbohydrate restriction has the ability to target the range of markers with a single intervention" and thus represents an unified approach to improved overall health. These findings are consistent with the 2005 Institute of Medicine Macronutrient Report stating that in comparison to diets higher in fat, low-fat and high-carbohydrate diets may be more deleterious with regard to the development of CHD and diabetes [31].

In addition to improved lipid profiles, subjects on an LCD typically evidence improvement on numerous additional physiological markers. Frassetto et al. [15] found that among healthy sedentary adults a LCD improved not only lipid profiles, but glucose tolerance, blood pressure, insulin secretion and sensitivity, and vascular reactivity without weight loss, increase in physical activity, or use of medications among healthy sedentary subjects after only 2 weeks. Westman et al. [39] and Johnstone et al. [68] noted significantly decreased insulin secretions and increased insulin sensitivity among individuals following a LCD, within 3–4 days on the diet, as well. Yancy et al. [69] also reported significantly greater improvements in blood pressure in a VLCKD group compared to a LFD plus Orlistat group. LCDs have proven beneficial for individuals suffering from epilepsy [70,71], narcolepsy [72], heartburn [73,74], and dermatitis herpetiformis [75]. Moreover, intracellular changes resulting in decreases of reactive oxygen species (ROS) are evident with the metabolism of fatty acids and ketones [39]. Since ROS facilitates apoptosis, a VLCKD may reduce the risk of diseases associated with ROS generation including Alzheimer's diseases and a variety of cancers [76].

INSULIN AND PHYSICAL ACTIVITY

Any discussion of weight loss and maintenance invariably includes the role of physical activity (PA). Over the past 40 years, as a result of the adoption of the thermodynamics hypotheses, the relationship between exercise and weight loss/maintenance has focused on creating a negative energy balance through exercise. As has been the case with nutrition, this advice has been predicated upon faulty logic and information. Exercise plays an undeniably important role in maintaining health. However, the role of PA in reducing overweight and obesity is far more complex than the achievement of a negative energy balance. The same insulin-sensitivity hypothesis applicable to weight loss is relevant to the role PA plays in achieving maximum health.

An examination of trends in PA over the same course of time in which the rise in weight status has been noted is very

revealing. A random annual telephone survey conducted by the Centers for Disease Control and Prevention from 1990 to 1998 showed that although many Americans were not meeting health activity recommendations, the self-reported level of PA in which the U.S. population engaged remained stable [77]. A more rigorous test of the relationship between PA and weight status involves the use of the doubly labeled water (DLW) technique to assess energy expenditure. Numerous such studies, reviewed by Westerterp and Speakman [78], showed that from 1988 to 2006, a slight increase in PA was noted across Europe and North America. However, during that same time period, obesity rates rose from 5% to 10% in the European samples and 8% to 22% in the North American samples [79].

Perhaps the rise in obesity despite an increase in PA is reflective of increased caloric consumption among those who are physically active. Another study using the DLW technique followed 40 healthy nonobese adults with an average age of 27 over 11 years [79]. This study assessed activity related energy expenditure, PA levels, and BMI. Interestingly, participants with high-baseline PA gained more weight at follow-up than those participants with lower baseline PA. In addition, on average, all members, regardless of PA level gained approximately 5 lb/year. The authors suggest that although many participants changed from a physically active lifestyle to one that was less active across the study's 11 year span, participants' caloric intake was not commensurately reduced [79].

It is generally accepted among PA researchers that weight loss cannot be accomplished by PA alone [80–82]. Although recommended activity levels of moderate intensity are related to improved health indices, they are not associated with clinically significant weight loss. In fact, the position statement of the organization arguably the most likely to declare an association between PA and weight loss (American College of Sports Medicine) states, "despite the intuitive appeal of the idea that physical activity helps in losing weight, it appears to produce only modest increments of weight loss beyond those achieved by dietary measures and its effects no doubt vary among people" [83; p. 1087, 84].

Although theories involving increased PA in an effort to balance a thermogenic energy equation have failed, there are other metabolic advantages of PA that indirectly contribute to weight stability and loss. Exercises designed to increase muscle tissue may decrease the amount of free-floating glucose eventually stored in fat cells. Not because of the sheer number of calories burned, but due to the impact of increased myocytes on glucose clearance. A greater amount of muscle mass in relation to fat mass results in a greater balance and regulation of insulin delivery and metabolism. Because muscle burns approximately 7–10 times more glucose than fat [85,86], a physiological balance in favor of greater muscle mass than fat mass increases the efficiency and expediency through which glucose is metabolized and cleared [51].

In order to fully appreciate the role of PA in weight loss and maintenance, attention must shift from energy expenditure to insulin regulation and the role myocytes and adipocytes play in conjunction with energy intake. An optimal diet and PA regimen is one which limits carbohydrate intake (and thus insulin production) and involves the engagement of muscle tissue in clearing remaining glucose in addition to burning protein and ketones for energy. Unfortunately, even a cursory review of the PA components of obesity treatments reveals a predominance of prescriptions for long periods of moderate activity. These approaches often require long and repetitive periods of PA, which do not maximize neuroendocrine adaptation. In contrast, an approach to physical fitness receiving increased focus is high intensity functional training (HIFT), which appears to maximize the benefits of exercise including metabolic and physiological adaptations in cardiac muscle cells and endothelial function, blood pressure, cardiac contractility, lipid oxidation, glucose and insulin levels, body composition, and skeletal muscle adaptations [87–90]. HIFT facilitates these improvements in substantially less time, or training volume, than traditional exercise approaches. Importantly, HIFT has been found to be safe even for medically compromised individuals, including patients with heart failure (HF), CAD, and chronic obstructive pulmonary disease (COPD) [88,91,92].

WEIGHT GAIN, SLEEP, AND STRESS

As the link between hormones and weight gain becomes increasingly clear, the relationships between sleep and stress and their impact on obesity, are gaining further attention. It is very likely that HG slept and worked in accordance with the rising and setting sun, establishing circadian rhythm patterns, which influence the release of hormones in a similar fashion still for modern man [93]. Studies involving participants including children, adolescents, and adults have confirmed a link between sleep and weight status. A lack of sleep clearly decreases leptin secretions, which generally peak during nighttime sleep [94]. In addition, ghrelin, which signals hunger, becomes elevated in a sleep-deprived state [95,96]. The decrease in leptin and concomitant increase in ghrelin result in sleep-deprived individuals reporting increased hunger and appetite. However, even more significantly, individuals in such a state crave sugary, starchy, and salty foods over all others [95]. While a metabolic or thermodynamic explanation would suggest that such cravings would be necessary to account for increased energy expenditure during wakeful times, participants in sleep-restriction studies were often required to remain in bed or sitting in a comfortable chair [95]. While HG may have benefitted from a metabolic advantage when hunting at night, modern man, when experiencing a sleepless night, rarely engages in PA to counterbalance the hormone-driven cravings and hunger.

To make matters worse, in addition to increased ghrelin and decreased leptin, sugary and starchy food cravings, and the resultant hunger, sleep-deprived individuals typically evidence decreased glucose tolerance. A 4 h sleep reduction across six nights produced a 30% reduction in insulin response to glucose in healthy men [97]. Individuals who remain sleep deprived can reach a state of insulin resistance bordering on prediabetes [98]. Across longitudinal

and cross-sectional studies, an inverse relationship has been established between sleep and BMI. A study of 1772 participants over 15 years of age in Spain found that those sleeping more than 9 h a night had less than half the risk of obesity in comparison with their counterparts sleeping 6 or fewer hours per night [99]. Gangwisch et al. [93] in analyzing data from NHANES I from 1982 to 1992, reported similar results leading them to suggest that weight control efforts should place greater emphasis on sleep quality and quantity.

In addition to direct effects, sleep deprivation is also associated with stress and depression, which, in turn, are related to weight gain. Stress, whether brought on by sleeplessness or environmental conditions, is associated with metabolic changes as well as changes in eating patterns. Metabolically, stress can moderate the responsiveness of the hypothalamic-pituitary-adrenocortical (HPA) pathway [100]. There is strong evidence to suggest that weight status is impacted via elevations of cortisol produced under conditions of prolonged activation of the HPA axis and thus resulting in insulin resistance [100–104]. Frequent dieting is correlated with emotional stress [105] perhaps due to the negative emotional consequences of calorie restriction or low-fat intake or the associated repetitive chores including calorie counting and food monitoring [106]. Tomiyama et al. [107] found participants in a 2 (calorie restriction vs. no calorie restriction) × 2 (caloric-monitoring vs. no caloric-monitoring) study who were tasked with monitoring caloric intake reported increased perceived stress and participants in groups restricting caloric intake evidenced increased total cortisol production.

Prolonged stress may also contribute to quantitatively and qualitatively different patterns of food intake. Among college students, studies suggest that stress and depression are associated with less fresh fruit and vegetable consumption, greater intake of sweets and fast foods [108,109], and binge eating [110,111]. Vicennati et al. [112] have demonstrated that subsequent to the culmination of a stressful event, a preference for carbohydrates persists. This phenomenon may be particularly strong among women [113]. The preference for carbohydrate foods as a result of stress can be understood in light of the relationship between cortisol, glucose, and insulin. Elevated secretions of cortisol, a stress hormone and insulin antagonist [114], are related to increased glucose intolerance [115]. Glucocorticoids directly impact insulin action and down-regulate sensitivity to lipase while inhibiting peripheral tissue uptake of glucose. This in turn, drives the cravings for starchy, high glycemic, carbohydrates. Therefore, chronic hypercorticolemia results in increased fat mass, particularly in visceral adipose tissue where glucocorticoid receptor density is high [116]. Thus, a strong relationship exists between chronic stress, high cortisol levels, and metabolic syndrome [117,118]. In one study of work-related stress, employees with chronic stress were two times more likely to develop metabolic syndrome than their nonstressed colleagues [119]. Overall, clinical, as well as epidemiological studies, document a significant relationship between stress due to adverse life events and psychological as well as psychosocial challenges and abdominal obesity and metabolic syndrome.

SUMMARY

For the past three decades, conventional wisdom has concluded that obesity is the result of an imbalance between energy intake and expenditure as predicted by the energy balance equation. Also, the theoretical basis for dietary prescription was dominated by the lipid hypothesis, which warned that dietary fat, particularly saturated fat, promoted heart disease. Obesity, it has been argued, is the result of sloth (declining rates of physical activity) and gluttony (increasing intake of dietary fat and total calories). These two hypotheses remain highly influential among segments of the academic community and still largely guide advice from government agencies. For instance, a recent ranking presented in U.S. News and World Reports' "Best Diets" focus on low-fat, semistarvation diets despite their anemic outcomes in clinical trials. In this chapter it is argued that a comprehensive analysis of nutritional science, biochemistry, epidemiology, and evolutionary biology literature presents a significant challenge to the conventional wisdom about obesity. Evidence is mounting that, as Hite et al. ([11]: p. 922) have concluded, although the initial goals were admirable, the application of the dietary recommendations for low-fat and reduced-calorie diets have "constituted a population-wide dietary experiment that should be brought to a halt" as the "'potential for harmful effects' has in fact been realized." In addition, a critical analysis of the literature on PA rates over that past several decades casts doubt on the notion that sloth is a significant cause of the obesity epidemic. We argue that obesity research is ripe for a paradigm shift away from the conventional wisdom which has failed to adequately impact the global obesity epidemic toward fresh approaches, which are better grounded in the larger scientific literature and which offer new hope for those who suffer from obesity and its related disorders.

It seems clear that future investigations should strive to increase understanding of the insulin-sensitivity hypothesis of weight gain, potentially assist in creating new U.S. dietary guidelines based on this appreciation, and help inform the public of metabolic pathways to health and wellness. To do so, the public must first be educated about the influence of carbohydrates, insulin, and other hormones in weight gain and health parameters. The role insulin plays in a host of seemingly unrelated physiological markers including poor lipid profiles, hyperinsulinemia, hyperglycemia, increased inflammation, and decreased apoptosis in endocrinological cancer cells should also be of primary concern to nutrition researchers. Moreover, the increased prevalence rates corresponding to the population-wide increased consumption of carbohydrates have been noted in such varying conditions as diabetes, metabolic syndrome, allergies, headache, gout, acne, Alzheimer's disease, heartburn and reflux, irritable bowel syndrome, ADD/ADHD, epilepsy, schizophrenia, and narcolepsy and are potentially due to inflammation resulting from excessive carbohydrate intake deserves further investigation. The existence of such a unifying explanation for so many modern medical conditions is strong evidence for the insulin-sensitivity hypothesis. Carbohydrate restriction,

consistent with the hominin genotype can potentially target the majority of markers in one singular unifying approach while concomitantly reducing rates of overweight and obesity.

Given the relative newness of the insulin-sensitivity hypothesis with regard to weight gain and its physiological correlates specific additional areas of study warrant consideration. First, it appears clear that various hormones play significant roles in the gain and loss of weight as well as nutrient metabolism. It would therefore, be prudent to devote additional research efforts to expanding our understanding of the differences such hormones play in weight gain and loss between the sexes and among pre- and postmenopausal women. Second, further research efforts should be directed toward the study of free-living participants and their ability to maintain a LCD or a VLCKD over time. As these areas and more are further defined and explicated, a strong alliance between biochemists, food scientists, weight-loss researchers, and other specialists should be forged. Continuing to partition knowledge among professionals will continue to hinder advancement. Along similar lines, the creation and delivery of an unified message from various specialists to policy makers should be explored. Obesity, and morbidity, and mortality rates will not decline while political interests in certain agricultural commodities continue to take precedence.

INTRODUCTION

Exercise immunology is a relatively new area of scientific endeavor, with the majority of papers published during the past 25 years [1]. Most studies have focused on the acute and chronic effects of various exercise workloads on the immune system and immunosurveillance against pathogens. For the practicing physician, two areas of investigation from exercise immunology have the greatest clinical and public health implications: (1) chronic anti-inflammatory influence of exercise training and (2) reduction in risk of upper respiratory tract infections (URTI) from regular moderate exercise training.

CHRONIC ANTI-INFLAMMATORY INFLUENCE OF EXERCISE TRAINING

Acute inflammation is a normal response of the immune system to infection and trauma. Intense and prolonged exercise similar to marathon race competition causes large but transient increases in total white blood cells (WBC) and a variety of cytokines including interleukin-6 (IL-6), IL-8, IL-10, IL-1 receptor antagonist (IL-1ra), granulocyte colony stimulating factor (GCSF), monocyte chemoattractant protein 1 (MCP-1), macrophage inflammatory protein 1 beta (MIP-1β), tumor necrosis factor-alpha (TNF-α), and macrophage migration inhibitory factor (MIF) [2,3]. C-reactive protein (CRP) is also elevated following heavy exertion, but the increase is delayed in comparison to most cytokines. Despite regular increases in these inflammation biomarkers during each intense exercise bout, endurance athletes have lower levels when measured during rest in contrast to overweight and unfit adults. For example, mean CRP levels in long-distance runners (rested state) typically fall below 0.5 mg/L in comparison to 4.0 mg/L and higher in obese, postmenopausal women [3,4].

The persistent increase in inflammation biomarkers is defined as chronic or systemic inflammation, and is linked with multiple disorders and diseases including atherosclerosis and cardiovascular disease (CVD), the metabolic syndrome, diabetes mellitus, sarcopenia, arthritis, osteoporosis, chronic obstructive pulmonary disease, dementia, depression, and various types of cancers [5–7]. CRP is the most frequently measured inflammatory biomarker, and individuals with CRP values in the upper tertile of the adult population (>3.0 mg/L) have a twofold increase in CVD risk compared to those with a CRP concentration below 1.0 mg/L [7]. An elevated fasting IL-6 concentration is a significant component of the chronic low-grade inflammation that underlies the metabolic syndrome, CVD, diabetes, and various cancers [8]. Athletes typically have plasma IL-6 concentrations that fall below 1.0 pg/mL in contrast to values above 2.0 pg/mL in older and obese individuals [3,8].

Physical Activity, Fitness, and Chronic Inflammation

Large population observational studies consistently show reduced WBC, CRP, IL-6, TNF-α, and other inflammatory biomarkers in adults with higher levels of physical activity and fitness, even after adjustment for potential confounders [9–14]. The inverse association between physical activity/fitness and inflammation is related in part to the effect of activity on fat mass [11]. In most studies, however, adjustment for body mass index (BMI) and adiposity attenuates but does not negate the strength of the relationship between inflammatory biomarkers and physical activity/fitness [11,15]. For example, in a study of 1002 community-dwelling adults (age range, 18–85 years), a general linear model (GLM) analysis adjusted CRP means for frequency of physical activity, BMI, and several other lifestyle and demographic factors [15].

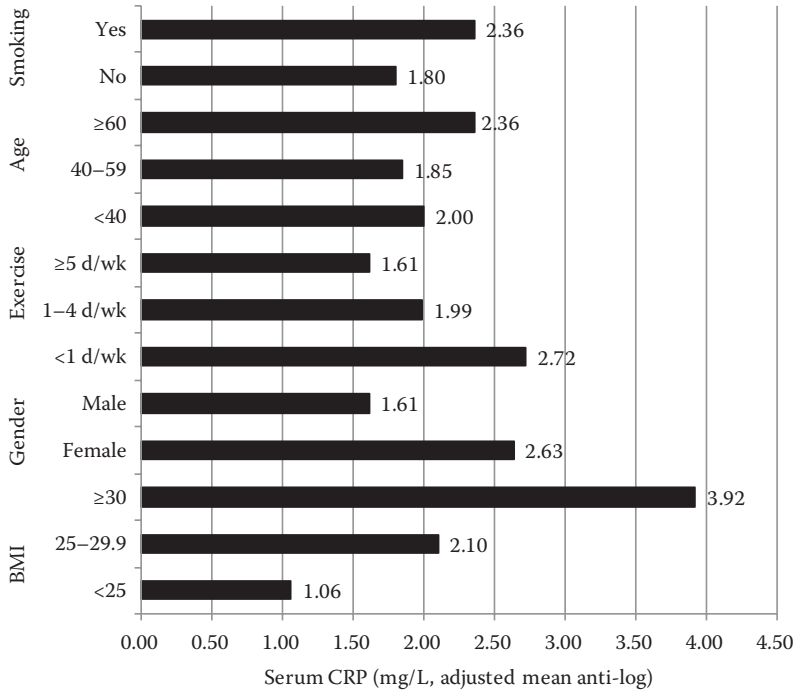

FIGURE 47.1 The relative influence of aerobic exercise frequency and other lifestyle and demographic factors on C-reactive protein. Means are adjusted statistically after weighting for each factor through a general linear model. (From Shanely, R.A. et al., *Scand. Med. Sci. Sports Exerc*., 2011, in press.)

BMI had the strongest effect on CRP followed by gender (higher in females), exercise frequency, age, and smoking status (Figure 47.1).

Randomized, controlled exercise-intervention studies provide equivocal support for the inverse relationship between increased physical activity and reduced systemic inflammation [11,16–22]. One explanation is that in comparison to the large variance evaluated in observational studies, the change in aerobic fitness and activity levels is typically of low magnitude in randomized exercise trials, the duration of training seldom extends beyond 6 months, and the number of subjects is relatively low [17,18,20,21]. Nonetheless, data from both study formats support that in order for reductions in chronic inflammation to be experienced, a large change in a combination of lifestyle factors is needed including weight loss, near-daily moderate-to-vigorous physical activity of 30–60 min duration, avoidance of cigarette smoking, and increased intake of fruits and vegetables [22,23]. For example, if an obese, older individual adds three weekly 30 min walking sessions to the lifestyle, reductions in chronic inflammation are unlikely to be experienced unless the exercise workload is increased in combination with significant weight loss and improved diet quality.

Potential Mechanisms

When successful, exercise training may exert anti-inflammatory influences through a reduction in visceral fat mass and the induction of an acute anti-inflammatory environment with each bout of exercise that over time becomes chronic [24,25]. These effects may be mediated in part through muscle-derived peptides or myokines, but this proposed mechanism needs further testing [25]. Contracting skeletal muscles release myokines (e.g., IL-6, IL-8, IL-15) that may exert both direct and chronic anti-inflammatory effects.

The first identified and most studied myokine is IL-6. During prolonged and intense exercise, IL-6 is produced by muscle fibers and stimulates the appearance in the circulation of other anti-inflammatory cytokines such as IL-1ra and IL-10 [26]. IL-6 also inhibits the production of the proinflammatory cytokine TNF-α and stimulates lipolysis and fat oxidation [26]. With weight loss from energy restriction and exercise, plasma levels of IL-6 fall, skeletal muscle TNF-α decreases, and insulin sensitivity improves [27,28]. Thus IL-6 release from the exercising muscle may help mediate some of the health benefits of exercise including metabolic control of type 2 diabetes [27,28].

Muscle IL-6 release, however, is very low during moderate physical activity. For example, during a 30 min brisk walk on a treadmill, plasma IL-6 concentrations increased from 1.3 to 2.0 pg/mL in female subjects [29]. The increase in IL-6 during brisk walking is probably insufficient to mediate anti-inflammatory and other beneficial health effects, and additional research is needed to determine the relative contribution of myokines compared to other exercise-induced factors. The acute exercise-induced increase in IL-6 after heavy exertion (e.g., typically above 5, 10, and 50 pg/mL following 1, 2 h, and marathon-race running bouts, respectively) may indeed orchestrate anti-inflammatory influences, lipolysis, and improved insulin sensitivity, but this amount of physical activity is beyond levels achievable by most overweight/obese individuals.

A moderate exercise program of near-daily 30 min walking bouts, without diet control, has small influences on visceral fat, even in long-term studies [30]. This is further evidence that the myokine hypothesis does not apply at the activity level attainable by most middle-aged and elderly individuals. Thus moderate physical activity training must be increased to the highest levels acceptable to an individual (e.g., 60 min/day) and combined with weight loss through tight control of energy intake and improved diet quality to achieve reductions in systemic inflammation.

URTI RISK REDUCTION FROM REGULAR MODERATE EXERCISE TRAINING

URTI is the most frequently occurring infectious disease in humans worldwide [31–33]. More than 200 different viruses cause the common cold, and rhinoviruses, and coronaviruses are the culprits 25%–60% of the time. The National Institute of Allergy and Infectious Diseases reports that people in the United States suffer 1 billion colds each year with an incidence of 2–4 for the average adult and 6–10 for children [31]. URTI imposes an estimated $40 billion burden in direct and indirect costs on the U.S. economy [32].

Low- to high-exercise workloads have a unique effect on URTI risk, and can be modeled using a J-curve relationship [34] (Figure 47.2). Regular physical activity improves immune function and lowers URTI risk while sustained and intense exertion has the opposite effect. Marathon race competitions and heavy exercise training regimens increase URTI risk, but relatively few individuals exercise at this level, limiting public health concerns. The second half of this chapter will review the benefits of regular, moderate activity in improving immunosurveillance against pathogens and lowering URTI risk. This information has broad public health significance and appeal, and provides the clinician with an additional inducement to encourage increased physical activity among patients.

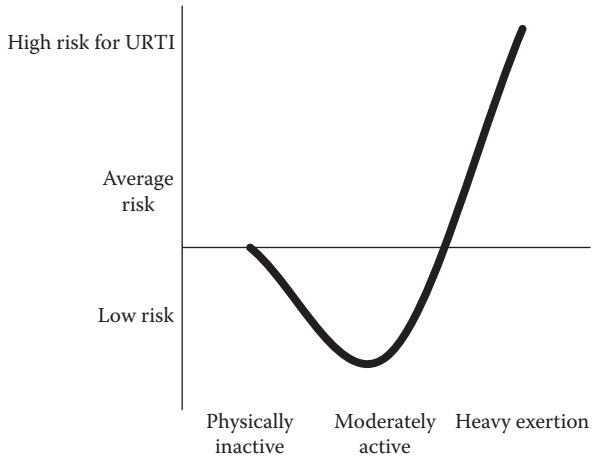

FIGURE 47.2 J-Curve model on the relationship between exercise workload, and URTI risk. Animal and human data support a reduction in URTI risk with moderate activity in contrast to an elevated risk following heavy exertion.

Moderate Physical Activity and URTI Risk

Several lines of evidence support the linkage between moderate physical activity and improved immunity and lowered infection rates: survey, animal, epidemiologic, and randomized training data. Survey data consistently support the common belief among fitness enthusiasts that regular exercise confers resistance against infection. In surveys, 80%–90% of regular exercisers perceive themselves as less vulnerable to viral illnesses compared to sedentary peers (Figure 47.3) [35,36].

Animal studies are difficult to apply to the human condition, but in general, support the finding that moderate exercise lowers morbidity and mortality following pathogen inoculation, especially when compared to prolonged and intense exertion or physical inactivity. Mice infected with the herpes simplex virus, for example, and then exposed to 30 min of moderate exercise experience a lower mortality during a 21 day period compared to higher mortality rates after 2.5 h of exhaustive exercise or rest [37]. Another study with mice showed that 3.5 months of moderate exercise training compared to no exercise prior to induced influenza infection decreased symptom severity and lung viral loads and inflammation [38].

Retrospective and prospective epidemiologic studies have measured URTI incidence in large groups of moderately active and sedentary individuals. Collectively, the epidemiologic studies consistently show reduced URTI rates in physically active or fit individuals. A 1 year epidemiological study of 547 adults showed a 23% reduction in URTI risk in those engaging in regular versus irregular

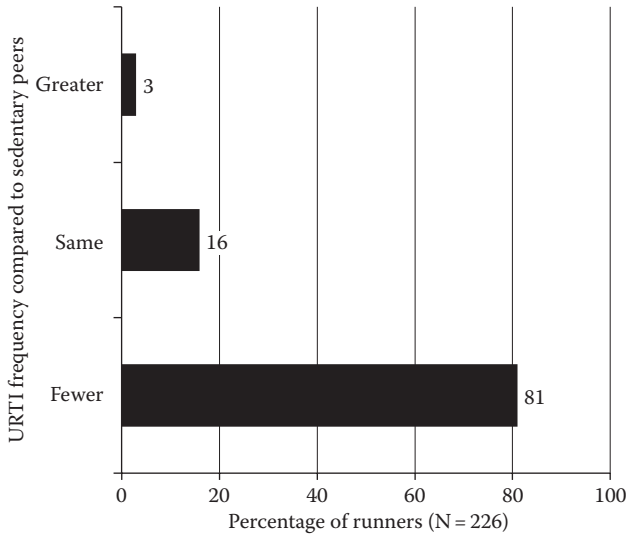

FIGURE 47.3 Survey responses by endurance athletes in response to this question: "Compared to others who do no run or exercise do you feel that you generally have _____ episodes of sickness with the common cold or flu?." (From Nieman, D.C., *Med. Sportiva*, 13, 189, 2009.)

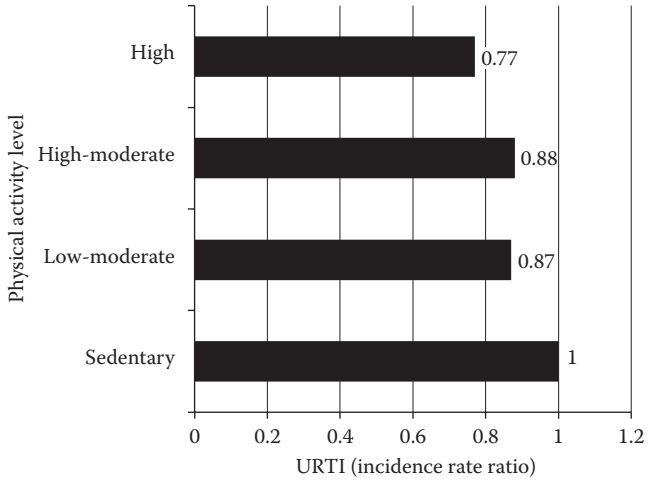

FIGURE 47.4 This 1 year epidemiological study of 547 adults showed a 23% reduction in URTI risk in those engaging in regular versus irregular physical activity. (From Matthews, C.E. et al., *Med. Sci. Sports Exerc.*, 34, 1242, 2002.)

moderate-to-vigorous physical activity (Figure 47.4) [39]. In a group of 145 elderly subjects, URTI symptomatology during a 1 year period was reduced among those engaging in higher compared to lower amounts of moderate physical activity [40]. During a 1 year study of 142 males aged 33–90, the odds of having at least 15 days with URTI was 64% lower among those with higher physical activity patterns [41]. A cohort of 1509 Swedish men and women aged 20–60 were followed for 15 weeks during the winter/spring [42]. Subjects in the upper tertile for physical activity experienced an 18% reduction in URTI risk, but this proportion improved to 42% among those with high perceived mental stress.

A group of 1002 adults (ages 18–85 years, 60% female, 40% male) were followed for 12 weeks (half during the winter, half during the fall) while monitoring URTI symptoms and severity using the Wisconsin Upper Respiratory Symptom Survey [43,44]. Subjects reported frequency of moderate-to-vigorous aerobic activity, and rated their physical fitness level using a 10-point Likert scale. The number of days with URTI was 43% lower in subjects reporting an average of 5 or more days of aerobic exercise (20 min bouts or longer) compared to those who were largely sedentary (≤1 day/week). (Figure 47.5). This relationship occurred after adjustment for important confounders including age, education level, marital status, gender, BMI, and perceived mental stress. The number of days with URTI was 46% lower when comparing subjects in the highest versus lowest tertile for perceived physical fitness, even after adjustment for confounders.

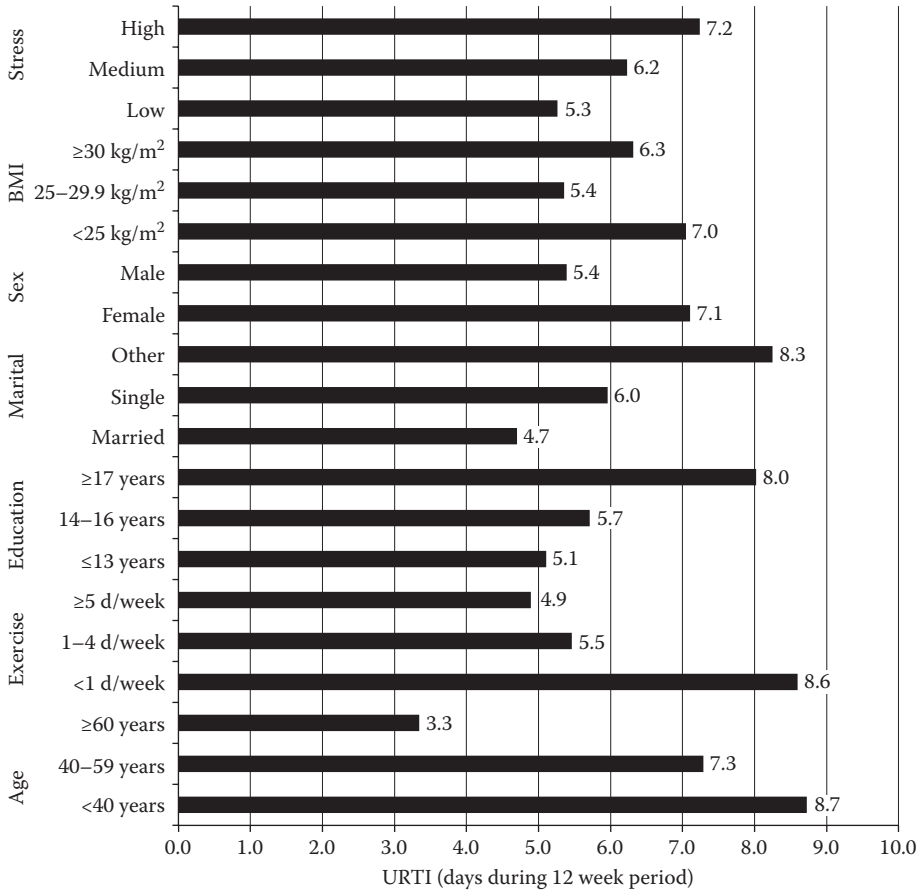

FIGURE 47.5 The number of days with URTI during a 12 week period (winter or fall) in a group of 1002 adults (ages 18–85 years) by exercise frequency and other lifestyle and demographic factors. Means are adjusted statistically after weighting for each factor through a general linear model. (From Nieman, D.C. et al., *Br. J. Sports Med.*, 2011, in press.)

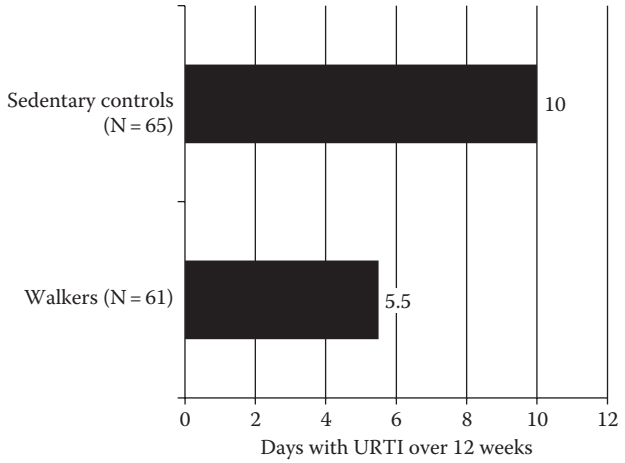

FIGURE 47.6 The number of URTI symptom days was decreased by approximately half through a walking program (5 days/week, 45 min/session, for 15 weeks) by previously sedentary, overweight adult women. (From Nieman, D.C. et al., *Int. J. Sports Med*., 11, 467, 1990; Nieman, D.C. et al., *Med. Sci. Sports Exerc*., 30, 679, 1998.)

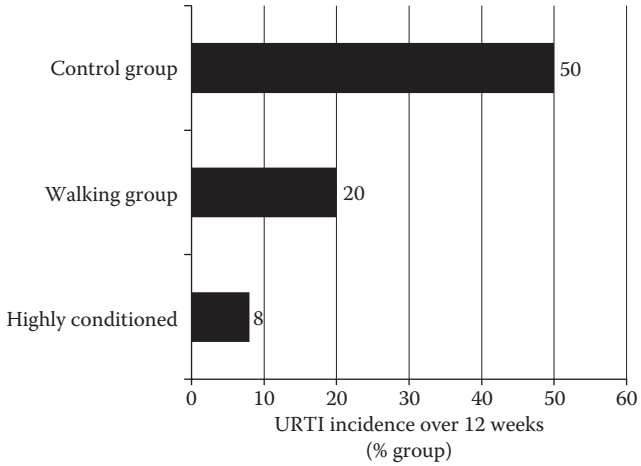

FIGURE 47.7 URTI incidence in three groups of elderly women during 12 weeks: highly conditioned, walkers, and controls. (From Nieman, D.C. et al., *Med. Sci. Sports Exerc*., 25, 823, 1993.) Physically inactive controls had the highest URTI incidence during the fall cold season.

Regular physical activity may lower rates of infection for other types of diseases, but data are limited due to low disease prevalence. For example, women with a high frequency of walking experienced an 18% lower risk of pneumonia compared with women who walked the least [45]. In the same cohort, women who reported running or jogging more than 2 h/week had a reduced pneumonia risk compared with women who spent no time running or jogging [45].

Randomized experimental trials provide important data in support of the viewpoint that moderate physical activity reduces URTI symptomatology. In a randomized, controlled study of 36 women (mean age 35 years), subjects walked briskly for 45 min, 5 days/week, and experienced ½ the days with URTI symptoms (5.1 versus 10.8) during the 15 week period compared to that of the sedentary control group (Figure 47.6) [46].

The effect of exercise training (45 min walking sessions/week at 60%–75% maximum heart rate) and/or moderate energy restriction (1200–1300 kcal/day) on URTI was studied in obese women (N = 91, body mass index 33.1 ± 0.6 kg/m^2) randomized to one of four groups: control, exercise, diet, exercise, and diet [47]. Energy restriction had no significant effect on URTI incidence, and subjects from the two exercise groups were contrasted with subjects from the two nonexercise groups. The number of days with URTI for subjects in the exercise groups was reduced 40% relative to the nonexercise groups (5.6 versus 9.4), similar to the level of nonobese, physically active controls (N = 30, 4.8 days with URTI).

In another study, 30 sedentary elderly women (mean age, 73 years) were assigned to walking or sedentary groups [48,49]. The exercise group walked 30–40 min, 5 days/week, for 12 weeks at 60% heart rate reserve. Incidence of URTI in the walking groups was 21% compared to 50% in the calisthenic control group during the study (September through November) (Figure 47.7).

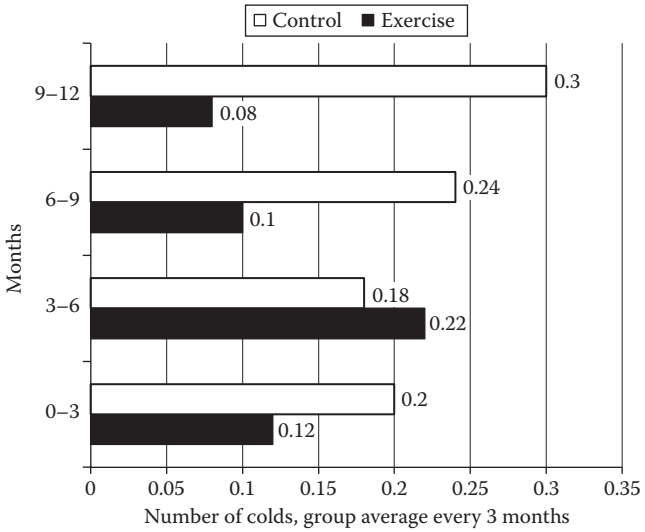

FIGURE 47.8 A 1 year randomized study of 115 overweight, postmenopausal women showed that 166 min/week (~4 days/week) of moderate exercise lowered URTI risk compared to controls (stretching), especially during the last 3 months. (From Chubak, J. et al., *Am. J. Med*., 119, 937, 2006.)

A 1 year randomized study of 115 overweight, postmenopausal women showed that regular moderate exercise (166 min/week, ~4 days/week) lowered URTI risk compared to controls (who engaged in a stretching program) [50]. In the final 3 months of the study, the risk of colds in the control group was more than threefold that of the exercisers (Figure 47.8).

MODERATE PHYSICAL ACTIVITY AND ENHANCED IMMUNOSURVEILLANCE

During moderate exercise several transient changes occur in the immune system [29,51–53]. Moderate exercise increases the recirculation of immunoglobulins, and neutrophils, and

natural killer cells, two cells that play a critical role in innate immune defenses. Animal data indicate that lung macrophages play an important role in mediating the beneficial effects of moderate exercise on lowered susceptibility to infection [54]. Stress hormones, which can suppress immunity, and pro- and anti-inflammatory cytokines, indicative of intense metabolic activity, are not elevated during moderate exercise [29].

Although the immune system returns to preexercise levels within a few hours after the exercise session is over, each session may represent an improvement in immune surveillance that reduces the risk of infection over the long term. Other exercise-immune-related benefits include enhanced antibody-specific responses to vaccinations. For example, several studies indicate that both acute and chronic moderate exercise training improves the body's antibody response to the influenza vaccine [55–58]. In one study, a 45 min moderate exercise bout just before influenza vaccination improved the antibody response [55].

These data provide additional evidence that moderate exercise favorably influences overall immune surveillance against pathogens. Taken together, the data on the relationship between moderate exercise, enhanced immunity, and lowered URTI risk are consistent with guidelines urging the general public to engage in near-daily brisk walking.

CONCLUSIONS

Although methodology varies widely and evidence is still emerging [59], epidemiologic and randomized exercise training studies consistently report a reduction in URTI incidence or risk of 18%–67%. This is the most important finding for the practicing physician that has emerged from exercise immunology studies during the past two decades. Animal and human data indicate that during each exercise bout, transient immune changes take place that over time may improve immunosurveillance against pathogens, thereby reducing URTI risk. The magnitude of reduction in URTI risk with near-daily moderate physical activity exceeds levels reported for most medications and supplements, and bolsters public health guidelines urging individuals to be physically active on a regular basis.

Regular physical activity should be combined with other lifestyle strategies to more effectively reduce URTI risk. These strategies include stress management, regular sleep, avoidance of malnutrition, and proper hygiene [33,60–63]. URTI is caused by multiple and diverse pathogens, making it unlikely that a unifying vaccine will be developed [33]. Thus lifestyle strategies are receiving increased attention by investigators and public health officials, and a comprehensive lifestyle approach is more likely to lower the burden of URTI than a focus on physical activity alone.

The anti-inflammatory effect of near-daily physical activity may play a key role in many health benefits, including reduced CVD, type 2 diabetes, various types of cancer, sarcopenia, and dementia [9–18]. This is an exciting area of scientific endeavor, and additional research is needed to determine how immune perturbations during each exercise bout accumulate over time to produce an anti-inflammatory influence. As with URTI, multiple lifestyle approaches to reducing chronic inflammation should be employed with a focus on weight loss, high volume of physical activity, avoidance of smoking, and improved diet quality.

The influence of exercise training on host defense and indices of immune function have been studied for over four decades. There is strong evidence that exercise training plays a role in altering immunity, but there are a number of unresolved issues. The potential changes in immunity that may be induced by regular exercise or strenuous exercise training will be addressed in this chapter. The objective of this chapter is to identify practical implications of chronic exercise that are applicable to both fitness exercisers and athletes. The influence of chronic exercise on innate and adaptive immunity will be reviewed along with the effect of excessive exercise training on selected immune parameters and resistance to infection. The chapter will further address the influence of moderate exercise training on inflammation, wound healing, and the efficacy of vaccines.

EFFECT OF CHRONIC EXERCISE ON LEUKOCYTE NUMBER AND FUNCTION

Leukocytes are the circulating cells of the immune system and are involved in all stages of mounting an immune response to foreign organisms. Leukocytes are found in the blood and lymphatic system and are derived from bone marrow hematopoietic stem cells. Regular intense exercise does not appear to alter resting peripheral blood leukocyte number [1–3]. However, regular moderate physical activity can alter phenotype and influence the function of specific subsets of leukocytes. These changes potentially mediate the systemic anti-inflammatory effects of chronic exercise as evidenced by lower levels of circulating markers of inflammation (IL-6 and CRP). In this section we will summarize current literature to show how regular exercise can elicit changes in number, function, and phenotype of the major leukocyte subsets.

EFFECT OF CHRONIC EXERCISE ON INNATE IMMUNITY

Monocytes and Tissue Macrophage

Monocytes are circulating cells of the innate immune system. They are immature precursor cells for tissue macrophage and dendritic cells. Monocytes can respond to infection or tissue damage by migrating to the site of insult and differentiating into tissue-specific macrophage or dendritic cells (e.g., Kupffer cells in liver, macrophage in adipose tissue). These resident cells have multiple roles, including phagocytosis and responding to inflammatory signals (both exogenous and endogenous) via germ line–encoded pattern recognition receptors (e.g., toll-like receptors). Antigen presentation and

subsequent cytokine release help to coordinate the responses of the adaptive immune system. Chronic low-grade activation of the monocyte/macrophage lineage is thought to contribute to the pathophysiology of obesity, insulin resistance [4], and development of atherosclerosis [5].

Several researchers have highlighted the role of chronic exercise-induced alterations in monocyte phenotype/inflammatory response as a possible mechanism underlying the anti-inflammatory effects of exercise. Cross-sectional and longitudinal training studies show that chronic exercise can reduce *ex vivo* mitogen-stimulated whole blood production of inflammatory cytokines [6,7]. Further investigation suggested that the degree to which toll-like receptor (TLR) 4 is expressed on circulating monocytes mediates mitogen-stimulated cytokine production [8]. This finding may be significant as monocyte/macrophage TLR4 activation is implicated in the pathophysiology of atherosclerotic plaque development and peripheral tissue insulin resistance. Exercise training per se has also decreased monocyte TLR4 expression [8–10]. Taken together, this emerging evidence implies that regular exercise can reduce expression and reactivity of the innate immune receptor TLR4, an important factor in monocyte/macrophage activation.

Circulating monocytes are phenotypically classified based on cell-surface expression of CD14 and CD16. CD14++CD16− cells are called classical monocytes and make up ~90% of the circulating monocyte population [11]. CD14+CD16+ monocytes are called inflammatory monocytes and are a subpopulation (~10% of total monocytes) with a proclivity for production of inflammatory cytokines. For example, when stimulated cultures are depleted of CD14+CD16+ monocytes, roughly 80% of inflammatory cytokine production is lost [12]. Researchers recently reported that the circulating inflammatory monocyte percentage was elevated in patients with subclinical atherosclerosis and obesity [13]. Compared with classical monocytes, inflammatory monocytes adhere more robustly to activated endothelial cells [14] and may be precursors to CD16+ macrophages found distributed throughout atherosclerotic lesions and adipose tissue [15,16]. Based on these studies, researchers believe that inflammatory monocytes play a role in the pathogenesis of several diseases linked to inflammation. Recent data indicate that aerobic/resistance training program can reduce the inflammatory monocyte population [17,18], thus providing another potential mechanism by which exercise reduces inflammation.

More recently, researchers have begun to examine the effect of exercise training on adipose tissue macrophage recruitment and activation. Activation of adipose tissue macrophages is associated with obesity and peripheral tissue insulin resistance [19]. Production of TNF-α by activated adipose tissue macrophages is believed to be a major contributor to peripheral tissue insulin resistance in obesity and type 2 diabetes [20]. Bruun et al. reported that a 15 week hypocaloric diet and exercise intervention reduced macrophage-specific markers and inflammatory cytokines in adipose tissue [21]. This effect was concomitant with improved insulin sensitivity. However, a 12 week exercise only and exercise with diet intervention in 79 obese subjects did not elicit changes in adipose tissue markers of inflammation [22]. Others have also found no effect of exercise training on markers of adipose tissue inflammation [23]. Currently, these are the only human studies to examine the effects of exercise on adipose tissue macrophage activation and recruitment and it is clear that further studies are needed.

There is strong evidence in support of the concept that regular exercise can reduce monocyte/macrophage inflammation, possibly through modulation of TLR4 expression and/or altering the phenotype of circulating monocyte subpopulations. However, more studies need to be conducted to clarify the effect of regular exercise on adipose tissue macrophage recruitment and activation. This body of work is clinically important as activation of the monocyte/macrophage lineage is implicated in the pathophysiology of diseases such as diabetes and cardiovascular disease (CVD).

Natural Killer Cells

Natural killer cells are cytotoxic lymphocytes and are a major constituent of the innate immune system. They protect against certain tumors and virally infected cells by releasing granules containing proteases and perforins that induce apoptosis in the target cell. A number of cross-sectional and training intervention studies have been conducted in which the effects of chronic exercise on basal NK-cell number or activity were examined. The results of these studies are varied, with exercise reported to suppress [24], increase [25–28], or not change the cytotoxic activity or number of natural killers cell [6,29–32]. For example, Yan et al. reported that the concentration of NK-cells (CD16+CD56+) significantly increased in elderly subjects who exercised regularly, compared to that of the age-matched control subjects [33]. On the other hand, a baseline comparison revealed that endurance-trained elderly women had greater NK-cell activity compared to sedentary elderly women. However, 12 weeks of moderate aerobic exercise did not alter NK-cell activity or number in these previously sedentary women [3]. It should be noted that a number of these studies were conducted on elderly subjects [6,26,32] and cancer survivors [27,28]. Given the development of immunosenescence that occurs with aging and the confounding effect this may have, data generated from elderly cohorts should be interpreted with caution. Furthermore, a paucity of data exists on the effects of chronic exercise on basal NK function/activity in younger and middle-aged adults. In summary, despite a good deal of research examining the effect of exercise training on NK-cells, it appears that a consensus has not been reached.

Neutrophils

Neutrophils are polymorphonuclear cells and are the most abundant leukocyte subtype. Neutrophils are the first responders of the innate immune system and migrate to the site of infection or injury within minutes. In athletes,

resting circulating neutrophil number is similar to sedentary individuals [2,34]. However, there was a recent report on the effects of moderate exercise on neutrophil number. An exercise training program lowered neutrophil number in overweight women with multiple risk factors for CVD [35]. Furthermore, the decrease in neutrophil number was correlated with improvements in insulin sensitivity. It may be that in the context of chronic inflammation, such as is evident with CVD, exercise training can impact neutrophil number. In athletes however, it appears that regular intense exercise may reduce neutrophil function [3,36,37].

EFFECT OF CHRONIC EXERCISE ON ADAPTIVE IMMUNITY

T- and B-Lymphocytes

T- and B-cells are the primary circulating cells of the adaptive immune system. T-cells are involved in cell-mediated immunity and B-cells are primarily responsible for producing antigen-specific antibodies (humoral immunity). Immunosenescence refers to the natural decline in immune function that occurs with aging and is thought to contribute to age-associated morbidity [38]. Hallmarks of immunosenescence include, among others, a reduced population of antibody-producing B-cells and T-cell functional dysregulation brought about primarily by thymic involution [39]. Regular exercise may also impact number, function, and *ex vivo* proliferative response of T-cell populations in elderly subjects and, as such, may be an important modality for maintaining immune health as one grows older. Cross-sectional studies in which elderly runners were compared to sedentary individuals showed that *ex vivo* lymphocyte proliferative response to PHA was significantly higher in elderly runners [40,41]. Koizumi et al. reported that exercise training increased the absolute numbers of T-cells and T-helper cells in elderly humans (2003). T-cell proliferation in response to mitogen increased following a 6 month aerobic exercise intervention [32]. However, others have shown that *ex vivo* lymphocyte responses are not affected by regular exercise [42]. *Ex vivo* T-cell proliferation did not change after 12 weeks of exercise training [3]. Resistance training for 10–12 weeks did not alter proliferative response to mitogens [30,43]. Finally, a 12-month moderate resistance exercise program for elderly women did not alter circulating numbers of lymphocytes [31]. Currently, there is a lack of consensus on the effects of regular exercise on *ex vivo* lymphocyte proliferative response.

A number of studies have examined the effects of regular exercise on the immune response to antigens *in vivo* in older adults. The assays of lymphocyte response utilized in these studies may have greater physiological relevance than studies using *ex vivo* mitogen-induced stimulation of lymphocytes. In fact, the *in vivo* measure of immune response employed can be compared to a live challenge with a pathogen. Kohut et al. showed that regularly exercising older adults had a greater titer for anti-influenza IgG and IgM following immunization when compared to sedentary controls [44]. The response to keyhole-limpet hemocyanin (KLH) antigen was determined in cohorts of young and old, active and inactive individuals [45]. Anti-KLH antibodies (IgM, IgG, IgG1) were all elevated in the older active adults compared with the sedentary controls following intramuscular injection of KLH. In these studies, measures of B-cell function and T-cell function were enhanced in the older adults. Taken together, these studies suggest that immune response to antigen challenge may be improved with regular exercise in older adults. For the fitness enthusiast, a successful exercise program will result in improved physical performance, such as endurance or strength, and perhaps a desirable change in weight or body composition. However, it is clear that in addition to changes at the whole body level, there are also benefits at the cellular level. Current research suggests that regular exercise can improve immune function at the cellular level, resulting in improved response to immunization and lower levels of chronic inflammation. These potential benefits of exercise are vital to maintaining good health.

Excessive Training and Immunity

Excessive training can result in a wide range of negative clinical signs and symptoms. This symptom complex is quite often referred to as overtraining syndrome, but the reader will also frequently see "overtraining" used as a synonym. Clinical symptoms of overtraining syndrome are many and include lethargy, fatigue, mood disturbances, underperformance, poor healing of cuts and scratches, and immune suppression. Athletes who train intensely are believed to become ill more frequently and there are several anecdotal examples of elite athletes forced to leave high-level competition due to a mysterious illness or infection.

As noted previously, resting immunity is not substantially different between athletes and healthy, sedentary individuals, but it appears that intensive training could negatively affect several immune measures. Changes in NK-cell activity and T-cell function have been observed after intensified training programs, but it is unclear whether the changes in the immune system induced by hard training are to blame for a higher incidence of infection in athletes [32]. Nevertheless, the collective toll of excessive training on the immune system would appear to render athletes more susceptible to infection.

The immune variable that responds most consistently to repeated, hard exercise is the mucosal secretion or secretion rate of immunoglobulin A (IgA), considered a first line of defense against infection. IgA has also been more strongly and consistently linked to infection risk in athletes than other measurable aspects of immunity [46].

Th1/Th2 Balance

CD4+ T-helper cells can be divided into two distinct subpopulations, type 1 (Th1) and type 2 (Th2). Activated Th1 cells are generally considered proinflammatory, producing TNF-α and INFγ, whereas activated Th2 cells are considered antiinflammatory and produce IL-4, IL-5, and IL-10. The ratio of

Th1/Th2 cytokines is often used as an index of the inflammatory signaling milieu. The Th1/Th2 distribution has been consistently shown to be influenced by intensive training, with a shift toward Th2 dominance [47]. A pronounced shift in cytokine production typical of the Th2 antiinflammatory milieu likely renders the vigorous exerciser more susceptible to infection [46,48]. However, moderate training appears to induce a positive, subtle shift toward a Th2 cytokine profile, balancing the Th1/Th2 response and inducing the antiinflammatory influences of regular exercise [48].

A shift toward Th2 dominance is frequently found in elderly subjects, but Th1 dominance may be regained after 6 months of moderate training [49]. Thus, while it appears that both moderate and intensive exercise can alter Th1/Th2 balance, there appears to be an optimal balance that may be both age and training status specific. Intense training, tilting the balance too far in favor of Th2, is associated with a reduction in cell-mediated immunity and immunosuppression.

An important part of the Th1/Th2 ratio that has not been well studied in an exercise or intensified training context is the T regulatory cells or T regs (CC4+CD25+). T regs play an important role in suppressing the activity of other immune cells and maintaining discrimination between self and nonself antigens during an immune response, thereby preventing autoimmune diseases. The only available exercise training studies examining T reg function were conducted with a Tai Chi intervention. Yeh et al. found evidence of increased T reg function in both healthy middle-aged adults [50] and subjects with type 2 diabetes [51] after 12 weeks of Tai Chi training. It is not known how T regs respond to a period of intensified training and there is little evidence to show how T regs respond to a period of moderate training.

Toll-Like Receptors

Hard bouts of exercise have also been linked to downregulation of TLR4 cell-surface expression [52]. Oliveira and Gleeson found that cycling for 90 min (75% VO_{2peak}) resulted in a transient reduction in TLR4 that was sustained for 1–4 h after exercise [52]. TLRs help orchestrate the innate immune response to a wide range of pathogens, which led the authors to conclude that postexercise TLR4 depression could contribute to postexercise immune depression. This premise, however, was based on a single bout of exercise and there is a lack of research examining the response of sustained, intensified training on TLR downregulation. Therefore, while it is possible that regular bouts of hard exercise might transiently reduce TLR expression increasing susceptibility to infection, moderate intensity, long-term training has been shown to reduce TLR4 expression in hyper-inflammatory groups (sedentary, overweight/obese, and elderly). Reduced TLR4 expression is generally viewed as a positive adaptation due to its potential to influence systemic inflammation. Thus, there is likely a differential response to repeated bouts of intense exercise where the goal is improved performance, which could lead to immune depression, and long-term moderate exercise programs, in which the goal is to improve fitness and the outcome improve overall health.

Excessive Training: URS or URTI?

Athletes who train hard are frequently reported to have an increased incidence of upper-respiratory symptoms (URS) related to upper-respiratory tract infection (URTI) [53]. Elite athletes are believed to have a higher incidence of URTI than fitness exercisers or sedentary individuals. These findings, along with the fact that several indices of immune function are suppressed by heavy exercise, led to the assertion that heavy exercise lowers immune defenses and increases URTI risk. Two important factors remain unclear in this regard. First, whether excessive training suppresses immune function to the extent possible to result in an increased susceptibility to infection has not been determined [32]. There is a general consensus that several immune parameters are depressed following prolonged or severe exercise, most notably and consistently mucosal immunoglobulin A (IgA), but it is not known whether the immune depression is causative of an increased incidence of URTI. Second, it is not clear whether the URTIs reported by athletes in the majority of studies are pathogen based or a result of local airway irritation or inflammation [54]. Problematically, most of the studies in which the incidence of URTI has been assessed in conjunction with heavy training largely relied on self-report. Researchers from a small number of studies have called that practice into question, largely due to a lack of the presence of an infectious pathogen in sputum of athletes reporting symptoms of URTI [54]. However, most researchers also acknowledge that the ability to detect these pathogens in sputum is far from an exact science. It is interesting to note that the daily use of an antiinflammatory throat spray, 1 week before and 2 weeks after a half-marathon, did not influence the number of reported URTI episodes in a relatively small group of runners (n = 25 treatment; n = 20 controls) but may have influenced the severity scores (trend) [55]. Thus, while evidence is mounting that regular, modest exercise reduces the risk of URTI [3] and prolonged, intense, or excessive exercise training increases the risk of URTI [53], there is considerable controversy in this area which prevents us from making concrete conclusions about the links between hard exercise and illness.

No increase in the rate of infectious episodes was found in marathon runners when runners with a prerace infection were removed from the cohort [56], casting further doubt on the relationship between hard exercise and URTI. Thus, while there are conflicting data on the relationship between infection risk and hard training, the conflict is difficult to rectify when considering feasibility and research design issues. Logistically, the excessive time and cost make it difficult to include quantitative cellular immune measures in large cohort studies of infection incidence and prevalence. There are some larger scale studies in which salivary IgA has been measured and negatively correlated with URTI

incidence [29]. Gleeson et al. [46] monitored 80 athletes for several months, with training and illness logs recorded and blood and saliva samples obtained. These authors identified a subgroup of "illness-prone" subjects who had higher training loads, higher levels of multi-antigen-stimulated anti-inflammatory cytokines—illustrating a Th2-dominant response—and lower salivary sIgA secretion and flow rates. In addition, the highest quartile of IL-10 producers had higher training loads, higher production of inflammatory and anti-inflammatory cytokines, lower IgA, and higher URTI incidence than the lowest quartile. The authors suggested that IL-10 might be a useful predictor of infection risk in physically active individuals [46]. There is clearly an increase in upper-respiratory symptoms associated with hard training. Further research is required to document what proportion of these illnesses are pathogen based or linked to airway inflammation/irritation.

Glutamine

Glutamine showed promise as a marker of overtraining syndrome and a potential cause of immune suppression associated with hard training [57]. Glutamine is a preferred substrate of rapidly dividing cells and is favored by immune cells. Glutamine levels are believed to be challenged when gluconeogenesis-related liver uptake is increased during prolonged exercise [58]. Kargotich et al. [59] found that plasma glutamine levels were lowered by high-intensity exercise in swimmers and glutamine was proposed as a marker of overtraining syndrome. Others have found less consistent results when glutamine levels were monitored along with normal training or intense training, leading to overtraining and reported that glutamine levels were not linked with URTI [2], casting doubt on the premise that glutamine provides a sensitive marker of overtraining syndrome.

Branched chain amino acid supplements could help sustain plasma glutamine levels during hard training and reduce potential immunosuppressant effects, as suggested in studies from Bassit et al. [60]. These researchers provided BCAA supplements or placebo to elite male triathletes (Olympic distance) and/or marathoners for 30 days before and 1 week after competition. There was a substantial reduction in plasma glutamine levels postrace in the placebo groups, but glutamine did not decline in BCAA group. Lowered glutamine occurred concomitant with impaired lymphocyte and monocyte function, suggesting that maintaining glutamine levels is linked to postrace susceptibility to infection [61].

Prostaglandin E2

Prostaglandin (PG) E2 is produced from arachidonic acid through the cyclooxygenase pathway by macrophages and dendritic cells and has inhibitory effects on immune function. Specifically, PGE2 can polarize dendritic cells, resulting in a suppression of Th1 and activation of Th2 subpopulations [62]. The influence of exercise training on PGE2 has not been closely studied; however, damaging exercise is linked to elevated PGE2 levels, which in turn are likely related to the pain associated with delayed-onset muscle soreness [63].

An intriguing hypothesis to explain the immune suppression associated with overtraining syndrome was proffered by Smith [47]. Athletes who are training intensely undergo repeated tissue trauma, which results in the production of stress hormones (catecholamines and cortisol) and inflammatory cytokines (e.g., PGE2). These endocrine shifts promote Th2 dominance and suppress cell-mediated immunity [47]. Thus, the repeated tissue trauma is deemed responsible for the Th2 dominance, which Smith claims is not immunosuppression but rather aggressive activation of Th2 cells and a loss of cell-mediated immunity.

PGE2 has been clearly shown to inhibit interferon-gamma and promote Th2 dominance [64]. Cortisol, which may also be elevated in overtrained athletes, has also been shown to favor Th2 balance [65]. There is some support in the literature for Smith's hypothesis [46], but there are few studies in which PGE2 has been studied in an overtraining or moderate exercise training context in healthy humans.

Production of the immune-suppressing PGE2 from monocytes is known to be higher in aged humans and animals [66], which helps explain the Th2 dominance frequently observed in older humans. High levels of PGE2 might also help explain the immunosenescence observed in older subjects [66], but there are no studies in which the effect of exercise training on PGE2 production has been examined in older humans.

MODERATE TRAINING AND IMMUNITY

Exercise and Inflammation

The role that inflammation plays in the development and exacerbation of chronic disease has grown substantially in importance over the last decade. Inflammation or inflammatory biomarkers have been clearly linked to CVD [67], type 2 diabetes [68], osteoporosis [69], and several other chronic diseases not previously believed to have an inflammatory etiology. For example, CVD was long believed to be a disease of deranged lipid storage; however it is now clear that inflammation plays a major role in the pathophysiology of atherosclerosis and CVD. In fact, inflammation is known to contribute to every stage of vessel plaque development [70], up to and including the potentially lethal plaque rupture [25].

Exercise is known to provide substantial benefits for individuals with chronic diseases, with a strong role in prevention of disease and amelioration of symptoms in those with disease. There is growing evidence that exercise has anti-inflammatory effects, but it is not clearly known to what extent the anti-inflammatory effects of exercise prevent or help ameliorate the symptoms of chronic disease. Early evidence suggests that this effect may be substantial.

Observational or population studies provide consistent evidence of an anti-inflammatory benefit of exercise. That is to say, inflammatory biomarkers are significantly lower

in segments of the population with moderate to high levels of physical activity [71]. Not surprisingly, intervention studies provide less consistent support of an anti-inflammatory effect of exercise. Small subject numbers, different exercise modes and intensities, supervised versus unsupervised exercise, and different choice of biomarkers all likely contribute to these inconsistencies. Nevertheless, there is a fairly strong intervention literature to support the observation that exercise training has anti-inflammatory effects in serum or circulating cells [10,17], muscle [72,73], and to a lesser extent, adipose tissue [21,22].

There is some support for a required intensity threshold, such that lower doses of exercise or home-based exercise studies may not elicit a significant anti-inflammatory effect. In contrast, Butcher et al. [74] showed an anti-inflammatory action via PPAR gamma when subjects increased their pedometer counts to above 10,000 steps 3 days/week, suggesting that regularly performed, low-intensity exercise may be sufficient to exert an anti-inflammatory action.

It seems reasonably clear that increasing physical activity level or engaging in an exercise training regimen can exert anti-inflammatory effects. An issue that remains unresolved is whether exercise training can exert an anti-inflammatory effect in the absence of changes in body fat [22,75]. The literature in this area is mixed, but there are several examples of exercise providing an independent anti-inflammatory effect. In a recent review by Beavers, Brinkley, and Nicklas [71] (2010), the authors identified 19 studies in which self-reported physical activity level was linked to biomarkers of inflammation, and an additional nine studies during which the fitness level was measured. These authors concluded that accounting for obesity "… attenuated, but did not negate, the strength of the relationship between inflammatory biomarkers and physical activity." There are few studies in which an exercise intervention with and without fat losses have been compared. Christiansen et al. [22] recently reported that both diet and diet + exercise reduced blood and tissue markers of inflammation, but exercise training alone did not exert significant anti-inflammatory effects.

If exercise training can exert anti-inflammatory effects independent of reductions in total body adiposity, we speculate that it could be due to small but significant reductions in visceral fat. These changes in visceral fat with exercise training, at a level that does not significantly alter total body fat [76], could be responsible for exercise's ability to exert anti-inflammatory effects. However, there are a myriad of additional potential mechanisms for the anti-inflammatory effect of exercise that remain to be tested.

Inflammatory biomarkers and inflammation have been linked to the risk of several chronic diseases, the risk of physical frailty, and linked to the risk of dementia in older adults [77]. A practical example is the link between inflammation and type 2 diabetes. High levels of inflammation are linked to peripheral tissue insulin resistance, impaired insulin receptor function, and severity of diabetic complications. Exercise training has been shown to reduce NFKB expression and TLR4 expression in type 2 diabetics. TLR4 activation has also been shown to mimic several features of the diabetic state, but regular exercise reduces nuclear factor kappaB (NFκB) and TLR4 expression in diabetic subjects [78,79]. Thus, it appears that the ability of exercise to ameliorate the symptoms of chronic disease may be linked, in part, to the anti-inflammatory action.

In summary, moderate exercise has anti-inflammatory effects. It is possible that there is an intensity threshold, but evidence in support of low-intensity exercise exerting anti-inflammatory effects suggests the need for further study. It appears that exercise can exert anti-inflammatory effects in the absence of significant changes in body fat, but the lack of controlled studies in which exercise and diet have been studied alone and in combination preclude definitive conclusions. Exercise is known to exert anti-inflammatory effects in persons with type 2 diabetes and a concomitant improvement in diabetic state and amelioration of symptoms without significant body fat changes. Thus, while some mechanisms remain to be determined, the anti-inflammatory effect of exercise has important health implications.

Wound Healing

Aging and several chronic conditions, such as diabetes, are known to slow the rate at which wounds heal. Bed sores are fairly common in older, institutionalized patients and are difficult and expensive to treat. Thus, it is important to examine potential low-cost interventions such as diet and exercise on wound healing. The nutrition literature is fairly strong and the positive effects of improved nutrition—especially in cases of malnutrition—on wound healing are well documented. The influence of exercise training or physical activity levels on wound healing have been studied in a relatively small number of investigations [80,81], but the limited, available information looks promising. As such, the inability of aging macrophages to produce angiogenic proteins could be modified by exercise training, and the anti-inflammatory effect of exercise training could also play a role in enhanced wound healing. Keylock et al. [81] showed significantly improved wound healing in older, exercise-trained mice; the trained mice also had lower TNF-α and MCP-1 levels in the wound. Emery et al. [80] divided 28 older adults into an exercise and nonexercise group and found a significantly improved healing rate of an experimental wound in the exercised group, compared with the nonexercised group. Although this research was limited by a fairly small number of subjects, the exercise effect in Emery's study was substantial, with 55% of the subjects in the exercised group having complete healing at day four compared with 0% on the nonexercised group. More work is needed to determine if simple, cost-effective interventions such as exercise training can alter the rate at which wounds heal. However, the paucity of literature on the topic prevents us from

making solid conclusions regarding practical strategies for clinicians or patients.

Exercise and Efficacy of Vaccines

Aging is associated with a decline in immune function [82], which is often characterized by a decreased ability of the adaptive immune system to respond to novel antigens [83] and can also result in low-grade chronic inflammation through activation of the innate immune system [84]. Aging-related immunosenescence contributes to the increased incidence and severity of infectious disease among elderly adults. Older adults experience a greater mortality rate from influenza infection and generally exhibit reduced vaccine efficiency. Influenza vaccine efficacy for older adults may be as low as 56% [85], compared to 68%–88% in younger adults [86,87].

Recently, exercise has been shown to improve immunocompetence among older adults who have been administered an influenza vaccine. Several cross-sectional studies in which physically active elderly subjects were compared to sedentary controls, have shown a greater influenza vaccine response [40,44,81]. Endurance-trained older adults exhibit greater T-cell response and production of cytokines responsible for mediating viral immunity including IL-2 and IFNγ, compared to sedentary controls [40]. A cross-sectional comparison of elderly physically active, moderately active, and sedentary groups showed that physical activity was associated with greater response to influenza immunization. The older physically active group developed greater flu-specific IgG and IgM titers 2 weeks postimmunization, compared to moderate activity and sedentary groups [44]. Peripheral blood mononuclear cell proliferation in vitro was also lower in the sedentary group. Keylock et al. demonstrated that physically active highly fit elderly individuals have higher antibody responses to fluzone vaccine and a Th2 skewing of the antibody response to tetanus toxoid when compared to sedentary low-fit older adults [81]. Taken together these studies suggest that lifestyle factors, including regular exercise may influence immune response to influenza immunization.

A number of longitudinal studies have also been conducted to examine the role of exercise training per se on influenza vaccine response. Kohut et al. reported that a 10 month exercise intervention resulted in a greater increase in influenza-specific antibody titer and IFN-γ production following flu vaccine [88]. These researchers also identified psychosocial factors such as depression and sense of coherence as potential mediators of response to influenza vaccine. In a larger trial 144 sedentary older adults were randomized to either a 10 month aerobic training (n = 74) or a flexibility and balance program (n = 70) [32]. The intervention resulted in a significant increase in seroprotection, determined as a hemagglutination inhibition (HI) titer of >40, 24 weeks after vaccination (30%–100%). This is significant as it suggests that an enhanced vaccine response following exercise training can be maintained over a period greater than the length of a typical flu season. However, and possibly more significantly, there was no difference in the incidence of URTI between the two groups, although the aerobic exercise group exhibited reduced overall illness severity and less sleep disturbance. To date the effects of exercise on vaccine response have not been reported to influence the incidence of URTI.

Several research groups have also examined the effects of an acute bout of exercise on influenza vaccine response. A single bout of eccentric exercise was shown to enhance INFγ response in men, but not in women [89]. Interestingly, antibody titers in women were enhanced by eccentric exercise, but not in men. In a follow-up study, it was found that the intensity at which an acute bout of eccentric exercise is conducted does not affect antibody response to influenza vaccines [90]. However, the authors found that exercise response was greatest with the low-immunogenicity antigen of the trivalent vaccine.

The timing of an eccentric bout of exercise relative to vaccination was also investigated to examine whether it affected the efficacy of the intervention. It was found that an acute bout of exercise immediately 6 or 48 h prior to administration of a standard trivalent influenza vaccine had no effect on antigen-specific serum antibody titers at 28 days postvaccination compared to control [91]. Cell-mediated immunity (in vitro stimulation of IFN production by blood with whole vaccine) was not different between groups. Campbell et al. suggested that exercise-induced immune enhancement was only observed when the control group had relatively poor responses [91].

The mechanisms responsible for mediating the effects of exercise on vaccine efficacy are not fully understood. However, a number of studies have shed some light on potential mediators of improvement. Immunosenescence in aging is associated with an elevation in the ratio of memory T-cells to naive T-cells, potentially reducing the ability of the adaptive immune system to respond to novel antigen. Exercise training has been previously shown to reduce the memory-naïve T-cell ratio [32]. In a mouse study, voluntary running enhanced OVA-specific CD4+ T-cell cytokine production and proliferation in all lymphoid organs [32]. Suzuki et al. found that voluntary wheel running can increase the rate of production and half-life of IgG when immunized against tetanus toxoid [92]. These studies suggest that exercise can prolong antibody response, potentially by restoring the naive T-cell level and subsequent ability to respond to novel antigen.

While most studies have concentrated on the effects of exercise on influenza vaccine, some suggest that being physically active may improve autoantibody response to HIV antigens. The sera of well-trained athletic individuals showed high reactivity with peptide NTM1 [93]. Autoantibody response to this antigen has been previously shown to contribute to control of HIV disease.

SUMMARY

It is clear that regular, moderate, or extreme exercise has the potential to alter indices of immune function. While it appears that regular exercise may offer some protection against URTI, provide anti-inflammatory actions, and enhance the

response to vaccine, many unanswered questions remain. For example, excessive training (overtraining) has been linked to increased risk of URTI, but researchers have questioned the reliability of both self-report of URTI and the direct method to detect pathogens in sputum.

The ability of exercise to improve the course of chronic disease via anti-inflammatory and other immune changes is an exciting avenue for researchers. These studies will help to close the gap between the myriad benefits of exercise training and the available mechanisms to explain the benefits. Despite the gaps in our knowledge, it is clear that athletes can train effectively without excessive illness and that fitness exercisers adapt in primarily positive immunological fashion to regular, moderate exercise.

INTRODUCTION

Although advances in the treatment of HIV and AIDS have reduced the number of AIDS-related cases and deaths worldwide, new cases of reported HIV infections have remained relatively stable, resulting in a continued increase in overall prevalence. Approximately 40,000 new infections of HIV are reported every year in the United States alone [1]. Since the discovery of antiretroviral therapy (ART) medications there have also been drastic changes in the pathogenesis of HIV disease and symptomatology of infection. People living with HIV/AIDS (PLWHA) no longer exhibit high rates of muscle wasting or AIDS-related opportunistic infections [2]. PLWHA have a variety of psychological and physiological symptoms associated with the virus itself, the related medications, or a combination of both. Due to the nature of concurrent symptoms being experienced at frequent rates, the general well-being and overall quality of life are often reduced [3,4]. Further, the frequency of reported symptoms is associated with increased disease progression, decreased functional capacity, reduced adherence to pharmacological treatment, self-medication, and increased psychological disturbances such as anxiety and depression [5–10]. Recent data indicate that the primary cause of death among PLWHA are chronic diseases generally associated with aging such as cardiovascular disease (CVD) and kidney failure, among others [11].

The use of exercise training to reduce the risk of chronic disease is supported within the literature and could potentially have similar health benefits among HIV-infected persons. The benefits of aerobic and resistance exercise have been established among general populations and various clinical groups from longitudinal investigations such as the Aerobics Center Longitudinal Study (ACLS) [12–14] and the Framingham Heart study (among others) [15–17]. Although shorter in duration, a number of studies indicate that PLWHA can obtain similar benefits within 6 weeks following a prescribed physical activity routine [18–21].

VIROLOGY AND INFECTION

Primary HIV Infection

The stage known as primary HIV infection (PHI) is best defined as the time between acute viral transmission lasting anywhere from 2 to 6 weeks until the onset of antibody production [22]. Current evidence indicates a massive CD4+ cell depletion occurring at mucosal sites within 2–3 days following viral transmission. Using polymerase chain reaction (PCR) techniques, Piatak and colleagues indicated that viral

reproduction was capable of reaching 10^6 or 10^7 viral particles/mL of plasma within the first 2 weeks of transmission [23,24]. At the onset of viral infection, symptoms generally appear anywhere from a few days to a couple of weeks. The majority of persons newly infected (70%) experience mild forms of symptoms generally associated with common colds, the flu, or stomach viruses. Due to these initial symptoms being mild in nature and the fact the PHI is short in duration, the initial infection often goes unnoticed until more severe symptoms appear, causing the person to seek medical attention. It is believed that the severity of these initial symptoms and how the immune system reacts is an indication for disease progression.

Asymptomatic (Active Latency)

Following PHI there is a sharp increase in plasma viral load as the virion is being disseminated throughout the entire body and spreading the infection to nearby peripheral and distal sites. Generally within 2–4 weeks, the sudden peak in viral load begins to regress, which is believed to be the result of the primary immune response involving cell-mediated immunity in addition to antibody production [22,25–27]. The appearance of HIV antibodies detected within plasma begins a period of clinical latency also referred to as seroconversion. With more advanced measurement techniques, it has been shown that during this stage of clinical latency the virus is actually in a state of active reproduction. Even though it appears to be in a state of inactivity, there is continued infection of nearby cells and production of viral strands.

Symptomatic (Accelerated Aging)

The widespread use of ART has successfully increased the lifespan of PLWHA with AIDS-related deaths declining annually. Instead, PLWHA are more likely to reach a stage of "accelerated aging," referring to the increased risk of developing chronic disease(s) known to primarily affect uninfected aging populations. Recent evidence indicates PLWHA are being diagnosed with and/or dying from CVD, diabetes, and other metabolic disorders with an early age of onset [28,29]. Mainly due to the toxic effects of some antiretrovirals, these adverse side effects can be found in Table 49.1.

SYMPTOMATOLOGY OF HIV INFECTION

Psychological Consequences

PLWHA are burdened with multiple psychosocial stressors at all stages of illness. Immediately upon diagnosis, patients must face life-changing issues such as managing the illness, affording appropriate health care, and the daily struggles that accompany living with the stigmatization of HIV. In addition to these personal stressors, various environmental factors could potentially exacerbate the levels of stress already experienced such as the living in a lower socioeconomic status, facing unemployment, reduced access to health care, and many others. The patients' ability to cope with these burdens ultimately depends on their psychological state, social support network, and their stage of HIV disease.

As is the case with any chronic disease patients, PLWHA are at an increased risk for psychiatric disorders like depression, anxiety, delirium, mania, HIV-related dementia, and psychosis. Many of these psychological complications are known to be treatable, and therefore it is imperative for caregivers and health care providers to learn to recognize the signs of these conditions so they may either treat the patient or refer them to a specialist for further evaluation. Effective treatment for depression, a common psychiatric disorder among PLWHA, has been shown to result in fewer physical symptoms, better sleep quality, and improvements in health-related quality of life.

Many studies of various chronic diseases have investigated consequences of distress among patients and reported positive associations with mood disturbances, poor treatment adherence, and negative health outcomes [10,30–33]. Similar findings have been reported among HIV-related investigations. Although distress has been identified as an important measure to manage mental health, and self-reported symptoms have become a common method used to indicate health status, the literature on self-reported symptom distress within the HIV-infected population is scarce.

Generally a level of distress is experienced when symptoms are present and emerging data have shown a negative impact of psychological distress on HIV disease progression [34–37]. Increases in symptom distress potentially have negative consequences to both physical and psychological health that have recently been discovered with a growing body of evidence supporting the psychoneuroimmunology (PNI) framework as discussed by McCain et al. [37,38]. Recent investigations have begun to show consistent reports of psychological distress and disturbances impairing immune function [39,40] as well as cytokine-induced changes in neurotransmitter and neuroendocrine function, which have been shown to correlate with onset of depression and/or fatigue [41,42]. The burden of frequent symptoms is known to negatively affect disease management and mental health [4,5,9,43]. Identifying factors that are associated with increased symptom distress may provide possible strategies to lessen the burden of HIV-infection and related symptoms while also improving treatment adherence.

Physical Consequences

All clinical populations face a large variety of disease-related physical and psychological symptoms, but prevalence rates of self-reported symptoms are generally over 50% among PLWHA ranging from a single symptom to multiple concurrent symptoms [3–5,44]. Common physical symptoms reported include diarrhea, loss of appetite, nausea, muscle weakness, peripheral neuropathy, fever, dry skin, and persistent cough. These are often experienced in conjunction with antiretroviral side effects for those placed on

Antiretroviral Toxicities

Nucleoside Analogs

Drug	Zidovudine (ZDV AZT, Retrovir)	Didanosine (ddI, Videx)	Stavudine (d4T, Zerit)	Lamivudine (3TC, Epivir)	Emtriva (FTC)	Viread (Tenofovir)	Abacavir (ABC, Ziagen)
Side effects	Headaches, fever, muscle soreness, nausea, lipodystrophy, fatigue	Peripheral neuropathy, upset stomach, diarrhea, insomnia	Peripheral neuropathy, lipodystrophy, headache, insomnia, anxiety	Headache, nausea, diarrhea, fatigue, insomnia	Headache, diarrhea, nausea, rash	Nausea, diarrhea, bone changes	Hypersensitivity reaction, vomiting, fatigue

Protease Inhibitors

Drug	Invirase (Saquinavir)	Reyataz (Atazanavir sulfate)	Aptivus (Tipranavir)	Lexiva/ Nelfinavir (Viracept)	Kaletra (Lopinavir/ Ritonavir)	Indinavir	Ritonavir (Norvir)
Side effects	Diarrhea, abdominal discomfort, vomiting	Dizziness, rash, elevated liver function	Nausea, vomiting, abdominal pain, headaches, fever, dizziness, liver toxicities	Nausea, rash, diarrhea, headache, vomiting, fatigue	Rash, diarrhea, nausea, muscle weakness, increased blood lipids	Headache, fatigue, nausea, diarrhea, joint pain	Weakness, peripheral neuropathy, weight loss, increased muscle enzymes

NNRTI

Drug	Intelence (Etravirine)	Nevirapine (Viramune)	Delavirdine (Rescriptor)	Efavirenz (Sustiva)
Side effects	Rash, diarrhea, nausea, headache, hypersensitivity	Headaches, nausea, vomiting, fever, rash, drug-induced hepatitis	Headaches, nausea, vomiting, fever, rash, lipodystrophy	Rash, nausea, diarrhea, insomnia, increased lipids

Entry Inhibitors: Integrase Inhibitor/Dual-Class Fixed Dose Combo

Drug	Fuzeon (Enfuvirtide)	Selzentry (Maraviroc)	Isentress (Raltegravir)	Atripla (Sustiva/ Truvada)
Side effects	Pneumonia, diarrhea, nausea, fatigue, possible hypersensitivity	Cough, fever, cold, rash, muscle and joint pain, dizziness, low blood pressure	Diarrhea, nausea, vomiting, headache, fever, abdominal pain, fatigue, weakness, dizziness, lipodystrophy	See Sustiva and Truvada

an ART regimen. As a result, the management of multiple symptoms has become a daily task for PLWHA in an effort to maintain an optimal quality of life [4,45].

As was the case before the discovery of antiretrovirals, the association between the number of self-reported symptoms and disease status still allows for the use of reported symptom frequency as an indicator of disease progression and health-related quality of life. More recently, this has begun to assist health professionals with monitoring how well a patient is responding to current antiretroviral combinations [4,46]. Symptoms lasting anywhere between a few days to a few weeks increase the burden of disease among individuals, often resulting in negative lifestyle habits. The side effects and symptoms of HIV infection often have many patients turning to self-medication by either altering their daily ART regimen or seeking additional alternative treatments that may include illegal narcotics [8,9,43,47]. Although the discovery of ART has led to an increased life span and decreased reports of AIDS and AIDS-related deaths, many scientists have reported a complex variety of symptoms and side effects associated with ART regimens creating a metabolic syndrome effect.

ANTIRETROVIRAL THERAPY

The total amount of time in which the virus replicates while evading immune system detection without proper treatment can be up to 10 years, but the total timeframe in which this occurs will vary between cases. Some viral genotypes can act swiftly and aggressively to destroy the immune system within 2–4 years following infection, whereas others focus on replicating before mutating into a more aggressive strand ensuring successful destruction of the invaded host. Recent data indicate ART medications are successful with preventing viral replication, increasing life expectancy, improving immunologic function and nearly eradicating AIDS cases and related deaths [48–50].

The timing for initiating treatment varies tremendously depending on viral infection as well as the patient's primary health care provider, but generally it is recommended that patients begin an antiretroviral regimen if asymptomatic but with a CD4 cell count ≤ 500 μL or symptomatic. For optimal results, treatment is suggested for asymptomatic patients with CD4 cell counts ≥ 500 μL [51]. Options for treatment range from early, aggressive intervention to postponing ART until a measurable increase in disease progression has been observed. Recent recommendations were released by the International AIDS Society–USA Panel in early 2010 (Table 49.2) stating the decision as to when patients should start treatment needs to be established after weighing "the benefits of treatment on morbidity and mortality against its risks, including toxicity, resistance, drug interactions, and the costs and inconvenience of lifelong treatment" [50]. Ultimately the primary factor determining success when deciding to begin ART is patient "readiness" to live with the daily burdens resulting from the treatment. But now with options becoming available for combination ART that can be administered with one pill there is hope that these treatments lead to a possible decrease in the risks associated with ART.

TABLE 49.2
2010 Recommendations of the International AIDS Society-USA Panel to Initiating Antiretroviral Treatment

Measure	Recommendation
Specific conditions	ART is recommended regardless of CD4 cell count
• Symptomatic HIV disease	
• Pregnant women	
• HIV-1 RNA > 100,000 copies/ml	
• Rapid decline in CD4 cell count > 100/μL per year	
• Active hepatitis B or C virus coinfection	
• Active or high risk for CVD	
• HIV-associated nephropathy	
• Symptomatic PHI	
• Risk for secondary HIV transmission is high, e.g., serodiscordant couples	
Asymptomatic, CD4 cell count ≤ 500 μL	ART is recommended
• CD4 cell count < 350/μL	
• CD4 cell count 350–500/μL	

TOXIC SIDE EFFECTS

The majority of side effects associated with ART are physiological in nature and directly alter metabolic processes, resulting in increased circulating blood lipids, lipodystrophy, and insulin resistance, thus creating a metabolic syndrome [28,29,44,50,52–54]. What was once a short-term muscle-wasting disease for PLWHA that ended in death over a period of several months has evolved into a chronic metabolic disorder with primary causes of mortality no longer being HIV/AIDS-related.

Symptoms and side effects from ART medications will vary depending upon specific antiretrovirals included in the patient's pharmacological regimen, as well as the total number of antiretroviral medications included. Table 49.1 provides a detailed list of antiretrovirals currently available, their toxic side effects, as well as other drug interactions. For example, NRTIs are associated with lactic acidosis, hepatic steatosis, and lipodystrophy. Evidence has shown lipodystrophy is more prevalent among individuals currently taking a combination of NRTI and a PI, both of which have known side effects disrupting metabolic function and disrupting adipocyte mitochondrial function [51,55]. Other symptoms specific to the type of NRTI being taken include pancreatitis, nausea, diarrhea, headache, insomnia, peripheral neuropathy, fatigue, malaise, anemia, and many others. The common side effects outlined in Table 49.1 are those that may directly inhibit exercise performance and/or adherence. For a more extensive list of all symptoms and side effects please refer to Bartlett 2000, *Medical Management of HIV Infection* [51].

Further caution must be considered for the possibility of drug interactions such as PI ritonavir, which has demonstrated interactions with the analgesics, cardiac medications, lipid-lowering agents, antimycobacterial, Ca^{++} channel blockers, antihistamines, antidepressants, neuroleptics, psychotropics, and ergot alkaloids (vasoconstrictors). The interactions with ritonavir appear to be through the use of these drugs of the cytochrome p450 activation system [51].

TREATING THE SIDE EFFECTS

Treatment of HIV-Related Symptoms

Additional medications are generally prescribed for viral symptoms and treatment-related side effects. Common prescription medications taken in addition to ARTs may include appetite stimulants, psychoactive drugs, soporific agents, antidiabetic drugs, analgesics, antibiotics, antilipemics, bisphosphonates, calcitonin, or hormone replacements. Some of the more common antidepressants and anxiolytics may be prescribed among those beginning an ART regimen to assist with maintaining treatment adherence.

Studies have consistently shown beneficial results in adherence to HAART when patients are treated with antidepressants as well [56,57].

The use of additional prescription medications in response to disease and ART side effects has not always yielded beneficial results. Each ART can have different interactions with other pharmaceuticals that could further exacerbate symptoms or even prevent the ARTs primary mechanism of action from working altogether without the patient's knowledge [58–62]. For example, in the treatment of anxiety in which someone taking a daily Valium or Klonopin to treat their anxiety at the same time as starting ART, the mechanism responsible for inhibiting serotonin reuptake may no longer be effective due to specific antiretroviral mechanisms. In fact, there are some PI medications, such as ritonavir, which metabolizes the antianxiety and other antidepressant medications completely [63,64]. Because of the unpredictable reactions that an antiretroviral may have on new prescriptions, or even over the counter medications, new treatment strategies are imperative.

A complementary treatment that may help address ART toxicities and viral-related side effects is exercise training [20,21,29]. Similar metabolic abnormalities within the general population respond positively to prescribed dosages of routine exercise. These exercise-induced changes include decreases in total cholesterol and triglycerides, decreased fat mass, increased lean tissue mass, decreased waste circumference, and increased insulin sensitivity [65–71].

Exercise as an Alternative Treatment to ART-Related Toxicities

In populations with a broad range of chronic diseases, there is a growing body of evidence showing that health benefits can be obtained by incorporating structured aerobic exercise into an individual's recovery and/or treatment plan. For those stricken with conditions such as HIV, cancer, and type 2 diabetes, aerobic combined with resistance exercises can have positive effects in alleviating symptoms associated with the diseases and side effects of the medical interventions. Only in the last few years has there been an association established between HIV and increased risk of chronic diseases such as CVD and diabetes. As a result, there is limited evidence to make a definitive statement as to whether or not exercise is a beneficial alternative to decreasing the risk of CVD among PLWHA. Although limited, the data that are available suggest even modest amounts of routine exercise can yield both psychological and physiological health improvements. Table 49.3 provides a list of studies completed after the implementation of ART indicating the form of exercise training and its effects among PLWHA.

Psychological Improvements Following Exercise

Early investigations conducted prior to widespread use of ART compared the effects of aerobic exercise on psychological components, such as depression and anxiety. Eight weeks of moderate-intensity aerobic exercise completed twice weekly for 60 min have shown significant reductions in anxiety and depression [72]. Other investigators reported significant improvements after only 5 weeks of aerobic exercise. Men who exercised for 45 min a day, 3 days a week, reduced anxiety and depression upon learning of their seropositive status [73,74]. As these investigations were performed before ART, the results are limited to symptoms specific to viral progression and not treatment. Further, the majority of study demographics also consisted of middle class homosexual males. Due to the shift in patient demographics and treatments, these findings lack generalizability with today's predominantly impoverished minority seropositive populations. It is unknown whether or not the virus, or any ART medications, would inhibit specific exercise-induced adaptations that are observed among other clinical and healthy populations.

In the era of widespread use of ART, there has only been one investigation utilizing aerobic exercise as the primary intervention for HIV-associated depressive symptoms.

ART, antiretroviral therapy; BMI, body mass index; HDL, high-density lipoprotein; QOL, quality of life; LBM, lean body mass; GH, growth hormone; IL-6, interleukin-6; sTNFrII, soluble tumor necrosis factor receptor 2.

Like those investigations previously discussed, reductions in depressive symptoms and/or significant improvements in quality of life were shown [75]. Findings from this study suggest that 60 min of aerobic exercise conducted 3 days a week can be used as a beneficial method for improving the psychological disturbances experienced by PLWHA.

Physiological Improvements with Exercise

Studies have consistently shown physiological improvements across clinical measurements of health such as body mass index (BMI), waist circumference, blood lipids, strength, and CRF (among others). A 24 week exercise intervention utilizing two levels of intensity (medium or high) found both intensities yielded significant improvements in CRF and reduced perceived stress. The medium-intensity group exercised three times a week at 50%–60% of their VO_2max for 40 min and the high-intensity group exercised three times a week at 75%–85% of their VO_2max for 24 min. A major limitation to that study, however, was the high attrition rate of 76%, which was possibly due to the long duration and/or intensity of the study [76]. In a similar clinical trial, participants were randomized into either a high-intensity or moderate-intensity aerobic exercise group and exercised for a total of 30 min, 3 days a week for 12 weeks. Findings showed similar significant improvements in functional capacity in both groups [55].

Interventions consisting exclusively of low-intensity aerobic exercise, but with a longer duration of 16 weeks, also have shown significant improvements among CRF and serum HDL cholesterol among PLWHA when compared to a control group. Findings have also indicated significant decreases in total abdominal adipose tissue, total cholesterol, and circulating triglycerides [77]. Similar results have been reported by other researchers who have found significant increases in CRF, oxygen pulse, and maximum tidal volume. In addition, aerobic exercise has demonstrated decreases in BMI, waist-to-hip ratio, body density, and body fat after a 12 week moderate-intensity aerobic exercise intervention [55,78]. The reported findings would, thus, indicate that PLWHA are able to elicit significant health improvements when following a prescribed exercise routine lasting 5 weeks or longer. These effects have been observed with various combinations of the exercise intensity, participant disease status, and/or current antiretroviral treatment [20,21,29,55,76,78–80].

In addition to the findings on physiological and psychological variables, no significant changes in CD4+ cell count have been reported in high- or moderate-intensity exercise groups [76,77,80]. Further, there have been no significant changes from baseline reported in CD8+ cell count, leukocytes, or lymphocytes following moderate- or high-intensity exercise [55]. Recently it was shown that patients with dyslipidemia and lipodystrophy had no significant changes in immunological variables after completing 12 weeks of moderate-intensity aerobic exercise as well [55]. Notably, there are no published reports of exercise-induced immunosuppression in PLWHA who participated in physical activity regimens designed to reduce the psychological or physiological symptomatology associated with HIV.

TABLE 49.4
HIV-Associated Changes to Exercise Testing

Disease Status	Response to Exercise
Asymptomatic	• Physiological parameters within normal limits (e.g., blood pressure, heart rate, VO_2) • Possible functional aerobic impairments due to sedentary lifestyle
Symptomatic	• Reduced aerobic capacity and muscular strength • Possibility of increased heart rate at rest and submaximal work rates • Increased difficulty in adhering to exercise prescription • ART side effects (see Table 49.1)
AIDS	• Drastically reduced aerobic capacity and muscular strength • Possible abnormal neuroendocrine responses at moderate- and/or high- intensity work rates

Recommendations for Exercise

Current exercise training recommendations as described in ACSM's *Exercise Management for Persons with Chronic Disease and Disabilities* (3rd edition) for PLWHA suggest a moderate-intensity aerobic and resistance training regimen [81]. This includes accumulating a total of 150 min of moderate-intensity physical activity a week, as well as 2 days of full body resistance training at approximately 60% of one repetition maximum. Regardless of disease status, it is strongly recommended that anyone living with HIV or AIDS receive medical clearance from their primary health care provider prior to beginning an exercise program. Even though the majority of PLWHA have a reduced aerobic capacity, most of the standard physical fitness tests are applicable to this population and can be completed with little or no risk to the individual. Table 49.4 outlines potential HIV-associated changes that may be observed during exercise testing and/or training according to disease state.

CHANGING DEMOGRAPHICS

Over the last decade, the United States has seen a dramatic shift in the demographics of HIV/AIDS including a rapid rise in the incidence of HIV infection among minority communities, primarily African Americans [48]. Although prevalence and incidence rates indicate homosexual Caucasian men remain the most prevalent group with primary infection, the disproportionate incident rates of new infections among minority heterosexual populations is having a profound effect on prevention and treatment strategies. While the number of reported cases among Caucasians has remained relatively stable over the past 10 years, African American and Hispanic populations have shown increases in reported infection rates [48,82,83]. It is also of growing concern that within these minority populations of new HIV cases heterosexual females continuously show an increase in the number of

reported infections every year and that a large percentage of persons testing seropositive report a lower socioeconomic status.

CONCLUSION

Evidence would suggest that PLWHA, regardless of disease status, can obtain similar short-term health benefits from routine physical activity reported within general populations. Research has shown significant improvements among psychological and physiological variables after moderate levels of routine exercise in as little as 6 weeks. It is also clear that across various populations routine moderate-intensity physical activity reduces the risk of chronic disease and that many of these conditions have been established as major causes of morbidity and mortality among PLWHA.

Research among PLWHA has demonstrated that aerobic exercise performed at low-, moderate-, or high-intensity does not negatively impact immune function or disease progression in HIV-infected individuals. This suggests that aerobic exercise can be both beneficial and safe for this clinical population. However, it is recommended that if aerobic exercise is to be performed by this population, that they do so at a low- or moderate-intensity level as data are lacking to draw the conclusion that a high-intensity aerobic regimen will not have a negative impact on overall health or quality of life in this population [18,21,29].

Responses and adaptations to exercise training will vary depending on disease status and whether or not that patient is currently on an ART regimen. Asymptomatic individuals generally respond in a manner similar to someone without HIV of the same body size, age, and gender. However some may be more deconditioned due to psychological disturbances commonly associated with daily sedentary behavior such as depression or anxiety, among many others. Further, individuals with a symptomatic status will generally be on a current ART regimen. Side effects of common antiretrovirals that could potentially hinder exercise performance are outlined in Table 49.1.

Although exercise itself is not going to eliminate the burdens of health care costs, social stigmatization, or other daily stressors, it could potentially reduce the health consequences of chronic stress, improve quality of life, and possibly increase the reduced life span of PLWHA. Most of the negative side effects from both the virus itself and treatment-related toxicities, including impaired glucose tolerance, fatigue, increased blood lipid profile, chronic inflammation, anxiety, depression, circulating cortisol, and others, are known to improve with routine exercise in various populations. Additional evidence from longitudinal studies have clearly shown modest increases in cardiorespiratory fitness can decrease the risk of all-cause mortality as well as the risk of most chronic diseases. Whether or not PLWHA would have a similar response to long-term exercise is unknown due to insufficient research. Further, there are no reported exercise-related interventions lasting longer than 6 months, making it impossible to determine the long-term effects on overall health and life longevity. However, benefits of exercise that have been shown in a short time frame as reported by multiple investigations would suggest long-term gains in the physical and psychological well-being of PLWHA who participate in physical activity.

INTRODUCTION

Restoration of immunological function is important for the improvement of quality of life of the elderly as the aging population is rapidly increasing throughout the world. Potential strategies have included grafting of cells and tissues, dietary manipulation, antioxidant supplementation, thymic peptides, endocrine manipulation, and exercise [1]. To date, there have been no widely used strategies proven efficacious in restoring immune function in the aged. However, there is evidence that regular moderate cardiovascular exercise is related to overall improved immune function in the elderly [2].

EXERCISE AND THE INNATE IMMUNE SYSTEM

Innate immunity acts as the first line of defense against invading pathogens and is mediated primarily by cellular components including neutrophils, macrophages, dendritic cells, and natural killer (NK) cells and by humoral components including cytokines. Upon antigen recognition, the innate system initiates a rapid, nonspecific response intended to limit pathogen replication and further infection of host cells until the adaptive cellular immune response eliminates the pathogen. A central aspect of the innate response is inflammation, which describes the cellular milieu produced by activated macrophages, including a multitude of chemokines, cytokines, and other effector proteins, which coordinate the immune response and create an environment inhospitable to pathogen survival [3]. The inflammatory response may be acute, as in a transitory physical injury or infection, or it may be low grade and chronic, as in long-term infections and autoimmune diseases [3].

EXERCISE AND "INFLAMMAGING"

In more recent years, it has become recognized that normal aging is associated with a state of chronic low-grade inflammation characterized by elevated levels of circulating IL-6, C-reactive protein (CRP), and tumor necrosis factor (TNF)-α, all of which may be involved in the pathogenesis of numerous age-related diseases including cardiovascular disease, diabetes, cancer, sarcopenia, impaired wound healing, and dementia. This state has been termed "inflammaging" [1]. With these findings, therapies and interventions aimed at attenuating age-induced low-grade inflammation have come to the forefront of behavioral and biomedical research. Exercise may be one such therapy, as both epidemiological and longitudinal data suggest that increasing physical activity is an effective means of reducing systemic low-level inflammation and chronic inflammatory diseases in aged individuals.

Physical Activity, Cardiovascular Fitness, and "Inflammaging": Cross-Sectional Studies

Cumulative data from cross-sectional studies demonstrate an inverse relationship between physical activity levels and circulating inflammatory biomarkers. Several large population cohorts such as the Third National Health and Nutrition Examination Study (NHANES III), the Cardiovascular Health Study (CHS), and the Health ABC Study support

this inverse relationship having reported negative correlations between physical activity levels and circulating CRP (all), IL-6 (NHANES III), and TNF-α (NHANES III) [4]. Furthermore, this relationship appears to occur in a dose-dependent manner, in that the lowest levels of inflammatory biomarkers were observed in elderly persons reporting the highest levels of physical activity [4].

While large cohort studies provide strong statistical power, they are often limited by their reliance on questionnaires to assess physical activity levels. For that reason, smaller cross-sectional studies that utilize accelerometry and fitness testing to assess physical activity/fitness may provide a more refined understanding of the relationship between physical activity and inflammation in aged adults. Interestingly, data from our laboratory found no significant relationship between accelerometry-based physical activity levels and circulating inflammatory markers, but did observe a negative correlation between body fat and CRP in 182 community-dwelling older adults [5]. These data partially coincide with our report demonstrating an inverse correlation between adiposity, cardiorespiratory fitness (VO_2 peak), heart rate recovery (HRR), and CRP in older adults, suggesting that elevated CRP levels may be related to increased visceral adipose tissue deposition and impaired parasympathetic activity frequently observed in aged adults [6]. Interpretation of these two studies supports the hypothesis that increasing physical activity levels alone may not be sufficient enough of a stimulus to reduce inflammation. Rather, physical activity volume or intensity must reach a threshold that reduces adiposity and/or increases parasympathetic tone in order to observe an improvement in inflammatory profile. Although the cross-sectional nature of these studies prevents the determination of cause-effect relationships, these data support the anti-inflammatory effect of exercise, which may be mediated by a reduction in adiposity and an increase in parasympathetic nervous system activity.

Exercise Training and "Inflammaging": Prospective Training Studies

Given the quantity of cross-sectional evidence suggesting a link between exercise and inflammation, several researchers have conducted longitudinal studies investigating whether exercise training reduces inflammation in aged adults. Our laboratory has recently published evidence that 10 months of aerobic exercise training (60%–70% VO_2 max) was able to reduce serum CRP levels in older adults, with no reduction in CRP levels of a similar group that underwent only flexibility exercise [7]. Additionally, we found that reductions in trunk fat associated with cardiovascular exercise were the best predictor of the reductions in systemic inflammation, further supporting the cross-sectional data, suggesting that adipose tissue accumulation may be at least partially responsible for the increases in basal inflammation seen in the elderly and other individuals [7]. In a similar study, Kohut et al. [8] examined the effects of 10 months of aerobic exercise (65%–80% VO_2 max) in elderly men and women compared to a flexibility control group. Results demonstrated that aerobic exercise induced significant reductions in serum IL-6, CRP, and IL-18, while both interventions were sufficient to cause a decrease in serum TNF-α.

The majority of the literature supports the anti-inflammatory effects of exercise observed in the previously cited studies; however, several longitudinal studies have failed to detect reductions in inflammatory biomarkers following exercise training intervention [9]. A potential explanation for the discrepancies between the studies could be attributed to differences in training intensity, duration, modality, subject population, and initial inflammatory profile. As body fat reduction and parasympathetic activity possibly mediate the relationship between training and inflammation, it is plausible the studies that failed to reduce inflammation did not reach an intensity or volume threshold significant enough to induce a reduction in adiposity and an increase in parasympathetic tone.

It must be noted that while the presence of a chronic inflammatory disease is one of the primary causes of mortality in the aged population, a normal innate immune response is necessary to protect against infectious disease. To this extent, further studies must examine the hormetic role of exercise mode, intensity, and duration on maintaining the necessary balance between an adequate inflammatory response and chronic inflammation in older adults.

POTENTIAL MECHANISMS OF ANTI-INFLAMMATORY EFFECTS OF EXERCISE TRAINING IN THE AGED

Adipose Tissue Modulation

Visceral adipose tissue has become increasingly recognized as a metabolically active organ capable of secreting inflammatory signals that can impact whole body physiology. Two recent reports indicate that *normal aging* leads to a dysregulated state in visceral adipose characterized by exaggerated inflammation and pinpoints adipose tissue as a primary source of inflammatory mediators during aging. Wu et al. [10] found that visceral adipose tissue from 22 to 24-month-old C57BL/6JNIA mice had increased gene expression of IL-1, TNF-α, IL-6, and COX-2 when compared to young counterparts. In another study, Starr et al. [11] demonstrated that the exaggerated systemic IL-6 response induced by intraperitoneal lipopolysaccharide administration was highly related to increased expression of IL-6 within visceral adipose depots of aged mice when compared to young controls. Accordingly, it has been hypothesized that exercise training may attenuate age-induced inflammation via a reduction in both visceral adipose tissue mass and inflammatory profile. Previous studies from our laboratory have demonstrated that moderate-intensity exercise training reduces adipose tissue and systemic inflammation in obese mice [12,13]. The biological mechanisms responsible for the antiinflammatory effects of exercise within adipose tissue are not known, but could be due to the regulation of cellular hypoxia, oxidative stress, adipocyte size, macrophage polarization, and energy

sensing pathways. Future elucidation of these factors will provide important data reconciling the relationship between adipose tissue inflammation and systemic inflammation.

Cholinergic Anti-Inflammatory Pathway

Work from Kevin Tracey's laboratory suggests that stimulation of the parasympathetic nervous system, via the efferent vagus nerve, inhibits proinflammatory cytokine production and protects against systemic inflammation [14]. They referred to this pathway as the "cholinergic anti-inflammatory pathway" and described it as a central homeostatic mechanism by which the sympathetic division of the autonomic nervous system stimulates the inflammatory response through the release of epinephrine and norepinephrine, while the parasympathetic nervous system works reciprocally to suppress this release of proinflammatory cytokine [14]. A primary function of the vagus nerve is to control heart rate, which is typically measured by HRR following exercise and heart rate variability (HRV). A major adaptation to long-term exercise training is a decrease in HRR and HRV, signifying that the parasympathetic nervous system becomes more efficient in stimulating the reciprocating sympathetic nervous system. Thus, exercise training may increase efferent vagus nerve activity, and this increased activity may contribute to the anti-inflammatory effect of exercise. This hypothesis is supported by our cross-sectional study, which demonstrated that HRR was the best predictor of CRP in aged adults [6]. However, this hypothesis has not yet been fully investigated in a prospective or definitive manner.

AGING AND T-CELL-MEDIATED IMMUNITY

Cell-mediated immunity (CMI), which largely involves the antigen-specific activation of T cells that mediate the activation of other effector immune cells (e.g., macrophages, NK cells, B cells, and other T cells), is diminished in older individuals. Thymic involution, or the shrinkage of the organ responsible for T-cell maturation, starts at a young age and is linked to reduced immune capability in the elderly. The immune risk profile (IRP) [15–17] characterizes multiple immune function biomarkers that are used to predict morbidity and mortality in older adults. Individuals over 60 with an inverted $CD4^+/CD8^+$ T-cell ratio, the main characteristic of IRP, have significantly increased mortality rates [18]. Other important characteristics of the IRP include reductions in naïve T cells, corresponding increases in memory T cells, decreased T-cell proliferation and activation, reduced costimulatory molecules expression, and diminished cytokine signaling and latent cytomegalovirus (CMV) and Epstein Barr virus infection [17].

Whereas age-related alterations in antigen-presenting cells and antibody-producing B lymphocytes and their migration are apparent [19–21], the dramatic decline in humoral and CMI responses to many immune challenges is predominantly the consequence of senescent T cells [22]. Indeed, virus-activated $CD4^+$ T-helper (Th) cells provide critical cytokine signals that stimulate B cells to differentiate and produce antibodies. Th1 cells stimulate antibody responses, interferon (IFN)-γ production, and CTL memory, whereas Th2 cells stimulate antibody responses and IL-10, which attenuate Th1 responses [23,24]. Aging results in reduced Th1 cytokine production in response to stimulation, creating a cytokine imbalance represented by low-IFN-γ and high-IL-10 production, which is directly related to poor responses and higher risk for infection [25–29].

The reasons for the age-related T-cell defects are not entirely understood, but experiments in T-cell receptor transgenic mice have implicated reduced output of recent thymic emigrants by the involuted thymus and homeostatic proliferation of peripheral $CD4^+$ naïve T cells as key contributors to increased T-cell longevity and accumulation of age-related intrinsic defects [30]. Indeed, the amount of time a T cell spends in the periphery reduces its ability to respond to antigenic stimulation [30]. Aged $CD8^+$ T cells also exhibit reduced responsiveness to newly encountered antigens, profoundly reduced IFN-γ expression, telomerase activity, and, interestingly, clonal expansions of $CD28^-$ memory cells resulting in a reduced T-cell repertoire diversity [23,31–33]. Frequently, a large fraction of expanded memory cells are specific for ubiquitous latent β-herpes viruses including, most prominently, CMV [34], which leads to reduced T-cell diversity and a "clogging" of immunological space. Many studies have found that these terminally differentiated effector-memory cells are highly related not only to poor vaccination responses [35–37] but also to autoimmune diseases [31] and faster HIV-1 disease progression [38].

EFFECT OF EXERCISE ON T-CELL-MEDIATED IMMUNITY IN THE AGED

Cross-sectional studies report that elderly runners exhibited a higher in vitro stimulated T-cell proliferative response and improved effector cytokine production compared to elderly sedentary [39]. Also, highly conditioned elderly women [40] and older male recreational runners [40] at rest displayed higher T-cell proliferative responses to mitogens than those of age-matched sedentary peers without any differences in absolute T-cell number. In a study by Kohut et al., lymphocyte proliferation to influenza antigen was greater in the participants reporting either regular activity or less intense activity compared to sedentary individuals [41]. Therefore, regular exercise training may be an effective method of preventing or retarding impaired immune function in aging individuals. Results from these studies indicate that older regular exercisers may have an improved Th1 response, which may enhance CMI, improve defense against intracellular pathogens, and reduce the risk of morbidity due to infections. It is not known, however, if exercise only acts in a preventative manner to delay immunosenescence or whether exercise has immune restorative properties in previously sedentary individuals.

Results from exercise training studies in this population have not reported consistent findings. Although Kapsai et al. [42] found no effect 8 months of endurance and resistance training on $CD4^+/CD8^+$ T-cell coreceptor expression in frail elderly, Shimizu et al. [43] reported that 6 months of combined moderate exercise has shown to be effective in increasing costimulatory receptor CD28 expression on circulating T cells in elderly subjects. Since costimulation through CD28 enhances production of IL-2 and IFN-γ in T cells activated by antigens and/or mitogens, these results indicate that longer-term multimodal exercise interventions can be effective in restoring T-cell responsiveness in this population while promoting strength and cardiovascular fitness.

In order to gain a better understanding of the potential mechanisms by which exercise might improve CMI with aging, Woods et al. [44] have shown that 4 months of treadmill running in mice improved naïve to memory T-cell subset ratios in both $CD4^+$ and $CD8^+$ cells in the spleen of old mice and that 6 months of moderate aerobic exercise training in elderly individuals may be sufficient to lead to minimal increases in some measure of immune function, while not affecting others in previously sedentary elderly [45]. Furthermore, Kohut et al. [46] reported greater Th1 cytokine production, IL-2, and IFN-γ, in response to HSV-1 infection after 8 weeks of moderate aerobic training in mice [46]. Conversely, not all studies report conclusive evidence that exercise definitively improves CMI [47,48]. Reasons for this may be a product of small sample size, relatively short interventions, and differences in exercise modality and intensity in which exercise is performed during these interventions.

Few studies have examined the impact of exercise on in vivo measures of CMI. Delayed-type hypersensitivity (DTH) reactions in the skin have been used to assess CMI in vivo. Sedentary elderly men have been shown to have decreased DTH response when compared to their physically active counterparts [49]. High-intensity resistance training has not been shown to change DTH responsiveness in aged individuals [50] but aerobic exercise combined with an enriched diet in an elderly population found a small exercise effect on the DTH response that was sustained over a 17-week period when compared to the control group that exhibited a decline [51]. An important aspect of these studies is the clinical relevance of DTH response, which has long been used as an overall indicator of the strength of CMI. However, a major limitation to using DTH as a functional measure of CMI is the large variability typically observed, making it difficult to interpret studies with small sample numbers. Clearly, further study is warranted with larger samples sizes to determine the effects of exercise training on CMI in aged individuals.

In summary, there is evidence that regular physical activity can have a beneficial effect on specific aspects of T-cell-mediated immune status in elderly individuals, with endurance exercise being the most beneficial. Both animal and human cross-sectional and interventional studies support the hypothesis that moderate exercise enhances T-cell immune function in older adults. Unfortunately, at this time, the mechanism for these improvements is unknown.

EXERCISE AND HUMORAL IMMUNITY

Among the many effects of aging is a general decrease in the ability of the body to respond to antigenic agents including not only pathogens but also vaccines [52]. An immune response to infection or vaccination results in the production of antibodies, which are capable of binding to and neutralizing foreign invaders such as pathogenic bacteria and viruses. This response is commonly known as humoral immunity and is one of the major components of the adaptive immune system. Antibodies are secreted into body fluids by plasma cells, mature B cells that respond to pathogens in an antigen-specific manner. The aging process is associated with both a loss of B-cell number and a reduction in B-cell function [53]; thus, interventions that counteract this effect and allow for increased potency of B-cell responses are of major interest. Of the currently available therapies that have been shown to partially ameliorate this aging effect, endurance exercise training stands out as one which is at once cheap, safe, easy to perform, and available to a wide range of individuals in all parts of the world. Thus, the effects of exercise on B-cell function and antibody production as a response to exercise training are of major interest to a number of researchers in the field.

CROSS-SECTIONAL STUDIES

A cross-sectional examination of antibody response to influenza vaccine in older highly fit men and women compared to less fit older adults demonstrated that the highly fit, physically active individuals had a greater antibody response to both the H1N1 and B strains of the influenza vaccine than did their less active counterparts [54]. Additionally, the highly fit subjects had a greater production of more potent IgG2 versus less potent IgG1 antibodies after recall vaccination with a tetanus toxoid booster, suggesting an exercise effect on antibody isotype switching that may be important for defense against infection in older individuals. In a similar study, it was found that older individuals who exercised vigorously had higher antibody, including both IgM and IgG isotype, responses to influenza vaccine when compared to individuals of the same age who exercised either moderately or not at all [41].

This evidence is further supported by a study that found that physical activity level is positively correlated with antibody response to influenza vaccination in older adults [55]. Recently, a study of patients with coronary heart disease demonstrated that regular physical activity in this population is independently associated with increased anti-influenza antibody titer after vaccination [56], a result that extends this finding to a population that has risk factors for poor immunological responses beyond that of the normal aging process. In addition to these results from influenza and tetanus toxoid vaccination, some evidence exists that exercise can improve antibody response to novel immune activators. Administration of keyhole limpet hemocyanin (KLH) was found to elicit increased antibody responses in physically active compared to sedentary older adults [49], importantly

demonstrating that exercise can generate greater protective immune responses even to antigens to which an individual has no prior exposure history.

PROSPECTIVE TRAINING STUDIES

These cross-sectional studies are further supported by prospective exercise training studies that examine the antibody responses in previously sedentary older individuals who undergo a standardized training program under the supervision of the researchers. A 10-month aerobic exercise training program has been shown to increase antibody responses to influenza vaccine at time points out to 3 months postvaccination in older adults when compared to control subjects who remained sedentary during the course of the study [57]. A similar clinical study using a relatively large number of subjects (n = 144) found that although 10 months of aerobic exercise training did not induce higher peak anti-influenza antibody responses in older adults when compared to older individuals who underwent a nonaerobic flexibility-only training program, it did increase the duration of the protective antibody response, which was sufficient to cover the entire influenza season [58]. This was important to demonstrate because aging results in a quicker reduction in protective antibody levels when compared to younger individuals in response to vaccination [59]. Importantly, this increase in duration of protection was concomitant with reduced symptom severity of upper respiratory tract infections in this group. In a smaller cohort of the same group of participants, it was further demonstrated that the exercise training program increased the antibody response to KLH administration [60], thus providing more evidence that endurance exercise can increase immune responses to antigenic agents even in the absence of prior exposure.

Supporting the earlier data on plasma antibody responses, several investigators have found positive effects of exercise on general salivary antibody levels, an important first-line defense against pathogens introduced by oral routes. Moderate-intensity cycling for 6 months caused a 40% increase in salivary IgA levels in older men and women with no change in the sedentary control group in one study [61]. A separate study demonstrated that an acute bout of exercise can increase both concentration and secretion rate of salivary IgA even in individuals >75 years of age [62]. However, a similar study involving 16 weeks of aerobic exercise in older adults found no exercise-induced changes in salivary IgA levels, although exercise did increase plasma IgA as well as plasma IgG and IgM antibodies as seen in other studies [63], suggesting that duration, intensity, or mode of exercise may play a major role in determining immunological outcomes in this population. This is partially supported by a study that included both endurance and resistance exercise components in a training program for older adults, which resulted in significant increases in both salivary IgA concentrations and secretion rates compared to the preexercise intervention time point [64].

Several studies have examined some of the aforementioned measures in rodent models of aging, which allows for a more in-depth look at potential mechanisms by which exercise might cause these changes. However, results from these studies have not always been consistent with those undertaken in humans, sometimes for reasons that are not yet clear. A training program involving 8 weeks of treadmill running failed to elicit a higher antibody response to herpes simplex virus in mice, although other markers of immune function including lymphocyte production of cytokines were increased by exercise training [46]. A similar study that subjected rats to 10 weeks of treadmill training demonstrated no increase in antibody or other responses to administration of KLH when these rats were compared to sedentary control animals [65].

Despite these challenges, mechanistic studies in older rodents have shed some light as to possible causes for the changes in antibody responses to vaccination and infection seen in older adults. Blockage of β-adrenergic receptors via nadolol ablated the exercise-induced increase in antibody- and cell-mediated immune function seen in response to herpes simplex virus infection in mice [66]. Similarly, blockage of endogenous opioid activity, which is increased with exercise, decreased antibody response to albumin injection compared to exercised mice, which received a placebo implantation [67]. Although these studies provide some insight into possible causes for exercise-induced increases in immune responses in older adults, much more work remains to be done on this front before a satisfactory mechanism for these changes can be provided.

SUMMARY

Overall, in healthy older adults, regular aerobic exercise appears to reduce chronic low-level inflammation and augment both cell- and antibody-mediated immune responses. The benefits of regular exercise on the immune system and other systems should persuade practitioners to suggest regular exercise to otherwise healthy older adults. Unfortunately, at this time, the mechanism(s) responsible for the beneficial effects on the aged immune system are unknown.

INTRODUCTION

Shortness of breath, cough, and wheezing are among the most common symptoms experienced by patients seeking medical care. As in most areas of medicine, the evaluation of patients with respiratory symptoms largely depends on a comprehensive and insightful history obtained by the physician. Information offered spontaneously by patients is the starting point in the evaluation of any problem, but knowledge of the pathophysiology and differential diagnoses underlying the symptoms allows the physician to probe further, to determine which areas of the physical examination require special attention, and ultimately to narrow, if not eliminate, the radiographic and laboratory testing required to confirm the diagnosis.

Often there is confusion between respiratory symptoms and signs. For example, patients are described as being "short of breath" as part of the physical examination. In fact, symptoms can only be described by the patient. Physicians may speculate that a patient is experiencing respiratory discomfort based on observing physical signs such as recruitment of accessory muscles of ventilation, tachypnea, or an inability to speak in full sentences. Nevertheless, *symptoms* characterize what patients are experiencing and can only come from them. The timing of respiratory symptoms and conditions that precipitate or alleviate the discomfort can clarify the impact of

the symptoms on the patient. Understanding the "language of dyspnea," developed from descriptive research of patients with a variety of respiratory diseases, can help clinicians understand the significance of their patients' symptoms.

This chapter focuses on the physiological and clinical significance of several common respiratory symptoms. The role for and utility of pulmonary function tests (PFTs) are briefly reviewed in the following text, but a more complete description is beyond the scope of this discussion. Clinical and pathophysiological details of specific disease states such as asthma and chronic obstructive pulmonary disease (COPD) will be addressed in other chapters. This chapter does cover how specific elements of the physical examination, in concert with reported symptoms, can narrow the differential diagnosis.

OBJECTIVE ASSESSMENT OF RESPIRATORY SYMPTOMS

Respiratory symptoms can be due to a variety of pathophysiological processes involving disparate organ systems. A general understanding of the use of PFTs is helpful in developing a preliminary physiologically based approach to respiratory symptoms. We will also comment briefly on some of the common pitfalls associated with the use of pulse oximetry.

Pulmonary Function Tests

Pulmonary function testing refers to maneuvers in which spirometry, lung volumes, and/or diffusion limitation of carbon monoxide (DLCO) are measured. Confusion regarding PFTs arises from imprecise use of the term "pulmonary function tests" in clinical practice to refer to measurements of spirometry alone. It is more precise to consider PFTs to include spirometry, lung volume, and DLCO measurements.

PFTs can provide objective data regarding a patient's specific respiratory impairment and can provide important insight into the cause of the patient's respiratory symptoms. Not all respiratory symptoms are best assessed by PFTs, but several common symptoms are due to diseases that may be diagnosed by PFTs. For example, the diagnosis of COPD, which may affect between 4% and 10% of adults in the United States [1], is dependent on spirometric measurements. COPD is typically suspected based on clinical symptoms, but further evaluation by measuring spirometry confirms or excludes the actual diagnosis.

When obtaining PFTs, a trained respiratory therapist or technologist can influence the quality of data obtained; the instructions, prompts, and encouragement provided to the patient prior to and during the test significantly affect the patient's respiratory maneuvers. Normal values for PFTs are determined from predictive equations developed from large descriptive studies and incorporate an individual patient's age, gender, ethnicity, and height [2].

Spirometry

Spirometry refers to measurements of the flow and volume generated when a patient performs a forced vital capacity (FVC) exhalation; these tests are critical for assessment of airway resistance. To perform an FVC exhalation, the patient takes in as big a breath as possible to completely fill the lungs with air (to total lung capacity [TLC]) and then forcibly exhales as rapidly as possible until no more air can be emptied from the lungs (to the residual volume [RV]). In addition to measuring the FVC, determining the volume of air the patient is able to exhale in 1 s (FEV1) is important in diagnosing obstructive airway diseases. If a patient has increased airway resistance and is unable to generate high flows from TLC, the FEV1 will be reduced.

Patients may develop increased airway resistance due to airway narrowing from airway inflammation, mucous buildup, and smooth muscle hypertrophy (e.g., as a consequence of chronic asthma) or from loss of tethering of the airways leading to airway collapse during active exhalation (e.g., COPD). Increased airway resistance causes obstruction of airflow during exhalation, which results in a decreased FEV1 out of proportion to the FVC. Therefore, the ratio of the FEV1 to the FVC (FEV1/FVC) will be reduced in such patients. In patients with severe airway resistance, expiratory time is insufficient to permit exhalation of a full vital capacity and RV may be elevated. Many clinicians and authors refer to this phenomenon as "air trapping."

Obstructive airway diseases are conditions that decrease the FEV1/FVC ratio. COPD and asthma are by far the most common causes of obstructive airway disease. Bronchiectasis and sarcoidosis are much less common causes. While a reduced FEV1, FVC, and a preserved (or increased) FEV1/FVC ratio suggest a restrictive pulmonary disease, lung volumes (particularly TLC) must be measured separately for confirmation.

Lung Volume Testing

Lung volumes may be measured by one of two methods. Plethysmography refers to measuring lung volumes based on the change of pressure and volume of a known quantity of air in a closed container (a so-called body box) to calculate a patient's lung volumes via Boyle's Law. Helium dilution refers to the measurement of lung volumes based on the difference in concentration of helium on exhalation after equilibrium has been established between the patient and a known quantity and volume of helium gas in an external container. Since helium is an inert gas that does not cross the alveolar–capillary basement membrane, the concentration of helium after the gas has equilibrated between a patient's lungs and the external container of helium provides a measurement of the patient's lung volumes. Helium dilution may underestimate lung volumes in patients with poor ventilation (e.g., patients with large bullae) or patients with global hypoventilation (e.g., patients with severe COPD and gas-trapping).

A TLC measurement below 80% of predicted is consistent with restrictive disease. When TLC and functional residual capacity (the volume of gas in the lung at the end of a relaxed exhalation) are greater than the predicted value, one should consider the presence of reduced elastic recoil of the lung, most commonly seen in a patient with significant emphysema. A TLC of >120% of predicted is consistent with

hyperinflation, usually the consequence of reduced lung elastic recoil. Gas-trapping and an elevated RV will commonly be present in such patients as well.

Diffusion Limitation of Carbon Monoxide

The DLCO measures the transfer of carbon monoxide (CO) across the alveolar–capillary basement membrane. DLCO is considered a surrogate for oxygen transfer across the basement membrane and into the circulation. A patient performs the DLCO maneuver by inhaling air with a small known concentration of CO up to TLC and holding his breath for 10 s to allow sufficient time for diffusion of CO into alveoli and for transfer of CO across the alveolar–capillary basement membrane. The amount of CO transferred into the blood stream is determined by the difference in the quantity of CO in the inhaled air (which is known) minus the quantity of CO in the exhaled air (which is measured).

The severity of the reduction is expressed as the percent predicted. A DLCO between 60% and 79% of predicted is considered to be consistent with a mild reduction in DLCO, between 40% and 59% a moderate reduction, and <40% a severe reduction. The DLCO is reduced when there is destruction of the alveolar–capillary interface (reduced surface is for diffusion) or there is an increase in the distance between the alveolus and the capillary across which the gas must diffuse. Table 51.1 lists diseases associated with a decreased DLCO.

Pulse Oximetry

Assessment of oxygen saturation with a pulse oximeter is common in both the inpatient and the ambulatory environment. Normal oxygen saturation does not mean that the patient's lungs are functioning appropriately. Patients with many cardiopulmonary conditions leading to dyspnea (e.g., asthma, pulmonary embolism, pneumonia, congestive heart failure [CHF]) may hyperventilate. This can lead to normal oxygen saturation with a low $PaCO_2$ and mask the presence of severe pulmonary disease. An accurate interpretation of the oxygen saturation must include an overall assessment of the patient's status and/or an accompanying arterial blood gas.

DYSPNEA

Definition

The word *dyspnea* derives from the Greek term for difficult breathing but has come to represent a more global set of sensations that can be grouped as "respiratory discomfort." Dyspnea, or breathlessness, may be experienced by healthy individuals when exercising to the limits of their aerobic capacity, may represent primary pulmonary or cardiac disease, or may be a manifestation of a severe metabolic acidosis. In a study of more than 1000 randomly selected adults, investigators discovered the presence of dyspnea in approximately 35% of adult patients without known, underlying cardiopulmonary pathophysiology [3]. Dyspnea was associated with increased morbidity and possibly mortality as compared to patients without dyspnea [3,4].

Given the frequency with which physicians encounter patients with dyspnea, having a clear understanding of the physiology and causes of dyspnea is critical in making the correct diagnosis. A summary of common cardiopulmonary conditions and the associated pathophysiological mechanisms that cause dyspnea is outlined in Table 51.2.

TABLE 51.1
Causes of Decreased DLCO Categorized Based on Lung Volume

	Causes of Decreased DLCO
High lung volumes	Advanced COPD
	Bronchiectasis
	Cystic fibrosis
Normal lung volumes	Pulmonary vascular disease (e.g., pulmonary vasculitis or primary pulmonary hypertension)
	Early pulmonary fibrosis
	Anemia[a]
Low lung volumes	Pulmonary fibrosis
	Sarcoidosis
	Congestive heart failure
	Pneumonectomy[b]

[a] Anemia causes reduced DLCO by reducing hemoglobin-binding sites for carbon monoxide; this will occur even in the presence of normal lungs and pulmonary vasculature.

[b] DLCO corrected for alveolar volume (DLCO/VA) should be normal assuming the remaining lung tissue functions normally.

TABLE 51.2
Relationship of Possible Mechanisms of Dyspnea to Selected Conditions

Asthma	Increased sense of effort
	Stimulation of irritant receptors in airways
Neuromuscular disease	Increased sense of effort
COPD	Increased sense of effort
	Hypoxia
	Hypercapnia
	Dynamic airway compression
Pulmonary embolism	Stimulation of receptors in pulmonary vasculature or right atrium (?)
Congestive heart failure	Stimulation of J-receptors in the lung
	Stimulation of receptors in pulmonary vasculature (?)
	Hypoxia
	Stimulation of ergoreceptors (?)
Deconditioning	Stimulation of ergoreceptors (?)

Question marks indicate that the data in support of the listed mechanism are limited.

Physiology of Dyspnea

Dyspnea associated with respiratory disorders appears to arise due to a variety of physiological mechanisms that involve stimulation of receptors in the upper airways, lungs, and chest wall as well as peripheral and central chemoreceptors (Figure 51.1). In addition, there are believed to be neural discharges, termed *corollary discharges*, between the motor and sensory cortices that are activated when ventilation is consciously increased. The physiology of cardiac dyspnea is less well understood but likely involves many of these mechanisms as well as others unique to low cardiac output states.

In the presence of increased mechanical load on the respiratory system, the motor cortex must increase the neural signals it sends to the ventilatory muscles to overcome the load. These outgoing messages, or efferent signals, are associated with a simultaneous corollary discharge to the sensory cortex that is hypothesized to provide the individual with a sense of how much "effort" or "work" is being expended in the act of breathing [5]. Dyspnea associated with muscle weakness (e.g., myasthenia gravis, Guillain–Barre syndrome) is also attributable to this mechanism. Dyspnea results when the system does not respond as expected for a given level of neural drive to breathe, and the larger the discrepancy, the more intense is the dyspnea experienced. This discrepancy between respiratory center output and the mechanical response of the system has been termed *efferent–afferent* or *neuromechanical dissociation* [6,7].

Conditions resulting in a reflexive or automatic increase in the neural output from the brainstem respiratory control centers are also associated with breathing discomfort, generally described as a sense of "air hunger" or an increased "urge to breathe." Stimulation of peripheral chemoreceptors by hypoxia and hypercapnia and central chemoreceptors by hypercapnia and metabolic acidosis is thought to produce dyspnea by this mechanism. Interestingly, inducing either hypoxia or hypercapnia in healthy volunteers results in similar levels of "air hunger" for each condition, demonstrating the importance of the corollary discharge from the brainstem in creating the sensation of dyspnea [8]. Stimulation of pulmonary receptors (e.g., from asthma or pulmonary embolism) may also result in an increase in ventilation and be responsible for part of the breathlessness in these conditions.

Bronchoconstriction is associated with a sensation of chest tightness [9–11], which is believed to arise from stimulation of pulmonary receptors by the bronchoconstriction [5]. Studies of the palliative effects of inhaled furosemide demonstrate decreased dyspnea scores in subjects experiencing limited tidal volume excursion, acute hypercapnia, and resultant breathlessness [12]. The mechanism of action of inhaled furosemide likely involves stimulation of pulmonary stretch receptors, thereby creating a sensation that the lung is inflating more than it actually is, resulting in a decreased sensation of breathlessness.

Cardiac dyspnea may occur due to impaired systolic or diastolic function and resultant high left ventricular diastolic pressure. This leads to increases in pulmonary capillary wedge pressure and, in some instances, transudation of fluid into the pulmonary interstitium and alveoli. As a result, the lung becomes less compliant, increasing the mechanical load

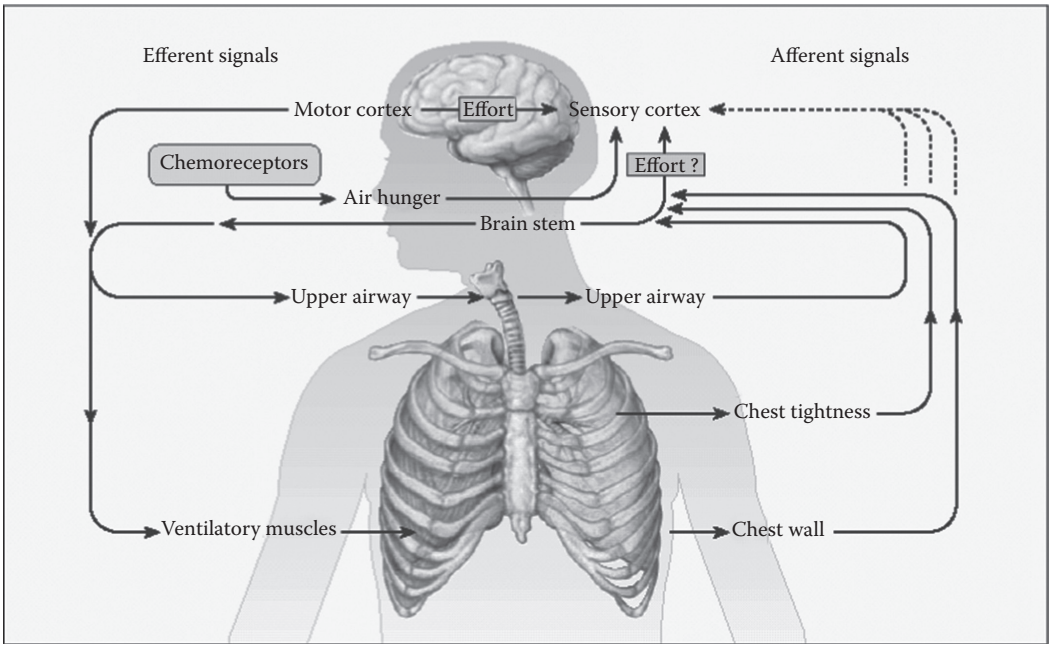

FIGURE 51.1 Physiological mechanisms producing dyspnea. Respiratory symptoms included in the term dyspnea result from stimulation of a range of receptors throughout the respiratory system as well as from corollary discharge thought to originate in the motor cortex when efferent neural discharges are sent to the ventilatory muscles. Qualitative phrases used to describe the sensations are noted based on research on and interviews with patients experiencing dyspnea. (From Manning, HL and Schwartzstein, RM, *N. Engl. J. Med.*, 333, 1547, 1995. Copyright 1995 Massachusetts Medical Society. All rights reserved.)

on the respiratory system, and hypoxia may occur. Increased pulmonary vascular pressures and stimulation of pulmonary receptors by interstitial fluid may also directly lead to respiratory discomfort. Low cardiac output states may also lead to reduced blood flow to the ventilatory muscles, resulting in muscle weakness and fatigue [13]. Furthermore, CHF appears to alter respiratory control mechanisms, leading to increased levels of ventilation compared to control subjects for any given level of exercise [14]. Stimulation of the neural drive to breathe may lead to dyspnea. Finally, there appear to be receptors (ergoreceptors) in the peripheral muscles that are sensitive to increases in the by-products of anaerobic metabolism and may contribute to the increased ventilation and breathing discomfort associated with low cardiac outputs [15].

Qualities of Dyspnea

Do patients with CHF, COPD, pulmonary embolism, and asthma all experience the same sensations of respiratory discomfort? Can we differentiate distinct types of dyspnea by the questions we ask patients? Studies demonstrate that dyspnea, like pain, is actually multiple qualitatively distinct sensations and that attention to the "language of dyspnea" can provide insights into a patient's disease.

Using a questionnaire (Table 51.3) derived from interviews with patients and studies in which normal subjects were made breathless while performing a range of ventilatory tasks [16], various cardiopulmonary conditions associated with dyspnea could be characterized by a unique set of verbal phrases [9]. These findings were confirmed in an investigation using a similar approach but with an expanded questionnaire [10]. Responses offered by patients when asked to describe their breathing discomfort have been shown to be reproducible over time [11].

TABLE 51.3
Descriptors of Dyspnea

1. My breath does not go in all the way
2. My breathing requires effort
3. I feel that I am smothering
4. I feel a hunger for more air
5. My breathing is heavy
6. I cannot take a deep breath
7. I feel out of breath
8. My chest feels tight
9. My breathing requires more work
10. I feel that I am suffocating
11. I feel that my breath stops
12. I am gasping for breath
13. My chest is constricted
14. I feel that my breathing is rapid
15. My breathing is shallow
16. I feel that I am breathing more
17. I cannot get enough air
18. My breath does not go out all the way
19. My breathing requires more concentration

TABLE 51.4
Language of Dyspnea: Association of Qualitative Descriptors and Physiological Mechanisms of Shortness of Breath

Qualitative Descriptors	Pathophysiology
Chest tightness or constriction	Bronchoconstriction, interstitial edema (asthma, myocardial ischemia)
Increased work or effort of breathing	Airway obstruction, neuromuscular disease, chest wall disease (COPD, moderate-to-severe asthma, myopathy, kyphoscoliosis)
Inability to get a deep breath	Hyperinflation (COPD, asthma)
Air hunger, need to breathe, urge to breathe	Increased drive to breathe (CHF, pulmonary embolism, moderate-to-severe airway obstruction)
Heavy breathing, rapid breathing, breathing more	Deconditioning

From these and related studies, a language of dyspnea has emerged (Table 51.4). Patients with bronchoconstriction commonly describe a sensation of "chest tightness." Increased mechanical loads (typical of airway obstruction), interstitial disease, and chest wall abnormalities usually result in increased "effort of work" of breathing. Neuromuscular weakness produces a sensation of increased effort to breathe. Significant hyperinflation, as in severe COPD, may cause a sensation of an "inability to get a deep breath" [17]. In experimental conditions, acute hypercapnia produces a discomfort characterized as "air hunger" or an increased urge to breathe [18]. Air hunger occurs in diseases associated with an increased urge to breathe (e.g., severe asthma, pulmonary embolism, acute hypoxia). Air hunger may include the sense of an inability to get a deep breath, seen with hyperinflation. Patients may express several of these sensations simultaneously, as many diseases are characterized by multiple pathophysiological derangements (e.g., asthma may result in chest tightness due to bronchoconstriction and increased effort of breathing due to hyperinflation and airway resistance).

Deconditioning, the inability to achieve maximal workloads with exertion because of reduced aerobic capacity of the heart and limb muscles, afflicts both healthy people and patients with cardiopulmonary diseases. It deserves special attention because deconditioning is a state that can be corrected with an exercise program [19,20]. Often patients with underlying cardiopulmonary diseases are assumed to be limited by their disease when they are actually deconditioned. For example, when patients with asthma were asked why they had reduced exercise capacity, they stated that it was because of their asthma. When that same group was subjected to formal exercise testing, their primary limit was cardiovascular deconditioning, not airway reactivity [19]. Patients with COPD, even those with severe airway obstruction (FEV1 < 40% predicted), are often limited

by leg fatigue rather than by poor ventilatory reserve [21]. Dyspnea associated with deconditioning has been characterized as "heavy breathing," "breathing more" [11], or "huffing and puffing."

When questioning a patient with shortness of breath, it is best to inquire about the nature of the "breathing discomfort." This phrase is generic and allows one to elicit specific qualities of a patient's distress without introducing bias toward a particular sensation. At times, it may be helpful to show patients a dyspnea questionnaire and ask them to select up to three phrases that best describe their breathing discomfort. Patients may have different sensations (and different kinds of dyspnea due to different problems) under varying conditions (e.g., a patient with interstitial lung disease and superimposed airway reactivity, or a patient with asthma who also is deconditioned). It is also important to distinguish between dyspnea due to chest wall pain and breathing discomfort, which is a primary sensation. For example, patients with a fractured rib may have severe pain with inspiration and express a sensation of "inability to get a deep breath" or "air hunger" despite the absence of pulmonary or cardiovascular pathology.

Essentials of the History

Timing: Acute versus Chronic Dyspnea

There are relatively few conditions that result in an abrupt onset of breathing discomfort (Table 51.5). These tend to be due to sudden changes in airway resistance, sudden hypoxemia, or sudden increases in pulmonary vascular pressures. With treatment, these conditions often improve as rapidly as they begin. On occasion, dyspnea may develop acutely in a patient with a chronic pulmonary disease and limited pulmonary reserve from a sudden metabolic stress (e.g., a patient with severe COPD who develops an infection with a high fever and metabolic acidosis). The need to increase ventilation in the setting of a sudden metabolic stress to meet the increased demands for oxygen consumption and/or carbon dioxide elimination may result in a combination of increased work of breathing and an increased urge to breathe.

TABLE 51.5
Acute Causes of Dyspnea

Bronchospasm
Acute asthma
Acute interstitial edema
Hypoxemia
Acute mucous plugging of airways
Pulmonary embolism
Pneumothorax
Increases in pulmonary vascular pressures
Myocardial ischemia
Pulmonary embolism
Sudden increased demand for ventilation
Acute metabolic acidosis

Chronic dyspnea tends to develop slowly over the course of weeks or months. Often, patients have difficulty pinpointing the exact onset of symptoms or attribute it to a respiratory infection despite resolution of all systemic infectious symptoms with the exception of chronic breathing discomfort. Not infrequently, the date that a patient gives up cigarette smoking is, in retrospect, consciously or unconsciously related to the onset of dyspnea. Causes of chronic dyspnea include COPD, fibrotic lung disease, pleural effusion, progressive chest wall deformities, chronic CHF, and recurrent pulmonary emboli. The chronicity of these conditions may be masked by lifestyle changes. As walking up stairs becomes progressively difficult, a patient with COPD may move to a building with elevators or to the ground floor. Children are called upon to do the shopping. Deconditioning becomes superimposed on the underlying cardiopulmonary disorder making even routine tasks uncomfortable. Patients may present complaining of seemingly new symptoms over the course of a few weeks. The reality is that the patient has a chronic condition and is only able to avoid recurring dyspnea because of avoidance of physical activity.

Timing: Night versus Day

Nocturnal dyspnea, awakening in the middle of the night with acute respiratory distress, can be an extremely frightening experience for a patient. The majority of cases are due to one or more of three problems: bronchospasm, aspiration, and CHF.

Patients with asthma may have worsening symptoms at night because of a trough in the level of bronchodilator medications, triggering of bronchospasm by gastroesophageal reflux through a reflex mediated by the vagus nerve when acid enters the esophagus, or as a result of exposure to allergens localized to the bedroom. Nocturnal sensations are usually similar to daytime asthma attacks (e.g., chest tightness and increased effort to breathe) although the precipitating factors are generally different. At times, patients may cough without discernible wheezing. The association of the symptoms with changes in the home environment (e.g., new carpeting or a new pet) may give clues to the diagnosis.

Recurrent aspiration causing nocturnal dyspnea can be an elusive diagnosis. Reports of witnessed aspiration or gagging are rare. The presence of partially digested food on a patient's pillow is infrequently reported, but if present is suggestive of regurgitation and aspiration. The diagnosis is usually suspected in a patient with a history of gastroesophageal reflux or hiatal hernia, infiltrates on chest imaging in dependent portions of the lung, and no history of asthma.

Nocturnal dyspnea characterized as a sense of air hunger or a suffocating feeling is most typical of CHF and is termed *paroxysmal nocturnal dyspnea* (PND). Clues to the diagnosis of PND include the presence of peripheral edema and relief of the respiratory discomfort shortly after assuming an upright position. Redistribution of

edema fluid to the central circulation during the night with consequent increases in pulmonary vascular pressures in a patient with compromised left ventricular function is believed to be the pathophysiological basis for this condition. Acute myocardial ischemia at night may mimic PND, but is unlikely to have a recurring pattern, may be associated with chest pain, and is less likely to be relieved by sitting upright.

One cause of dyspnea that never occurs while sleeping is hyperventilation syndrome. The primary clinical manifestation of hyperventilation syndrome is intermittent episodes of tachypnea and subjective discomfort characterized by air hunger or an urge to breathe. Despite taking large tidal volumes, patients perceive that they cannot get a deep breath. Patients with hyperventilation syndrome experience dyspnea during the day, but objective assessment reveals normal spirometry, normal DLCO, and normal chest imaging. While sleeping, these patients have normal breathing patterns and appear quite comfortable.

Position

Dyspnea that occurs with or is relieved by changes in position should prompt a consideration of abnormalities in the ventilatory pump (i.e., the muscles of ventilation and the configuration of the chest wall), focal lung abnormalities that lead to hypoxemia when blood flow is increased to that area, or redistribution of fluid into the central circulation in patients with a history of CHF.

Orthopnea is dyspnea that occurs in the recumbent position. The most common explanation is a redistribution of blood pooled in the dependent veins back into the central circulation, leading to increased pulmonary vascular pressures in the setting of compromised cardiac function. However, given the very rapid onset and resolution of orthopnea with change in position, it is probably secondary to stimulation of intracardiac (possibly the right atrium) or pulmonary vascular receptors rather than the development of interstitial edema. In very obese patients or patients with a distended abdomen due to ascites, the large abdomen reduces chest wall compliance and increases the work of breathing. The complaint that dyspnea is severe when bending over to tie one's shoes is common in these patients. Lying down, which removes gravity as a factor in pulling the abdomen away from the diaphragm, worsens dyspnea in these individuals. Patients with cervical spinal cord injury who lack active intercostal inspiratory muscles may also suffer from orthopnea.

Arteriovenous malformations (AVMs) in the pulmonary circulation lead to shunting of blood from the right to the left side of the heart (i.e., the blood never passes through the pulmonary capillaries and is sent to the systemic circulation with a low oxygen saturation). Any position that increases the gravity-dependent flow of blood through the AVM will lead to worsening hypoxemia and dyspnea. Focal areas of atelectasis or pneumonia will lead to similar gas exchange derangements when the body position is such that blood flow to that region of lung is enhanced. Consequently, the guiding principle in these circumstances is "good lung down" when positioning a patient to maximize gas exchange and minimize dyspnea.

Platypnea describes the development of tachypnea and hyperventilation when the patient is in the upright position. It is a physical finding rather than a symptom, although the patient may also complain of associated breathing discomfort. The exact mechanism of platypnea is unclear, but it probably relates to the presence of pathology at the lung bases with stimulation of pulmonary receptors or worsening gas exchange when blood flow is increased to these areas with the patient upright.

COUGH

Definition and Physiology

A cough is a sudden expiratory maneuver, associated with high intrathoracic pressures, intended to clear secretions and foreign material from the airways. An effective cough starts with a deep breath, which expands the lungs and chest wall to a point of elevated elastic recoil. This elastic recoil works in synchrony with the optimally contracting expiratory muscles to produce high intrathoracic pressures against a closed glottis. The sound of the cough is associated with the sudden opening of the glottis and the subsequent explosive release of pressurized intrathoracic gas with vibration of the vocal cords. Vibration may help to loosen secretions from the larynx.

Impaired inspiratory or expiratory muscle function leads to weakened cough. Patients with vocal cord paralysis or tracheostomy are unable to seal the glottis and cannot generate the high intrathoracic pressure needed to effectively clear secretions. Such patients are at increased risk for lower respiratory infection and may complain of increased chest congestion. The triggers for cough are complex; selected examples are reviewed in Table 51.6.

TABLE 51.6
Selected Causes of Cough Stimulation

Anatomic Location	Mechanism of Cough Stimulation
Larynx	Activation of epithelial irritant receptors
Trachea and large airways	Activation of epithelial irritant receptors
Lung parenchyma	Activation of stretch receptors Activation of C fibers
Pleural space	Activation of irritant receptors
Esophagus	Reflex mechanism in response to reflux of gastric acid
Tympanic membrane	Stimulation of irritant receptors in the external auditory canal

Clinical Causes of Cough

The most common etiologies of cough are outlined in Table 51.7. The differential diagnosis for cough varies whether a patient has an acute, subacute, or chronic cough. The differential diagnosis for chronic cough is further subdivided based on a normal versus abnormal chest x-ray.

Acute Cough

Acute cough is a cough that has been present for less than 3 weeks [22]. The most common cause of acute cough is a respiratory infection and is characterized by sputum production and may be accompanied by a "raw" substernal sensation. Chest congestion may also be present. Fever, malaise, and other systemic symptoms of a viral or bacterial infection are likely to coexist.

Subclinical bronchospasm is another cause of acute (as well as chronic) cough. In patients with mild asthma, wheezing may not be present. Sudden exposures to allergens, cold air, or exercise may result in transient cough. A high index of suspicion, along with appropriate PFTs including spirometry and possibly bronchoprovocation maneuvers, is needed to make this diagnosis.

Inhalation of toxic fumes (e.g., cleaning agents, smoke) can damage the airway epithelium and produce cough. Airway hyperreactivity may also result. As with acute infections, a raw substernal sensation is often present. Dyspnea commonly accompanies inhalational exposures. Foreign body aspiration (e.g., food particle or, in children, a small toy) may not be recalled by the patient. A cough may occur immediately after aspiration, but in some cases can be delayed for hours or days at which point airway inflammation is probably contributing to the cough. A focal wheeze is appreciated on examination of the chest in some cases, and a post-obstructive pneumonia can develop if the foreign material occludes the greater portion of the airway lumen.

TABLE 51.7
Common Clinical Causes of Cough

Acute cough
Respiratory infection, airway inflammation
Bronchospasm
Inhalational injury
Aspiration
Subacute cough
Infectious or postinfectious cough (*Bordetella pertussis*)
Sinus infection/inflammation resulting in postnasal drip
Chronic cough with clear chest x-ray
Upper airway cough syndrome (postnasal drip)
Bronchospasm
Gastroesophageal reflux
Chronic bronchitis
Bronchiectasis
Endobronchial neoplasms
Chronic cough with abnormal chest x-ray
Interstitial lung disease
Recurrent aspiration
Endobronchial neoplasm
Indolent infections (e.g., *Pneumocystis jerovici*, pneumonia, tuberculosis)

Subacute and Chronic Cough with Clear Chest X-Ray

Chronic cough is defined as a cough lasting for more than 8 weeks, while subacute cough lasts 3–8 weeks [22]. There is considerable overlap in the causes of subacute and chronic cough, and they are generally considered together in this section. However, postinfectious etiologies are an important cause of subacute, but not chronic cough. A history of recent airway or sinus infection should be sought in patients with subacute cough. Subacute cough and normal pulmonary exam may be due to sinus infection and inflammation resulting in postnasal drip. In the appropriate clinical scenario, sinus imaging and/or treatment with nasal decongestants and antibiotics for bacterial sinusitis may be warranted [23].

Paroxysms of cough resulting in post-tussive emesis or, less frequently, cough that produces a "whooping" sound, are clues to a potential diagnosis of *Bordetella pertussis* infection. For patients with cough and these symptoms, *B. pertussis* infection should be considered the diagnosis barring clinical evidence of another cause being more likely [22]. Although infants are typically vaccinated against pertussis, immunity wanes over 5–10 years. As such, adolescents and adults are at risk for developing infections from *B. pertussis* [24]. While early antibiotic treatment (macrolides are particularly effective) can reduce the severity and duration of cough due to *B. pertussis*, the efficacy of antibiotics after 2 weeks of symptoms is unclear. General consensus based on the available studies is that after 4 weeks of symptoms, it is not appropriate to provide antibiotics; rather, care should focus on symptom management [22,25].

Chronic cough without significant dyspnea and with a normal chest x-ray is commonly seen both by primary care physicians and by pulmonary specialists. This entity has been well studied [23,26], and the vast majority of patients will have one or a combination of three findings: upper airway cough syndrome (UACS), asthma, and gastroesophageal reflux disease (GERD).

UACS includes the spectrum of rhinosinosal causes of postnasal drip. From perennial rhinitis to the sequela of upper respiratory infections, UACS encompasses the breadth of diseases that result in secretions from the posterior nasopharynx descending to the larynx, causing an irritating feeling or a "tickle" in the throat. Cough due to UACS may be nonproductive or result in small amounts of white sputum. UACS due to chronic sinus infections may result in purulent sputum. Typically, the cough worsens when patients assume a supine position to go to sleep, both because of positional worsening of the nasal drainage and a greater awareness of the "irritation" in the absence of typical distractions one encounters during the day. Not uncommonly, patients will not be aware of a "drip," per se, but when questioned about the source of the cough (i.e., where the cough seems to be

originating), they will localize it to the throat rather than the chest. Frequent "throat clearing" may be a clue suggestive of UACS. Friends or family members may be more aware of frequent throat clearing than the patient. Frequent throat clearing may be observed during the interview. A history of allergies may be suggestive of UACS due to rhinitis, particularly if there is seasonal variation of the frequency or severity of the cough. However, in most cases, patients are unaware of specific allergens, and skin testing may be necessary if symptoms persist despite treatment.

Hyperactive airways without wheezing can present as chronic cough and has been termed *cough-variant asthma* [27]. In a patient without a prior history of asthma, symptoms often follow a respiratory infection. The systemic infectious symptoms will clear over several weeks, but cough persists. In many cases, the cough will resolve spontaneously in 8–12 weeks, but it can continue indefinitely. Typically, the cough will be nonproductive or result in small amounts of clear to white sputum. In contrast to cough due to UACS, patients with cough-variant asthma localize the origin of the cough to the chest. Exposure to cold air, exercise, smoke, and toxic fumes characteristically worsens cough arising from airway reactivity. Spirometry is often normal when patients are seen by their physician, and the diagnosis may be made based on response to a therapeutic trial of bronchodilators or by bronchoprovocation tests. Patients with cough-variant asthma are typically quite responsive to treatment and generally achieve symptom control more easily than patients with classic asthma symptoms [27,28].

GERD completes the triad of common causes of chronic cough. GERD may produce cough on its own or exacerbate cough in a patient with airway reactivity. Cough due to GERD is typically nonproductive and localizes to the chest. A history of heartburn or reflux symptoms is helpful but is frequently absent. In addition to asking about heartburn, one should inquire about "waterbrash," the sudden sensation of a sour taste in the mouth, which is typically associated with reflux of gastric contents. Treatment of cough due to GERD should focus on lifestyle modifications (e.g., raising the head of the bed at night, avoiding foods that dilate the lower esophageal sphincter, and avoiding eating shortly before lying down.) Proton pump inhibitors are no better than placebo in treating cough due to GERD [29].

Other less common causes of chronic cough with a normal chest x-ray include nonasthmatic eosinophilic bronchitis (NAEB), bronchiectasis, chronic bronchitis, and bronchial carcinoid. NAEB causes cough by allergic airway inflammation in response to an environmental stimulus. NAEB is not associated with airway hyperresponsiveness in response to bronchoprovocation maneuvers such as a methacholine challenge, as compared to chronic cough due to asthma. The definitive diagnosis of NAEB requires the presence of eosinophils in sputum or bronchial washings, or bronchial mucosal biopsy demonstrating increased eosinophil concentrations [30]. Given that these diagnostic modalities are not practical for most patients, empiric treatment may be appropriate when NAEB is suspected. The best treatment for NAEB is identification and avoidance of a causative environmental stimulus. When that is not possible or not effective, empiric treatment with glucocorticoids can be tried. Typically, patients with NAEB return to their premorbid baseline after treatment with glucocorticoids or avoidance of causative environmental stimuli.

Patients with bronchiectasis typically have a cough productive of purulent sputum, although upper lobe disease, which tends to drain well throughout the day, may be associated with a dry cough or scant secretions. Sputum may be occasionally streaked with blood. A history of prior pneumonia(s) is suggestive but not diagnostic. Bronchiectasis increases the risk of recurring respiratory infections associated with low-grade fever, worsening cough, and sputum production. Growth of *Pseudomonas aeruginosa* on repeated sputum cultures is very suggestive of this condition. Although the chest x-ray is often normal, focal areas of fibrosis or fibrocystic disease may be present, and chest computerized tomography (CT) scan is quite sensitive in defining the extent of disease.

Chronic bronchitis is defined as a productive cough present for ≥3 months of the year for 2 years. Chronic bronchitis is due to chronic airway inflammation induced by cigarette smoking or other environmental irritants. The cough is typically most pronounced early in the morning and tends to diminish as the day progresses. Patients localize the cough to the chest. Sputum is occasionally mixed with blood. Due to associated obstructive lung disease, these patients can have dyspnea on exertion.

Endobronchial neoplasms in central airways can produce cough and, in the absence of significant airway obstruction leading to focal atelectasis, will usually have a normal chest x-ray. Although bronchogenic carcinoma can present in this manner, bronchial adenomas or carcinoid tumors are more likely in this setting. These tumors, which usually behave as very low-grade malignancies with a small potential for distant metastases, may have a polypoid appearance that in some cases leads to a positional cough due to intermittent positional airway obstruction from the adenoma.

Chronic Cough with an Abnormal Chest X-Ray

Interstitial lung disease typically presents with the gradual onset of dyspnea on exertion, but nonproductive cough may be the prominent (or only) symptom early in the disease. Patients localize the cough to the chest. Chest x-ray findings may be subtle in early disease; later in the clinical course, chest x-ray frequently demonstrates low lung volumes and reticular interstitial changes [31]. For patients with normal chest x-rays but suspected interstitial disease, high-resolution CT scan is a very sensitive tool for confirming the diagnosis [31]. The interview should include questions about the occupational history (e.g., exposure to inorganic or organic dusts), joint symptoms or peripheral skin nodules suggesting collagen-vascular disease (e.g., rheumatoid arthritis, systemic lupus erythematosus), and eye symptoms or lower extremity joint pain suggesting sarcoidosis. Patients with symptomatic interstitial fibrosis typically have a restrictive defect on spirometry and lung volume testing.

Bronchogenic carcinomas in the central airways may cause partial or complete obstruction of a segmental or lobar bronchus leading to focal atelectasis on chest x-ray and chronic cough. The cough is typically nonproductive but may be associated with intermittent hemoptysis.

Although cough due to lower respiratory infections usually presents acutely, there are indolent infections that can present with a chronic cough and minimal systemic symptoms. Pneumocystis jerovici pneumonia in patients with acquired immunodeficiency syndrome due to human immunodeficiency virus is characterized by a nonproductive cough and dyspnea on exertion over weeks to months. Similarly, early reactivation of *Mycobacterium tuberculosis* can present with cough, fatigue, and mild weight loss. Chest x-ray usually provides evidence of the infection.

HEMOPTYSIS

Definition and Physiology

Hemoptysis refers to the coughing or expectoration of blood or blood-tinged sputum. As a general principle, the term is reserved for blood that originates in the lower respiratory tract (i.e., below the larynx). However, it may be difficult to determine whether blood is coming from the lungs versus the posterior nasopharynx or the gastrointestinal tract, especially if vomiting is associated with a paroxysm of cough. It is worth noting that the normal tracheobronchial tree should not bleed even in the presence of a coagulopathy. Thus, hemoptysis in the setting of anticoagulation should be considered as a potentially pathologic finding.

The four major sources of blood in the lower respiratory tract are airways, pulmonary parenchyma, pulmonary circulation, and bronchial circulation. Inflammation or irritation of airway epithelium (e.g., with acute pulmonary infections, chronic bronchitis, or foreign body aspiration) usually results in small-volume hemoptysis, often mixed in with sputum. Bleeding from the pulmonary parenchyma occurs with pulmonary infarction or contusion. In the presence of pulmonary AVMs or greatly elevated pulmonary vascular pressures (e.g., from mitral stenosis), bleeding may occur as well. Finally, the bronchial circulation may result in hemoptysis in patients with bronchiectasis or large intrapulmonary cavities.

Massive hemoptysis is generally defined as production of $\geq$600 mL of blood in 24 h. Patients commonly overestimate the amount of blood they have expectorated because of concomitant anxiety. Therefore, it is important to compel the patient to be as explicit as possible when quantifying the amount of blood. One should show the patient, and witnesses to the episode, various-sized containers to assist them in estimating the quantity expectorated. While massive hemoptysis can occur from an endobronchial carcinoma, it is more commonly associated with erosions of bronchial vessels in large intrapulmonary cavities or with bronchiectasis [32].

Etiology

There are six etiologic categories to be considered when evaluating a patient with hemoptysis (Table 51.8). Determining the reason for a patient's hemoptysis depends on the presence or absence of additional symptoms beyond hemoptysis itself.

Lower respiratory tract infections cause airway inflammation, which can result in bleeding. This is most common with bacterial tracheobronchitis, but can also occur with bacterial pneumonias. Typically, hemoptysis in the setting of an acute infection is small in volume (<50 mL) and resolution of hemoptysis is coincident with improvement in the other associated symptoms (e.g., cough, fever, malaise). Bronchiectasis and chronic bronchitis predispose patients to acute infections and are associated with occasional episodes of blood-streaked sputum, typically in the presence of an acute infection. Bronchiectasis infrequently leads to massive hemoptysis.

Lung cancers, most commonly bronchogenic carcinoma, are a common cause of hemoptysis. Lung cancer should be especially considered in patients over age 40 with a significant smoking history and more than 10 days of hemoptysis [33]. Patients with an extrathoracic malignancy that can metastasize to the lungs (e.g., breast carcinoma or sarcoma) are at increased risk of hemoptysis due to cancer. Bleeding due to cancer usually occurs in the absence of other symptoms and presents as frank blood without sputum.

Hemoptysis in association with joint symptoms, rashes, dyspnea, and/or renal dysfunction suggests collagen-vascular disease as an etiology. Pulmonary–renal syndromes (e.g., systemic lupus erythematosus, Wegener's granulomatosis, and Goodpasture's syndrome) may present with hemoptysis as part of the symptom complex. In most cases, hemoptysis is not an isolated finding.

AVMs, pulmonary emboli, pulmonary edema, and mitral stenosis are cardiovascular causes of hemoptysis. Pulmonary edema classically produces pink sputum, and lung biopsy reveals hemosiderin-laden macrophages consistent with pulmonary hemorrhage. Gross blood is uncommon in CHF without concomitant coagulopathy. Bleeding may occur as the first symptom of an AVM, and massive hemoptysis has been reported [34]. Hemoptysis from pulmonary emboli or mitral stenosis usually occurs with other symptoms such as dyspnea and chest discomfort.

Foreign body aspiration can lead to hemoptysis either by causing direct airway trauma or local inflammation.

TABLE 51.8
Etiologic Categories for Hemoptysis

Pulmonary infections
Neoplasms
Collagen-vascular and immunologic lung diseases
Cardiovascular diseases (including pulmonary vascular and valvular diseases)
Aspiration of foreign bodies
Chest trauma with pulmonary contusion

Pulmonary contusions result most commonly from blunt chest trauma and are associated with other trauma such as rib fractures, pneumothorax, and cardiac contusion. Hemoptysis in these settings is usually small in quantity.

WHEEZING

Definition and Physiology

Wheezing is a sound that emanates from lower airways (i.e., below the larynx), resulting from turbulent air flow. It is a "continuous" sound, as compared to the intermittent or staccato sounds that accompany chest congestion with mucus in the airways. Wheezing may occur during expiration, inspiration, or throughout the respiratory cycle. It is both a symptom, a sound that patients report hearing with breathing, and a physical finding appreciated when one examines a patient.

The sound is produced by turbulent flow through narrowed airways and in some cases may reflect the rapid oscillation of the airway walls [35]. There are multiple causes of airway narrowing (Table 51.9). Wheezing, a sound originating in the airways, should be distinguished from stridor, a primarily inspiratory sound. Stridor is qualitatively similar to wheezing, but it arises from the larynx and upper airways. During inspiration, transmural pressure across the *intrathoracic* airways favors expansion (due to negative pleural pressures). As such, inspiratory wheezing is relatively uncommon. In contrast, atmospheric pressure surrounding *extrathoracic* airways is greater than the negative pressure inside of them; consequently, the extrathoracic airways tend to collapse during inspiration. Collapse of extrathoracic airways during inspiration accentuates any preexisting airway narrowing. Thus, wheezing that worsens during inspiration is likely due to an obstruction in the extrathoracic airways (transmural pressure in the extrathoracic airway, i.e., the trachea and larynx, during inspiration favors narrowing of the airway), whereas wheezing that is more pronounced on expiration likely originates in the intrathoracic airways. When the intensity of wheezing is constant throughout the respiratory cycle, a fixed obstruction is likely.

Etiology

The most common cause of wheezing is asthma, although asthma may occur in the absence of wheeze. Historical data suggestive of asthma include wheezing associated with exposure to inhaled allergens or irritants, cold air, and exercise. Decreased wheezing in response to inhaled bronchodilators also suggests asthma. Physical examination reveals diffuse expiratory wheezing when a patient is suffering from acute asthmatic symptoms and is usually normal in the absence of symptoms. With acute symptoms, PFTs demonstrate an obstructive ventilatory defect with a decreased FEV1 and a reduced FEV1/FVC. In the absence of symptoms, between asthma exacerbations, PFTs are typically normal. Airway hyperresponsiveness can be elicited by performing bronchoprovocation maneuvers such as a methacholine challenge, which is sensitive but not specific for a diagnosis of asthma.

Mucous hypersecretion due to infections and/or airway inflammation may also cause wheezing. Since lower respiratory tract infections can also produce transient airway hyperreactivity, it may be difficult to distinguish wheezing from infection and/or inflammation from asthma. Rapid improvement of wheezing after cough or bronchopulmonary hygiene, however, is more suggestive of mucous hypersecretion than asthma.

"Cardiac asthma," wheezing in association with increased pulmonary capillary pressures and interstitial edema, is another common cause of wheezing. Generally, there is other evidence of CHF in the history (orthopnea, PND) and physical examination (distended jugular veins, S_3 gallop, peripheral edema). However, acute CHF secondary to myocardial ischemia may be difficult to distinguish from asthma in a patient with a history of airway reactivity.

Partial endobronchial obstruction can lead to focal or localized wheezing. The patient may not recognize the focal origin of the sound nor be able to localize any internal sensations associated with the wheeze. Bronchogenic neoplasms, either carcinomas or adenomas, and aspirated foreign bodies can cause focal wheezing.

Expiratory wheezing may originate from the upper airways when laryngospasm is present. Termed paradoxical vocal cord dysfunction (PVD), this condition is due to adduction of the vocal cords during expiration; expiratory wheezing originating from the upper airways can be extremely difficult to distinguish from asthma by history alone. Frequently, PVD occurs in young women, often with a history of emotional and/or psychiatric difficulties. PVD is commonly treated as asthma for months or years before the diagnosis is recognized [36]. Clues to the diagnosis are a very rapid symptom onset, an association of psychological stress with wheezing, and inconsistent bronchodilator response. Fiber-optic laryngoscopy during an attack can confirm the diagnosis by directly visualizing adduction of the vocal cords during expiration. Treatment is speech therapy and psychological counseling to assist patients in understanding the cause and nature of their symptoms and to teach techniques to develop better vocal cord control.

Vocal cord swelling from infection, allergic reaction, or chemical or smoke inhalation narrows the upper airway, increases turbulent flow, and may lead to stridor. As inhalational injuries can damage both upper and lower airways, laryngeal edema and inspiratory wheezing may be associated with intrathoracic airway hyperresponsiveness and classical expiratory wheezing. Allergic reactions causing laryngeal

TABLE 51.9
Common Causes of Wheezing

Primary airway reactivity (e.g., asthma)
Interstitial edema
Airway inflammation and mucous hypersecretion
Endobronchial obstruction (e.g., neoplasm or foreign body)
Vocal cord dysfunction

edema can be differentiated from inhalational injuries both from the history and from an association with urticaria and angioedema.

NOCTURNAL RESPIRATORY SYMPTOMS: SNORING AND APNEA

Definition and Physiology

The prevalence, clinical importance, and societal impact of nocturnal respiratory symptoms have increased markedly over the past decade. The primary cause of the increased frequency and severity of nocturnal respiratory symptoms is the marked increase in obesity in the general population. Over one billion people in the world are overweight or obese [37]. In the United States, the National Health and Nutrition Examination Surveys have demonstrated progressive increases in obesity (defined as a body mass index of $\geq 30\,kg/m^2$) since the 1960s. Even over the short period from 2000 to 2006, the prevalence of obesity in adult men has increased from 27.5% (1999–2000) to 33.3% (2005–2006) [38].

Snoring is defined as noisy breathing during sleep. The prevalence of snoring varies between studies, ranging from 10% to 60% [39]. Loud snoring is more commonly reported by men than women [40]. The prevalence of snoring increases with age up to 50–60 years of age, after which time prevalence decreases [41]. Snoring occurs due to vibration of the soft palate and faucial pillars. The likelihood that snoring will occur is dependent upon the size of the airway, the tone of the soft tissue structures in the airway, and one's body position.

The clinical significance of snoring is uncertain. Generally, in the absence of observed or measured apneic episodes, snoring is considered to be benign. However, the decrease in the prevalence of snoring that occurs with advancing age (>50–60 years of age) may indicate a survivorship phenomenon [39]. It is unknown whether snoring indicates pathologically narrowed airways causing comorbid conditions and death, or whether snoring is simply a marker of comorbid conditions that ultimately cause morbidity and death. Regardless, when a patient (or a patient's bed-partner) complains of snoring, a history of signs or symptoms of the obstructive sleep apnea (OSA) syndrome should be performed.

Nocturnal apneas are defined as a cessation of airflow during sleep. The term apnea specifically describes a cessation of airflow for ≥10 s; hypopnea is a transient reduction in airflow (a reduction in the respiratory rate and/or tidal volume) that lasts for ≥10 s and is associated with a ≥4% decrease in oxygen saturation. Frequent nocturnal apneas and hypopneas may result in hypoventilation. The diagnostic criteria for clinically significant OSA is an average of >5 apneas and/or hypopneas per hour of sleep (the "apnea–hypopnea index" [AHI]). Polysomnography (i.e., a "sleep study") must be performed to accurately measure one's AHI.

The clinical syndrome of OSA is the combination of an AHI of ≥5 with daytime symptoms due to chronic nocturnal hypoventilation. Daytime symptoms associated with the OSA syndrome include fatigue, somnolence, and morning headache. These symptoms are common even in patients without nocturnal hypoventilation, but clinical suspicion of the OSA syndrome is increased in patients with concomitant obesity, snoring, and/or comorbid conditions such as hypertension, coronary artery disease, and cerebrovascular disease. Cognitive issues (specifically difficulty concentrating), erectile dysfunction, enuresis, and depression may also be associated with the OSA syndrome, due to end-organ damage from the systemic consequences of chronic nocturnal hypoventilation and cyclical hypoxemia.

The severity of daytime somnolence can be assessed and quantified by the Epworth Sleepiness Scale (ESS) [42]. The ESS asks patients to rank their sleepiness in eight scenarios, such as "sitting quietly after a lunch without alcohol" or "in a car, while stopped for a few minutes in traffic" (see Table 51.10) [42]. Patients with a high score (≥9) have increased daytime sleepiness, but the ESS has not been validated as an independent predictor of the OSA syndrome.

There are multiple pathophysiological mechanisms in the OSA syndrome that account for the epidemiologic association between OSA and cardio- and cerebrovascular diseases (see Table 51.11). Essential hypertension occurs in at least 50% of patients with the OSA syndrome [43]. CHF, arrhythmias, coronary artery disease, myocardial infarction and

TABLE 51.10
Epworth Sleepiness Scale

How likely are you to doze off or fall asleep in the following situations, in contrast to just feeling tired? This refers to your usual way of life in recent times. Even if you have not done some of these things recently, try to work out how they would have affected you. Use the following scale to choose the *most appropriate number* for each situation:

0 = would *never* doze
1 = *slight* chance of dozing
2 = *moderate* chance of dozing
3 = *high* chance of dozing

Situation	Chance of dozing
Sitting and reading	
Watching TV	
Sitting, inactive in a public place (e.g., a theater or a meeting)	
As a passenger in a car for an hour without a break	
Lying down to rest in the afternoon when circumstances permit	
Sitting and talking to someone	
Sitting quietly after a lunch without alcohol	
In a car, while stopped for a few minutes in the traffic	

TABLE 51.11
Mechanisms of End-Organ Damage in the OSA Syndrome

Pathophysiological Mechanism	Systemic Effects	End-Organ Consequences
Increased sympathetic tone due to apneas/hypopneas	Increased systemic vascular resistance	Hypertension Cardiovascular disease Cerebrovascular disease
Increased systemic inflammation due to intermittent hypoxemia	Accelerated atherosclerosis	Coronary artery disease Cerebrovascular disease Peripheral vascular disease
Systemic oxidative stress due to cyclical hypoxemia and reoxygenation	Atherosclerotic changes Tissue ischemia	Cardiovascular disease Cerebrovascular disease
Endothelial dysfunction (uncertain mechanism)	Increased thrombogenesis	Coronary artery disease Cerebrovascular disease

Chronic nocturnal hypoventilation results in increased sympathetic tone during airway obstruction, which leads to increased systemic vascular resistance and hypertension. Intermittent hypoxemia results in increased systemic inflammation, which accelerates vascular atherosclerotic changes and increases the risk cerebrovascular and/or coronary artery disease [38]. Systemic oxidative stress is increased due to the nightly cycle of hypoxemia and reoxygenation [43]. Endothelial dysfunction occurs, resulting in increased thrombosis, although the mechanism is speculative.

cerebrovascular disease, including stroke, are all associated with and likely due to systemic physiological derangements caused by OSA [44].

The "obesity-hypoventilation syndrome" (OHS) is the constellation of chronic hypoventilation with chronic hypercapnia and obesity. Right ventricular dysfunction, due to elevated pulmonary arterial pressures and left heart dysfunction, is commonly present in patients with OHS.

Of note, certain cerebral pathologies, particularly abnormalities involving areas of nonvoluntary respiratory control, may result in a rare condition called central sleep apnea syndrome. Central sleep apnea is not associated with obesity, while OSA and obesity are clearly directly correlated.

Etiology

While snoring can be a normal finding, it may be associated with the OSA syndrome. As noted previously, the extrathoracic airways, including the hypopharynx, are prone to collapse during inspiration due to the combination of positive atmospheric pressure outside the airway and negative intraluminal pressure during inspiration. Snoring is more likely to occur in obese patients, as the hypopharynx is already narrowed from increased soft tissue fat. Conditions that reduce the muscle tone of the surrounding tissue (e.g., alcohol, sedative agents) further increase the risk of hypopharyngeal obstruction and snoring. Rapid eye movement sleep is associated with decreased muscle tone, and snoring occurs most commonly during this phase of sleep.

The tongue is a major component of the anterior wall of the hypopharynx, and movement of the tongue can contribute to upper airway obstruction. When the tongue falls posteriorly, obstruction is worsened. Given the lack of bony support to maintain patency of the hypopharynx, intact glossal and pharyngeal muscle tone is necessary to keep the airway from collapsing. Patients who sleep in the supine position are more likely to have snoring or more severe obstruction because of the propensity of the tongue to be pulled posteriorly by gravity.

Children with large tonsils or adenoids may present with snoring although significant airway obstruction is unusual in this clinical setting.

Essentials of the History

Snoring, unlike many symptoms, is less likely to be reported by patients than by bed-partners. It may be valuable to distinguish between nasal and mouth snoring, as nasal snoring is generally not considered indicative of a pathologic process. If possible, the physician should ascertain whether the patient has been observed to experience apneas, either central (when there is no evidence of airflow or chest wall movement) or obstructive (no airflow but preserved chest wall motion). The presence of loud snoring or loud snorts (which may occur at the end of the obstructive episode) is an indicator of intermittent airway obstructions. Additional questions are focused on the daytime symptoms of the OSA syndrome as outlined earlier.

The chronicity of snoring, changes in weight, and/or drug and alcohol use are also important components of the history. For example, a middle-aged, nonobese woman whose snoring dates back to adolescence and who has otherwise been well is likely to have a benign condition. Alternatively, a middle-aged man with a 20-lb weight gain over the last year and 6 months of snoring should be questioned about symptoms of the OSA syndrome.

Definitive diagnosis of OSA requires the presence of associated daytime symptoms and an AHI of ≥ 5. AHI can only be measured by formal polysomnography, which requires a patient to spend a night in a sleep laboratory. There is no role for PFTs or chest imaging in diagnosing OSA, although these studies may be helpful in searching for associated conditions.

SUMMARY

Respiratory symptoms are extremely common in clinical practice. As the lungs and upper airways have fairly limited ways to respond to pathologic changes, the challenge for clinicians is to understand the nuances of the descriptions of the sensations and the sounds that patients report, and to ask probing questions that elicit these subtle distinctions.

An understanding of the physiology underlying respiratory symptoms can help a physician perform a focused yet thorough history, determine what further testing is needed, and recommend targeted and effective interventions. And, perhaps equally important, having a better understanding of the physiology of respiratory symptoms augments one's intellectual enjoyment when assessing and managing patients with these symptoms.

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is one of the leading causes of morbidity and mortality worldwide. COPD is the fourth leading cause of death in the United States, causing more than 120,000 deaths/year. It is estimated that by the year 2020, COPD will be the third leading cause of death worldwide.[1] The overall prevalence of COPD is 4%–10% worldwide and approximately 7% in the United States, which translates to approximately 16–20 million people living with the disease.[2] The high prevalence of COPD creates an economic burden on our health care system that approaches $50 billion in costs for 2010.[3] Chronic medication use, frequent emergency department and office visits, as well as frequent hospitalizations for acute exacerbations all contribute to this economic impact.

It is important to recognize the symptoms of COPD and to diagnose the disease early. With proper pharmacologic and non-pharmacologic treatment, patients can have a decrease in their symptoms, exacerbation rates, and mortality. Also, lifestyle modifications such as smoking cessation and proper diet and exercise are of paramount importance in the treatment of COPD.

This chapter will focus on the diagnosis of COPD as well as management of stable disease and acute exacerbations. More importantly, issues such as smoking cessation as well as nutrition and exercise will be discussed.

DEFINITION

The hallmark characteristic of COPD is progressive airflow limitation that is not fully reversible. The overwhelming majority of cases occur in former or current smokers, though exposure to occupational dusts, chemicals, and indoor air pollution may also contribute to the disease.[4] Traditionally, COPD was divided into the two subgroups of chronic bronchitis and emphysema. Chronic bronchitis is defined as a chronic productive cough for at least 3 months occurring in each of two successive years. Chronic bronchitis may or may not be associated with significant airflow limitation. Emphysema is defined as destruction of airspace walls distal to the terminal bronchioles, without evidence of obvious fibrosis. This is often associated with severe airflow limitation as well as hyperinflation. The most current definition by the Global Initiative for Chronic Obstructive Lung Disease (GOLD), a comprehensive and widely accepted report by the World Health Organization and the National Heart, Lung, and Blood Institute, does not include the terms chronic bronchitis and emphysema. The GOLD definition of COPD is as follows.

COPD is a disease state characterized by airflow limitation that is not fully reversible. The airflow limitation is usually both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases.[5]

COPD is commonly associated with risk factors such as smoking and can lead to multiple comorbidities as well as extra-pulmonary manifestations.

CLINICAL FEATURES AND DIAGNOSIS

History

COPD usually occurs in patients over the age of 40 years with a history of prior or current smoking of tobacco products. Genetic factors as well as exposure to occupational dusts (i.e., coal miners) also play a role in the development of COPD.[6] The classic symptoms of COPD are chronic cough, sputum production, and/or dyspnea. The cough may not be productive and may be intermittent. Patients will often initially complain of dyspnea on exertion that may progress to dyspnea at rest as lung function continues to decline. Any patient who presents with progressive or persistent dyspnea, chronic cough, or sputum production with a history of smoking or environmental exposures should be evaluated for COPD with spirometry. Important measurements of spirometry are the forced expiratory volume in 1 s (FEV_1) and the forced vital capacity (FVC). The characteristic findings on spirometry are a reduced FEV_1 and FEV_1/FVC ratio (see Pulmonary Function Testing section). Other symptoms may include wheezing, weight loss, muscle weakness, and fatigue. Symptoms such as morning sputum production should also increase clinical suspicion for COPD. COPD is a disease that often goes unrecognized by both the patient and his or her medical provider. These patients will often unknowingly limit their own activity and lead an increasingly sedentary lifestyle.[7] Therefore, it is important to carefully investigate subtle symptoms in patients at risk for developing COPD.

Risk Factors

The normal lung continues to grow through adolescence and peaks at approximately age 20. With further aging, lung function decreases secondary to a decrease in elastic recoil of the lung tissue, loss of respiratory muscle power, as well as a decrease in chest wall compliance. These changes lead to an average decrease in $FEV_1$of approximately 27 mL/year in men and 22 mL/year in women. Smoking and presumably other risk factors associated with developing COPD accelerate this rate of decrease in lung function. For example, heavy smoking (>20 pack years) can lead to an annual decrease in FEV_1 up to nine times that of a lifelong nonsmoker.[8] Over time, this leads to a substantial reduction in lung function that eventually leads to symptomatic disease.

The risk for developing COPD is dependent upon the interaction between both external as well as host factors. The most important modifiable risk factor is cigarette smoking. Smoking appears to be the responsible cause in up to 85% of COPD cases worldwide. In a retrospective cohort study of 8045 smokers, at least 25% will develop clinically significant COPD after 25 years.[9] Cigar and pipe smoking appear to also increase the risk of developing COPD, though not as much as cigarette smoking. Passive smoke exposure (second hand smoke) may also increase the risk of developing COPD.[10] The risk of developing COPD is also greater in individuals with first degree relatives who developed COPD.[11] This is consistent with the belief that host factors leading to an increase in susceptibility to tobacco smoke also play a role. The fact that not all smokers demonstrate a rapid decline in lung function supports that hypothesis.

There are many other possible external risk factors that can lead to the development of COPD. Both coal and gold miners are exposed to occupational dusts that can lead to clinically significant COPD in nonsmokers. The risk appears to be dose related and much higher for gold workers when compared to nonsmoking coal miners.[12] In developing countries, the use of biomass fuels (wood, crop residue, etc.) is an extremely common source of energy. It is estimated that biomass fuels are used in up to 50% of households worldwide. Exposure to biomass smoke has been linked to an increased risk of developing COPD in both smokers and nonsmokers.[13] A history of pulmonary tuberculosis also appears to increase the risk of obstructive lung disease independent of prior history of smoking or exposure to biomass fuels.[14]

Though there are many possible genetic factors that can increase the risk of developing COPD, alpha-1 antitrypsin (AAT) deficiency is the most well known and studied. AAT is serum protease inhibitor that is made in the liver and is responsible for inactivating specific enzymes such as neutrophil elastase. Neutrophil elastase, if left unchecked by AAT, can lead to destruction of lung connective tissue and eventual obstructive disease. Though a complete review of AAT deficiency is beyond the scope of this chapter, a few points should be noted regarding this deficiency. AAT is coded on a single gene but its effectiveness is determined by the expression of two independent alleles. Patients who are at the highest risk of developing

COPD are those with homozygous deficiency of both alleles (termed PiZZ) and who also smoke. Characteristics that should increase the index of suspicion for AAT deficiency are the development of COPD at a young age (<45 years old), COPD in a nonsmoker, or a patient that is found to have predominantly bilateral lower lobe emphysema on an imaging study. For a comprehensive review of the diagnosis and treatment of AAT deficiency, please see the American Thoracic Society/European Respiratory Society consensus statement.[15]

Physical Examination

The value of physical examination in aiding in the diagnosis of COPD is uncertain. For patients with early or mild COPD, examination of the chest may be normal. As lung function declines, signs of increased obstruction can become more apparent. Physical examination may demonstrate signs of hyperinflation with an increase in anteroposterior chest diameter and depression of the diaphragm. Diminished breath sounds as well as wheezing and prolonged, slow exhalation become more prominent.[16] Other common findings are distant heart sounds, accessory respiratory muscle use, and pursed lip breathing. Signs of cor pulmonale include pedal edema, enlarged liver, and distended neck veins. Severe COPD can lead to hypoxemia and cyanosis as well as asterixis from severe hypercapnia.

Imaging

Chest radiography and computed tomography studies are not required to make the diagnosis of COPD. In early COPD, chest radiographs may be normal. If there is prominent hyperinflation, a chest radiograph will demonstrate flattened hemidiaphragms, a narrow cardiac silhouette, and an increase in retrosternal airspace. Radiolucent areas corresponding with bullous disease may also be noted. Chest computed tomography, especially high resolution, has a much better sensitivity and specificity for detecting emphysematous changes compared to standard chest radiographs.[17] Though imaging studies may not be helpful in making the diagnosis of COPD, they are invaluable in ruling out alternative causes of respiratory failure, dyspnea, and cough as well as planning for possible lung volume reduction surgery (see the following section).

Pulmonary Function Testing

Pulmonary function studies are extremely important for diagnosing COPD, determining a patient's stage of disease, and for stratifying risk. Though routine screening of asymptomatic patients at risk for developing COPD is not currently recommended, all patients who exhibit symptoms of COPD with an appropriate risk factor should undergo pulmonary function testing.[18]

Spirometry

Spirometry is used to diagnose airway obstruction and to determine its severity. Airflow obstruction is determined by measuring the FEV_1 and FVC, and examining the ratio of the two (FEV_1/FVC ratio). If the FEV_1/FVC ratio is below the lower limit of normal (<0.70), then airway obstruction is present.[19] The percent predicted for the FEV_1 then determines the severity of the airway obstruction.[20] An FEV_1% predicted greater than 70% corresponds to a mild degree of airway obstruction; 60%–69% moderate; 50%–59% moderately severe; 35%–49% severe; and less than 35% very severe. Assuming alternative reasons for airway obstruction are ruled out (e.g., vocal cord dysfunction, tracheal stenosis, and asthma), a diagnosis of COPD can be made in a patient that has risk factors, symptoms, and spirometric evidence of obstruction. As FEV_1 decreases, morbidity and mortality increases. This value is often used in combination with symptoms and other physiologic factors in the staging of COPD and to guide therapy (see Staging and Prognosis section). Spirometry can sometimes be useful in distinguishing asthma from COPD. In patients with asthma, there is usually a brisk response to short-acting bronchodilators with an increase in FEV_1 and or FVC of >200 mL and 12%. Asthmatic patients will also demonstrate evidence of bronchoconstriction when exposed to a stimulus such as methacholine. COPD patients, on the other hand, often have an insignificant response to inhaled bronchodilators and are less likely to demonstrate hyperresponsiveness to methacholine. This does not hold true in all patients, however, as up to 42% of patients with COPD can be responsive to inhaled bronchodilators.[21] Differentiating asthma and COPD is discussed later in this chapter.

Lung Volumes and Diffusing Capacity

Measurement of lung volumes and the single breath carbon monoxide diffusing capacity (DLCO; diffusion limitation of carbon monoxide) are not required in making the diagnosis of COPD. However, lung volume measurements may demonstrate a decrease in inspiratory capacity and an increase in total lung capacity and residual volume, all findings consistent with airtrapping and hyperinflation. DLCO has been shown to decrease as the severity of emphysema increases. A decreased DLCO in conjunction with spirometric data may be helpful in differentiating COPD from other obstructive disease processes, such as asthma.

Blood Testing

Arterial blood gas sampling is often used to guide therapy both in stable patients (oxygen therapy) and those having an acute exacerbation. Hypoxemia is often the initial abnormality seen. Hypercapnia may develop when the FEV_1 falls below 1 L. During an acute exacerbation, the patient may develop severe hypoxemia, hypercapnia, and acidosis. Arterial blood gas measurement is often used to guide the need for mechanical ventilation and assess the response to treatment.

Brain natriuretic peptide (BNP) is a blood test that can often be helpful in distinguishing the cause of dyspnea in an acutely ill patient. BNP is a hormone that is predominantly secreted by the cardiac ventricles and is used to regulate vascular tone and extracellular volume. In patients with

congestive heart failure (CHF), BNP values are elevated. Though mild elevations can be seen in patients with COPD, these values do not approach the elevations seen in CHF.[22]

Differential Diagnosis

The major differential diagnosis for COPD includes asthma, CHF, and bronchiectasis. Infections such as tuberculosis as well as some interstitial lung diseases can also present similarly to COPD.

Asthma usually presents at a younger age (<35 years) than COPD and symptoms often vary from day to day as opposed to being slowly progressive. Airway obstruction caused by asthma is largely reversible on post bronchodilator spirometric testing. There is often a family history of asthma as well as a history of atopy. Symptoms of chronic productive cough are usually absent.[23]

Heart failure can be distinguished from COPD by physical exam and chest radiograph. Though patients with CHF can have wheezing, the most common finding is fine crackles on auscultation of the chest. Chest radiograph often demonstrates pulmonary edema, cardiomegaly, and pleural effusions. Serum BNP levels are often extremely elevated.

Bronchiectasis is a disease that is characterized by voluminous production of purulent sputum as well as dilatation and thickening of bronchial walls on chest imaging. Infectious etiologies such as tuberculosis can be diagnosed by history of exposure, symptoms, as well as abnormalities seen on chest radiography.

PATHOPHYSIOLOGY

The pathophysiology of COPD is complex and not yet fully elucidated. COPD is thought to be an inflammatory disease triggered by an external irritant such as cigarette smoking. Multiple inflammatory cells are involved including neutrophils, macrophages, lymphocytes, and fibroblasts. These cells release various proteinases and inflammatory mediators and increase mucous production. There is also an increase in oxidative stress that leads to the destruction of large and small airways as well as the lung parenchyma. These destructive changes lead to emphysema, airway obstruction, and hyperinflation as well as an increase in sputum production. Inflammatory mediators are also thought to be responsible for the systemic manifestations of COPD such as weight loss and muscle wasting.

STAGING AND PROGNOSIS

The natural history and prognosis of COPD is variable and dependent on many factors, including rate of FEV_1 decline, genetic factors, continued environmental exposure, and comorbid conditions. Most patients with the disease remain relatively asymptomatic for decades until their lung function gradually decreases to a symptomatic level. Though there are different clinical guidelines related to staging and prognosis of COPD, the two most commonly used are the GOLD staging system and the BODE index. The GOLD (http://www.goldcopd.org) system uses FEV_1 values as the major determinant of severity of COPD. This system, however, does not take into account the importance of extra pulmonary manifestations of COPD in predicting outcome. The BODE index takes into account the patient's body mass index, airway obstruction (FEV_1), as well as dyspnea and exercise capacity. A patient's dyspnea is assessed using the Medical Research Council dyspnea score (ranging from 0 when asymptomatic to 4 when breathless while dressing) and exercise capacity is assessed using 6 min walk distance.[25] The BODE index appears to be superior in predicting both mortality as well as risk of hospitalization when compared to using FEV_1 alone.[26] Other predictors of increased mortality in patients with COPD are advanced age (>70), continued cigarette smoking, HIV infection, and evidence of pulmonary emphysema on chest CTstudies.[27–29]

MANAGEMENT OF STABLE COPD

The major goals of therapy for stable COPD are to slow the progression of disease, improve quality of life, provide symptom management and relief, as well as reduce the rate of hospitalizations, acute exacerbations, and mortality. A comprehensive approach should be used when managing these patients, utilizing both pharmacologic as well as nonpharmacologic therapy.

Smoking Cessation

Cigarette smoking is the world's leading preventable cause of death and the most important modifiable risk factor for the development of COPD.[30] Abstinence from cigarette smoking can lead to a sustained decrease in the rate of lung function decline and, therefore, delay the onset or progression of respiratory symptoms in patients with COPD. Though the majority of smokers surveyed state that they want to quit, only 5%–7% of smokers remain abstinent after 1 year if their quit attempt is unaided. With optimal treatment, however, the 1 year abstinence rate can be as high as 30%.[31] Therefore, it is imperative for health care providers to identify patients who are actively using tobacco and to assist them in quitting.

The two most important barriers to smoking cessation are addiction to nicotine and the conditioning to certain triggers that patients associate with the effects of tobacco. Therefore, physician-delivered intervention should focus not only on the pharmacologic aspects of nicotine withdrawal, but also should provide intensive psychosocial counseling.

A variety of behavioral counseling techniques have been studied. These include in-person counseling, telephone counseling, group programs, computer programs, and clinician directed counseling. Virtually all of these modalities have been shown to increase the rate of successful abstinence. The cornerstones of behavioral counseling are to identify patients that are ready to quit, to pick a specific quit date, to educate on the effects of nicotine withdrawal, and to have a predetermined plan to deal with nicotine cravings. Close follow-up, whether by practitioner-mediated

telephone calls, office visits, or group meetings, is extremely important in the days following the quit date.

Pharmacotherapy is used to aid in the prevention of nicotine withdrawal. Unless medically contraindicated, all smokers should be offered some form of pharmacotherapy when they are trying to quit. The combination of behavioral counseling plus pharmacotherapy leads to much higher success rates than either modality alone.[49]

The choice of therapy will vary with each patient and a treatment plan should be tailored to the individual. Alternate treatments may be selected if a patient has a history of an underlying psychiatric illness or has failed a certain treatment in the past. The three major pharmacologic treatments are nicotine replacement therapy, bupropion, and varenicline.

Nicotine replacement therapy provides nicotine to the patient and helps relieve withdrawal symptoms. These products come in various forms such as transdermal, gum, lozenges, nasal spray, and inhalers. The nicotine patch is often selected as a first line agent as it is long acting, and compliance with the patch. The other forms of nicotine replacement are shorter acting, have a more rapid onset, and are often used in conjunction with the patch to control cravings.

Bupropion is an antidepressant that enhances noradrenergic and dopaminergic release in the central nervous system. The use of bupropion doubles the likelihood of successful smoking cessation.[32] The addition of the nicotine patch plus a nicotine inhaler, appears to increase the success rate as well.[33] Currently, the drug is used at a dosage of 150–300 mg/day for up to 12 weeks. However, it can be continued for up to 6 months to prevent relapse. Side effects are usually mild (insomnia, dry mouth, and headache). The major contraindication to the use of bupropion is that it lowers the seizure threshold and therefore should not be used in patients with an underlying seizure disorder. Along with varenicline, there is a possible association with an increase in suicidal events when using this medication even in patients with no prior history of psychiatric disease. Therefore, close follow-up after initiating therapy is necessary. Patients and families should be aware of this possibility and the patient should be instructed to discontinue the medication if there is any change in behavior or mood.

Varenicline is thought to be a partial agonist of the nicotinic receptor. Multiple studies have demonstrated the efficacy of varenicline. There is ongoing controversy as to whether varenicline is superior to bupropion and nicotine replacement therapy. As with bupropion, the most serious side effect is the increase in suicidal behavior and close monitoring after initiation of therapy is necessary.

There are currently no consensus guidelines for the form of pharmacotherapy that should be initiated first. The choice should be made depending on patient preference, co-morbid medical conditions, as well as previous experience with a medication.[34]

Pharmacotherapy

Medications are used to decrease symptoms, improve exercise capacity, and reduce the frequency of exacerbations. The most common medications used are short-acting bronchodilators, long-acting bronchodilators, and inhaled glucocorticoids. The medications are often added in a stepwise fashion to control patient symptoms and decrease exacerbations. Antidepressants are used to treat depression that is commonly associated with COPD and to assist in smoking cessation.

Bronchodilators

Bronchodilators form the cornerstone of treatment of COPD. Short- and long-acting medications most commonly prescribed are the beta adrenergic agonists and anticholinergics. All bronchodilators have been shown to decrease symptoms and increase exercise capacity. They are most commonly administered either via metered dose inhaler (MDI) or by nebulizer. The inhalation route is preferred as it maximizes the bronchodilator's effect on the airways while minimizing systemic effects. When used correctly and in equivalent doses the efficacy of the metered dose inhaler administered with a spacer device is equivalent to that of a nebulizer. All patients with COPD should be prescribed a short-acting bronchodilator to use as needed for shortness of breath.

Short-acting beta agonists like albuterol have a rapid onset of action with a duration of approximately 4–6 h. They are usually prescribed to use three to four times per day as needed. With greater doses, there is an increase in side effects such as tremor, tachycardia, and, in extreme cases, hypokalemia. They have been shown to improve symptoms as well as lung function.[35]

Short-acting anticholinergic agents (ipratropium) have also been shown to decrease symptoms and improve lung function including FEV_1, FVC, and dyspnea scores.[36] The duration of action is similar to that of albuterol. They are associated with minimal side effects such as dry mouth.

When compared to each other, both medications appear to improve symptoms and lung function to a similar degree. When combined treatment is used, the degree of bronchodilation achieved appears to be additive.[37] Beta adrenergic agonists and cholinergic antagonists each function through different mechanisms and have different side effect profiles so the combination treatment is well tolerated. Many experts recommend prescribing combination therapy because of these reasons.

Long-acting beta agonists such as salmeterol have been shown to decrease exacerbation rates, improve lung function, and improve quality of life when compared to placebo.[38] They have a longer duration of effect than the short-acting beta agonists and are therefore used twice per day. They are generally well tolerated with minimal side effects.

The long-acting anticholinergic medication tiotropium has also been shown to improve lung function as well as decrease dyspnea and exacerbations. Tiotropium is longer acting than the other anticholinergic antagonists and is therefore used only once per day. There has been some concern regarding the possible increase in adverse cardiovascular effects with its use, but there are recent data supporting the safety of its use.[39]

For patients with COPD that is not well controlled with short-acting bronchodilators, a long-acting bronchodilator

should be added. Many experts recommend the addition of tiotropium over salmeterol as it has a more convenient dosing schedule and may induce a greater improvement of lung function.

Theophylline is an oral medication from the xanthine family of drugs (similar to caffeine) that has multiple effects. It relaxes bronchial smooth muscle, increases heart rate and contractility as well as blood pressure. Due to its narrow therapeutic window and significant side effects and toxicities (including seizures, cardiac arrhythmias), it is now rarely used in the treatment of COPD.

Inhaled Glucocorticoids

Inhaled corticosteroids may reduce inflammation of the airways in COPD. Though they do not appear to affect lung function or mortality when used alone, when used in combination with a long-acting beta agonist they appear to improve lung function and decrease exacerbation rates when compared to placebo or bronchodilators alone. The combination also may decrease mortality.[38] The addition of an inhaled glucocorticoid to a long-acting beta agonist is recommended for patients that are poorly controlled or who have frequent exacerbations with a long-acting bronchodilator. For patients with advanced COPD, the combination of long-acting beta agonist, anticholinergic, and inhaled corticosteroid is often used.

Systemic Glucocorticoids

Systemic corticosteroids are frequently used for acute exacerbations of COPD (see the following). Chronic therapy with systemic corticosteroids is not recommended as there is no evidence of long-term improvement in lung function to offset the significant side effects.[40]

Mucolytics

Mucolytic agents such as acetylcysteine have not shown any benefit in the treatment of COPD. When given by inhalation, N-acetylcysteine may induce severe bronchospasm in some patients. Mucolytics are not currently recommended in the treatment of COPD.

Oxygen Therapy

Current Medicare guidelines recommend that oxygen should be prescribed for COPD patients if the arterial PaO_2 is <55 mm Hg or the arterial oxygen saturation is <88%. For patients with electrocardiogram evidence of P pulmonale, pedal edema, or erythrocytosis, oxygen is recommended if the PaO_2 is <59 mm Hg. These recommendations are based on two studies that demonstrated a mortality benefit as well as improvement in quality of life measures when oxygen was used for >15 h/day.[41–42] Oxygen is often prescribed for patients who desaturate with exercise and while sleeping. Supplemental oxygen during exertion may improve dyspnea and increase exercise tolerance, but no mortality benefit has been demonstrated.[43] There may be, however, improvements in health-related quality of life.[44]

When prescribing oxygen for a patient, the goal for arterial oxygen saturation should be approximately 90%. Patients should be instructed in the care of their oxygen devices, as well as important safety measures. Patients must be instructed to never smoke while wearing their oxygen nor should they allow others to smoke near them. They should also avoid using open flame appliances while cooking. If the patient plans on traveling by airplane, the flow of their oxygen should be increased (usually ~2 L/min), as passenger planes are not pressurized to sea level.

Nutrition

Many patients with severe COPD develop protein-calorie malnutrition. A BMI < 21 is associated with increased mortality, increased fatigue, and impaired respiratory muscle function. Unfortunately, there are currently no clinical trials that demonstrate long-term benefit of instituting dietary supplements or appetite stimulants. Patients may also complain of increasing dyspnea while they are eating. For these patients, it may be helpful if they eat more frequent, smaller meals. Nutrition or dietary consultation is often helpful in managing these patients.

Pulmonary Rehabilitation

Pulmonary rehabilitation programs have been shown to improve exercise capacity as well as improve quality of life and should therefore be considered for all patients with advanced COPD. A comprehensive review of pulmonary rehabilitation is provided in Chapter 54.

Treatment of Obstructive Sleep Apnea

Hypoxemia and hypercapnia may worsen at night in patients with severe COPD. However, it is now recognized that up to 20% of patients with COPD also have coexisting obstructive sleep apnea.[45] For patients that complain of daytime somnolence or have witnessed apneas, a full laboratory polysomnogram should be obtained.

Vaccinations

It is recommended that patients with COPD receive the pneumococcal vaccine as well as an annual influenza vaccine.

Education

One of the most important aspects of management of COPD is education and communication between the health care team and the patient. Adherence to a treatment plan improves when there is better overall communication between the patient and his or her providers.[46] Patients should be educated about their disease, the proper use of their medication, and instructed in self-management. Practitioners should address concerns regarding cost of medications, polypharmacy, and the patient's psychosocial well-being.

Advanced Treatments

There are currently many advanced bronchoscopic and surgical techniques being used to treat severe COPD. These include endobronchial valve placement, bronchial thermoplasty, lung volume reduction surgery, and lung transplant. Most of these should be provided only in the context of a well-designed clinical trial. Discussion of these treatments is beyond the scope of this chapter.

MANAGEMENT OF ACUTE EXACERBATIONS

An acute exacerbation of COPD is variably defined in the medical literature. Most consensus panels agree that it involves an acute increase in symptoms such as cough, dyspnea, or sputum production above the patient's baseline. Patients may also present with increased wheezing, tachypnea, and tachycardia. The most common precipitating factors are bacterial and viral respiratory tract infections, though up to a third of cases of acute exacerbation are from an unclear etiology.

The severity of an exacerbation can vary from mild to severe with impending respiratory failure and death. All patients should be evaluated and triaged to treatment as outpatient, acute care inpatient, or intensive care unit settings. The American Thoracic Society/European Respiratory Society proposed some criteria for hospitalization that includes changes in mental status, worsening hypoxemia or hypercapnia, high risk co-morbidities, significant increase in dyspnea, inadequate response to outpatient management, and acute respiratory acidosis.[47] Patients should be evaluated for potential alternative diagnoses such as heart failure, pulmonary embolism, and pneumonia.[48]

Treatment should focus on the precipitating cause, improvement of symptoms, and assuring adequate oxygenation. Specific therapies include supplemental oxygen to maintain a saturation of approximately 92%, short-acting bronchodilator medication, systemic corticosteroids, and antibiotics. Short-acting bronchodilators are usually given via nebulizer as it is often difficult for a patient with an acute exacerbation to coordinate the use of a metered dose inhaler. Usually, both a beta adrenergic agonist and anticholinergic are given.

The use of systemic corticosteroids has been shown to improve symptoms, reduce hospital length of stay, and reduce the rate of treatment failure.[49] The current optimal dose and duration of steroid treatment is not known. However, we agree with the current GOLD guidelines that the majority of patients can be treated with an equivalent dose of prednisone 30–40 mg/day for 7–10 days. For patients with severe exacerbations, especially those requiring an intensive care unit, this dose can be increased and is often given intravenously (methylprednisolone) until the patient is stable enough to take medication orally. Of note, concerns for possible adrenal suppression are unwarranted in patients who receive steroids for a duration of less than 3 weeks.

Antibiotics are typically given to patients with moderate to severe COPD exacerbations demonstrating increased dyspnea, sputum production, and purulence, especially those requiring mechanical ventilation. The use of antibiotics for mild COPD exacerbations is controversial; however, there does appear to be a decrease in the risk of developing a new exacerbation.

For patients who develop severe respiratory acidosis, increase work of breathing, and impending respiratory failure, the use of noninvasive positive pressure ventilation (NIPPV) should be considered prior to intubation. Numerous studies have demonstrated a decreased need for invasive mechanical ventilation and a reduction in hospital mortality.[50] NIPPV is contraindicated in patients that have facial trauma or burns, are unable to cooperate due to poor mental status, have cardiac instability such as hypotension or acute myocardial infarction, or have respiratory arrest.

Unfortunately, patients who are admitted to the hospital with an acute COPD exacerbation have an estimated 14% predicted mortality within the next 3 months.[51] Patients who are admitted with an elevated $PaCO_2$ have an even poorer prognosis.

SUMMARY

Chronic obstructive pulmonary disease is a leading cause of morbidity and mortality worldwide and the prevalence of the disease is increasing. Early recognition, diagnosis, and treatment can lead to a decrease in hospitalizations as well as improvement in quality of life. Smoking cessation is the most important modifiable risk factor associated with this disease.

Asthma is an inflammatory disease of the airways characterized by intermittent symptoms, including chest congestion, cough, and wheezing. These symptoms are associated with airway responsiveness and variable airflow obstruction.

Approximately 22 million individuals in the United States have asthma [1]. Therefore, the prevalence of asthma is approximately 5%–7%. Despite the constant development of new medications to treat asthma over the last decade, there has been a rising hospitalization rate, and it remains a frequent cause of absenteeism from both school and work. Most concerning is that approximately 3500 deaths in the United States occurred in 2007 due to asthma (CDC Vital Signs, May 2011).

The prevention and treatment of disease are highly dependent upon a variety of interventions, both pharmacologic and non-pharmacologic. The daily habits and activities of patients with asthma play an important role in disease management and prevention. Minor alterations in lifestyle practices can make substantial differences in the long-term health of the asthmatic patient.

This chapter focuses on the traditional asthma topics of pathogenesis, diagnosis, and treatment. More importantly, the environmental issues important to asthma are discussed. Asthma symptom prevention and enhanced control of disease are stressed, and the effect of exercise, occupation, stress, and pregnancy on asthma is discussed.

CLINICAL FEATURES

Clinical symptoms of asthma are dyspnea, cough, chest congestion and tightness, and noticeable wheezing. Milder cases of asthma may only be recognized by a cough that is worse at night, or dyspnea during or following exertion. In more severe attacks, some or all of the symptoms have been occurring over several days before the patient seeks medical help; however, a minority of patients have a rapid onset of severe symptoms over just a few minutes or hours. Very severe attacks may lead to respiratory failure requiring tracheal intubation and mechanical ventilation.

An asthma patient may be able to identify a certain trigger that destabilizes his or her asthma. Often symptoms occur during exercise, viral infections, exposure to furry or feathered animals, or exposure to environments laden with dust, mold, smoke, or other noxious fumes or chemicals.

Changes of weather, emotions such as laughing or crying, and menses may destabilize the asthmatic patient. There are certain patients who have attacks following the ingestion of aspirin or other medications. Eczema, hay fever, rose fever, or a family history of asthma is often associated with asthma, but their presence is not required for its diagnosis.

The patient will often have a normal physical examination when asthma is not active. However, in patients who are having asthma symptoms, the physical examination often reveals an increase in respiratory rate with a prolonged expiratory time and wheezing. Wheezing becomes accentuated on forced expiration and coughing generally occurs. With more severe asthma, the use of the accessory muscles of ventilation occurs, the chest appears to be hyperinflated, and the patient may be diaphoretic and not able to speak in full sentences. These clinical features of asthma have been used to develop a clinical classification of asthma severity based on frequency of these symptoms and nighttime awakenings, interference with activities, lung function impairment, and their frequency of exacerbations (Figure 53.1) [1].

PATHOGENESIS

Airway narrowing leading to increased airway resistance and airflow obstruction occurs through three major mechanisms:

Airway smooth muscle contraction
Increased airway lumen debris
Airway wall thickens from inflammation, edema. With long-standing asthma, airway fibrosis also plays a role [1].

Damaged epithelial cells detach from the mucosal surface of asthmatic airways. Airway wall thickening occurs in patients with persistent asthma as a result of the unimpeded inflammatory process. The effects of inflammation accumulate over time, leading to smooth muscle hypertrophy, epithelial basement membrane thickening, connective tissue deposition, and proliferation and hypertrophy of mucus-producing glands. All of these factors contribute to progressive airflow obstruction, which is further compromised by the presence of thick tenacious mucus, ineffective mucociliary clearance, and edema in the walls of the bronchi, especially during an acute asthma exacerbation.

Assessing severity and initiating treatment for patients who are not currently taking long-term control medications					
Components of severity		Classification of asthma severity ≥12 years of age			
			Persistent		
		Intermittent	Mild	Moderate	Severe
Impairment Normal FEV_1/FVC: 8–19 y 85% 20–39 y 80% 40–59 y 75% 60–80 y 70%	Symptoms	≤2 days/week	>2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings	≤2x/month	3–4x/month	>1x/week but not nightly	Often 7x/week
	Short-acting β_2-agonist use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week but not daily, and not more than 1x on any day	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	• Normal FEV_1 between exacerbations • FEV_1 >80% predicted • FEV_1/FVC normal	• FEV_1 >80% predicted • FEV_1/FVC normal	• FEV_1 >60% but <80% predicted • FEV_1/FVC reduced 5%	• FEV_1 >60% predicted • FEV_1/FVC reduced >5%
Risk	Exacerbations requiring oral systemic corticosteroids	0–1/year (see note)	≥2/year (see note) →		
		← Consider severity and interval since last exacerbation. → Frequency and severity may fluctuate over time for patients in any severity category. Relative annual risk of exacerbations may be related to FEV_1.			
Recommended step for initiating treatment (See "Stepwise Approach for Managing Asthma" for treatment steps.)		Step 1	Step 2	Step 3 and consider short course of oral systemic corticosteroids	Step 4 or 5 and consider short course of oral systemic corticosteroids
		In 2–6 weeks, evaluate level of asthma control that is achieved and adjust therapy accordingly.			

FIGURE 53.1 Classification of asthma severity. (Adapted from National Heart, Lung and Blood Institute, National Asthma Education and Prevention Program, *J. Allergy Clin. Immunol*., 120, S94, 2007.)

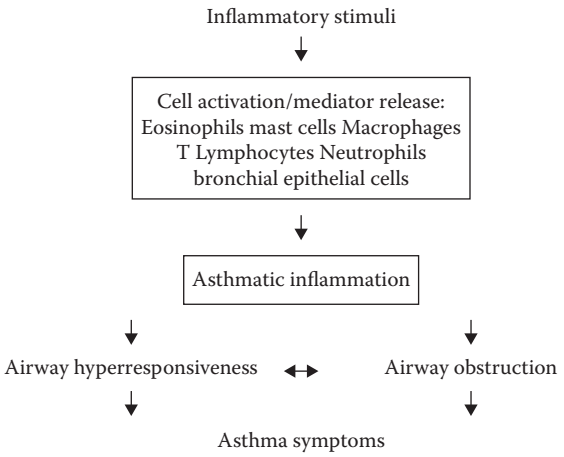

FIGURE 53.2 Steps involved in the asthmatic inflammatory cascade. These include the introduction of inflammatory stimuli to cell activation and mediator release, to asthmatic inflammation and bronchial hyperresponsiveness, and finally clinical asthma.

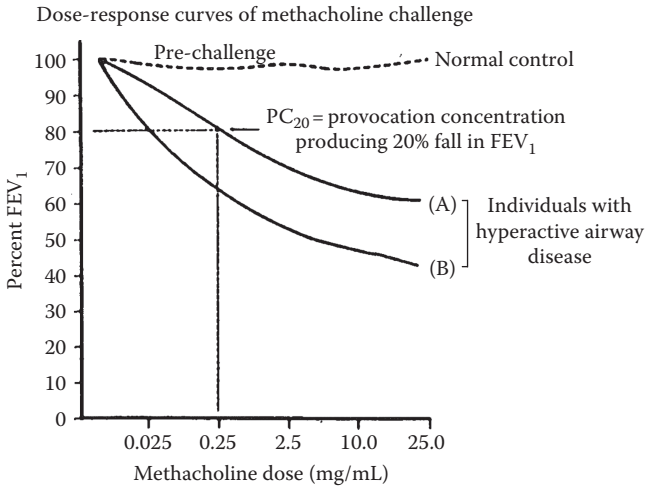

FIGURE 53.3 Asthmatics have hyperresponsive airways that are overly sensitive to immunologic or non-immunologic stimuli. Bronchial provocation testing can serve as a useful tool to measure the severity of bronchial hyperresponsiveness and is helpful to confirm the diagnosis of asthma.

Finally, episodic smooth muscle contraction further leads to the variability of symptoms in asthma.

Multiple mechanisms produce airway inflammation, and they involve a variety of interactions between pro-inflammatory and inflammatory mediators. The asthmatic inflammatory cell matrix is made up of mast cells, macrophages, eosinophils, and activated lymphocytes (Figure 53.2). Both immune and nonimmune factors can activate the disease process. When an asthmatic is exposed to a specific activating antigen, the release of a variety of mediators occurs via high-affinity immunoglobulin E (IgE) receptors, which are found on bronchial mast cells, and low-affinity IgE receptors on macrophages and eosinophils. Lymphocytes control these processes. Both antibody-mediated and cell-mediated immune systems are involved. The chemical mediators from these activated cells can directly contract airway smooth muscle, stimulate mucus secretion, enhance vascular permeability, and result in airway edema, all of which contribute to airflow obstruction. Furthermore, some mediators actually attract other inflammatory cells and activate them, and these activated cells further damage the airway. Part of the inflammatory reaction causes a disruption of airway epithelial cell wall integrity, which allows increased permeability to inhaled allergens and other triggering substances and decreases mucociliary clearance of airway debris, enhances cholinergic-mediated airway hyperreactivity, and predisposes asthma patients to bacterial and viral infections.

Inflammation can be acute or chronic. The acute inflammatory response involves early recruitment of cells to the airway. This is followed by an evolving inflammatory reaction, as recruited and resident cells are activated and produce a complex pattern of inflammation. Chronic inflammation can lead to permanent airway damage.

Airway hyperresponsiveness is a hallmark of asthma. Airway inflammation induces hyperresponsiveness (Figure 53.2). This hyperresponsiveness, along with the inflammatory changes of the airways, contributes further to airflow obstruction. Certain triggers may not only activate but also propagate inflammation and drive airway responsiveness to a more severe state. The magnitude of airway hyperresponsiveness seems to correlate with the activity of airway inflammation. Furthermore, airway hyperresponsiveness seems to correlate with the clinical symptoms and signs of asthma.

Hyperresponsiveness is assessed by measuring airflow before and after the inhalation of increasing doses of inhaled methacholine or histamine (Figure 53.3) [2]. Hyperresponsive airways will develop obstruction at lower cumulative doses of these chemicals than normal airways. This increased "twitchiness" of the airways is thought to protect the lungs from the detrimental effects of irritating inhalants. Airway hyperresponsiveness is not unique to asthma. Hyperresponsive airways are found in other airway inflammatory diseases, like chronic bronchitis and sarcoidosis. The treatment of asthma does diminish, but may not eradicate airway responsiveness, suggesting that additional factors are involved.

Monitoring Disease Activity

The goals of asthma therapy are as follows: (1) prevent symptoms and help the patient achieve normal lung function and activity, especially during exercise; (2) prevent exacerbation of asthma, no matter how mild; (3) minimize the need for emergency department visits or hospitalizations; (4) meet patient and family expectations for asthma care; and (5) provide optimal pharmacotherapy with minimal adversity [1].

In order to ensure that these goals are met, periodic assessment and ongoing monitoring of asthma are recommended [1]. If the patient has minimal signs and symptoms, with optimal airflow during exertion and sleep, then overall patient-perceived quality of life improves. Physician assessment and patient self-assessment are part of the asthma monitoring process.

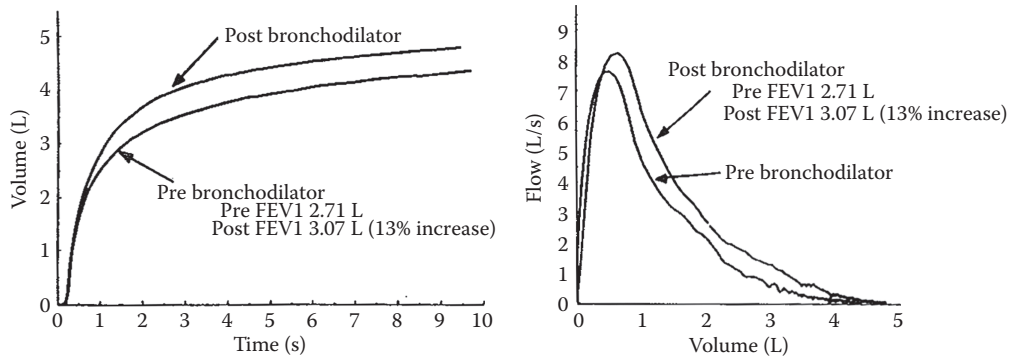

FIGURE 53.4 Spirometry pre/post-bronchodilator in the asthmatic. Administration of an inhaled bronchodilator improves airflow significantly. The left panel depicts the volume–time curve and shows improvement in FEV_1. The right panel shows the flow–volume curve and improvement in PEFR over exhaled lung volume. The dependent portion of the curve is also curvilinear (not straight) consistent with airflow obstruction. (From National Heart, Lung and Blood Institute, National Asthma Education and Prevention Program, Expert Panel Report 2, Guidelines for the diagnosis and management of asthma, Full Report 1997.)

Spirometry is recommended at the time of initial assessment, during treatment, and when changes in symptoms or home monitoring of peak expiratory flow (PEFR) have occurred [1,3]. A spirometer is a simple device used to measure certain lung volumes and airflows [4,5]. The patient takes a deep breath and forcefully exhales air from the lungs until all airflow has ceased (Figure 53.4). Airflow obstruction is shown by a decrease in the forced expiratory volumes, the forced vital capacity (FVC), and the forced expiratory volume in 1 s (FEV1) and a decreased FEV1/FVC ratio. The FEV1 is the most important airflow measurement, and usually the asthmatic has a reduction in the FEV1. These measurements are generally taken before and after a bronchodilator. The asthmatic typically shows significant improvement in these airflows following a beta-2 agonist treatment, indicating reversible airways disease. This is determined by an increase in either FVC or FEV1 by 12% or more with a minimum absolute change of 200 mL pre/post-bronchodilator. The asthmatic can also measure airflow at home on a daily basis, using a handheld device made of durable plastic to measure PEFR rates.

The airflow obstruction of asthma waxes and wanes with variations in the degree of inflammation and smooth muscle constriction. With these changes, there are alterations in FEV1 and PEFR (Figure 53.4). There are variable needs for the use of medication to relieve symptoms. As the asthmatic becomes better controlled with therapeutic interventions, overall airflow improves, variability in airflow decreases, and the need for short-acting beta-2 agonist medication to relieve symptoms substantially decreases. As all of these factors change, overall quality of life improves. This translates into better sleep at night and improved resistance to asthma exacerbation during exposure to environmental challenges. It is important to teach patients to recognize symptom patterns that indicate inadequate asthma control. The NAEPP 2007 Guidelines recommend a written asthma action plan for all asthmatics based on signs and symptoms, changes in PEFR, or both. Written asthma action plans may be particularly helpful for those with poorly controlled asthma, moderate or persistent asthma, or a history of severe exacerbations. The more chronic and severe the asthma, the greater is the importance of a written asthma action plan.

THERAPY OF ASTHMA

Environmental Control

Environmental control measures, such as allergen avoidance, should always be included in asthma management strategies [1]. A comprehensive approach to control of allergen or irritant exposure is needed since single measures for avoidance of allergens is not effective. Exposure of asthma patients to certain irritants or allergens increases asthma symptoms and often precipitates exacerbations. As a team, the physician and the patient should do everything possible to identify those allergens and irritants causing asthma symptoms. The common inhalant allergens that are known to cause asthma exacerbations are animal allergens; house dust mites; cockroaches; indoor and outdoor fungi; and outdoor plant allergens such as tree, grass, and weed pollens. The NAEPP guidelines 2007 have a questionnaire to help determine environmental factors and other factors that worsen asthma symptoms [1,6]. A history of likely sensitivity to seasonal allergens from the questionnaire and positive skin testing or in vitro IgE blood testing to assess the sensitivity to perennial allergens can be helpful in identifying these sensitivities [6]. Generally, seasonal allergens in early spring are trees; late spring, grasses; late summer to autumn, weeds; summer and fall, Alternaria, Cladosporium, mites; and cold months in temperate climates, animal dander [1]. Allergy skin or blood testing is the only way to determine sensitivity accurately to year-round indoor allergens.

Certain environmental exposure rules should be followed. If an asthmatic knows what irritants or allergens destabilize his or her disease, everything should be done to avoid these exposures. Exposure to tobacco smoke should be avoided [7,8]. Asthmatic patients should avoid beta-blocker therapies: if possible [9,10] or foods that contain sulfites [11], preservatives that often exacerbate the asthmatic condition. Aspirin and other nonsteroidal anti-inflammatory agents should be avoided [12,13], especially in patients who have nasal polyps.

Finally, rhinosinusitis [14] and gastroesophageal (GE) reflux [15], which have been implicated as asthma destabilizers, should be controlled.

The most important step in controlling allergen-induced asthma is to reduce exposure to relevant indoor and outdoor allergens. Major indoor allergens are animal dander, dust mites, mold, and cockroaches. All warm-blooded pets can cause allergic reactions. If there are pets in the patient's home and the patient is sensitive to that animal, then the most effective measure is to remove the animal from the house [1]. At a minimum, the animal should be kept out of the patient's bedroom by keeping the bedroom door closed and remove any carpets and cloth-covered furniture from the home. It should be kept clean [16], and all air ducts that lead into the bedroom should be covered with a filter.

House dust mite allergen is a major environmental factor in asthma [1]. House dust mites are universal in areas of high humidity, which includes most of the United States. In addition to high humidity, mites depend upon human dander for survival. Dust mites thrive in mattresses, pillows, carpets, upholstered furniture, and soft toys. In patients who are house dust mite sensitive and demonstrate a clinical picture consistent with allergy to the mite allergens, there are a variety of desirable control measures that should be considered [17]. Mattresses and pillows should be encased in an allergen-impermeable cover. The sheets and blankets on the patient's bed should be washed weekly in hot water, which must be >130°F to kill mites. Indoor humidity should be maintained at less than 50%, and carpets, upholstered furniture, and stuffed animals should be removed from the area. Although there are a variety of chemical agents available for killing mites and denaturing the antigens, they are not as effective as the measures described earlier.

Molds are fungi, which proliferate in humid environments, especially homes that have dampness problems. Creating a drier environment by fixing old water leaks and eliminating water sources reduces mold growth. Reducing indoor humidity to less than 50% substantially limits mold growth.

If cockroach infestation is present in the home, it is very important to institute chemical control measures to reduce this antigen load [1]. Asthma severity seems to increase with increasing levels of cockroach antigen. Food should be kept out of bedrooms and food and garbage should be kept in closed containers. When chemical agents are used to control infestation, the home should be well ventilated and the patient should not return to the home until the odor has substantially dissipated.

A variety of measures can be taken to reduce allergen in the home by modifying indoor air. Vacuuming carpets twice a week, preferably with a cleaner loaded with a high-efficiency particulate air filter, can reduce house dust accumulation, but the patient should not be in the room when the vacuuming is occurring. Air conditioning and the use of a dehumidifier are helpful. Humidifiers and evaporative coolers are not recommended for use around dust mite-sensitive patients with asthma. Indoor air cleaning devices should not substitute for the measures previously described. High-particulate air filters and electrostatic precipitating filters have been shown to reduce certain animal dander, mold spores, and the particulate from tobacco smoke. However, these devices do not have an impact on house dust mite and cockroach allergens, which are heavy particulates and do not remain airborne, and thus are not effected by air filtering.

A variety of tree, grass, and weed pollens and seasonal spores contribute to the outdoor allergen loads that affect many asthmatic patients. By staying indoors with windows closed, generally in an air-conditioned environment, patients with outdoor allergen problems can be relatively protected. Pollen and spore counts are highest during the midday and afternoon, at periods of brightest sunlight. For the asthmatic who has a significant outdoor allergen problem, conducting outdoor activity shortly after sunrise or before sunset can result in a reduced pollen exposure.

Allergen immunotherapy can be helpful in certain asthmatic patients [1,18,19]. According to the NAEPP Expert Panel Report 3, subcutaneous immunotherapy should be considered for patients that have allergies and have mild-to-moderate persistent asthma (steps 2–4) [1]. However, it is preferable to have clear evidence of a relationship between asthma symptoms and exposure to the allergen in question. Finally, symptoms should be nearly perennial and difficult to control with pharmacotherapy alone. The whole concept of allergen immunotherapy is under constant debate, in terms of long-term benefit. If allergen immunotherapy is started, it should be given under the careful guidance of a well-trained physician immunotherapist who is capable of treating any life-threatening reaction that may occur [20]. The immunotherapy should be directed at a single or only a very few antigens. There is a paucity of data support for use of multiple-allergen mixes. Finally, the course of allergen therapy is typically 3–5 years in duration, but a recognizable favorable improvement in asthma should occur early in treatment.

Pharmacologic Therapy

The pharmacologic treatment of asthma includes two broad categories of drugs: bronchodilators that relax airway smooth and anti-inflammatory drugs that reduce the influx of inflammatory cells and the release and/or effects of a large variety of chemical mediators from these cells.

Bronchodilators include short- and long-acting beta-2 receptor agonists (beta agonists), methylxanthines, and anticholinergics. Anti-inflammatory agents include glucocorticoids, cromones (cromolyn and nedocromil), omalizumab, and leukotriene blockers.

In the chronic management of asthma, pharmacologic therapy is given by the oral or inhalation route, but inhalation therapy seems to be preferred because of the higher concentration of medication directly delivered to the lungs, often with greater efficacy and lower risk of adverse effects [21]. The inhalation of medication can be performed through a small-volume nebulizer or a metered-dose inhaler. An inhaler is sometimes attached to a tube spacer device, in order to

TABLE 53.1
Controller and Quick-Relief Therapies for Asthma

Controllers	Quick Relief
Inhaled corticosteroids	Short-acting beta-2 agonists
Cromolyn	Systemic corticosteroids
Nedocromil	Ipratropium bromide
Leukotriene modifiers	
Long-acting bronchodilators	
Systemic corticosteroids	
Omalizumab	

reduce certain oropharyngeal adverse effects and, for some patients, enhance aerosol drug delivery into the lungs.

Medications are characterized into two general treatment classes: long-term controller medications, which are used to achieve and maintain control of chronic asthma, and quick-relief medications, or relievers, which treat acute symptoms during an asthma exacerbation (Table 53.1) [1]. The most effective medications for long-term controller therapy are those that have clearly demonstrated anti-inflammatory effects.

Chronic Controllers

Corticosteroids are the most potent and effective anti-inflammatory medications available for the management of asthma. The inhaled form of medication from a metered-dose inhaler, often attached to a spacer device, is used for the long-term control of asthma. Systemic corticosteroids administered orally are used to gain control of asthma following a period of destabilization and are avoided for long-term control. However, some patients with severe chronic disease may require systemic corticosteroid therapy on a regular basis. Corticosteroids reduce airway inflammation and airway hyperresponsiveness. Glucocorticoids also prevent asthma exacerbations and bronchial wall remodeling, which is known to occur with chronic inflammation and is responsible for the development of fixed airflow obstruction later in life [22–25].

There are many different products and delivery devices for the administration of inhaled corticosteroids, and their per-inhalation doses vary [1]. The lowest daily dose of an inhaled corticosteroid should be used in order to control disease.

Cromolyn and nedocromil sodium are nonsteroidal, anti-inflammatory inhaled medications used in the chronic management of mild and moderate asthma. The mechanisms of action of these medications are not fully understood [1]. These medications prevent bronchospasm caused by an inhaled allergen and have been shown to decrease nonspecific bronchial hyperreactivity, decrease asthma symptoms, and improve airflow obstruction [23,26]. These therapies are used as initial long-term controller medication for children and adolescents, but their response is less predictable than that of inhaled corticosteroid therapy.

Another group of anti-inflammatory agents is the leukotriene receptor blockers and synthesis inhibitors. These are oral therapies that block or inhibit the production of leukotrienes, which are by-products of the arachidonic acid-metabolic pathways and are potent bronchoconstrictors and inflammatory stimulants in humans [23]. Leukotrienes are released from a variety of inflammatory cells, such as lymphocytes, eosinophils, and mast cells, and not only induce bronchoconstriction but increase vascular permeability, mucous secretion, and other inflammatory cells. When these additional cells enter the airway, they are activated and release other powerful chemicals that propagate the inflammatory state even further [23]. There are three agents currently being used in the United States and include zafirlukast and montelukast, which are leukotriene receptor blockers and zileuton, a 5-lipoxygenase inhibitor. Zileuton acts earlier in the arachidonic acid/leukotriene pathway and potentially could have greater effects. Zileuton is taken twice a day and requires liver function monitoring. Leukotriene-pathway agents improve lung function, diminish asthma symptoms, and reduce the need for the rescue use of short-acting inhaled beta agonists [24,25,27]. Their efficacy has been shown in patients with mild-to-moderate asthma, and the improvements seen are modest when compared to inhaled corticosteroid therapy [28] but some studies show no difference [29]. These agents have also been shown to reduce bronchoconstriction caused by exercise [30], aspirin [31,32], and inhaled allergen exposure [33,34].

Omalizumab is a subcutaneously injected recombinant humanized monoclonal IgG antibody that binds to IgE antibody that has been used for the treatment of patients with moderate to severe persistent allergic asthma [35–38]. Other controller medications do not inhibit IgE production. Recommendations from the NAEPP 2007 guidelines consider it for allergen-associated severe persistent asthmatics (age 12 years or older), in steps 5 (inadequately controlled on high-dose inhaled corticosteroids and LABAs) or 6 (requiring oral corticosteroids on a daily or alternate-day basis) [1]. Omalizumab prevents IgE binding to high-affinity receptors on mast cells, basophils, and other cells and leads to decreased mediator release from these cells [1]. Patients on omalizumab have been able to reduce the dose of their inhaled steroids and frequency of exacerbations [39–43] including those requiring hospitalization [35,44–46]. However, in patients already on therapy for asthma, omalizumab does not improve spirometry, that is, FEV1 [36,44]. There is also little to no effect on bronchial hyperresponsiveness [47], but it does decrease some airway inflammatory markers [40,41,47,48].

Omalizumab is an expensive medication even in the lowest doses, determined by both body weight and IgE levels, and may require once or twice a month injections. Treatment will also affect the accuracy of most allergen-specific assays. The drug is not recommended for use in pregnant women. In rare circumstances, it has been used in occupational asthma with beneficial effects [49,50]. It can have adverse effects including anaphylaxis [51], local reactions such as

injection-site reactions, and others [51]. Anaphylaxis associated with omalizumab has been reported as any combination of bronchospasm, angioedema of throat or tongue, hypotension, syncope, and/or urticaria [51]. Anaphylaxis may occur at a rate of less than 1 in 500 patients [51]. Most patients (61%) who develop anaphylaxis will develop it within the first three injections [52] and within 2 h after a dose, but some patients may not develop symptoms for more than 12 h after a dose [51]. Overall, 75% of the reactions would be seen if monitored for a period of 2 h for the first three doses and 30 min for subsequent omalizumab injections. In our experience, anaphylaxis has been less common than reported. The Omalizumab Joint Task Force Report on omalizumab-associated anaphylaxis in 2007 has made safety and management recommendations for patients being prescribed omalizumab. Those recommendations are summarized elsewhere [52].

Theophylline, a methylxanthine compound, acts as a modest bronchodilator and may also improve asthma through certain anti-inflammatory effects and reductions in bronchial reactivity [53,54]. When theophylline is administered in a sustained-release oral therapy form, it has a long duration of action and can further control asthma when used in combination with inhaled corticosteroid therapy [55,56]. Theophylline should be considered as an alternative controller therapy to that of inhaled corticosteroids [1]. Theophylline's narrow therapeutic margin of safety, multiple medication interactions, and weak bronchodilating effect have placed it as a third-line controller therapy for chronic asthma. It is often used in patients with moderate to severe asthma after inhaled corticosteroid therapy has been optimized and a second-line controller therapy, such as a leukotriene blocker or an inhaled long-acting beta agonist, has been employed. Some patients may adhere better to an oral regimen than an inhaler-administered regimen. For each patient, the dose must be titrated to optimize efficacy and minimize the potential for drug toxicity. The target level for theophylline is recommended to be approximately 5–15 mg/L [1,57,58]. It is well known that the theophylline level may be affected by a number of factors. These include conditions that decrease the level (e.g., smoking), conditions that increase the level (e.g., heart failure, cor pulmonale, cirrhosis, hypoxia, hypothyroidism, fever, pregnancy), and drugs that increase or inhibit metabolism. Theophylline itself decreases the effect of certain sedative benzodiazepines such as lorazepam and midazolam and levels of certain antidepressants such as lithium. Seizure medications such as carbamazepine, phenytoin, and phenobarbital can also affect theophylline levels. After the patient is on a stable dose of theophylline, drug levels should be checked at least once a year as long as the patient remains stable and has no changes in health or other medications. It has also been used as additional therapy in the ICU for a patient not responding to conventional therapy for status asthmaticus.

Sustained-release oral beta-agonist tablets and a long-acting inhaled beta agonist may be used as controller therapy in addition to anti-inflammatory therapy. Patients with moderate and severe asthma generally require at least two or three controller medications to optimize their pharmacologic therapy [1]. Inhaled beta agonists that are more selective for the beta-2 receptor are preferred. Long-acting beta-agonist inhalers and tablets can have a duration of action at least of 12 h, far longer than that of the short-acting beta agonists that are needed by inhalation for the acute control of symptoms [59].

Quick-Relief Medications

In order to achieve immediate relief of bronchoconstriction and the discomforting symptoms associated with asthma, quick-relief medications such as fast-onset short-acting beta-2 agonists and anticholinergics are used. Short-acting beta-2 agonists relax airway smooth muscle within minutes and improve airflow. These agents are the drugs of choice for treating asthma exacerbations [1]. They are also used for preventing exercise-induced bronchospasm [1]. Inhaled anticholinergic therapy, such as ipratropium bromide, can also be used as a bronchodilator in this setting, but a beta agonist should be used first. Ipratropium bromide may provide some additional benefit during a moderate to severe asthma exacerbation and may also be considered as an alternative for those who absolutely cannot tolerate beta agonists [1].

Systemic corticosteroid therapy can speed the resolution of airflow obstruction and reduce the rate of relapse of severe asthma [1]. Therefore, systemic corticosteroid therapy is used in more serious asthma exacerbations, as part of the quick-relief medical plan.

Because short-acting beta-2-agonist therapies like albuterol should only be used for the symptomatic relief of asthma, the use of this medication can also serve as a marker of asthma stability. The more albuterol necessary to control symptoms, the greater the airway inflammation that is present and the stronger is the need for optimization of inhaled anti-inflammatory therapy. Using a short-acting beta-2-agonist inhaler at the rate of one or more canisters per month has been associated with an increase in asthma morbidity and mortality [60]. The majority of chronic asthma patients in this country should be able to be controlled to a level of mild episodic asthma. Mild episodic asthmatics have two or less mild asthmatic attacks a week. Therefore, if more than four puffs of a short-acting beta agonist are used weekly, then enhanced asthma control is necessary. A well-controlled asthmatic should only need one or two canisters of a short-acting beta-2 agonist per year, not counting the therapy that would be used to prevent exercise-induced bronchospasm. This should be the case for 70%–80% of asthmatics.

MANAGEMENT OF ASTHMA ACCORDING TO SEVERITY AND CONTROL CLASSIFICATION

A stepwise approach has been proposed for the pharmacologic therapy of asthma [1] (Figure 53.5). The amount and frequency of medication is dictated by asthma severity in those patients not currently on medication (Figures 53.1 and 53.5).

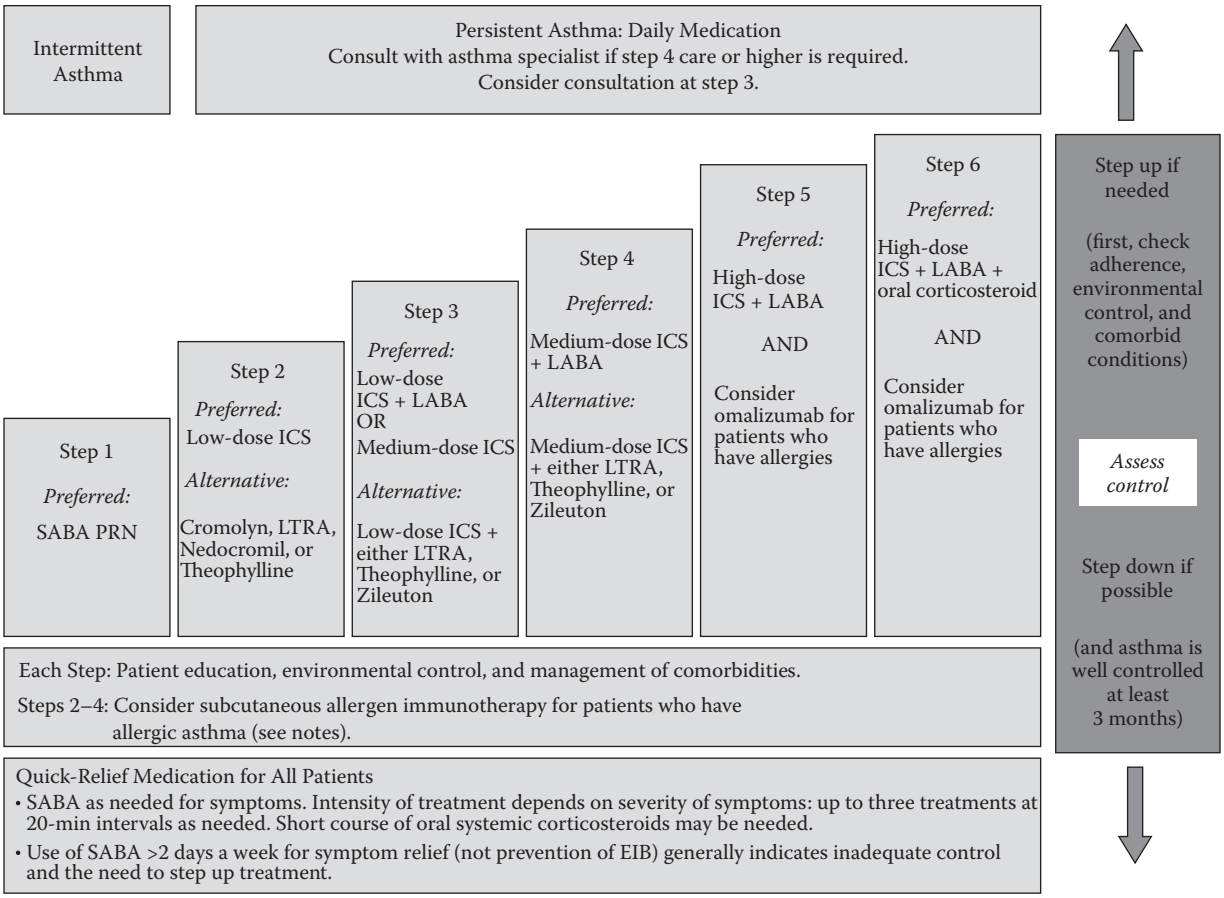

FIGURE 53.5 Stepwise approach for managing asthma. (From National Heart, Lung and Blood Institute, National Asthma Education and Prevention Program, *J. Allergy Clin. Immunol*., 120, S94, 2007.)

The level of severity is determined by assessment of both impairment and risk components [1]. According to the Expert Panel 3, the level of severity is based on the most severe impairment or risk category. The components of impairment include symptom frequency, medication use (short-acting beta agonist), and lung function measurement by spirometry. The risk assessment includes frequency of exacerbations of asthma requiring systemic corticosteroids over the last year. However, there is not enough information to correlate the frequency (specific number of exacerbations) and severity of exacerbations with the various step classification levels of asthma severity. The guidelines suggest that patients with a risk component of two or more exacerbations per year would be considered as having persistent asthma despite impairment levels that would not indicate this degree of severity. Once the severity level is assessed, the suggested step level of therapy can be determined (Figure 53.5). Therapy is directed toward treating airway inflammation. Therefore, controller therapies are emphasized, with anti-inflammatory therapy considered the mainstay. Controller therapies are often initiated at a higher level than the patient's step of severity at the onset in order to gain immediate control of disease.

Patients should be evaluated within at least 2–6 weeks after starting therapy. Once the patient returns for follow-up appointment or for a patient already on long-term controller therapy, the asthma control is assessed to adjust the current therapy (Figure 53.6). Determination or measurement of asthma control is based on impairment and risk components [1]. According to the NAEPP guidelines Expert Panel Report 3, the level of control is based on the most severe impairment or risk category. The components of impairment include symptom frequency, medication use (short-acting beta agonist), and lung function measurement by either FEV1 or peak flow. The impairment component is based on the last 2–4 weeks. If a longer period is being evaluated, it is recommended to use an overall assessment by the patient as to whether their asthma is better or worse. There are also validated questionnaires that can be used to assess impairment, but these do not assess the lung function component or even risk category. The three validated questionnaires include the Asthma Therapy Assessment Questionnaire, the Asthma Control Questionnaire, and the Asthma Control Test (ACT). The ACT can be administered quickly, and the score is based on the answers to five questions assessing symptoms, interference with activities, and beta-agonist use over the past 4 weeks [61]. Based on these parameters, asthma control is determined to be well controlled, not well controlled, or very poorly controlled.

After control has been achieved, then therapy is reduced or stepped down. Step-down therapy (Figure 53.5) is essential if

Components of control		Classification of asthma control (≥12 years of age)		
		Well Controlled	Not well controlled	Very Poorly Controlled
Impairment	Symptoms	≤2 days/week	>2 days/week	Throughout the day
	Nighttime awakenings	≤2x/month	1–3x/week	≥4x/week
	Interference with normal activity	None	Some limitation	Extremely limited

Risk	Exacerbations requiring oral systemic corticosteroids	0–1/year	≥2/year (see notes)	
		Consider severity and interval since last exacerbation		
	Progressive loss of lung function	Evaluation requires long-term follow-up care.		
	Treatment-related adverse effects	Medication side effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk.		
Recommended action for treatment (See "Stepwise Approach for Managing Asthma" for treatment steps.)		• Maintain current step. • Regular follow-up at every 1–6 months to maintain control. • Consider step down if well controlled for at least 3 months.	• Step up 1 step. • Re-evaluate in 2–6 weeks. • For side effects, consider alternative treatment options.	• Consider short course of oral systemic corticosteroids. • Step up 1–2 steps. • Re-evaluate in 2 weeks. • For side effects, consider alternative treatment options.

FIGURE 53.6 Classification of asthma control. (From National Heart, Lung and Blood Institute, National Asthma Education and Prevention Program, *J. Allergy Clin. Immunol*., 120, S94, 2007.)

one is to identity the minimum medication necessary to maintain disease control. During this process, it is helpful that airflow is monitored and correlated with asthma symptoms and signs and the intermittent use of inhaled short-acting beta-2 agonist. Patients may relapse if inhaled corticosteroids are completely discontinued.

Patients with intermittent symptoms are treated with a beta-2 agonist, which has a quick onset and short duration of action. Albuterol by metered-dose inhaler or nebulizer, used on as-needed basis, is the quick-relief therapy of choice, but other medications can also be used [1]. However, when any one of these medications is being used on more than two times per week for the relief of asthma, then the patient no longer has episodic asthma and must be classified as having a more persistent form of asthma. Persistent asthma is most effectively controlled with the daily long-term use of a controller medication. Inhaled glucocorticoid therapy is most often used and should be added to the beta-agonist therapy, which still should be on an as-needed basis [1].

The clinician must treat each individual patient, paying attention to the needs and circumstances of the patient in his or her stepwise treatment process. In order to initially gain disease control, it is often necessary to initiate anti-inflammatory therapy at a more aggressive level than that required in the long run by the patient's actual clinical disease severity [1]. Therapy can be then reduced. Many times, a short course of systemic corticosteroid therapy is used to gain control, along with a reasonable, perhaps more intermediate, daily dose of inhaled corticosteroids. Once asthma is controlled, oral therapy is quickly reduced and stopped. Within a brief period of time, inhaled corticosteroid may even be reduced to a lower daily dose. With reduced inflammation, asthma symptoms and signs should improve, PEFR should increase, variability of airflow over each 24-h time period should decrease, and finally the dependency on the use of inhaled albuterol for rescue should decrease. Enhanced control should eliminate nocturnal awakenings and activity limitation.

Most patients with moderate and severe chronic asthma require not only a higher daily dose of inhaled corticosteroid therapy but a second- or third-line controller medication. These medications include the preferred long-acting inhaled beta agonist like salmeterol or formoterol, or alternatively a leukotriene blocker therapy or perhaps a sustained-release

theophylline. However, before going to daily doses of an oral corticosteroid at step 6, you may consider a trial of high-dose inhaled corticosteroids, a long-acting beta-2 agonist, and either a leukotriene modifier or theophylline to enhance disease control, thereby improving the asthma patient's overall quality of life. Long-acting beta-2 agonist or theophylline may be especially helpful in controlling nocturnal breakthrough symptoms [62]. For patients with perennial allergen sensitivity at step 5 or 6, we would also consider omalizumab.

The most severe persistent asthmatic population requires high daily doses of an inhaled corticosteroid in addition to other controller therapies in an effort to reduce the need for daily, every-other-day, or frequent bolus-taper courses of systemic corticosteroid therapy. This group of patients should see an asthma specialist on a regular basis.

With regular follow-up visits, the clinician may be able to reduce inhaled corticosteroid therapy by 25% every 3 months, until an optimal daily dose is achieved and disease control is maintained. A chronic asthmatic who is completely withdrawn from inhaled corticosteroid therapy often relapses [63]. Therefore, there should be an excellent reason why inhaled corticosteroid therapy or other anti-inflammatory controller therapy is completely discontinued.

This discussion has focused on inhaled corticosteroid therapy as the anti-inflammatory medication of first choice. However, other anti-inflammatory therapies can be used in the first-line management of persistent asthma. These medications include inhaled cromolyn and nedocromil sodium and oral leukotriene blocker therapy [1]. This point is particularly important for children and other patients who are unable to use inhaled corticosteroid therapy on a regular basis, perhaps because of the occurrence of bothersome local adverse effects such as dysphonia and thrush. If there is difficulty in gaining control or maintaining control with reasonable doses of controller therapy, then an asthma specialist should be consulted (Table 53.2) [1]. If the asthma is not well controlled, then the following factors must be considered before increasing therapy:

TABLE 53.2
Referral to Asthma Specialist for Consultation or Comanagement

1. Patient has had a life-threatening asthma exacerbation
2. Patient has needed more than two bursts of oral corticosteroids in 1 year or required hospitalization
3. Patient is not meeting the goals of asthma therapy after 3–6 months of treatment or is unresponsive to therapy
4. Diagnosis unclear
5. Conditions complicating asthma or its diagnosis (e.g., sinusitis, nasal polyps, aspergillosis, severe rhinitis, VCD, GERD, COPD, psychosocial problems)
6. Further diagnostic testing is needed (e.g., allergy skin testing, rhinoscopy, complete pulmonary function studies, provocative challenge, bronchoscopy)
7. Consideration for immunotherapy
8. Patient requires step 4 care or higher or even consider referral for step 3 care
9. Patient education and guidance on complications of therapy, problems with adherence, or allergen avoidance
10. Confirmation of possible occupational or environmental inhalant or ingested substance contributing to asthma

Other Issues in Long-Term Asthma Management

Patient Medication Adherence and Inhaler Technique

Examination of inhaler technique is often forgotten by the busy clinician but needs to be checked when prescribing either a dry powder or metered-dose inhaler for asthma. This is very important as the patient frequently may be taking the medication but ineffectively delivering the medication to the lungs. The patient may believe that the drug does not work and discontinue it. It should be checked on the initial clinic visit and then periodically depending on their inhaler skill.

Educating the patient on the roles of the medications, especially the short-acting beta-2 agonist and the inhaled corticosteroids, is paramount. Moreover, the role of the anti-inflammatory medication especially the inhaled corticosteroids should be emphasized. It is not infrequent that patients will stop their inhaled corticosteroid because they do not notice an immediate effect. Patients must understand the type of therapeutic benefit and the time of onset of the benefit. These should be reiterated during clinic visits.

To enhance compliance with anti-inflammatory medication, it is often helpful to the patient to try and integrate the medication frequency in with their lifestyle or their ability to adhere to the regimen. For patients who are uncontrolled or even controlled on their current regimen, it is important to determine if the patient is taking their medication as prescribed, especially inhaled corticosteroids, because it is not uncommon to find that patients dosed on a twice-daily regimen will remember their morning dose but tend to forget their evening dose. This may also depend on their work schedule whether they work days, evenings, or nights. To improve patient adherence to their inhaled corticosteroid dose regimen, it may be better to determine if it is easier for the patient to take the medication (e.g., inhaled corticosteroids) all in the morning or evening instead of two divided doses.

Review of Comorbid Conditions

Moreover, in the not well-controlled asthmatic, the physician should also evaluate for other comorbid conditions: allergic bronchopulmonary aspergillosis, GE reflux, smoking, obstructive sleep apnea, rhinosinusitis, paradoxical vocal cord dysfunction, and chronic stress or depression.

Asthma Complications

Complications from asthma can occur acutely or chronically. An acute asthmatic attack is associated with a variety of complications, including pneumothorax, pneumomediastinum, a variety of cardiac arrhythmias, lung atelectasis, and respiratory failure. Rarely, death can occur. The young and the elderly are at particular risk for death because the severity of their disease is either not appreciated or is ignored. Asthma death can be sudden in onset, possibly associated with laryngospasm. However, most asthmatic deaths are slow in evolution to the point at which respiratory failure occurs as a multitude of metabolic problems develop [64]. Table 53.3 shows the factors that have been implicated in asthma exacerbation and mortality.

With poorly controlled asthma over a long period of time, irreversible airflow obstruction develops [65,66]. Recurrent airway infection is associated with fixed airflow obstruction [67]. In a few patients, allergic bronchopulmonary aspergillosis occurs, often with mucoid airway impaction and secondary bacterial infection. Allergic bronchopulmonary aspergillosis associated with asthma is characterized by episodes of severe recurrent asthmatic exacerbations [68]. Fever can be associated with this condition, as can chest pain; mucous impaction causes transient infiltrates to develop on the chest x-ray, usually in the upper lung fields. Associated blood eosinophilia and an increased serum IgE level are associated with allergic bronchopulmonary aspergillosis, but a positive skin prick test and serum precipitating antibodies to the fungus *Aspergillus fumigatus* are confirmatory for this particular form of chronic asthma. This condition generally requires high doses of inhaled corticosteroids each day, often with oral corticosteroid therapy.

Skin Testing and Immunotherapy

The discovery of IgE as the antibody responsible for allergic reactions has led to the development of certain blood tests, which can measure the amount of IgE in response to certain allergens. This form of in vitro testing is commonly an immunoassay [6]. Skin testing is less expensive and more sensitive than in vitro tests, often providing results within 1 h. There are two types of skin tests. The epicutaneous test is often referred to as the scratch or prick technique. Also there is an intracutaneous or intradermal test. These skin tests are generally easy to perform and cause little patient discomfort. When the skin test is positive, the patient can see the positive skin test, which encourages the patient to enhance their compliance with environmental control measures. Immunoassay require expertise in technique, there is no risk of an allergic systemic reaction, and it can be performed on patients who are taking medications that often suppress the skin test reaction (antihistamines, prednisone, singulair, tricyclic antidepressants).

When a positive result is found with skin testing or immunoassay, the clinician is obliged to look for clinical significance of the positive allergy test in the context of the patient's medical history. If this relationship is clear and the allergen cannot be avoided and it is difficult to control symptoms with pharmacologic therapy (mild-to-severe persistent asthma, steps 2–4), then immunotherapy should be considered [1]. Evidence is strongest for house dust mites, animal danders, and pollens [1]. However, immunotherapy should not be used until environmental control has been maximized. Allergen immunotherapy should be administered by a physician in the office or the hospital where facilities are available to treat the serious adverse reactions that can occur as a result of this form of therapy [69]. It is better to use immunotherapy for a single allergen—the more allergens that are being treated for, the higher is the incidence of failure [1]. Although multiple-allergen mixes are used for immunotherapy, only a few studies clearly support this practice [70]. Allergy immunotherapy is typically administered for 3–5 years.

There are controlled studies and a meta-analysis that support the use of immunotherapy in the treatment of asthma, which do show some benefit for asthma symptoms, bronchial reactivity, and reduced medication use [1,19,71,72]. Immunotherapy is felt to reduce not only the frequency of symptoms but also the extent of symptoms and to minimize the need for bronchodilator medications. Immunotherapy is most effective for some types of seasonal pollens (tree, grass, weed) and house dust mites with some success in pet allergy, particularly cat, in controlled studies [19,71,72]. Immunotherapy is not a cure, but may reduce asthma and allergic rhinitis symptoms and signs. The success of immunotherapy is dependent upon identifying the correct potential allergens.

There are certain risks associated with immunotherapy [69]. The most common reaction to an allergy shot is swelling, erythema, and pruritus at the site of the injection. This type of a reaction is usually short-lived and can be minimized by using topical anti-inflammatory therapy in the form of a cream or an oral antihistamine. The most serious reaction from an allergy shot is anaphylaxis. Anaphylaxis can occur quickly after the injection. Therefore, immunotherapy should be performed in the presence of a physician experienced in treating anaphylaxis. Sufficient time should be allowed for

TABLE 53.3
Factors Associated with Increased Risk of Asthma Exacerbations or Mortality

1. Severe airflow obstruction, as detected by spirometry
2. Two or more ED visits or hospitalizations for asthma in the past year; past intubation or ICU admission, especially in past 5 years
3. Patients feeling in danger or frightened by their asthma
4. Patient characteristics: female, nonwhite, nonuse of ICS therapy, and current smoking
5. Psychosocial factors: depression, increased stress, socioeconomic factors
6. Attitudes and beliefs about taking medications

Source: Adapted from National Heart, Lung and Blood Institute, National Asthma Education and Prevention Program, *J. Allergy Clin. Immunol.*, 120, S94, 2007.

the reaction to occur, so patients should remain at the physician's office for 15–30 min after each injection. Less serious reactions include nasal congestion and sneezing, asthma itself, difficulty swallowing and talking because of a swollen tongue or larynx, and light-headedness. With these reactions, there is often an increase in heart rate and perhaps even a slight change in blood pressure.

Exercise and Asthma

Exercise-induced asthma (EIA) or bronchoconstriction (EIB) is typically a transient airway narrowing and airflow obstruction that occurs during or after exercise [2,73]. Nearly 90% of persistent asthmatics have EIB, and patients with allergic rhinitis and even normal relatives of asthmatics can demonstrate this phenomenon. The most common symptoms are cough, wheezing, chest tightness, shortness of breath, and what the patient describes as an inability to take in a full breath of air during or following exercise. Symptoms start several minutes after exercise has stopped and usually improve within 1 h, even without medication. The typical fall in airflow is seen between 5 and 20 min after exercise and resolves in about 60 min (Figure 53.7). EIB can seriously and adversely affect athletic performance if not recognized and controlled.

EIB is thought to be associated with the exchange of heat and water that occurs in the airways during exercise in which minute ventilation is increased. The main factors affecting the severity of EIB during exercise are the amount of minute ventilation attained and sustained as well as the inspired air water content and temperature. Because of the high minute ventilation, there is a cooling and drying effect on the airway that somehow influences airway inflammation in a way that expresses itself more intensely [2,73]. During exercise, the airways cool down as minute ventilation increases. This cooling and drying effect of the airways sets the stage also for rapid rewarming of the airways that occurs with resting. The high flow ventilation may dry the surfaces of the airways and cause an increase in osmolarity, which may trigger the release of inflammatory mediators. Well-controlled chronic asthma should not exacerbate following exercise. It is realistic to expect that if chronic asthma is controlled, patients can participate in athletic activities at a reasonable level to maintain body conditioning and enjoy themselves. This is important because the lifestyle changes of reduced exercise may increase the risk for asthma [74]. There are interventions that should be followed to control exercise-induced bronchospasm.

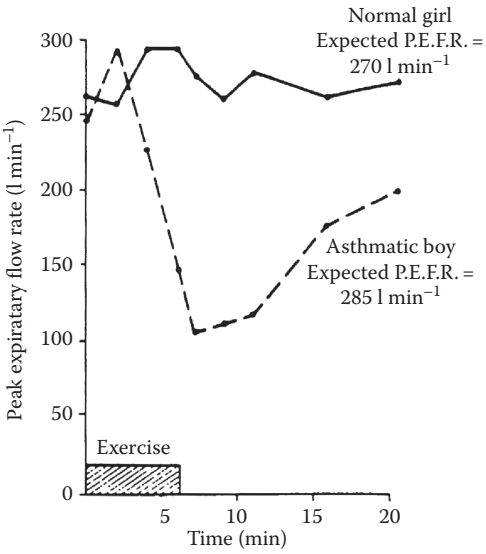

FIGURE 53.7 Response to exercise of a boy with asthma and a healthy girl whose resting peak expiratory flows were within the normal range. The boy with asthma developed a typical attack of exercise-induced bronchospasm.

Exercise-induced bronchospasm can be diagnosed simply for the majority of patients. We have had the experience of measuring PEFRs prior to exercise. After an exercise challenge, airflow is measured sequentially at 5, 15, and 30 min. The patient with EIA often has a drop in airflow within this time period. When airflow falls, especially when associated with symptoms consistent with asthma, the diagnosis can be made. This evaluation process can be done by a physician or under the guidance of a physician by instructed individuals such as trainers or coaches. Patients that are known to have asthma should be screened for EIB breakthrough. Also individuals that may be at high risk for EIB should be screened. We have found that as many as 14% of high-performance athletes will have bronchial hyperresponsiveness, including bronchoconstriction associated with exertion. There is also a substantial rate of unrecognized EIB among urban varsity athletes. In one study, we have found that during screening for asthma and EIB, approximately 10% of 238 students had a history of treated asthma and another 9% had unrecognized EIB. This suggests that active screening for EIB, especially for students residing in poverty areas, may be indicated [75].

The prevention and control of EIB can be accomplished by both non-pharmacologic and pharmacologic approaches. For some athletes, it is important to choose a sport that does not require sustained exercise, such as baseball, golf, or weight lifting. When the exercise is performed, it is preferable to avoid cold, dry environments. However, in cases when exercise is performed in colder environments, a mask or scarf covering the mouth may help reduce exercise-induced bronchospasm [76]. A warm (but not too warm) and moist environment can often be helpful in minimizing EIB. Finally, it is not only the type of sport that one plays but the position selected. For example, a football lineman is at less risk than a running back.

The use of an extended warm-up session and special breathing techniques that help minimize hyperventilation and also promote relaxation can be helpful. There is some literature that reports a warm-up period before exercise results in a refractory period or reduction in EIB for less than an hour [77,78]. The athlete should begin warming up slowly to loosen the muscles and elevate the heart rate. With the beginning of a light sweat, the athlete can perform the exercise at or close to his or her maximum exertion for up to 5 min and then take a rest. More accomplished athletes can continue this warm-up process recurrently for 30–40 min. Another strategy is to do brief bouts of exercise for 2–3 min followed

by 3–5 min of rest. These repetitive exertional challenges should occur over a 30- or 40-min period. It is important for the individual athlete to find out which warm-up protocol works best for him or her. Some athletes require a warm-up period of as long as an hour.

Just as important as warming up appropriately is concentrating on breathing maneuvers during and following exercise. Symptoms can be reduced by breathing warm, humid air rather than cold, dry air. Therefore, swimmers are likely to tolerate their disease better than football players. Certain athletes have learned to breathe through their nose instead of their mouth. This is a difficult technique to master. When athletes breathe through their nose, especially during periods where heavy breathing is unnecessary, the air that is brought into their lungs is humidified and heated. By breathing deeper and more slowly, the cooling and drying effect of the hyperventilation of exercise can be minimized.

The postexercise period is also very important. The cooldown phase after a workout or competition should resolve taking deep, slow breaths. Cooling down in a warmer but not too warm environment can be helpful.

Often, drug therapy is necessary to prevent EIB. There are numerous inhaled beta-agonist medications that can be used shortly before exercise and even during and after exercise to prevent or relieve asthma symptoms [1]. Beta agonists administered by inhalation will prevent EIB in more than 80% of patients. Administering a short-acting inhaled beta agonist such as albuterol approximately 15–30 min before exercise provides protection for 2–3 h. When asthma breaks through, these medications can be safely administered by a metered-dose inhaler. The inhaled long-acting beta-2 agonists (formoterol, salmeterol) can be helpful for controlling frequent need for short-acting or daily need for short-acting beta-2 agonists. Salmeterol has been shown to prevent EIB for 10–20 h [79] and is valuable for prolonged prevention when the athlete will reexpose himself or herself to the exercise challenge over this time period. Long-acting beta-2 agonists should not be used alone as daily prophylaxis of EIB as the duration of effect may be masking less suboptimally controlled asthma [1]. Other therapies can be used in addition to the beta agonist. Inhaled cromolyn or nedocromil, although less effective than short-acting beta-2 agonists, can be taken approximately 30 min to 1 h prior to exercise, often in addition to the pre-exercise use of the short-acting inhaled beta agonist for further control in those patients who fail single preventative therapy [80]. Administered in a single-dose pretreatment manner, the leukotriene receptor antagonists can decrease EIB in approximately half of patients within hours of administration [1,81].

Most EIB occurs in the chronic asthmatic, making control of chronic asthma with the therapies described earlier crucial. Inhaled corticosteroids can decrease airway responsiveness over the long term and decrease EIB. When chronic asthma is controlled, the frequency and severity of EIB are reduced [82].

Occupational Asthma

It has been estimated that occupational factors account for approximately 9%–15% of cases of asthma in adults of working age, including new onset or recurrent disease [83]. A variety of substances in the workplace have been implicated in the development of asthma, including a large variety of animal proteins, flour and grain dust, wood dust, cotton dust, chemical compounds such as isocyanates and hydrides, metal salts, and even pharmaceuticals [83]. The workers most commonly reported for occupational asthma include paint sprayers, bakers and pastry makers, animal handlers, nurses, chemical workers, welders, food processing workers, and timber workers [83].

The causes of occupational asthma can be grouped into immunologic and non-immunologic causative agents. Up to 90% of cases have been of the immunologic type. Some causative agents can produce occupational asthma through both immunologic and non-immunologic mechanisms. The immunologic agents can be divided into high- and low-molecular-weight substances (Table 53.4). The high-molecular-weight agents are complete sensitizing agents while the low-molecular-weight agents need to combine with a protein to form a sensitizing agent. The high-molecular-weight agents are usually mediated through IgE. There is a time delay between exposure to the offending agent and the development of symptoms of occupational asthma.

It is important to recognize occupational asthma as soon as possible, because the likelihood of complete resolution of symptoms decreases over time [1]. Occupational asthma is suspected when either the patient or the clinician realizes that there is a relationship between asthma symptoms and work exposure. Many times, the patient will improve on the days that he or she is away from the workplace, particularly during vacations. Sometimes coworkers have similar symptoms, and

TABLE 53.4
Select Causes of Allergic and Nonallergic Occupational Asthma

Allergic	
High-Molecular-Weight Substance	*Occupations*
Animal protein	Laboratory workers
Papain	Brewers, lens workers
Wheat flour	Bakers, millers
Trypsin	Plastic/pharmaceutical workers
Soybean dust	Farmers, food workers
Vegetable gums	Printers, food workers
Low-molecular-weight substance	
Platinum	Jewelers, refiners
Trimellitic anhydride	Plastic and epoxy resin workers
Phthalic anhydride	Plastic and epoxy resin workers
Nonallergic	
Isocyanates	Spray painters, foundry workers
Polyvinylchloride	Meat wrappers
Western red cedar	Carpenters

sometimes asthma can occur during the night. Serial peak flow measurements at work and away from work can help diagnose occupational asthma [83]. There are some allergens available, which are not well standardized, for skin prick testing and blood tests for specific IgE for high-molecular-weight agents but only a few for low-molecular-weight agents. Occupational asthma can usually be diagnosed without using specific bronchial provocation testing, although occasionally a specific bronchial provocation challenge done in a specialized laboratory with a suspected allergen or irritant from the workplace can be helpful [83].

The management of occupational asthma can be difficult, and the patient may have to be referred to an occupational asthma specialist. Diagnosing patients early and avoiding further exposure to the causative agent will give the worker the best opportunity for a complete recovery. Often, the employee must avoid the triggering substance. If impossible, then the employee should be moved to an area of low or occasional exposure with increased monitoring. The use of respiratory protection by wearing a ventilator mask can be helpful. Many times the patient must completely avoid exposure to the irritating agent; therefore, a new job position may be necessary. The outcome of any intervention for patients with confirmed occupational asthma depends on factors such as age and the type of agent [83]. Unfortunately, some patients will have persistent asthma despite removal of the inciting substance. A variety of chemicals, dust, and other particulates can sensitize the airways and actually induce chronic asthma [84]. This is different than allergen- or irritant-induced asthma, in which these substances aggravate preexisting asthma but do not actually initiate the disease process. A single high-intensity exposure to a non-immunologic irritant can produce the syndrome known as reactive airways dysfunction syndrome, in which symptoms occur in minutes and may last for years.

Stress

Asthma is not a psychosomatic illness. However, there is emerging evidence that stress plays an important role in precipitating asthma exacerbation and may act as a risk factor for the increased prevalence of this disease [85]. Since emotional upset does contribute to the asthma symptom picture, a variety of psychological interventions may be necessary to enhance overall asthma care. Stress exacerbation of asthma may involve enhanced generation of pro-inflammatory cytokines, but more importantly, psychosocial factors associated with stress influence the asthmatic's personal sphere and often lead to a poor outcome [86]. Conflict that develops between the patient, the family, and the medical staff often interferes with appropriate asthma care. It is true that the poorly controlled chronic asthmatic can despair, and his or her disease can have a significant negative effect on personal relationships, family life, and self-image. Enhanced asthma control and careful discussion of these issues with the patient and family can help the overall asthma care process. The asthmatic who needs psychosocial assistance should take the advantage of appropriate professional counseling with a psychologist, psychiatrist, social worker, or other licensed practitioner [1]. There are a variety of psychologically oriented approaches to asthma care that can be helpful, including family counseling, educational seminars, and psychotherapy. Ignoring one's asthma symptoms and neglecting to use medication can adversely affect asthma control. Asthma education has been associated with enhanced confidence in the patient's management of chronic asthma [1].

Food Hypersensitivity

Food allergy may rarely precipitate asthma symptoms alone. (The diagnosis and management of food allergy is discussed in Chapter 55.)

Medication-Induced Asthma

The ingestion of aspirin in sensitive individuals may result in nasal congestion, eye irritation, facial flushing, and asthma exacerbation, which usually occurs rapidly after ingestion, often within 30 min [87]. Approximately 4%–20% of asthmatics are sensitive to aspirin and related compounds [88], especially nonsteroidal anti-inflammatory agents. Severe and even fatal asthma exacerbations have been associated with aspirin ingestion. Adult patients with severe persistent asthma who have nasal polyps should be carefully instructed not to use any aspirin or aspirin-like medication. Some safe alternatives to aspirin to consider include salsalate, acetaminophen, and celecoxib [89], but highly sensitive patients may even react to these [1,12]. Nasal polyposis and chronic rhinosinusitis occur in nearly 90% of the patients with aspirin sensitivity (Samter's syndrome) [90]. The prevalence of aspirin sensitivity increases with age and the severity of the asthma. There is no known familial predilection to aspirin sensitivity. It is not known to be associated with atopy. Medications that interfere with leukotriene synthesis or leukotriene receptor antagonists are helpful in the management of aspirin-induced asthma. Patients are treated according to asthma guidelines but usually include a leukotriene-modifying agent [31,32,91]. The treatment of aspirin-exacerbated asthma also includes avoiding all NSAIDs that inhibit COX-1 enzyme. An alternative to complete avoidance is aspirin desensitization and daily aspirin therapy [1].

Tartrazine or yellow food dye No. 5 can induce asthma symptoms in some individuals. This food coloring is found in a number of foods and in some medications.

Beta-blockers, including a variety of eyedrop preparations, can induce asthma symptoms and should be avoided in asthmatic patients [1,9,10]. The more cardioselective may be better tolerated by the asthmatic [92], but in order to be safe, an asthmatic should avoid beta-blocker therapy, unless this form of medication is unavoidable for the cardiac or eye condition. The NAEPP Asthma Guidelines 2007 suggest avoiding nonselective beta-blockers [1]. However, patients who have mild-to-moderate airflow obstruction are often able to tolerate selective beta-blockers, and we recommend using

them if needed after careful consideration in patients with appropriate cardiac disorders [1].

Gastrointestinal Reflux

GE reflux results when some of the liquid contents of the stomach regurgitate into the esophagus. The GE reflux material does not have to be aspirated into the lungs to induce asthma. Reflux of the acidic fluid into the esophagus likely destabilizes asthma either by enhancing the cholinergic autonomic nervous system influence or by microaspiration or both. GE reflux should be suspected in patients with poorly controlled asthma, particularly those who have nocturnal symptom breakthroughs [1]. Reflux symptoms do not have to be present, which makes the diagnosis difficult. However, when GE reflux is symptomatic, patients usually complain of "heartburn" or sometimes note food regurgitated into the throat [1]. A patient who has a hiatal hernia is at particular risk for GE reflux.

Treatment of patients with symptomatic GE reflux has been associated with improvement in some aspects of their asthma [93,94]. Patients with nocturnal symptoms and/or regurgitation are more likely to show improvement in their asthma with treatment [1,95]. However, a recent study indicated that treatment of asthmatics without GE reflux symptoms did not improve their asthma [96]. If GE reflux symptoms are present, medical management includes the following: (1) avoidance of eating food and drinking liquids within 3 h prior to bedtime; (2) sleeping with the head of the bed elevated by using 6–8 in. blocks; (3) eating smaller, and if necessary more frequent, meals; (4) pharmacologic therapy with H_2 receptor blockers or proton pump inhibitors; and (5) cessation of alcohol, cigarettes, and caffeinated foods [1]. Also theophylline can reduce the lower esophageal sphincter tone and predispose the asthmatic to GE reflux.

If the medical management as described earlier fails or the patient has other disturbing symptoms, then further evaluation by a gastroenterologist and other treatment options should be considered. Some patients may have to be referred to a surgeon for evaluation.

Pregnancy and Asthma

Asthma is the most common medical condition during pregnancy, occurring in 4%–8% of pregnant women [97]. The risk of asthma exacerbation during pregnancy is higher for woman who had asthma before becoming pregnant. For the patient who has had asthma and is now pregnant, there is a chance that the asthma will remain the same, improve, or worsen [1]. Whatever way the asthma changes during the first pregnancy, it is likely that similar symptoms will occur with subsequent pregnancies. Patients with more severe and difficult-to-control asthma generally have worse symptoms during pregnancy. As a general rule, one-third of all pregnant asthma patients improve, one-third remain the same, and one-third have worsening disease during pregnancy [1]. It is important for every asthma patient who becomes pregnant to be carefully managed medically during the pregnancy.

Asthma may also have an effect on pregnancy complications [98]. Uncontrolled asthma itself is a risk for the fetus. One large study showed that asthmatic patients had an increased risk of infant mortality, preterm birth, and low-birth-weight infants compared to non-asthmatics [98]. Those with more severe asthma have a higher risk of complications [98]. However, this study did not find an increased risk of congenital defects [98]. A mother whose asthma is well controlled and free of complications imposes no additional risk on the fetus.

The goals of asthma treatment during pregnancy are to prevent acute exacerbations and to optimize lung function with medications shown to have the lowest potential adverse effect on the fetus. This should provide maximum benefit to the health of the mother and the fetus [1,99]. The majority of asthma medications that are used in practice present little to no risk during pregnancy although prospective well-designed and well-controlled clinical trials do not exist for most medications. The U.S. Food and Drug Administration has classified medications into five categories (A through D and X) related to their potential for adverse effects on pregnancy. These classifications are based on animal and human data and also risk–benefit. The safest is category A, but there are no asthma medications in this group. Both systemic and inhaled corticosteroids can be used during pregnancy. The inhaled steroid, budesonide, has long been listed as category B and preferred [1] during pregnancy because of the large amount of safety data obtained from the medical birth registry in Sweden [1]. However, patients that are doing well on other inhaled corticosteroids could be continued. Inhaled beta-agonist therapy with albuterol, which has the most safety data during human pregnancy [1], should be used for symptom breakthrough. During pregnancy, the leukotriene inhibitors, montelukast and zafirlukast, are not the preferred therapy for mild persistent asthma. Allergy immunotherapy can be continued through pregnancy but should not be started or altered during this period.

Inhaled therapy should be selected over systemic therapies during pregnancy. Over-the-counter medications should be avoided. The obstetrician and the primary care physicians should work together to create the safest treatment regimen for the pregnant asthmatic patient. When questions arise, the local asthma expert, generally an allergist or pulmonary specialist, should be consulted.

DEFINITION

The American Thoracic Society (ATS) and European Respiratory Society (ERS) have defined pulmonary rehabilitation as follows:

> … an evidence-based, multidisciplinary, and comprehensive intervention for patients with chronic respiratory diseases who are symptomatic and often have decreased daily life activities. Integrated into the individualized treatment of the patient, pulmonary rehabilitation is designed to reduce symptoms, optimize functional status, increase participation, and reduce health care costs through stabilizing or reversing systemic manifestations of the disease. [1]

History and Development

Until the 1950s, patients with COPD were advised to minimize physical exertion to avoid dyspnea [2]. Dr. Alvin Barach suggested that emphysema patients could obtain a training benefit from exercise that was similar to the exercise benefits seen in healthy people [2,3]. Barach suggested that exercise-based rehabilitation would lead to increased capacity for physical exertion [4].

Pulmonary rehabilitation took a significant step forward with Dr. Thomas Petty's concept of a "comprehensive care program" that he developed and refined in the 1960s. In his formulation of this program, patients with chronic airway obstruction received outpatient-based, individualized educational sessions about bronchial hygiene and breathing techniques in addition to exercise sessions and optimization of pharmacologic therapy. In 1969, he published the seminal paper that outlines many of the concepts still used in pulmonary rehabilitation programs today [5]. Petty demonstrated that patients who completed the program had improved exercise capacity and reduced hospitalization. Other benefits included a "return to gainful employment" in some patients [5].

Broad acceptance of pulmonary rehabilitation as a valid option for COPD treatment was hampered by the fact that pulmonary rehabilitation did not improve spirometry, which was the main parameter that defined the severity of COPD [6]. As of the mid- to late 1980s, there was still debate about the true benefit of pulmonary rehabilitation in COPD [7]. That skepticism also stemmed from the belief that patients with significant airway obstruction would have a ventilatory limitation to exercise and that this impairment would prevent them from achieving work rates high enough to produce a training effect on the muscles [8].

Development of Measurement Tools

The introduction of other clinical outcome measures for investigation facilitated the development and growth of

pulmonary rehabilitation. The principle of the minimally clinically important difference (MCID) is an essential concept to properly understand the results of these measures. The MCID is the smallest difference in a measure that a patient would perceive as beneficial. This is the amount of change needed to indicate a change in treatment, in the absence of side effects or extreme cost [9].

The Baseline Dyspnea Index (BDI) and Transitional Dyspnea Index (TDI) [10], Chronic Respiratory Disease Questionnaire (CRDQ) [11], and St. George's Respiratory Questionnaire (SGRQ) [12] are tools designed to examine changes in dyspnea and health-related quality of life (HRQOL). The BDI consists of three components: functional impairment, magnitude of task, and magnitude of effort. Each component is scored from 0 to 4. The TDI measures the changes from BDI and is scored anywhere from +3 to –3 for each component. One unit change is generally accepted as the MCID [13]. The CRDQ is a 20-item interviewer-administered questionnaire that looks at respiratory illness-related quality of life. It is comprised of four domains and is scored using a 7-point numerical scale. Higher scores indicate better quality of life. A change of 0.5 on the 7-point scale is the minimum clinically significant change [9]. SGRQ is a 76-item questionnaire that was developed for patients with fixed and reversible airway obstruction. The SGRQ had three domains—symptoms, activity, and impacts. Scores are from 0 to 100 with higher scores indicating poorer health status. A change of four units is clinically significant [12]. Measures to quantify exercise capacity, such as the 6-minute walk test (6MWT), were also developed [14]. The test is conducted by asking a patient to simply walk as far as he can within 6 min in a premeasured hallway or corridor. Normal subjects can travel anywhere from 400 to 700 m [15]. A change of 54 m is commonly accepted as the minimal clinically significant difference in patients with COPD [16].

IMPACT OF PULMONARY REHABILITATION

Effects on Dyspnea, Exercise Capacity, and Quality of Life

The use of these measurement tools facilitated the demonstration of benefits of Pulmonary Rehabilitation. In 1991, Casaburi published a landmark paper that proposed a physiologic mechanism for the increase in exercise capacity seen after pulmonary rehabilitation [17]. In that study, 19 patients with COPD participated in an inpatient 8 week pulmonary rehabilitation program consisting of exercise and education. Participants were randomly divided into two groups—a high work-rate group (exercise intensity of 90% of the anaerobic threshold work rate or 80% of maximally tolerated work rate as determined by a prior exercise test) and a low work-rate group (work rate of 60% of the difference between the anaerobic threshold and VO_2 max work rate or 50% of the maximally tolerated work rate). After pulmonary rehabilitation, the high work-rate group lactate threshold increased by 24%. Also, for a given level of exercise, blood lactate decreased by 38% and minute ventilation decreased by 12%. CO_2 production was also decreased. The changes in these parameters in the low work-rate group were significantly less. The authors concluded that high-intensity exercise leads to superior physiologic outcomes and that the basis for the benefit of pulmonary rehabilitation is a lower production of lactic acid during exercise. This leads to less ventilatory demand for a given level of exercise in muscles that achieved a training effect.

Reardon investigated 20 COPD patients who were randomized to receive either a 6 week outpatient pulmonary rehabilitation program with educational sessions or a control group that did not undergo pulmonary rehabilitation [18]. The target intensity for the exercise component was a heart rate or dyspnea severity of 70%–85% of that seen during maximal exercise testing. In the pulmonary rehabilitation group, dyspnea at maximum workload decreased from 74% to 50% while there was no change in the control group. The rehabilitation group also had higher TDI scores, indicative of decreased dyspnea. Two physiologic parameters, dyspnea at maximum workload divided by VE_{max} and dyspnea at maximum workload divided by VO_2 max, were also improved in the rehabilitation group. This was the first randomized clinical trial demonstrating the benefit of pulmonary rehabilitation in COPD patients.

Ries published a large randomized controlled trial of 119 patients randomized to 8 weeks of pulmonary rehabilitation program or an education only program [19]. The exercise goal was "steady-state exercise consisting of continuous walking at the highest tolerated symptom limited level for as long as 30 minutes." The pulmonary rehabilitation group had significantly greater improvements in exercise endurance, perceived breathlessness during exercise, and dyspnea with daily activities when compared to the control group. Other studies showed similar gains in exercise capacity and health-related quality of life after pulmonary rehabilitation [20–22].

Ries et al. published a large study looking at 1218 patients selected from the National Emphysema Treatment Trial (NETT) [23]. These patients underwent a comprehensive pulmonary rehabilitation program prior to being randomized into the lung volume reduction surgery (LVRS) arm or medical management arm. Selected patients had a mean FEV_1 of 26.9%. After completing the rehabilitation program, patients had improved dyspnea, health-related quality of life, and exercise capacity. Patients who had no prior pulmonary rehabilitation experience had a larger improvement compared to those patients who had prior rehabilitation.

Lacasse et al. reviewed the literature on pulmonary rehabilitation in a meta-analysis in 1996 [24] as well as a Cochrane review in 2009 [25]. The 2009 Cochrane review included 31 randomized clinical trials. Significant improvements were seen in health-related quality of life. 6MWT improvement was near, but did not exceed, the MCID of 54 m.

IMPACT ON HEALTH CARE UTILIZATION

Clinical data suggest that patients who complete a pulmonary rehabilitation program utilize fewer health care resources. The patients reported in Petty's original paper

spent fewer days in hospital in the first year after participation in the program [5]. Ries et al. demonstrated a decrease in hospitalization in the pulmonary rehabilitation group of 2.4 days per patient per year versus an increase of 1.3 days per patient per year in the control group in the year after pulmonary rehabilitation [19]. Griffiths et al. calculated that pulmonary rehabilitation has a probability of 0.645 that it will result in a negative cost per quality adjusted life year (QALY) gained [21]. This is comparable to other interventions such as hip replacement, coronary artery bypass grafting, and insulin treatment in type 2 diabetes. Bourbeau published a multicenter clinical trial that randomized COPD patients to an intervention program consisting of daily home educational sessions and an individualized action plan versus usual care [26]. The patients were given an exercise prescription that consisted of a typical pulmonary rehabilitation session—warm-up/stretching activities and then either stationary biking, walking, or stair climbing. In the intervention group, there were significant decreases in hospitalizations for COPD exacerbations, emergency department visits, and unscheduled doctor visits. Hospital admissions for non-COPD issues were diminished as well. Other studies also documented reductions in hospitalization rates, length of hospital stay, hospital readmissions, and interval to readmissions [27,28]. A large study of more than 600 patients participating in 9 pulmonary rehabilitation centers in California [29] demonstrated that program participants had fewer physician visits, phone calls to health care providers and hospital days at 3, 6, 12, and 18 months when compared to the 3 months prior to joining pulmonary rehabilitation.

An observational study looked at how the BODE index changes with pulmonary rehabilitation [30]. The index has four components, the *B*MI, severity of *O*bstruction as measured by FEV_1, *D*yspnea as measured by the Medical Research Council score, and *E*xercise capacity as measured by timed walking distance [31]. Each of these parameters separately have been shown to impact mortality and combined together predict mortality better than spirometry alone [31–36]. The rehabilitation group had diminished length of hospital stay and hospitalization when compared to the non-rehabilitation group [30]. Hospital length of stay decreased by approximately 20% in those patients who completed pulmonary rehabilitation. A larger improvement in the BODE index was associated with a larger decrease in hospital length of stay.

Currently, pulmonary rehabilitation is considered the standard of care in symptomatic patients with COPD. In the latest ACCP/AACVPR clinical practice guidelines [37], pulmonary rehabilitation was given the strongest possible recommendation (1A) as a modality for improving dyspnea and health-related quality of life. In fact, in comparison with the known treatment benefit of inhaled therapies for COPD such as salmeterol [38] and tiotropium [39], pulmonary rehabilitation demonstrates similar efficacy in improving health-related quality of life.

PHYSIOLOGIC BASIS OF PULMONARY REHABILITATION

Pulmonary rehabilitation programs improve exercise capacity without any significant changes in lung function such as FEV_1 [17] or oxygenation [40]. If spirometry and oxygenation does not improve with pulmonary rehabilitation, what is the mechanism of benefit?

It had been previously postulated that the benefits seen in pulmonary rehabilitation may be due to other factors such as dyspnea desensitization (due to the reassuring presence of health care personnel during exercise training) and anxiety reduction [41], or improved muscle function. Of these potential explanations, it now appears that improved muscle function is the most important factor.

A vital concept in the practice of pulmonary rehabilitation is the "dyspnea spiral" or the "fear-dyspnea cycle" [6,42]. This describes a situation where a patient with a chronic respiratory disease gradually limits physical activity to avoid the unpleasant sensation of dyspnea. Consequently, the patient becomes increasingly more sedentary and deconditioned such that progressively lower levels of physical exertion lead to breathlessness. The exercise component of pulmonary rehabilitation is designed to break this cycle and improve a patient's exercise capacity.

It has been demonstrated that exercise limitation in patients with COPD may not always be due to a ventilatory or gas exchange limitation but can also be due to leg fatigue and muscle weakness [43,44]. Saey et al. reported a small group of COPD patients who completed cycling exercises until the onset of quadriceps contractile fatigue [45]. In the group who developed muscle exhaustion, there was evidence of a ventilatory limitation to exercise as well. However, when these patients were pretreated with ipratropium such that their FEV_1 increased by 11%, endurance time did not increase. This suggests that lower extremity weakness is an important factor that limits exercise capacity in patients with COPD. This muscle weakness may simply be due to deconditioning and muscle wasting as COPD patients tend to be progressively more sedentary or due to a more specific "COPD myopathy."

There are increasing data supporting the concept of COPD as a systemic disease not limited to pulmonary symptoms and manifestations [46–49]. Increased systemic levels of inflammatory markers such as CRP, fibrinogen, leukocytes, TNF-α, IL-6, and IL-8 have been found in patients with COPD [50]. It has been suggested that systemic inflammation occurs when inflammatory mediators from COPD do not remain localized within the lung and leaks out into the systemic circulation [48,51,52]. These inflammatory mediators then can cause extrapulmonary manifestations. Among the proposed extrapulmonary consequences are the following: osteoporosis, anemia, coronary artery disease, diabetes, and muscle abnormalities [46,53–58].

Skeletal muscle dysfunction is the change that has the most significance to pulmonary rehabilitation. Patients with COPD have distinct skeletal muscle pathologies in addition to a decrease in skeletal muscle mass in the lower extremities.

Patients with COPD have less muscle capillarity. In a study by Jobin involving biopsies of the vastus lateralis muscle, COPD patients had a significantly lower number of capillaries per square millimeter as well as a reduced capillary to fiber ratio when compared to nonsmoking, non-exercising controls [59]. Furthermore, vastus lateralis biopsies of patients with COPD has shown reduced type I fibers and increased type IIb fibers [59,60]. Type I fibers are slow twitch fibers and are more resistant to fatigue; type IIb fibers are fast-twitch fibers and are more prone to fatigue as they use anaerobic glycolysis [61]. Agusti demonstrated that quadriceps femoris biopsies from COPD patients with low BMI have increased apoptosis when compared to healthy subjects and sedentary patients [62]. In subjects with COPD, body mass index (BMI) was inversely related to degree of apoptosis. Apoptosis was also associated with lower exercise capacity given similar lung function. Muscle apoptosis may be partially responsible for the weight loss frequently seen in patients with COPD.

In 1996, Maltais et al. published a paper investigating the skeletal muscle oxidative capacity of COPD patients [63]. They measured the activity of two oxidative enzymes: citrate synthase (CS) and 3-hydroxyacyl-CoA dehydrogenase (HADH). They found that oxidative enzyme activity was lower in COPD patients and that the rate of increase in lactic acid concentration with exercise was steeper in COPD patients as well. It was postulated that the early rise in lactic acid may be due to this impaired muscle oxidative capacity. The same investigators also demonstrated that CS activity decreased in tandem with decreasing functional status and that CS activity correlated with exercise capacity independent of lung function [64]. The net result of this muscle dysfunction is that lactic acidosis occurs at a lower level of exertion which results in exercise limitation. Lactic acidosis may also indirectly lead to the sensation of breathlessness, as it serves as a stimulus for increased ventilation which patients with a ventilatory limitation are unable to meet.

The cross-sectional area of type I and II muscle fibers increase after participation in rehabilitation [60]. More importantly, Maltais et al. demonstrated that after a 12 week exercise program, exercise lactate threshold increases and levels of oxidative enzymes citrate synthase (CS) and 3-hydroxyacyl-CoA dehydrogenase (HADH) increase as well [63]. The logical and prevailing hypothesis is that the decrease in lactic acid production is due to increased skeletal muscle oxidative capacity resulting from higher oxidative enzyme activity.

CURRENT PRACTICE OF PULMONARY REHABILITATION

Patient Selection

Pulmonary rehabilitation is typically done as an outpatient hospital-based program (Figure 54.1) although several other models exist—inpatient, home-based, or inpatient initially and continued as outpatient [28,40,65,66]. Any patient with a chronic respiratory disease with exercise limitation or significant limitations of activities of daily living (ADLs) can be considered for the program. There are no specific spirometric or pulmonary function test cutoff points as patients may have significant exercise limitation despite mild impairment in tests. The most recent Global Initiative for Chronic Obstructive Lung Disease (GOLD) statement [67] recommends pulmonary rehabilitation for all stages of COPD.

FIGURE 54.1 An outpatient, hospital-based setting for pulmonary rehabilitation.

Pulmonary rehabilitation programs are best implemented by a multidisciplinary team. At a minimum, a pulmonary rehabilitation team should consist of a medical director, program coordinator, and rehabilitation specialist [68]. Other health care professionals such as nutritionists, psychiatrists, and occupational therapists may participate and provide valuable patient services. Before being accepted to the program, a patient is first screened by the medical director to ensure that pulmonary rehabilitation is an appropriate intervention for the patient. Contraindications to pulmonary rehabilitation would include those conditions that would preclude a patient from doing exercise testing safely such as active myocardial ischemia, serious arrhythmias, dissecting aneurysm, and severe aortic stenosis [69]. Other conditions such as severe psychiatric disorders, disruptive behavior, poor cognitive function, severe orthopedic problems, or unwillingness to engage in the program would also prevent a patient from effectively participating in the other components of pulmonary rehabilitation such as educational sessions and psychosocial interventions. If the patient is considered appropriate, he or she meets with other members of the team for psychosocial assessment, nutritional assessment, goal development, and evaluation of rehabilitation potential. The patient's current level of physical activity and ADL limitations are also evaluated. Baseline measures of HRQOL such as the SGRQ and CRDQ are obtained. A pre-rehabilitation exercise test is done to rule out potentially serious cardiovascular issues that may hinder exercise training as well as to establish baseline exercise capacity. The need for supplemental oxygen is also assessed and documented.

Exercise Training

Once a patient is accepted into the program, an individualized exercise prescription is developed based on the patient's existing level of functioning, desired goals, and pre-rehabilitation exercise test results. The exercise prescription will be modified in the course of the rehabilitation program, as the patient's exercise capacity may increase during the course of the program. Pulmonary rehabilitation programs are typically anywhere from 6 to 12 weeks in duration, meeting 3–5 times a week, with each session lasting 2–4 h. Typically, the bulk of each session is dedicated to exercise training with the remaining time for educational, psychosocial, or nutritional counseling.

Exercise is typically done with activities designed to increase the endurance of the lower extremities as they are the main muscles of ambulation. Activities may consist of walking, using the treadmill or elliptical machine, and stationary biking. High-intensity regimens may be superior to low-intensity prescriptions. High-intensity training yields a more demonstrable training effect when compared to low-intensity training [17]. Other papers have confirmed the benefits of high-intensity training on the level of dyspnea at rest, submaximal exercise lactate level, peak VO_2, anaerobic threshold, and 12 min walk distance [70].

On the other hand, there are data showing that low-intensity aerobic exercise may also lead to increased exercise capacity and endurance [71]. Clark et al. showed that low-level exercises targeting peripheral muscle groups in isolation, without high-intensity aerobic activities, can still improve endurance in patients with COPD [72]. Furthermore, there are studies that suggest that a physiologic improvement in exercise capacity is not always necessary to improve health-related quality of life. Puente-Maestu et al. published a study where they looked at 41 COPD patients who were randomized to self-monitored walking for 8 weeks versus supervised treadmill walking for 8 weeks [73]. The goal for self-monitored group was to walk 3–4 miles/day for 4 days a week while the supervised group did physiotherapist-supervised treadmill walking for 60 min a day for 4 days a week. Both groups had similar increases in CRDQ despite a greater increase in physiologic parameters such as the VO_2 max in the supervised group. Normandin et al. demonstrated larger increments in treadmill endurance time, VO_2 max, and dyspnea severity in a high-intensity exercise group when compared to a lower intensity group [74]. Despite this, there was no difference between the improvement seen post-rehabilitation in the health status outcomes as measured by CRDQ and TDI.

Currently, the ideal exercise intensity (or the variable to use to measure intensity) has not been definitively established but several parameters have been used. Among them:

- Target heart rate: (peak heart rate − resting heart rate) × 0.6 [6]
- Target heart rate: 70%–85% found on maximal exercise testing [18]
- Dyspnea: moderate to relatively severe dyspnea on Borg scale [20]
- 75% of peak work rate demonstrated on pre-PR incremental exercise test [75]
- Above anaerobic threshold [76]
- 60%–80% of maximal work attained [69]
- Targeting 20 min on a treadmill [40]
- Borg scale of 3–4 [26]
- Borg score of 4–6 for dyspnea or fatigue [1]

Exercise regimens typically consist of warm-up activities for 5–10 min, aerobic exercise for 25–35 min, and cooldown for 5–10 min. Appropriate rest periods between activities are important. Supplemental oxygen should be used for patients who develop exertional hypoxemia [1] (Figure 54.2). However, there are some data to suggest that prescribing supplemental oxygen during exercise to patients without hypoxemia during exercise may allow patients to exercise at a higher intensity and theoretically obtain a greater training effect. In two separate studies, Casaburi and colleagues demonstrated that patients without hypoxemia exhibited higher work rates and improved exercise endurance when given supplemental oxygen for exercise when compared to similar patients who were not given supplemental oxygen [77,78]. A recent Cochrane analysis concludes that the current clinical evidence "does not provide solid conclusions for oxygen-supplemented exercise training. The evidence at this time indicates that oxygen does little to accentuate the benefit of exercise training" [79]. The latest ACCP/AACVPR guidelines do not recommend routine use of supplemental oxygen during pulmonary rehabilitation in patients without exertional hypoxemia [37].

In addition to lower extremity training, the AACVPR and ATS also recommend upper extremity training (Figure 54.3) targeted to ADL performance and strength training as core components of the exercise prescription [1,37]. Whether inspiratory muscle training during pulmonary rehabilitation is truly beneficial or improves outcomes remains unclear and is not routinely recommended at this point [37].

FIGURE 54.2 Upper extremity exercises are an important part of the exercise component of pulmonary rehabilitation.

FIGURE 54.3 Educational sessions are a core component of pulmonary rehabilitation.

FIGURE 54.4 Supplemental oxygen should be given to patients who have exertional hypoxemia.

Educational Component

The purpose of educational sessions is to increase patient knowledge about their disease, instill self-confidence, and enable as well as empower them through self-management education. Self-management education has been defined as "formalized patient education program aimed at teaching skills needed to carry out medical regimens specific to the disease, guide health behavior change, and provide emotional support for patients to control their disease and live functional lives" [26]. A Cochrane analysis was published in 2009 to objectively assess the value of self-management education programs in COPD [80]. The meta-analysis looked at 14 trials and showed that self-management education reduced the probability of hospital admission and was associated with a small decrease in dyspnea as measured by the Borg scale.

There appears to be no clear benefit of education alone without the exercise component of pulmonary rehabilitation in terms of improving health-related quality of life and exercise capacity. Nevertheless, educational sessions are considered a core component of a comprehensive pulmonary rehabilitation program. These sessions are often done in small groups (4–10 patients) with a pulmonary rehabilitation staff facilitating the session; patient participation is obviously key and very strongly encouraged (Figure 54.4). The topics typically discussed during these sessions may include basic pathophysiology of COPD, proper use of medications and inhalers, how medications and inhalers work, adverse effects of medications, signs of an acute exacerbation and when to seek medical attention (action plan), smoking cessation, breathing strategies, energy conservation, lung irritants and avoidance, normal lung and airway anatomy, vaccinations, end-of-life issues, air travel, secretion clearance, etc. Obviously, this can vary greatly between programs, and should be tailored to suit participant needs. Visual aids such as pictures, slide shows, 3D models of the lungs and airways, and take-home handouts likely facilitate learning.

Psychosocial Component

Psychological disorders, especially anxiety and depression, are fairly common in patients with COPD. It has been reported that the prevalence of depression is anywhere from 10% to 42% while that of anxiety is from 10% to 19% [81]. In a recent retrospective study looking at 35,722 patients with COPD and the same number without COPD, the prevalence of diagnosed depression was higher in the COPD group than in the non-COPD group, 23.1% versus 16.8% [82]. In another study, the prevalence of anxiety (28.2%) and depression (18.8%) in patients with COPD was much higher when compared to healthy subjects [83]. There was no difference in the prevalence of depression and anxiety between patients with mild obstruction and those with very severe obstruction.

A study looking at 121 stable COPD patients showed that 19.8% had moderate to severe depressive symptoms and that the presence of such was a predictor of mortality independent of age, sex, and exercise capacity [84]. Patients with high depressive symptoms had almost twice the risk of dying when compared to low depressive symptoms. In 2007, Paz-Diaz published a small randomized clinical trial looking at 24 patients with severe COPD who were randomized to pulmonary rehabilitation or no pulmonary rehabilitation [85]. The pulmonary rehabilitation sessions were conducted three times per week for 8 weeks. Psychological evaluation was done before and after the study and consisted of the Beck Depression Inventory score and State Trait Anxiety Inventory (STAI) score. In addition to this, dyspnea and health-related quality of life measures were also followed. As expected, patients in the pulmonary rehabilitation group had significant improvements in dyspnea and quality of life. No changes were seen in the control group. Depression and anxiety improved in the pulmonary rehabilitation group but not in the control group. Interestingly, there was no observed correlation between the improvement in dyspnea and improvement in the depression score [85].

Psychosocial intervention includes screening for depression and anxiety, screening for substance abuse, smoking cessation counseling, sessions discussing stress relaxation techniques, encouraging adherence to the prescribed medical regimen, identifying adequate social support and network, and referral to qualified psychiatric professionals if necessary. Working with the patient's family and loved ones and getting them involved will likely lead to better results. In the latest ACCP/AACVPR practice guidelines [37], psychosocial evaluation and support is recommended. As with the educational component of pulmonary rehabilitation, psychosocial support only, without the exercise component, is not recommended and has not been proven to be effective [19].

Nutrition

Poor nutritional status is commonly found in patients with COPD. Sahebjami et al. reported that 23% of their COPD patients were underweight and 24% were overweight [86]. A Spanish study reported that 47% of 177 patients had evidence of muscle wasting [87]. Nutritional depletion is an independent predictor of poor outcome and death [34]. BMI is one of the components of the BODE index, which is a powerful predictor of COPD mortality. Efforts have been made to improve nutritional status in subjects with COPD with the expectation that this will result in improved patient outcomes. A recent Cochrane review by Ferreira et al. evaluated 14 randomized controlled trials that investigated whether caloric supplementation of 2 weeks or more would improve exercise capacity, pulmonary function, and nutritional parameters in patients with COPD. The pooled data show an increase in body weight but no clinically significant improvement in exercise capacity or health-related quality of life [88]. Steiner randomized COPD patients to receive a carbohydrate-rich supplement or a placebo while undergoing a 7 week outpatient pulmonary rehabilitation program [89]. Subjects in both groups had similar improvement in exercise capacity (as measured by shuttle walk tests) and health status (as measured by the CRDQ). In patients with normal nutritional status (BMI > 19 kg/m^2), the increase in the incremental shuttle walk test was greater in the caloric supplementation group than the placebo group.

Nutritional interventions during pulmonary rehabilitation may include educational sessions emphasizing proper diet, maintenance of ideal weight, weight reduction, and formal referral to a nutritionist if a more comprehensive evaluation is deemed necessary. There are insufficient data showing that improving nutritional status with anabolic steroids [90–93], creatine [94], or growth hormone [95] is of benefit.

ONGOING CONTROVERSIES

Maintenance of Benefits

It is well-established that most of the benefits obtained from pulmonary rehabilitation will dissipate with time. For example, Guyatt et al. found that 6 months after a 4–6 week pulmonary rehabilitation program, only 11 of 24 patients had maintained improvements seen in 6MWT and CRDQ [96]. By contrast, patients given a home exercise prescription and access to an exercise therapist maintained 89% of peak exercise capacity [97].

Other studies have had less encouraging results. Ries et al. followed 57 patients who participated in a pulmonary rehabilitation program and reported that the differences between control and intervention groups waned over time [19]. Ketelaars et al. demonstrated that SGRQ scores regressed toward baseline levels 9 months after pulmonary rehabilitation [65]. Vale et al. [98] found that at the mean follow-up time of 11 months, 12 min walk distance declined by 10% and CRDQ worsened by 7%. However, both remained significantly above pre-rehabilitation levels.

Various strategies to maintain benefits accrued from pulmonary rehabilitation have been suggested and include repeat pulmonary rehabilitation, maintenance exercise sessions, home exercise prescriptions, and telephone follow-up/encouragement from rehabilitation personnel. For example, a simple, daily self-monitored walking program after a 7 week pulmonary rehabilitation program was enough to maintain gains in endurance shuttle walk test and SGRQ 6 months after the program but at 12 months a decline in both parameters was already evident [99]. Repeat pulmonary rehabilitation is hampered by the fact that the benefit of the initial program is lost by the time of the repeat program and the gains of subsequent programs are diminished in comparison to the original [100]. The study by Vale et al. [98] mentioned earlier divided the subjects into 19 patients who had post-pulmonary rehabilitation structured maintenance exercise sessions and 32 who did not. The post-pulmonary rehabilitation intervention was a weekly exercise program and was in addition to the prescribed home exercise prescription given to patients after program completion. There was no benefit seen in the

group attending the structured exercise sessions in terms of maintaining the benefits obtained from pulmonary rehabilitation. Ries compared an experimental group that received weekly telephone calls discussing compliance plus a monthly "reinforcement session" consisting of a 60 min educational session, 30 min social session, and a 90 min supervised exercise session compared to referral back to the primary care physician with written instructions for home-based exercise [101]. During the 12 month study period, the experimental group had significantly better 6MWT distance, maximum treadmill workload, and health status as measured by CRDQ while these parameters actually decreased in the nonintervention group. By the second year (2 years after pulmonary rehabilitation and 1 year after the intervention), both groups were close to pre-pulmonary rehabilitation levels. A small randomized controlled study by du Moulin looked at a maintenance program versus usual daily activities [102]. At the end of 6 months, the group receiving the maintenance intervention had superior 6MWT and CRDQ scores.

These studies demonstrate that a specific post-rehabilitation maintenance program that allows patients to maintain the gains from pulmonary rehabilitation beyond 2 years has yet to be developed. However, it appears that potentially successful maintenance programs involve regular contact with clinical staff who provide ongoing education, feedback, and monitoring.

Optimal Duration

The optimal duration of pulmonary rehabilitation is unclear. Programs as short as 3 weeks [102,103] have been shown to improve exercise capacity and health-related quality of life. Sewell published a randomized controlled trial comparing a 4 week program to a 7 week program [104]. In both groups, there were improvements in the incremental shuttle walk test and endurance shuttle walk test as well as the CRDQ at program completion but there was a partial regression toward baseline at 6 months. At 7 weeks and at 6 months, the 7 week pulmonary rehabilitation program did not prove superior in terms of endurance and incremental shuttle walk test results and self-reported CRDQ scores. Rossi compared a 20-session pulmonary rehabilitation program to 10-session program [105]. 6MWT and SGRQ scores were significantly higher in the 20-session group than the 10-session group.

Currently, authorities in the field believe that longer programs are superior to shorter ones. The ACCP and AACVPR state that 6–12 week programs are beneficial (grade 1A recommendation), although programs longer than 12 weeks may result in "greater sustained benefits than shorter programs" (grade 2C recommendation) [37]. The ATS and ERS have made no firm recommendations regarding duration of pulmonary rehabilitation programs but suggest that at least 20 sessions given 3 times/week would be expected to "achieve physiologic benefits" [1]. As with the ACCP/AACVPR guidelines, the ATS/ERS believe that "longer programs yield larger, more endurable training effects" [1].

Mortality Benefit

It is unclear whether the benefit of pulmonary rehabilitation extends to improving mortality in patients with COPD. At this point, there has been no randomized, placebo-controlled clinical trial that has conclusively demonstrated improved mortality with pulmonary rehabilitation. As discussed previously, the BODE index is simple yet powerful prognostic tool for patients with COPD. However, while two of the components of the BODE index are definitely improved with pulmonary rehabilitation (dyspnea and exercise capacity) there has not been conclusive evidence that altering these parameters with pulmonary rehabilitation can actually lead to an extension of life. Currently, given the undeniable alternate benefits of pulmonary rehabilitation, it may be inappropriate to conduct a true prospective, randomized controlled trial with a proper placebo or non-pulmonary rehabilitation arm to further investigate any mortality benefit of pulmonary rehabilitation.

Pulmonary Rehabilitation in Other Chronic Respiratory Conditions

The bulk of the data establishing the efficacy and value of pulmonary rehabilitation has been obtained from patients with COPD. Pulmonary rehabilitation has been used in other chronic lung disorders such as interstitial lung disease [106,107], restrictive lung disease [108], pulmonary arterial hypertension [109–111], lung cancer [112,113], and prior to surgical procedures such as lung cancer resection [114]. The benefits of pulmonary rehabilitation in these disorders are not as well-defined as the benefits seen in patients with COPD.

SUMMARY

Pulmonary rehabilitation has come a long way from being an intervention that was thought to be of dubious efficacy to being one of the standards of care of patients with COPD. The key conceptual breakthrough was rejecting the assumption that patients with COPD could not and should not exercise. This breakthrough was related to the realization that muscle dysfunction is at the very least as important as ventilatory limitation in producing exercise intolerance in COPD patients. There is convincing evidence that patients with COPD have decreased skeletal muscle oxidative capacity and that this abnormality is improved after pulmonary rehabilitation. There are ample scientific and clinical data demonstrating that pulmonary rehabilitation improves exercise capacity, shortness of breath, and health-related quality of life despite not having any beneficial effect on spirometry and oxygenation. Clinical data strongly suggest that health care utilization is decreased in patients who complete pulmonary rehabilitation. Furthermore, comprehensive pulmonary rehabilitation programs address extrapulmonary issues such as poor nutritional status, anxiety, and depression which are common in patients with COPD and have substantial impact on their quality of life. The effect of pulmonary rehabilitation

on mortality is unclear at this point. Although predominantly used for COPD, pulmonary rehabilitation has been used for other chronic respiratory conditions but its benefit in those conditions is less well defined.

INTRODUCTION

Food allergy has become an issue of major national and international public health significance. Hospitalizations for food-related anaphylaxis have increased an incredible 350% over the past 10 years [1]. Repercussions of this increasing incidence can be seen almost everywhere. Parents of school-aged children wrestle daily with its implications as they struggle to make "safe" lunches. Schools, restaurants, airlines, food manufacturers, and others have required alterations in their basic functioning in order to cope with the impact of food-related allergies. Public awareness has created exceptional responses to implement protection against food allergies. In many ways, the increasing incidence has impacted lifestyle decisions from infancy through adulthood.

Despite the enormity of the problem, the scientific foundation underlying the understanding of food allergy has not yet provided sufficient support to yield firm diagnostic options and new treatment options. As a result, there is a tremendous amount of erroneous attribution of food allergy risk both by the general public and health care personnel. In addition, without adequate scientific understanding, implemented practices of presumptive avoidance have been widespread.

This chapter discusses the current understanding of food allergy. Initial sections discuss the basic biology of food allergic reactions, focusing on anaphylaxis, the most severe manifestation of food allergy. Diagnosis, management, and prevention are also discussed.

DECIPHERING SYMPTOMS RELATED TO FOOD INGESTION

The prevalence of food allergy has created a heightened awareness regarding food-based reactions. As a result, there is tremendous concern about food allergy and confusion about potential health implications from various experienced food-based symptoms. The term "food allergy" has not been universally defined and has become an umbrella term under which various food-related, though not life-threatening, reactions occur [2].

Self-report of food allergy has grown exponentially over the past decade. One study found self-reported prevalence of

peanut and tree nut allergy to be 1.2% of the U.S. population based on survey data gathered between 1997 and 2002 [3]. A more recent follow-up study found the self-reported incidence of food allergy to be similar among adults. However, a survey performed in 2008 reported that peanut allergy in children more than tripled [4]. While this is an astounding increase, it correlates with similar data from other countries including Canada. A study investigating self-report across more than 10,000 households found incidence of peanut allergy to be around 1% [5]. When combined with the reported rates for other foods, perceived food allergies result in more than 20% of adults and children restricting foods from their diets due to concern for risk of subsequent reactions [6]. This can lead to significant impact on nutrition and wellness. However, when confirmation by allergy testing is implemented, these "prevalence" numbers fall significantly. A recent study demonstrated clear differences between rates of self-reported and confirmed food allergies [5]. Both patients and health care providers often overreported food allergy. The disconnect between perception of and actual food allergies arises for a multitude of reasons.

There are numerous potential effects that can occur after the ingestion of food. Many of these result in uncomfortable symptoms, but do not carry the same severe implications as anaphylaxis. For example, mild food poisoning, lactase deficiency, and reflux can cause uncomfortable symptoms but do not pose a risk for shock. Anaphylaxis is caused by antibody-mediated recognition of food proteins with subsequent activation of immune cells, triggering release of inflammatory mediators. While there are a number of other conditions in the spectrum of food allergy, the remainder of this chapter uses "food allergy" to distinctly reference antibody-mediated reactions potentially giving rise to anaphylaxis. This process is discussed in further detail later in the chapter. Because of this characteristic biologic cascade, the timeline and symptoms of reactions are fairly uniform.

A focused history can quickly provide clear insight into the underlying biologic processes causing a reported reaction. The most critical answer to establish is whether the symptoms portend risk for anaphylaxis with reintroduction of the food. A history of the type of food and the amount ingested should first be ascertained with as much certainty as possible. While this seems obvious, it is often difficult for people to recall specifics. In the case of possible food allergy, specifics are critical [7]. The time course from ingestion of a food to the onset of symptoms must be established. Typically, antibody-mediated reactions occur very quickly—usually within seconds to minutes and, at most, 2 h from ingestion [8]. Food reactions occurring many hours after ingestion suggest other causes. Symptoms of antibody-mediated reactions are very characteristic. Due to a high concentration of causative cells in locations such as the skin, gastrointestinal tracts, and respiratory system, symptoms almost always appear in one or more of these areas. Typical symptoms include flushing, hives, itching/swelling inside the mouth, abdominal cramping, vomiting, diarrhea, wheezing, or other breathing difficulties [8]. Additional systems may be involved, leading to symptoms such as tachycardia, syncope, anxiety, headache, sneezing, congestion, and conjunctival injection [9]. Cutaneous symptoms are exceedingly common in food allergy-related reactions. However, it is important to note that cutaneous symptoms can be absent in 10%–20% of anaphylactic episodes [10]. Anaphylaxis is now "briefly defined" to include two or more of the previously mentioned symptoms documented after allergen exposure. When symptoms are more severe, hypotension can be recorded, providing evidence for shock. This can often be missed in infants and young children [11]. Assessment of blood pressure is crucial as circulatory collapse can occur rapidly, with intravascular volume decreasing by a third within 10 min [12]. For these reasons, it is critical to distinguish allergic reactions from other possibilities.

Emergent treatment is necessary to decrease potential morbidity and mortality. However, allergic symptoms can sometimes be transient, or at other times be overlooked as not being indicative of a systemic reaction. A high index of suspicion must be maintained, especially in a pediatric setting. Only about half of over 450 pediatricians correctly recognized and recommended appropriate treatment for food-induced anaphylaxis in one study [13]. In addition, there can be age-related variation in the presentation of anaphylaxis. In a recent study children under 2 represented the largest proportion of patients presenting to an ED with anaphylaxis over a 6 year period [14]. Symptoms in infants more often included vomiting and hives while wheezing was more commonly seen in older children. This study also found documentation of hypotension in children to be infrequently practiced, which can complicate diagnosis and prevent a diagnosis of anaphylaxis.

Fatal food-induced anaphylaxis is not common, occurring in less than 1% of anaphylactic episodes. There are clear risk factors associated with fatal reactions. Adolescents and young adults represent the majority of fatalities. Peanut and tree nut allergies were the cause of greater than 90% of fatal reactions in one study [15]. Asthma is also a major contributing risk factor. Reactions that were fatal were more commonly associated with respiratory symptoms than with shock [16]. In children and young adults with asthma, food-induced reactions/anaphylaxis may be mistaken for asthma exacerbations. This results in either lack of or delayed use of epinephrine. In one study, only 10% of people who died from food allergy were carrying epinephrine with them [17].

When the history is supportive of food allergy, it is important to conduct appropriate testing to confirm the diagnosis. This allows for identification of specific food allergens, education regarding avoidance, and the prescription of proper medications. Without this evaluation and education, anaphylaxis can occur again, with perhaps more severe repercussions. In addition, given the discrepancies between self-report and actual allergy, investigation of a reaction is necessary to decrease erroneous attribution of food allergy and resultant food removal.

BIOLOGY OF ANAPHYLAXIS

The immune system is designed to provide dynamic, continuously evolving recognition of and responses to potential outside threats. Thus, there is literally continuous surveillance and assessment of various exposures. Antibodies are proteins designed to recognize specific potential danger and act as a bridge between identification and response. Understanding this mechanism is key to understanding the clinical features of food allergy. The distribution of cells involved leads to systemic reactions that occur quickly and diffusely. In addition, the biological mechanism of food allergy that leads to a process of testing can help identify those at risk for possible food induced anaphylaxis.

There are four major categories of antibodies: IgG, IgA, IgM, and IgE. Each one varies in major qualities such as tissue distribution, half-life, and, most importantly, downstream response. IgE is the central antibody in the allergic response. B cells are responsible for generation of antibodies. These B cells can alter the types of antibodies they produce based on external factors allowing them to "switch" from IgG to IgE, for example. External factors promoting this type of switch originate from various other cells including T cells, basophils, and mast cells. Cytokines including IL-4 and IL-13 provide potent induction and amplification of IgE production by B cells [18]. The tendency to shift B cell production toward IgE antibodies results in a higher likelihood for allergy.

Cytokines can have powerful influence over B cells and their increased concentration and resultant signaling produces greater risk for anaphylaxis. Receptors for these cytokines are distributed widely, creating the potential for systemic reactions to allergic stimuli. In a mouse model, increased signaling through the IL-4 receptor can cause both increased specific IgE production to ingested proteins and simultaneously increase the risk of anaphylaxis from the same protein [19]. Thus, high levels of these cytokines predispose the immune system to elevated levels of IgE and resultant escalated risk for allergy. Certain IL-4 genetic polymorphisms have been associated with increased risk of food allergy [20].

As with all antibodies, IgE contains both constant and variable structural components. The variable region confers specificity by recognizing only very specific genetic sequences of a protein. The antibody can bind to these peptides and generate responses entirely as the result of recognition of this food. Thus, the variable portion of the antibody allows diversity in recognition and surveillance. On the other hand, the constant component of the IgE antibody promotes the immune system response after recognition of the allergen. The constant portion of the antibody provides its capability to elicit reactions from other cells. For IgE, its constant portion is recognized by a specific receptor on effector cells such as the mast cell, referred to as the Fcε receptor I or the high-affinity IgE receptor. Given this high affinity, IgE will bind to this receptor at concentrations that are miniscule. This allows a high proportion of IgE to be bound to this receptor, despite very low serum concentrations [21].

Mast cells can be found in numerous tissues throughout the body, but are specifically concentrated in skin, lung alveoli, and the mucosal surfaces of both the intestine and the eye. Their easily identified granules contain preformed mediators responsible for the bulk of symptoms characteristic of allergic reactions [22]. These cells are literally covered with IgE receptors. When multiple IgE antibody-food antigen complexes interact with these receptors, they become "cross linked" and will cluster geographically on the cell surface. This is a critical event required to perpetuate an allergic reaction. The Fcε receptors are tethered to multiple proteins inside the mast cell. When these receptors congregate, the intracellular machinery is dragged along as well, increasing protein interactions, resulting in higher intensity downstream signaling [23]. Early repercussions of this signaling include the hallmark of allergic reactions—release of preformed mediators contained within mast cells. Clinical symptoms occur very quickly in that situation because the mediators being released are preformed.

Histamine is the most important of the preformed mast cell mediators. It strongly promotes vasodilation, increases vascular permeability, bronchial smooth muscle contraction, and bronchoconstriction [24]. These biological responses form the hallmarks of allergic reactions and anaphylaxis. Other preformed mediators include tryptase, platelet-activating factor, and several more than may have various roles in both allergy and other mast cell functions. In summary, IgE antibodies loaded with food-related antigens bind their high affinity IgE receptor on mast cells. The result is an orchestrated intracellular response leading to rapid degranulation of cellular contents with resultant reactions driven largely by histamine. Clinically, this leads to the symptoms previously described in diverse locations such as the eye, nose, skin, airways, and intestines. Shock may occur due to histamine release and decreased intravascular volume.

EPIDEMIOLOGY OF FOOD ALLERGY

The number of people with food allergy seems to be escalating substantially. Determining a true national prevalence is difficult due to several factors including excessive self-reporting and a lack of established definition and criteria for diagnosis of food allergy. Recently, more than 8000 participants from 30 sites across the United States took part in the National Health and Nutrition Examination Survey. Part of the survey was testing for several common food allergies. This study demonstrated an estimated food allergy prevalence of 2.5%. Notably, the prevalence was clearly higher in children under 5 years (4.2%) and decreased with age [25]. This estimate of food allergy closely correlates with other recent findings. The CDC/NCHS published a brief in 2008 suggesting 4 out of 100 children have food allergy. Hospital discharges for children with food allergic reactions were almost four times greater from 2004 to 2006 than from 1998 to 2000 [26].

Food allergy does appear to carry some genetic susceptibility, although this has only been shown for certain foods.

For example, a child with a parent or a sibling with peanut allergy has a sevenfold risk of experiencing the same [27]. Certain polymorphisms have been shown to be correlated with food allergy. Genetic variations have been demonstrated in genes coding for various aspects of the immune response. Typically, the immune system generates a "tolerant" response to most ingested foods. Indeed, the acquisition of tolerance itself is not well studied or understood. Complex interactions within the gastrointestinal tract are likely responsible for inducing food-related tolerance. There are many aspects of these processes that are implicated in development of food allergy. These include a wide spectrum of possibilities including barrier dysfunction, variations in food allergen processing, alterations in immune cells that function to regulate the larger immune response, and many others [28].

The surrounding environment exerts enormous influence over immune system effects. Environmental influences clearly seem to play a role in the development of food allergy. Dr. David Strachan initially proposed the so-called hygiene hypothesis in 1989, based on his study documenting lower incidence of allergic rhinitis with increasing numbers of siblings [29]. In the intervening time, this hypothesis has generated tremendous controversy. However, several studies have demonstrated findings consistent with its general principle. A European study demonstrated variable food allergen sensitization patterns between children who lived on farms compared to those who do not [30]. Studies have generally placed the "hygiene hypothesis" in context with atopic dermatitis. However, several international experts have pointed out that food allergy frequently follows atopic dermatitis. Thus, these results may have some indirect importance relative to the development of food allergy [31].

FOODS IMPLICATED

Geography and culture exert major influences on the inciting foods most often implicated in allergic reactions. Therefore, worldwide variation exists with regard to most common food allergies. In the United States, a group of nine foods is largely responsible for IgE-mediated food allergy. In descending order of incidence, these include milk, egg, peanut, tree nuts, wheat, soy, fish, shellfish, and sesame. While it should be clearly stated that any food protein can cause an allergic reaction, these food proteins seem to be more likely to do so than others. These foods share particular structural characteristics that influence their allergenicity. Most are water soluble glycoproteins, essentially similar in size, and retain stable structure despite potentially degrading exposures including acid, heat, and proteases [32]. The ability to retain 3D structures in the face of these processes has been shown to be a major contributing factor for a food allergen's capacity to elicit reactions [33].

However, there is also evidence that food preparation contributes to increased allergenicity. This provides some explanation to the geographic variation in food allergies for foods eaten worldwide. As mentioned previously, heating of food proteins may generate structural alterations that can either accentuate or mitigate allergenic potential. Antibodies recognize very particular regions called epitopes in any given protein. Certain food protein's ability to bind with IgE antibodies requires a particular 3D arrangement of these epitopes. These are often referred to as "conformational epitopes" given the requirement of the underlying folded structure for antibody binding. Protein folding allows for optimal epitope arrangement which increases antibody-binding efficacy. Processes such as heating that undermine this 3D structure can lead to reduction in allergen potential. For example, ovalbumin, the major egg protein allergen, is quite sensitive to structural changes via heating [34]. In one study, 70% of children with known egg allergy tolerated extensively heated egg [35]. This is in contrast to epitopes that are more sequential and referred to as "linear" epitopes. This essentially literal description suggests that these antigens are much more resistant to various processes that can affect protein degradation. In turn, this has an effect on the allergenicity of the protein. For example, children with IgE antibodies specific for sequential epitopes of the major egg proteins seem to have more persistent allergy [36].

However, heating the major allergen in peanut does not change its ability to bind IgE [37]. In addition, certain forms of heating, such as roasting, lead to specific biochemical changes in the peanut protein that cause it to bind more IgE and, in turn, become more allergenic [38]. This may explain the persistence of peanut allergy over time. It also suggests a basis for the variable geographic predominance of peanut allergy. In China, where peanut allergy is not very common, cooking peanuts is generally done via frying or boiling. Peanut protein cooked via these methods binds much less IgE antibody than roasted peanut, the most common method of preparation in the United States [39].

In the United States, a relatively small group of foods is responsible for the majority of IgE-mediated reactions. These foods are widely consumed and share molecular characteristics making them more likely to elicit allergic responses. However, there are clear differences among these foods in terms of natural history. It is critical to consider this in evaluation of patients.

NATURAL HISTORY OF FOOD ALLERGY

Specific foods seem to exhibit characteristic ages of onset and potential for resolution. These variable features were previously unexplained. However, with improved understanding of food allergy, some of the explanations for these features are being identified.

Cow's Milk Protein Allergy

Milk protein allergy is the most common food allergy in children. It has an incidence of approximately 2.5%. There are various manifestations of milk protein allergy including non-IgE-mediated entities such as food protein-induced enterocolitis. One study found that only half of children with milk protein allergy have IgE-mediated mechanisms responsible

for their symptoms [40]. Milk protein allergy has a very early age of onset. The vast majority of milk protein allergy occurs in the first year of life. Despite this early onset, milk allergy rarely persists. The vast majority of children with this allergy will have resolution by their fifth birthday [41]. However, there does appear to be a trend toward longer persistence of this allergy. In a recent study of more than 800 children with cow's milk allergy, only about 40% had achieved measurable tolerance by age 8 and nearly 80% by age 16. It may be that rising rates of general atopy contribute to this trend [42]. Children with higher IgE levels and other coincident atopic conditions seemed to retain the allergy longer. In addition, children who recovered sooner seemed to have more prevalent "blocking antibodies" that prevented IgE from binding to milk protein allergens [43]. Retesting children with milk allergy is critical in their overall management.

Egg Allergy

Egg protein allergy occurs in about 1.6% of children. However, children with other allergic conditions are much more likely to have egg allergy as well. Like milk allergy, egg allergy is typically outgrown, though the age of resolution seems to be trending later. Children who are diagnosed at a younger age and with less severe presenting symptoms seem to experience egg allergy over a shorter duration [44]. Two major egg allergens—ovalbumin and ovomucoid—respond very differently to heating. Ovalbumin is significantly degraded with high heat while ovomucoid structure is retained in similar conditions, rendering it a more stable allergen (Joo et al. 2006). Due to this stability, children with IgE antibodies to ovomucoid tend to exhibit longer term, "retained" allergy to egg [35].

Peanut Allergy

Peanut allergy has been largely responsible for the sharp increase in public awareness of food allergies in general. Over a very short period of time, the incidence of this allergy seems to have escalated substantially. At the present time, the incidence of peanut allergy is 0.6% of the general population within the United States. However, self-reported peanut allergy in children nearly doubled between 1997 and 2002 [3]. This has had enormous impact on public health measures, perhaps more than any other food.

Reactions to peanuts in people with known peanut allergy constitute the greatest risk for mortality due to food-related anaphylaxis according to one study [17]. Peanut was the identified cause of food-related deaths in 17 out of 32 cases. The vast majority of these people also had coincident asthma. Thus, peanut allergy has received tremendous attention both for its sharp increase in incidence and also for its potential lethality. Even small amounts of peanut protein can cause severe reactions. Exposure to the equivalent of one peanut kernel has resulted in significant symptoms in persons of widely distributed ages [45]. In contrast to both egg and milk allergy, peanut allergy is largely believed to be persistent throughout life. However, it seems that children diagnosed before 2 years of age have nearly a 20% likelihood of outgrowing the allergy [46]. Follow-up testing has a role in children diagnosed early in life.

Tree Nut Allergy

Tree nuts are the second most common food causing food allergy-based mortality [17]. Currently, the incidence of tree nut allergy is approximately 0.5% of the U.S. population. Tree nuts are generally lumped together in one general category. Typical nuts included in this category include almond, Brazil nut, cashew, hazelnut, macadamia, pecan, pine nut, pistachio, and walnut [47]. In general, there seems to be about a 35% cross-reactivity rate among tree nuts [32].

Only approximately 9% of patients with tree nut allergy will experience resolution of symptoms [47]. As with peanut allergy, it is important to consider follow-up testing in patients who have been diagnosed with this allergy.

Seafood

Seafood allergy exhibits a slightly different pattern of onset than the previously mentioned food allergies. In general, seafood allergy is an adult-onset allergy, with an incidence of 0.6% for children compared to nearly 3% in adults [48]. The most common foods implicated are crustaceans including crab, shrimp, and lobster.

It is important to make a distinction between shellfish and finfish because the major allergenic proteins are quite different. The major allergenic protein in most shellfish is tropomyosin, whereas parvalbumin is the major allergen in finfish. There has not been documented cross-reactivity between the allergens in these two groups. Because of this, the term "seafood allergy" should not generally be used as a clinical diagnosis. There may be cross-reactivity between the major groups constituting shellfish, specifically crustaceans and mollusks. Therefore, patients with crustacean allergy may also experience reactions to mussels, squid, clams, scallops, oysters [49]. The incidence of allergies to both groups of seafood may continue to rise as seafood ingestion increases due to its general health benefits [50].

Soy

Soy is one of the more common foods introduced in early childhood. Soy is also a prevalent food additive, making its proteins difficult to avoid [51]. Soy allergy is present in about 0.4% of children. The majority of children with this allergy will become tolerant over time. A retrospective study of 133 children with soy allergy documented a 70% resolution rate by 10 years of age. Higher soy-specific IgE levels at diagnosis correlate with longer lasting allergy [52].

Wheat

IgE-mediated wheat allergy (to be distinguished from gluten sensitivity) is quite common, especially in childhood, occurring in about 0.4%–1.0% of children [53]. In the largest

study published to date of children with wheat allergy, the median age at resolution for wheat allergy was 6½ years of age. Therefore, this seems to be an allergy that is transient, with acquisition of tolerance occurring in most allergic children over time. As with other food allergies, higher IgE levels portend a longer time course to resolution [54].

POLLEN-FOOD SYNDROME

A subgroup of IgE-mediated food reactions results in local symptoms of itching and tingling of the mouth and throat and potential swelling of the lips and tongue [55]. Unlike reactions from the foods mentioned previously, pollen-food syndrome reactions tend not to involve additional systemic symptoms, though almost 2% of people can experience anaphylaxis [56]. Pollen-food syndrome typically occurs in the context of coincident pollen-derived nasal allergies. Allergic rhinitis is caused by IgE antibodies directed against certain pollen proteins resulting in mucosal mast cell degranulation and symptoms consistent with rhinitis. This pollen-directed IgE antibody can also recognize proteins in certain fruits and vegetables because of their genetic similarities to the pollens involved. The result is local symptoms in the oropharyngeal mucosa with ingestion of these foods. Classic cross reactivity occurs between birch pollen and many pitted fruits including apples, cherries, and apricots [55].

DIAGNOSIS AND MANAGEMENT OF FOOD ALLERGY

Risk Factors

The presence of other allergic diseases increases the risk that a particular patient has IgE-mediated food allergy. A detailed family history will often evidence atopy [7]. For example, atopic dermatitis is a major risk factor for development of food allergy, particularly to egg, milk, and peanut. In infancy, IgE to these foods can be demonstrated to be coincident with the presence of atopic dermatitis [57]. In one study, over 80% of children with peanut allergy also had atopic dermatitis [58].

Additional risk factors are important to consider. This includes increased incidence of peanut allergy for children living in homes with high consumption of peanut [59]. Vitamin D deficiency has also been linked to food allergy, thus geographic location may also predispose to food allergies [60].

Clinical Symptoms

The symptoms of food allergy are the symptoms that comprise anaphylaxis. These occur on a spectrum, ranging from mild cutaneous symptoms to overt shock and respiratory failure [7]. The timeline is critical in identifying whether the symptoms correlate with a food exposure because IgE-mediated symptoms occur within minutes to hours after ingestion the food. It is important to distinguish irritant and sensitivity reactions from possible IgE-mediated reactions. Testing is critical in making this distinction.

Brief Testing Overview

A thorough description of food allergy testing is beyond the scope of this chapter. It is briefly reviewed here in an effort to highlight inherent challenges in interpretation. All testing involves identifying the presence of IgE to a particular antigen. This can be done in two ways—skin testing and serum-specific IgE testing. However false-positives occur 50% of the time with both of these tests [61]. Therefore testing must be used in conjunction with a clinically relevant history. In the absence of such a history, the diagnosis becomes more difficult. Age and food variations make the interpretation of serum allergy testing particularly difficult [62].

The gold standard for demonstrating food allergy is an oral food challenge. In a recent pediatric study, over 80% of foods restricted based on IgE testing were able to be reintroduced after negative oral food challenge [63]. These challenges are time consuming and require close observation. They are most appropriately done in a setting where there are personnel trained in the process and management of reactions. There are other tests currently in development that may help increase the specificity of clinic based testing.

Treatment

Restriction of potentially allergenic foods is the most commonly implemented treatment strategy for IgE-mediated food allergy. The efficacy of this strategy has not been proven in randomized controlled studies [2]. Still this approach is sensible given the current shortcomings associated with allergy testing [7]. Patients and their families must be educated about techniques for identifying allergenic foods. This includes reading labels, inquiring about unknown ingredients, and other strategies.

Each patient who has food allergy should have an anaphylaxis action plan. Prescription of injectable epinephrine is critical for patients who may be at risk for anaphylaxis. Delay in epinephrine administration is one of the major contributing factors in food allergy related deaths [17]. A recent study indicated that two doses of epinephrine may be needed to treat food-related anaphylaxis [64]. Therefore patients should be provided with more than one dose to administer in the event of anaphylaxis. Excellent online resources are available for patients, families and providers to be educated about these critical management strategies (Food Allergy and Anaphylaxis Network http://www.faan.org).

Potential Future Therapies

Given the increasing incidence of food allergy, there are diverse potential interventions being pursued for modification of this risk. Food allergies may be treated via introduction of increasing amounts of the allergenic foods over time in a supervised setting. This has been demonstrated to be effective therapy for peanut allergy in recent studies [65].

Several interesting studies have identified a particular Chinese herbal medicine formulation that seems to provide complete protection against food-induced anaphylaxis in animal models [66].

Probiotics have become a potential consideration for treatment of many conditions. At the present time, support for treatment in allergy is conflicting. The literature regarding their usefulness in food allergy is unclear [67]. It is impossible to make strong recommendations regarding the use of these agents because potential probiotics are so vast in number and clinical populations vary much significantly [68].

Prevention of Food Allergy

The prevention of food allergy has received a great deal of attention, but robust evidence to support clear recommendations is lacking. However, there do seem to be some emerging data that allow for lifestyle modifications that may be potentially beneficial.

Early Life Exposures to Highly Allergenic Foods

The recently published expert panel on the management of food allergies does not recommend maternal dietary restrictions during either pregnancy or breastfeeding [7]. Available data are inconclusive with regard to whether early food exposures can either protect against or promote the development of food allergy. One study demonstrated that maternal consumption of peanut during pregnancy correlated with a higher likelihood of peanut specific IgE found in infants [69]. Other studies have shown no relationship between in utero or early exposures to allergenic foods and risk of food allergy [70]. These contradictory results highlight the lack of any consensus upon which to advise families on food allergy prevention.

Our understanding of cutaneous exposure as a risk for food allergy is slightly more clear. It has been shown that topical application of oils containing peanut protein can predispose children to risk of peanut allergy. Eczema is a risk factor for development of food allergy, likely attributable to increased use of emollients generally and perhaps to compromised skin barrier function [71]. One study demonstrated a clear increase in sensitization to peanut among infants living in homes where high levels of peanut protein were consumed [59]. The authors speculated that cutaneous exposure may also occur via accidental topical contact within the household. While the data are not entirely clear at this time, it may be reasonable to counsel complete household restriction of peanuts for families at high risk.

Vitamin D and Food Allergy

Vitamin D deficiency has become another topic of immense public health interest worldwide. There is an unmistakable correlation between the timing of increased incidence of allergic diseases and vitamin D deficiency. With regard to food allergy, it was demonstrated that prescriptions for self-injected epinephrine occurred with a "north-south gradient" in the United States. This relationship endured extensive multivariate analysis. The authors proposed a potential relationship between vitamin D deficiency and food allergy [72]. Subsequent studies have similar findings. Children born during the fall and winter months in Boston were found to have more than 50% higher odds of having food allergy compared to children born in spring or summer [73]. A possible molecular basis for the relationship between allergic disease and vitamin D deficiency was recently published. Calcitriol, the most active form of vitamin D, repressed the production of IgE via regulation at the gene level [74]. A full review of vitamin D and food allergy is beyond the scope of this chapter, but an excellent summary has been published [74].

CONCLUSION

Food allergy is a major public health issue due to a sharply increased incidence and a huge effect on school and business operations. The ramifications of these can be felt from individual homes all the way up to major institutions. Fortunately we now understand the mechanism and pathogenesis of food allergy much better than even a few years ago. While we remain in the early stages of this process, exciting new possibilities will influence diagnosis and management in the future. However the importance of an accurate clinical history remains at the forefront of diagnosing allergic disease. Future research will likely yield improved diagnostic aids to supplement the history and better therapies that improve quality of life for food allergy patients.

DEFINITION

Influenza is a contagious acute illness of the respiratory tract. The etiologic agent is the influenza virus. This common disease is the source of significant illness in the general population and can lead to death, especially in persons at "high risk" for complications of influenza.

HISTORY OF INFLUENZA

The name "influenza" is derived from the Italian, and arose from the notion that the disease was due to the "influence" of the stars. Clinical illness due to influenza virus has had many names over the years, including the "grippe" and epidemic catarrh. Influenza is commonly called "the flu"; however, the term "flu" is also frequently used by the general public for other acute febrile illnesses. Acute gastrointestinal illnesses are often referred to as the "stomach flu" despite the fact that they have no association with the influenza virus. Major influenza epidemics have occurred since at least the middle ages, but may have also occurred in earlier times. The high attack rate, the nature of the epidemic curve, and the characteristic of frequent cough allow the identification of past epidemics. The first influenza epidemic generally agreed upon by medical historians took place in 1580, originating in Asia, spreading across Europe over a period of 6 months and eventually reaching the American continent.[1]

VIROLOGY OF INFLUENZA VIRUS

Influenza viruses are members of the family *Orthomyxoviridae*. There are three types of influenza virus: influenza A, influenza B, and influenza C. Influenza viruses have been divided into these three types on the basis of major antigenic differences in the nucleoprotein (NP) and matrix (M) protein antigens. Influenza A viruses are the most virulent of the three influenza viruses and are the etiologic agents of all known influenza pandemics. Influenza B virus tends to cause milder disease than influenza A.[2] Influenza C virus causes infection in humans only infrequently, and its pattern of infection follows no seasonal variation. All three types of virus exhibit a host-cell-derived lipid envelope and a genome of segmented, negative sense single-stranded RNA. Influenza viral particles are variable in shape, from irregular spheres that measure 80–120 nm in diameter to long filamentous particles. Only influenza A viruses are subtyped. Influenza A is subtyped on the basis of two major surface proteins, neuraminidase (NA) and hemagglutinin (HA). These surface proteins project like spikes, densely covering the surface of the virus, and are important for cell entry. One additional protein, membrane protein M2, is also present in small amounts on the viral envelope. Influenza A viruses are named for their HA and NA surface proteins, for example, a virus called H3N2 will contain HA type 3 and NA type 2. In addition to subtype, influenza A viruses are further characterized on the

basis of the place and time that the virus was first isolated (i.e., A/California/7/2009) (H1N1).

At least 16 antigenically distinct HAs and nine distinct NAs have been described in influenza A viruses. However, viruses that lead to human infection generally contain one of the three most common antigenic subtypes of HA (either H1, H2, or H3) and one of the two most common subtypes of NA (N1 or N2). More recently, H5 and H7 and H9 influenza viruses have been found to infect humans, though sustained human-to-human transmission of these viruses has not been seen.

All influenza viruses are capable of infecting humans. Influenza A viruses are capable of infecting many animal species as well, including swine, horses, marine, mammals, and birds. Wild birds, particularly aquatic birds, are the natural hosts of influenza A virus. Influenza viruses of low pathogenicity do not necessarily lead to clinical illness in the birds they infect, but viruses that cause severe disease and death in birds do exist (e.g., H5N1). The isolation of influenza virus from ferrets in the laboratory took place in 1933 and ferrets continue to be the ideal animal model for the study of influenza. Virus culture in embryonated hen eggs was accomplished in 1936. These advancements allowed the study of virus properties and led to the development of vaccines in the 1940s. Animal cell cultures systems for propagating virus in tissue culture were developed in the 1950s.

GENETIC VARIATION

Influenza viruses are constantly changing their antigenicity. This evolution of influenza viruses is characterized on the basis of the two primary mechanisms by which this genetic variation occurs, antigenic drift and antigenic shift. All influenza viruses (A, B, and C) undergo antigenic drift. Only influenza A virus undergoes antigenic shift. Antigenic drift occurs continuously due to point mutations in the NA gene or (more commonly) the HA gene, both of which code for viral surface proteins. These mutations occur frequently, as the RNA polymerase of the influenza virus has relatively low fidelity and lacks proofreading capacity. Minor changes in the surface proteins occur due to these mutations and lead to what is known as antigenic drift. These antigenic changes lead to virus variants that a previously immune host could now be susceptible to, allowing for new outbreaks of disease. Antigenic shift in influenza A virus occurs in one of two ways. It occurs when reassortment of genome segments takes place between at least two strains of influenza A (usually a human and an animal strain) to produce a new influenza subtype. This reassortment can take place when a cell is infected with two (or more) different strains of influenza virus. Antigenic shift can also occur by direct spread of an animal strain of influenza (usually an avian strain) to a human. An example of this is the H5N1 "bird flu" which continues to cause sporadic human infection in Egypt and Asia.[3] Pandemic influenza can occur after antigenic shift, when a new strain of the flu emerges to which little or no immunity is present in the population.

EPIDEMIOLOGY OF INFLUENZA

It is estimated that 5%–20% of persons in the United States are infected with an influenza virus each year.[4] Influenza constitutes an epidemic when there is an outbreak in a particular location. Outbreaks are detected by monitoring patient visits for influenza like illness, and by surveillance of tests results that are ordered for the specific characterization of influenza like illness. The Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO) have collaborating laboratories for the purpose of influenza surveillance, viral detection, viral isolation, and characterization. Internet search engine queries for influenza have also been shown to be reliable markers of epidemics in a community when they show a rapid increase in frequency.[5] In temperate climates, epidemics of influenza occur most commonly in the winter months. In the Northern Hemisphere, seasonal epidemics of influenza typically occur between late fall and early spring. Influenza epidemics often begin abruptly, reach a peak over several weeks, and last for 2–3 months. In general, 10%–20% of the population will become infected during an outbreak. A major factor in the extent of the population that will become infected in an outbreak is the level of immunity in the population. The major determinant of immunity is the presence of neutralizing antibody to the HA glycoprotein on the surface of the virus. Children have the highest incidence of infection overall. Adults over the age of 65, children younger than 2 years of age, and persons with certain underlying health problems are the most likely to suffer serious consequences of influenza virus infection, including death. Estimates by the CDC suggest that 36,000 people in the United States die each year as a result of influenza virus infection and about a quarter of a million persons are hospitalized.[6]

Pandemics often occur outside the usual influenza season. On average, there have been five pandemics in each century that have been documented in written history. The WHO defines an influenza pandemic as an animal or human-animal reassortant virus causing sustained person-to-person spread which leads to community outbreaks in two or more countries in one WHO region and an outbreak of the same virus in at least one other WHO region. Most pandemic viruses have been due to human-animal reassortant viruses. Well-characterized pandemic influenza viruses from the past century include the 1918 H1N1 "Spanish Flu," H2N2 "Avian Flu" in 1957, the H3N2 "Hong Kong Flu" in 1968, and the latest pandemic, 2009 novel H1N1. The "Spanish Flu" pandemic in 1918–1919 had the largest human impact of any recorded influenza epidemic and is without a doubt one of the more dramatic events of recorded medical history. Although given the name "Spanish Flu," the first known outbreaks of 1918–1919 pandemic influenza were seen in military camps in the United States. This pandemic is estimated to have caused more than 20 million deaths worldwide, more deaths than occurred due to combat in World War I. It is estimated that 25% of people living in the United States and a fifth of the world's population were

infected during this pandemic. The brunt of this excess mortality was dealt to young people, with most deaths occurring in the 20- to 40-year-old age group. In a typical influenza epidemic, 0.1% of individuals who become infected will suffer mortality. The death rate of those who became infected with influenza virus in the 1918–1919 epidemic was 2.5%.[7] It is estimated that half of the deaths among American servicemen in World War I were due to influenza, as compared to deaths due to battle injuries.

The most recent influenza pandemic began in February 2009 with an outbreak in Mexico.[8] In early April 2009 the Mexican government began investigating increased numbers of influenza like illness and informed the Pan American Health Organization of a possible outbreak. Almost simultaneously, ongoing enhanced surveillance for Influenza A viruses that could not be subtyped, being conducted under the auspices of the CDC, identified a novel influenza virus in two patients in southern California.[9] This virus was characterized as a triple reassortant virus containing six genes from previously circulating North American swine viruses as well as two genes of Eurasian avian-like swine virus origin. The two index cases of 2009 H1N1 identified in California were epidemiologically unlinked children, neither of which had had contact with swine. By May 5, 2009, cases of 2009 H1N1 had been identified in 41 states. Many local outbreaks were related to school groups and other travelers returning to the United States from vacation travel to Mexico. By May 25, 2009, this pandemic virus H1N1 had spread to 43 countries, and 12,515 cases had been identified along with 91 deaths. The geographic spread of virus was unprecedented, covering in 6 weeks time what had taken a 6 month period of time in previous pandemics.[10] The CDC estimates that approximately 61 million persons in the United States were infected during this latest pandemic; approximately 265,000 people required hospitalization and 12,000 deaths occurred between April 2009 and February 2010. The virus preferentially infected younger people (i.e., under 25 years of age), most likely due to cross-protective antibodies in older persons who may have been exposed to antigenically related influenza viruses earlier in life.

Although most infections with 2009 H1N1 were mild, severe and fatal respiratory illness occurred in young, otherwise healthy individuals.[11] Medical conditions such as chronic cardiac or pulmonary disease traditionally associated with an increased risk of complications after infection with seasonal influenza were also risk factors for complications from 2009 H1N1 virus infection. Nonetheless, approximately 25%–50% of patients who were hospitalized or died due to infection with 2009 H1N1 had no reported coexisting medical conditions. Ninety percent of deaths due to 2009 H1N1 infection took place in persons less than 65 years of age. Hospitalization rates were highest for children less than 5 years old, and up to 45% of patients hospitalized with 2009 H1N1 were less than 18 years old. Pregnant women were at particularly high risk, accounting for up to 10% of persons who were hospitalized or who died from 2009 H1N1, even though they represent only 1%–2% of the general population. Spontaneous abortion, preterm labor and birth, and fetal distress were also associated with 2009 H1N1 infection. Metabolic syndrome and obesity, which had not been identified as risk factors in previous pandemics or with seasonal influenza, are also associated with the development of severe disease due to 2009 H1N1 virus. Indigenous peoples of North America and the Australasia-Pacific region were also disproportionately affected by 2009 H1N1.

ECONOMIC IMPACT

The CDC has estimated that direct medical costs due to influenza in the United States amount to approximately 10.4 billion dollars annually (2003 values).[12] Direct medical costs only make up a fraction of the economic consequences of influenza though a typical case of influenza is associated with 3 days lost from work or school.[13] Total lost earnings due to illness with influenza virus are estimated to be 16.4 billion dollars yearly. Yearly economic burden of influenza virus to the U.S. economy has been estimated at 87 billion dollars.

PATHOPHYSIOLOGY OF INFLUENZA

The predominant means of spread of influenza virus is from an infected person to a susceptible host at a distance of 6 ft or less.[14] Large (≥5 μm diameter) respiratory droplets are disseminated when an infected person coughs or sneezes. Transmission by aerosolized virus that can travel long distances can occur but is not a common method of viral spread and is not of great clinical significance. Although influenza virus can also be transmitted via hands contaminated with respiratory secretions or by fomites, the virus degrades quickly on human hands (within 5 min) and so this route probably plays a minimal role in spread of infection.[15] Once virus is deposited on respiratory epithelium, it attaches to columnar epithelial cells through interaction of the viral HA glycoprotein with sialic acid residues on host-cell receptors and penetrates via endocytosis. Virus replicates within the cells of the respiratory tract within 4 h. Cell death in infected cells takes place due to both direct necrosis and apoptosis. Dead and dying cells will then release virus that will then infect adjacent cells. The incubation period of influenza is 1–4 days (average 2 days), depending on viral inoculum, with more rapid onset of illness after a heavy viral exposure. Adults infected with influenza virus are able to spread the infection via viral shedding beginning about 1 day prior to the onset of symptoms and for 5–10 days after onset, but the heaviest period of viral shedding is the first 3–4 days of illness. Children may shed virus for a longer period of time, including for several days prior to the onset of illness, probably due to a relative lack of immunity. Among patients infected with the 2009 H1N1 virus viral shedding in intubated patients with viral pneumonia has been detected at higher levels and for longer periods in the lower respiratory in comparison to the upper respiratory tract.[16] Immunocompromised persons can shed virus for months.

CLINICAL ILLNESS

Seasonal Influenza

Influenza virus infection usually presents with the abrupt onset of fever, headache, malaise, myalgias, sore throat, rhinitis, and cough. Illness in children also commonly includes nausea and vomiting along with otitis media, but these had not been seen commonly in adults. However, some reports suggest that infection with 2009 H1N1 may be associated with an increased incidence (up to 25% of infected persons) of nausea, vomiting, and diarrhea, and less rhinorrhea and pharyngitis when compared to seasonal influenza.[16,17] Mild illness without fever, similar to that seen with a common cold, can also occur after influenza virus infection. The incubation period is generally 1–2 days. The duration of illness ranges from 3 to 7 days, though cough may persist for weeks.

Respiratory infection due to influenza virus is difficult to diagnose based on clinical symptoms alone, although systemic symptoms are generally more severe than those found with clinical infection due to other respiratory viruses. The likelihood that a respiratory illness is due to influenza virus will depend in part on whether influenza is currently circulating in the community. On physical examination, the patients may look acutely ill. Although sore throat is common, the pharynx is not usually injected and purulence over the tonsils is uncommon. Mild cervical lymphadenopathy is sometimes found. Lungs are generally clear on auscultation although rhonchi, wheezes, and rales can be found if pneumonia is present.

Pneumonia can occur due to direct viral infection of the lower airway or due to secondary bacterial infection. Viral pneumonia due to seasonal influenza is uncommon but may be quite severe. A common presentation of this entity is the typical onset of clinical disease due to influenza, followed by rapid onset of shortness of breath and cyanosis. Primary viral pneumonia may occur more commonly after infection with 2009 H1N1 virus when compared to infection with seasonal influenza virus. Pulmonary replication of the 2009 H1N1 virus has been noted to occur at higher levels in human bronchial epithelium and in lung tissue when compared to seasonal influenza in animal models. This may explain the propensity of this virus to cause severe viral pneumonia in humans. The principal clinical syndrome leading to hospitalization and the need for intensive care in persons with 2009 H1N1 infections is diffuse viral pneumonitis with severe hypoxia, and ARDS, commonly with association of shock and renal failure.[18] When viral influenza is present viral cultures of the sputum will reveal high titers of influenza virus and bacterial cultures will usually be notable for normal oral flora. The chest x-ray of primary viral pneumonia reveals bilateral infiltrates. Pathologic findings of influenza pneumonia include necrotizing bronchitis, hyaline membranes, alveolar hemorrhage, and edema.

A significant proportion of the mortality associated with influenza virus infection is due to pneumonia caused by secondary bacterial superinfection. The typical clinical picture associated with pneumonia due to bacterial superinfection is that of a typical influenza-like illness, then clinical improvement, followed by worsening with fever, cough productive of sputum and dyspnea. The most common bacterial pathogens leading to secondary infection of influenza are *Streptococcus pneumoniae, Staphylococcus aureus, Haemophilus influenzae*, and *Streptococcus pyogenes*. With the recent onset of community-acquired MRSA, severe necrotizing staphylococcal pneumonia complicating influenza virus infection has been described particularly in children and young adults.[19,20] Both primary viral pneumonia and pneumonia due to bacterial superinfection occur most commonly in older persons with underlying cardiopulmonary disease, although primary viral pneumonia also has a predilection for pregnant women and young adults. Immunosuppressed individuals, especially those with hematologic malignancies, persons who have had recent solid organ transplantation, and those with HIV and low CD4 counts are at increased risk of severe influenza infection including pneumonia.

Although influenza primarily affects the respiratory tract, involvement of other organ systems have been described including myositis with elevated creatinine phosphokinase, myoglobinuria, and occasionally rhabdomyolysis. Patients with myositis have muscle tenderness that most commonly affects the legs.[21] Myocarditis and pericarditis have been reported but are rare. Guillain–Barre syndrome has been reported after influenza but this may be coincidence rather than etiologic. Transverse myelitis and encephalitis due to influenza are rare.

Reyes's syndrome is seen almost exclusively in children who are taking aspirin. It appears more commonly after influenza B virus infection than with influenza A. Most patients with Reye's syndrome present initially with nausea and vomiting. This is followed by altered mental status manifesting variably as delirium, lethargy, seizures, and progressing at times to coma and respiratory arrest. Most patients will have elevated ALT and AST; bilirubin is generally not elevated. Elevation in serum ammonia level is universal. If a lumbar puncture is performed to evaluate altered mental status, cerebrospinal fluid will be unremarkable. Reye's syndrome has become less common due to warnings to avoid the use of aspirin in children with acute respiratory illnesses. The exact etiology of Reye's syndrome is unclear.

Avian Influenza

Sporadic human infection with influenza A viruses that predominately infect birds has been noted, and involves the H5, H7, and H9 subtypes. Despite concerns of a human pandemic due to avian influenza virus, these sporadic infections have not generally resulted in person-to-person transmission, with the exception of some limited spread between lengthy unprotected close contacts of those infected with H5N1 avian influenza virus. In 1997, the first recognized case of severe human illness with H5N1 avian influenza virus was reported in Hong Kong. At that time "bird flu" emerged resulting in 18 known human infections and

6 deaths. Millions of poultry were slaughtered in order to try and contain the disease. Despite these efforts, H5N1 avian influenza reemerged in humans and birds in Asia in 2003 and spread to Africa and Europe possibly by migrating wild birds. The virus has become entrenched in Africa and Asia. As of January 20, 2011, 518 laboratory-confirmed human cases of H5N1 avian influenza with 301 deaths have been reported to the WHO. Egypt and Indonesia have reported the majority of human cases, with additional cases reported in China, Cambodia, and Vietnam in 2010. In the vast majority of cases, there is a history of direct contact with sick or dead poultry. Transmission to humans probably takes place via the respiratory route but infection via the gastrointestinal tract is possible and has been demonstrated in zoo animals that were fed infected poultry and in human infections presenting with diarrhea after consuming raw duck blood. The incubation period appears to be slightly longer than that seen with seasonal influenza virus, about 2–4 days after contact with infected poultry. H5N1 influenza has a propensity to infect young individuals, with a median age of 20 years. H5N1 influenza preferentially infects the lower respiratory tract and most patients die from primary viral pneumonia.[3]

Along with the usual symptoms of cough, fever, and malaise, gastrointestinal symptoms are often prominent with nausea and vomiting. Encephalopathy can be seen. Multisystem organ failure and acute respiratory distress syndrome can develop and are ominous signs. Laboratory abnormalities such as leukopenia and thrombocytopenia and elevated transaminases are common. Although bacterial superinfection can occur, primary viral pneumonia is more common after infection with H5N1 influenza virus.

Most patients will present with bilateral infiltrates on chest x-ray. Respiratory failure may develop, requiring ventilatory support. Renal failure and multisystem organ failure can ensue. Unlike seasonal influenza, evidence suggests that H5N1 influenza virus can replicate in tissues outside of the respiratory tract and replicating virus has been isolated from peripheral blood in infected persons. Human infection with H5N1 influenza virus has a high mortality rate; approximately 58% of infected persons will succumb.

LABORATORY DIAGNOSIS OF INFLUENZA

Influenza virus can be readily isolated or detected from a variety of respiratory specimens. Nasopharyngeal swabs are the most reliable specimen source for most assays. Influenza can be diagnosed by rapid diagnostic methods including immunoassays, by polymerase chain reaction (PCR) or by more traditional and time-consuming methods such as cell culture.[22] Results are most likely to be positive in children, who shed higher titers of virus, and in any patient during the first 48–72 h of clinical illness when viral shedding is the greatest. Immunoassays detect viral NP from the influenza virus in patient secretions and results are reported as positive or negative. Some rapid tests can also differentiate between influenza A and influenza B. Results are available quickly, often in 15 min or less. Some of these assays are eligible for a Clinical Laboratory Improvement Amendment (CLIA) waiver and can be performed in a clinician's office. This can be useful for clinical decisions regarding provision of antiviral therapy. Limitations for rapid influenza immunoassays exist however, primarily due to false negative results. The sensitivity of the test is in the range of 40%–70%, with a specificity of 90%–95%. During the 2009 pandemic rapid influenza, assays were falsely negative up to 88% of the time.[23] A negative rapid influenza test should not be used to withhold antiviral therapy in a patient with a clinical syndrome consistent with influenza virus infection when therapy would otherwise be indicated. Reverse transcriptase polymerase chain reaction assays (RT-PCR) are now commercially available and are the best method for a quick diagnosis (within hours) of influenza virus infection. Available multiplex assays can detect not only influenza but a variety of respiratory viruses.[23] These assays are comparable with real-time PCR and are more sensitive than viral culture. In patients with lower respiratory tract illness, endotracheal or bronchoscopic aspirates have higher yields than nasopharyngeal samples; however, negative lower respiratory tract samples have been noted in 10% or more of patients with severe 2009 H1N1 virus infection. Specimens for viral culture or for RT-PCR should be collected, and then placed in containers of viral transport medium and brought promptly to the laboratory. Influenza virus replicates in a variety of cell types, kidney cell cultures are most commonly employed although embryonated eggs can also be used for viral culture. More than 90% of influenza viral cultures are positive within 3 days, and the remainder of positive cultures will be positive by 7 days after inoculation. Serologic testing can be used to retrospectively diagnose influenza virus infection. As most people have been infected with influenza virus in the past, diagnosis of a recent acute infection requires paired acute and convalescent serum specimens (the latter should be obtained 10–20 days after acute illness) run simultaneously to assess for an increase in antibody titer.

Decisions regarding treatment of influenza should not be exclusively based on the results of tests for the presence of influenza virus, especially when the virus is known to be circulating in the community and a patient presents with signs and symptoms consistent with influenza. Several studies have demonstrated that the clinical diagnosis of influenza can be made with 77%–90% accuracy when influenza is present in the community and patients present with typical symptoms.[24] It is reasonable to test only in those circumstances where the results will impact clinical decision making.

PREVENTION

Vaccination is the best way to prevent influenza virus infection. Some studies suggest that vaccinating children against influenza may be more effective in preventing the flu in the elderly than vaccinating older adults themselves, as children are very effective at spreading influenza, and older adults

may have a suboptimal response to vaccination.[25] As influenza virus is spread primarily by inhalation of small droplet particles, maintaining a distance of 6 ft from persons coughing or sneezing is prudent. Although environmental contamination is a relatively unimportant mechanism for the spread of influenza, cleaning hands after contact with common high-touch public areas, such as doorknobs, makes sense especially during flu season. This is particularly important before making hand contact with one's face or eyes. Persons ill with the flu or other respiratory viruses should make an effort to "cover their cough" with a tissue, or cough into their elbow or shoulder to avoid exhaling viral particles into the air and infecting others. After coughing into a tissue, it should be discarded in the trash and hands should be cleaned.

Vaccination

Immunity to influenza virus is mediated by secretory IgA and serum IgG antibodies specific for the viral surface proteins HA and NA. Infection results in resistance to reinfection with the same viral strain and possibly some degree of protection within a subtype. Due to ongoing antigenic changes of influenza virus that lead to escape from immunologic control, routine vaccination is the best strategy for control of influenza epidemics. The Advisory Committee on Immunization Practices (ACIP) issues yearly updated recommendations for influenza vaccination through the CDC.[26] In response to antigenic variation of influenza viruses, the content of influenza vaccine may change on an annual basis. Seasonal influenza vaccines are formulated as trivalent preparations, with two influenza A components and one influenza B component. The components of the seasonal vaccine may vary year to year and are chosen based on the viruses that are circulating at the end of the previous influenza season. Influenza vaccines are available as either live attenuated intranasal vaccine (LAIV) or intramuscular inactivated vaccine (TIV). Inactivated influenza virus vaccines were first licensed in the United States in 1943. Live attenuated influenza virus vaccines are licensed for persons aged 2–49 years and should not be given to persons who are immunocompromised or at high risk for complications of influenza, or children aged 2–4 with asthma. Antibody titers after live attenuated influenza virus vaccine are higher in children, and lowest in older adults. Whether this lower antibody titer would correspond to less protection after vaccination with LAIV is not clear. It is possible that the main mechanism of protection of LAIV is via mucosal antibodies. A new trivalent intramuscular vaccine containing a higher dose of antigen has recently been approved for adults aged 65 years or greater. Immunity develops about 2 weeks after vaccination but can take longer in children. Increases in HAI antibody are seen in about 90% of healthy adults after vaccination with inactivated influenza virus vaccine. Peak antibody titers occur about 2–4 months after vaccination and return to baseline prior to the next influenza season. A recent review of influenza vaccination studies, conducted in healthy adults, estimated that when high levels of influenza virus circulate, and there is a good match between vaccine strain and circulating virus, about 4% of unvaccinated adults will develop influenza symptoms versus 1% of vaccinated people, giving a protection rate in the 70% range.[27].

Currently, influenza vaccine is recommended yearly for all persons over 6 months of age. This recommendation is an expansion of previous target groups and was prompted in part by the fact that many persons who developed complications after infection with novel 2009 H1N1 were members of groups not previously recognized as at risk for severe disease. Children aged 6 months to 8 years of age who have not had a previous influenza vaccination are recommended to receive two doses of vaccine. Side effects of vaccination are generally mild. Local soreness at the site of injection is common after inactivated influenza virus vaccine. Low-grade temperature elevations can be seen after vaccine administration but these are only slightly more common than after placebo. Side effects of live attenuated intranasal influenza vaccine are nasal congestion and sore throat, which occur at a slightly higher rate than that seen with placebo. Live attenuated vaccine viruses can be transmitted to close contacts, although this does not seem to occur frequently. Hypersensitivity to hen eggs is a contraindication to administration of inactivated influenza vaccine; the vaccine is generally safe in people who can eat eggs or products containing eggs. In 1976, an elevated rate of Guillain–Barre syndrome (GBS) was observed in person who received the swine flu vaccine. The estimated risk was one in 100,000 vaccinees. Very slight increases in the risk of GBS have been seen after administration of other influenza vaccines, an excess of one case per one million persons vaccinated.

Chemoprophylaxis

Antiviral medicines taken daily during a period of exposure are 79%–90% effective at preventing influenza. Chemoprophylaxis should be started within 48 h of exposure to be effective. Indiscriminate use of prophylaxis is not recommended as it can promote antiviral resistance. The recommended dose of amantadine or rimantadine in adults for the prophylaxis of influenza A virus in adult patients under the age of 65 years is 100 mg orally twice daily. The recommended dose of oseltamivir for chemoprophylaxis against influenza in adults is 75 mg orally once a day. The recommended dose of zanamivir for prophylaxis of influenza (types A and B) in adults in a household setting is two inhalations (5 mg per inhalation) orally once daily. The recommended duration of postexposure prophylaxis is 10 days after a household exposure or 7 days following exposure in other situations. The dose should be given at approximately the same time each day.[28]

Self-Care for Persons with Influenza

Most persons with influenza virus infection do not need antiviral drugs or require attention from a medical professional. Persons more likely to develop complications, such as the elderly, young children, pregnant women, immunosuppressed patients, and those with asthma, should consult their

health care provider about whether they need to be examined, as should any person who is concerned about severe symptoms. The CDC recommends that persons remain at home and avoid public places as much as possible until at least 24 h after fevers abate (without antipyretic use). Antipyretics can reduce fever and aid in comfort, but aspirin should not be used by children or teenagers who have influenza. Persons with fever should consume adequate fluids to compensate for increased fluid losses associated with sweating and increased respiration. Usual activities including exercise can be resumed when recovery is adequate and the person who had influenza feels ready to take part in those activities. Whether hand washing prevents influenza transmission is unclear, as the virus is not known to survive for a long period of time on surfaces and transmission through the air via respiratory droplets is felt to be the most important means of transmission. However, hand washing has been shown to be of benefit for preventing transmission of other respiratory viruses and gastrointestinal illnesses and is prudent to practice. Covering the mouth when coughing should be practiced routinely no matter what the reason for the cough, using a tissue that is then discarded in a waste receptacle or by coughing into one's shoulder if a tissue is not available.

ANTIVIRAL THERAPY

Antiviral medicines active against influenza virus include the NA inhibitors oseltamivir and zanamivir, and the M2 inhibitors amantadine and rimantadine. The M2 inhibitors, classified as adamantanes, are only active against influenza A, which can limit their clinical usefulness unless a patient is known or highly suspected to be infected with a type A virus. The NA inhibitors are active versus both A and B viruses. The antiviral activity of amantadine and rimantadine is due to inhibition of the M2 ion channel in susceptible influenza A viruses. Disruption of the ion channel interferes with viral uncoating and thus viral replication. Amantadine is administered at a dose of 100 mg twice a day for 5 days in adults less than 65 years of age with normal renal function. Common side effects include dizziness, insomnia, and difficulty in concentrating. In the elderly, confusion can occur as a side effect of the drug. Seizures have been reported in those with an underlying seizure disorder. Amantadine is not metabolized by the body and has a half-life of 12–18 h. Dose adjustment is necessary in renal insufficiency and the elderly. Rimantadine is extensively metabolized and does not need dose adjustment unless the creatinine clearance is less than 10 mL/min. The usual recommended dose of rimantadine for the treatment of influenza A virus in adults is 100 mg orally twice daily. The dose of both drugs needs adjustment in the elderly. Efficacy of amantadine and rimantadine are essentially equivalent when compared in a randomized trial. They are associated with a decrease in duration of fever by approximately 24 h, more rapid cessation of cough as well as sore throat and less nasal discharge. In recent years, much of the circulating influenza virus has been resistant to adamantanes on the basis of single point mutations in the genes coding for the membrane spanning portion of the M2 viral protein. Resistant virus can be transmitted and cause disease in susceptible hosts. As an example, the 2009 H1N1 virus and most H3N2 viruses currently in circulation are resistant to the adamantanes.

The NA inhibitors oseltamivir and zanamivir inhibit the function of the NA protein of influenza viruses. This protein cleaves sialic acid residues and is necessary for budding of virus from infected cells. Although influenza A viruses are more sensitive to the NA inhibitors than influenza B viruses, influenza B viruses are inhibited well within achievable drug concentrations in humans. All avian influenza strains including H5N1 are sensitive to NA inhibitors. Oseltamivir is rapidly absorbed from the gut and is converted in the liver to the active metabolite. The metabolite is eliminated unchanged in the urine. Dose reduction is recommended for persons with creatinine clearance of less than 30 mL/min. There are no formal recommendations for dosing in renal failure. The most common side effect of oseltamivir is nausea and vomiting, which can be reduced if the drug is taken with food. Oseltamivir is not licensed for children under the age of 1 but was used for younger children during the H1N1 pandemic under an Emergency Use Authorization from the Food and Drug Administration that has since expired. Zanamivir is not orally bioavailable and is supplied as a dry powder for oral inhalation, given as a dose of two inhalations twice a day. It can precipitate bronchospasm if given to patients with underlying pulmonary disease. Zanamivir is not recommended for persons with underlying lung disease, that is, asthma or chronic obstructive pulmonary disease, or for children under the age of 7. The tolerability and efficacy of inhaled zanamivir has not been studied in persons with severe influenza but in some instances seriously ill persons given inhaled zanamivir have had respiratory distress. Intravenous zanamivir may be available for compassionate use and is currently in phase 3 clinical trials. Another intravenous NA inhibitor, peramivir, is also in clinical trials and may be available on a compassionate use basis for treating seriously ill adults.

Oseltamivir and zanamivir have similar efficacy in clinical trials of person infected with influenza A and influenza B. In healthy adults, early treatment (within first 36 h of illness) results in a 30%–40% shorter duration of symptoms and an earlier return to work. Antiviral medication can reduce the duration of illness when started within 2 days of onset of clinical illness. In a study among healthy volunteers, NA inhibitors reduced the duration of illness by 1–2 days. The standard dose of oseltamivir for treatment of mild-moderate illness with susceptible influenza virus is 75 mg orally twice a day in adults with normal renal function. Higher doses of oseltamivir (150 mg twice a day) and an increased duration of therapy have been used in severely ill patients.[29,30]

Antiviral therapy is indicated as early as possible for persons hospitalized with influenza, those with severe progressive illness and those at higher risk of severe illness.[28,30] Early therapy with oseltamivir in patients with 2009 H1N1 virus infection may have reduced the incidence of hospitalization and the risk of progression to severe disease. Initiating

therapy after 48 h should be considered for persons at high risk for complications of influenza as well as for hospitalized patients with severe illness. Persons at higher risk of severe illness recommended for antiviral therapy include children less than 2 years of age, adults aged ≥65 years old, women who are pregnant or less than 2 weeks postpartum, persons with chronic cardiac disease (except hypertension alone), chronic pulmonary disease, renal disease, hepatic disease, hematologic disease (including sickle cell), metabolic disorders including diabetes mellitus, neurologic or neurodevelopmental conditions, immunocompromised states including HIV, persons aged <19 on long-term aspirin therapy (due to the risk of Reye's syndrome), persons who are morbidly obese, and residents of long-term care facilities. Selection of antiviral therapy should take into consideration the susceptibility pattern of circulating influenza virus in the community. Oseltamivir is recommended for treatment of H5N1 influenza virus infection as isolates have been resistant to the adamantanes. It is unclear at this time what the therapeutic efficacy is of antiviral therapy for H5N1 virus infection. Drug resistant viruses have been detected including in persons who had no history of treatment with NA inhibitors. Many oseltamivir-resistant influenza viruses remain sensitive to zanamivir.

SUMMARY

Influenza is a common upper respiratory infection caused by a virus of the *Orthomyxoviridae* family. There are three viral subtypes although most illness is caused by influenza A or B. Genetic variation allows the influenza virus to escape host defenses and infect an individual multiple times during a lifetime. Clinical illness from influenza virus ranges from a mild upper respiratory illness to a fatal viral pneumonia depending on the virulence characteristics of the virus and the immune system and physical characteristics of the individual host. Complications of influenza virus infection can occur directly from viral infection and due to bacterial superinfection of the respiratory tree. Efforts to prevent or minimize the impact of seasonal influenza center on the use of vaccines. Antiviral medications are available and ameliorate disease in healthy adults and may also have an effect in seriously ill patients.

INTRODUCTION

Clean environmental air is a basic right for all humans. The relationship between health and air quality has been recognized as far back as Hippocrates. Indoor air quality is particularly important to humans since we spend up to 90% of time indoors.[1] Outdoor and indoor air quality in the United States of America is regulated by the U.S. federal government through the Environmental Protection Agency (EPA). Although indoor air quality is important in the workplace, this chapter concentrates on home indoor air quality and highlights the sources of potential morbidity of indoor air quality as it pertains to lung health.

One of the most important tasks of the health care worker meeting a patient for the first time is to take a comprehensive history of environmental exposures both at work and in the home. A comprehensive assessment of the respiratory history has been recently published.[2] The health care worker taking a complete exposure history will ask the patient about contemporary exposures and also about exposures "in the home in which you grew up."[2] Household factors which may affect respiratory health include home water damage, heating and ventilation, renovation work, cleaning product accidents, the presence of a pool or hot tub, and hobbies including arts and crafts and model building. Also discussed are activities such as do-it-yourself repair work, gardening, pet exposure, wood and, coal fume exposure, and dirty work clothes exposure. This chapter discusses also some of the latest findings on home exposure of secondhand smoke, which is now recognized as an important risk factor for respiratory disease.

SECONDHAND SMOKE

Today, the awareness of smoking and its adverse effects is at the peak at any point of time in history. Yet, smoking is still a highly prevalent lifestyle. Secondhand smoke exposure comes in a close second as a leading public health problem. Over the recent few years, there has been a concerted effort from various national and international organizations to increase the awareness of problems associated with secondhand smoke exposure.[3–6] There have also been multiple public health initiatives undertaken to minimize the levels of secondhand smoke exposure. In this section we attempt to summarize and outline the scope, effects, and dangers of secondhand smoke. We also summarize measures to reduce and combat secondhand smoke exposure.

Secondhand smoke is composed of side stream smoke (the smoke released from the burning end of a cigarette) and exhaled mainstream smoke (the smoke exhaled by

the smoker).[6] While secondhand smoke has been referred to as environmental tobacco smoke (ETS) in the past, the term "secondhand" smoke better captures the involuntary nature of the exposure. The 2006 Surgeon General's report uses the term "involuntary" in the title because most nonsmokers do not want to breathe tobacco smoke.[4] Individuals can be exposed to secondhand smoke in homes, cars, the workplace, and public places, such as bars, restaurants, and recreational settings. In the United States, the source of most secondhand smoke is from cigarettes, followed by pipes, cigars, and other tobacco products. The term "thirdhand smoke" has been referred to as cigarette byproducts that cling to smokers' hair and clothing as well as to household fabrics, carpets, and surfaces—even after secondhand smoke has cleared.[7] These invisible tobacco toxins pose danger to small children, who are especially susceptible when they come in contact with contaminated surfaces.[8]

Secondhand smoke exposure can be measured by testing indoor air for nicotine or other chemicals in tobacco smoke. Secondhand smoke exposure can also be tested by measuring the level of cotinine (a by-product of the breakdown of nicotine) in a nonsmoker's blood, saliva, or urine.[9] Nicotine, cotinine, carbon monoxide, and other smoke-related chemicals have been found in the body fluids of nonsmokers exposed to secondhand smoke.

More than 4000 chemicals that have been identified in secondhand tobacco smoke and more than 50 of the toxic chemicals in secondhand tobacco smoke are carcinogenic.[10] Table 57.1 contains a list of some of these compounds.

TABLE 57.1
Carcinogens and Suspected Carcinogens in Secondhand Cigarette Smoke

Carcinogens	Suspected Carcinogens
Arsenic	Acetaldehyde
Benzene	Acetone
Beryllium	Acrolein
1,3–Butadiene	Acrylonitrile
Cadmium	2-aminonaphthalene
Chromium	Ammonia
Ethylene oxide	Benzo[a]pyrene
Nickel	Butyraldehyde
Polonium-210	Carbon monoxide
Vinyl chloride	Catechol
	Cresol
	Crotonaldehyde
	Formaldehyde
	Hydrogen cyanide
	Hydroquinone
	Isoprene
	Lead
	Methyl ethyl ketone (MEK)
	Nicotine
	Nitric oxide
	NNN, NNK, and NAT
	Phenol
	Propionaldehyde
	Pyridine
	Quinoline
	Resorcinol
	Styrene
	Toluene

Carcinogens and Suspected Carcinogens Found in Secondhand Tobacco Smoke

Risks of Exposure to Secondhand Smoke

In June 2002, the International Agency for Research on Cancer (IARC) concluded that "involuntary smoking (exposure to secondhand or 'environmental' tobacco smoke) is carcinogenic to humans." Further, the IARC concluded that there is a "statistically significant and consistent association between lung cancer risk in spouses of smokers and exposure to secondhand tobacco smoke from their spouse who smokes. The excess risk is on the order of 20% for women and 30% for men."

In January 2005, the U.S. Public Health Service's National Toxicology Program issued its 11th report on Carcinogens. This report unambiguously states that "environmental tobacco smoke is known to be a human carcinogen based on sufficient evidence of carcinogenicity from studies in humans that indicate a causal relationship between passive exposure to tobacco smoke and human lung cancer. Some studies also support an association of environmental tobacco smoke with cancers of the nasal sinus."[11] Evidence for an increased cancer risk from environmental tobacco smoke stems from studies examining nonsmoking spouses living with individuals who smoke cigarettes,[16] exposures of nonsmokers to environmental tobacco smoke in occupational settings, and exposure to parents' smoking during childhood.[6,7] Many epidemiological studies, including large population-based case-control studies, demonstrate an increased risk of developing lung cancer following prolonged exposure to environmental tobacco smoke. A meta-analysis found an overall increase in risk of 20% for exposure to environmental tobacco smoke from a spouse who smokes. Exposure to environmental tobacco smoke from spousal smoking or exposure in an occupational setting appears most strongly related to increased risk. Lifelong nonsmokers living with smokers had, on average, a 24% higher chance of contracting lung cancer than those living with nonsmokers, and that those exposed to the heaviest smokers for the longest time had the highest risks.[13]

There is some evidence to suggest that secondhand smoke may have a causative role in other cancers such as breast cancer, nasal sinus cavity cancer, and naso-pharyngeal cancer in adults and increases the risk of leukemia, lymphoma, and brain tumors in children.[12] However, the proof is not conclusive as in the case of lung cancer, and more research is being done to answer these questions.

Secondhand smoke exposure may have other consequences. Individuals exposed to low-dose tobacco smoke

from the environment or occasional smoking are also at risk for developing respiratory symptoms. When small airway epithelial cells of individuals exposed to low-dose tobacco smoke was compared to those of nonexposed, biologic changes that are likely the earliest biologic abnormalities in the lung in response to smoke exposure were noted, and there were a significant number of genes up- and down-regulated in the low-level smoke-exposed individuals compared with the nonsmoker.[14]

Secondhand smoke also has significant effects on the cardiovascular system. Higher concentrations of serum cotinine among nonsmokers was shown to be associated with an excess risk of coronary heart disease of about 50%–60%.[15] In its 2009 report, the Institute of Medicine concluded that current data consistently demonstrates that secondhand-smoke exposure increases the risk of coronary heart disease and heart attacks and that smoking bans reduce this risk.

Children are particularly vulnerable to the effects of secondhand smoke. Children exposed to high doses of secondhand smoke are at a higher relative risk of asthma even in children who have not previously exhibited symptoms; sudden infant death syndrome and lower respiratory tract infections such as pneumonia and bronchitis are also increased. Children who regularly breathe secondhand smoke are also at increased risk for middle ear infections and may exhibit a small but significant reduction in lung function.[16–18]

Reducing the Risk

There is no safe level of exposure to secondhand smoke. Even low levels of secondhand smoke can be harmful. The only way to fully protect nonsmokers from secondhand smoke is to completely eliminate smoking in indoor spaces. Separating smokers from nonsmokers, cleaning the air, and ventilating buildings cannot completely eliminate exposure to secondhand smoke.

On the national level, several laws restricting smoking in public places have been passed. Federal law bans smoking on domestic airline flights, nearly all flights between the United States and foreign destinations, interstate buses, and most trains. Smoking is also banned in most federally owned buildings. The Pro-Children Act of 1994 prohibits smoking in facilities that routinely provide federally funded services to children. Many state and local governments have passed laws prohibiting smoking in public facilities, such as schools, hospitals, airports, bus terminals, parks, and beaches, as well as private workplaces, including restaurants and bars. Some states have passed laws regulating smoking in cars and multiunit housing to reduce the incidence of thirdhand smoke exposure which can also affect respiratory function. More than half of the states in the United States have enacted statewide bans on workplace smoking. Despite scientific evidence of its respiratory and cardiovascular consequences to innocent bystanders, the elimination of secondhand smoke in indoor air remains a challenge to individuals and public health officials nationwide.

RADON

Prevalence and Health Impact

Radon (Rn-222) is a radioactive colorless, odorless gas and is a breakdown product of radium (Ra) which is a breakdown product of uranium (U). Radon-222 has a half-life of 3.8 days and is found in the earth's rock and soil. Radon-222 itself does not pose a great biologic threat. However, radon breaks down via alpha decay into unstable polonium-218. Polonium-218 breaks down via alpha decay into lead-214, bismuth-214, and polonium-214, which are "short-lived" radioactive by-products referred to as "radon progeny." These "short-lived" progeny are hazardous to uranium workers and can decay via alpha radiation into the "long-lived" radon progeny of lead-210, bismuth-210, and polonium-210. These "long-lived" progeny are principally responsible for the radon found in homes.

Radon can easily dissolve into and evaporate out of water. Radon can seep through porous soil under buildings, through cracks or gaps in building foundations, floors, walls, and along with gaps around pipes, pumps, and drains.[19] In contrast to community water supplies, it is much more common for deep private well water to be infiltrated with radon if this water is in contact with rocks and soil containing uranium. This water in turn can enter the home through any home water supply such as showers, faucets, washing machines and dishwashers. Inhaled radon poses a much higher risk of lung cancer than radon which is ingested.[20,21] If radon is detected in home drinking water, it may be treated with "point-of-entry treatment," which can remove radon from the water before it enters the home, or "point-of-use" treatment devices. "Point-of-use" treatment devices only remove a small portion of the radon from water at the taps in the home leaving radon progeny which can be inhaled.

Inhaled radon progeny are the number one cause of lung cancer in never smokers and the second leading cause of lung cancer overall. The EPA estimates that radon exposure may account for over 20,000 lung cancer deaths each year including approximately 2,900 never-smokers and the remaining deaths in smokers with lifetime radon exposure of as low as 2 picocuries per liter of air (pCi/L). Simple home testing and correction of home radon levels above the EPA recommended action guideline level of 4 pCi/L per yearly average would reduce these deaths significantly. There is no safe level of radon exposure. According to the EPA, 1 out of 15 homes in United States has levels at or above the EPA action guideline level.[22] The chances of getting lung cancer from radon exposure is a function of the levels of radon in the home, the amount of time spent in the home, and whether or not one is a former or current smoker.[22]

Detection and Mitigation

Home short-term testing and long-term testing for radon are available. The EPA recommends testing for radon levels in schools and in all homes below the third floor as toxic levels are rarely seen in higher levels of high rise dwellings.

"Do-it-yourself" testing kits must have an accuracy of ±25% or ±1 pCi/L in order to meet the EPA approval. "Short-term" testing kits may be in your home for 2 or 3 days or for up to 90 days depending on the testing device. Several "passive" testing devices are available and include the activated charcoal canister, the alpha track device and the electret ion chamber which is used only by professional radon inspectors. These devices remain in the basement or first floor of the home while all windows and doors are kept closed, and fans bringing in outside air are shut off. Once testing is completed, the device is sent to a lab for analysis of radon levels via either gamma ray counting or liquid scintillation detectors. Because of their low cost and ease of use, the activated charcoal canister radon test kit accounts for approximately 95% of all radon testing, or approximately 250,000 test kits annually, in the workplace or in the home in the Unites States. An example of a short-term "active" device is the continuous radon monitor used for 48 h by professional radon inspectors with specialized training. This testing is usually reserved for real estate transactions.

"Long-term" radon testing devices are left in the home for more than 90 days and are usually performed with an alpha track device or an electret ion chamber. Long-term testing gives a better estimate of a home's year-round average radon level when compared to short-term testing. Long-term testing may be performed when a short-term testing radon level returns as 4 pCi/L or higher. The U.S. Congress has legislated that indoor radon levels be no more than 0.4 pCi/L of radon. This is the level usually detected in outdoor air and a level which is very difficult to achieve indoors. A more achievable indoor radon level is 2 pCi/L or below.

If high levels of radon are detected within a home, a radon contractor should be hired to evaluate the problem and decide which method would be best to treat that particular problem. Sealing cracks and gaps in the home foundation can help reduce radon levels. Another method to reduce radon is a vent pipe system and a fan known as a soil suction radon reduction system which removes radon from below the surface of the house via pipes and a sump suction pump. This system removes radon from the home through pipes vented to outside of the home. Even after installing a removal system, retesting for elevated radon levels should be conducted biannually. Recommendations from the EPA for building a radon-resistant new home may be located on the EPA website at: http://www.epa.gov/radon/rrnc/index.html

Perhaps the most significant event in radon risk reduction was the The Federal Radon Summit held on November 30, 2010. Convened by the EPA, representatives from the Department of Housing and Urban Development, Department of Defense, the Veterans Administration, the Department of Energy, the General Services Administration, the Department of Health and Human Services, the Department of Agriculture, and the Department of the Interior were also all in attendance. Leaders from these organizations discussed strategies available to the U.S. Government to reduce the risk of morbidity caused by radon in federally owned homes and buildings. Future follow-up meetings to discuss residential home radon reduction are planned.

CARBON MONOXIDE

Carbon monoxide (CO) is a colorless and odorless gas. It results from incomplete oxidation of carbon in the combustion processes. CO has a high affinity for hemoglobin forming carboxy-hemoglobin (COHb) and disrupts oxygen transport. Tissues with highest oxygen needs such as myocardium, brain, and exercising muscle are the first effected. The initial symptoms of low to moderate CO poisoning may mimic influenza and include headache, fatigue, shortness of breath, nausea, dizziness, and tachycardia. At higher concentrations, CO poisoning results in progressively more severe symptoms which include cognitive impairment, loss of muscle coordination, coma, and death. Symptom severity is related to both the CO level and the duration of exposure.[23–25]

Common sources of CO are unvented kerosene and gas space heaters, leaking chimneys and furnaces, back drafting from furnaces, gas water heaters, wood stoves, fireplaces, gas stoves, generators and other gasoline powered equipment, automobile exhaust from attached garages, and tobacco smoke. When power outages occur during emergencies (hurricanes or winter storms), using alternative sources of power can cause carbon monoxide (CO) to build up in a home and poison the people and animals inside. On average, about 170 people in the United States die every year from CO produced by nonautomotive consumer products.[24]

The Centers for Disease Control and Prevention estimates that several thousand people go to hospital emergency rooms every year to be treated for CO poisoning. Average levels in homes without gas stoves vary from 0.5 to 5 parts per million (ppm). Levels near properly adjusted gas stoves are often 5–15 ppm and those near poorly adjusted stoves may be 30 ppm or higher. Most people will not experience any symptoms from prolonged exposure to CO levels of approximately 1–70 ppm. As CO levels increase and remain above 70 ppm, symptoms become more noticeable. At sustained CO concentrations above 150–200 ppm, disorientation, unconsciousness, and death are possible.[25]

CO levels can be monitored at home with a commercially available detector. The Consumer Product Safety Commission (CPSC) recommends that a detector be located near the sleeping area, where it can wake you if you are asleep. They should not be directly above or beside fuel-burning appliances, as appliances may emit a small amount of carbon monoxide upon start-up. A detector should not be placed within 15 ft of heating or cooking appliances or in or near very humid areas such as bathrooms.[26]

NITROGEN DIOXIDE

Nitrogen dioxide (NO_2) is one of the nitrogen oxides, a group of air pollutants produced from combustion processes. In urban outdoor air, the presence of NO_2 is mainly due to traffic. Nitric oxide (NO), which is emitted by motor vehicles

or other combustion processes, combines with oxygen in the atmosphere, producing NO_2. Indoor NO_2 is produced mainly by unvented heaters and gas stoves. NO_2 and other nitrogen oxides are also precursors for a number of harmful secondary air pollutants such as ozone and particulate matter, and play a role in the formation of acid rain.

NO_2 is a major problem in individuals with respiratory illnesses such as asthma and chronic obstructive pulmonary disease (COPD). Exposure can irritate the lungs and increase the incidence of respiratory infections such as influenza. Major lung function effects shown in humans are reduction in forced expiratory volume in one second (FEV1), increased specific airway resistance (SRaw), and increased responsiveness in bronchial provocation tests. However, these effects are noted only in asthmatic subjects at levels relevant to exposures found in indoor and outdoor environments.[27] In people with mild asthma, NO_2 is capable of the inducing activation of prostanoids, leukotrienes, and histamine which may enhance airway inflammation.[28] The effects of short-term exposure are still unclear, but continued or frequent exposure to concentrations that are typically much higher than those normally found in the ambient air may cause an increased incidence of acute respiratory illness in children.[29]

The ratings for acceptable limits of NO_2 vary considerably among the various government and private organizations concerned with indoor air quality. The allowable limit according to Association of Heating, Refrigeration and Air conditioning is 0.3 ppm. To reduce exposure and minimize the effects of NO_2, all gas appliances are required to be properly fueled, adjusted, vented, and maintained. Wood stove doors should fit tightly and homes should be checked by an heating, vaccum, air conditioning (HVAC) or indoor air quality (IAQ) specialist for proper ventilation.[30]

FORMALDEHYDE

Formaldehyde is a common indoor air pollutant. It is used as a disinfectant and preservative and commonly found in wood building material, plastics, textiles, carpet, furniture, pesticides, paint glue, and cleaning products. It is one of the volatile organic compounds emitted from various building products like paint, adhesives, insulation, cabinets, false ceilings, etc. Formaldehyde levels are higher in residential homes because of relatively large ratio of pressed wood products to air volume in homes.[31] The main effect of this compound on the respiratory system is irritation of mucous membranes in the airways. Formaldehyde also interferes with airway epithelium integrity and function, and may modulate the onset and the severity of asthma.[32]

The conditions, concentration, and duration of formaldehyde exposure determine any potential effect it may have on the human respiratory system. The recommended maximum level of continual indoor exposure per the American Society of Heating, Refrigeration and Air Conditioning Engineers is 0.1 ppm. Levels greater than 0.5 ppm can cause burning of the eyes and irritation of the upper airways.[30] The recommended measures to reduce exposure are to use exterior grade pressed wood products and to use air conditioning and dehumidifiers to maintain moderate temperature and reduce humidity.[33]

HOUSEHOLD CLEANING AND COOKING

Household cleaning products when used properly and in small amounts are usually safe and do not effect indoor air quality adversely. However, it is well documented in the medical literature that accidents at home may entail the inhalation of toxic fumes and result in significant respiratory morbidity sometimes requiring emergency medical attention.[34] Although societal changes over the past several decades have seen more women in the workplace, women are still more at risk than men to experience a home chemical accident and inhalational injury which may affect their respiratory health.[35]

Household bleach consists of a 5.25% sodium hypochlorite solution (NaOCl). If bleach is mixed with an acid such as either 4% phosphoric acid (a rust, mineral deposit, water stain remover), household ammonia (NH_3) or hydrochloric acid (HCl), chlorine gas, and water are released. Chlorine gas and hydrochloric acid can cause both upper respiratory tract injury such as mucous membrane irritation and lower respiratory tract damage manifest as chest pain, shortness of breath, cough, pneumomediastinum, bronchospasm, pulmonary edema, and reactive airways dysfunction syndrome.[36,37] Chlorine released from aerosolized swimming pool tablets has also been reported to cause partially reversible asthma-like symptoms.[38]

Oven cleaners contain sodium hydroxide, monoethanolamine (MEA), diethylene glycol monobutyl ether, and butane or isobutene and may cause inhalation injuries especially if sprayed into a hot oven. Inhalation of these compounds has been reported to cause chemical pneumonitis, asthma-like symptoms, and bronchiolitis obliterans organizing pneumonia (BOOP).[39] It is known that janitors, maids, and other professional cleaners who use certain cleaning products may be at higher risk for asthma. However, it has been shown that frequent use of household cleaning sprays in the home in subjects 20–44 years old may also be an important risk factor for asthma. In subjects without a previous history of asthma, there was an association of asthma symptoms, the use of asthma medications and wheezing in 42% of those who used cleaning sprays at least once weekly. The diagnosis of asthma was higher in those who used sprays at least 4 days weekly. This association was linked to the most commonly used glass cleaner, air-freshener, and furniture cleaning sprays and was not related to atopy. The same association was not seen with liquid home cleaners presumably because aerosolized spray cleaners are more likely to be inhaled.[40]

Laundry detergents contain sodium phosphates, sodium carbonate, and sodium aluminosilicates and are alkaline with a pH of 10–12. Inhalation of granulated detergent with respiratory injuries usually occurs in young children, but may occur in adults and may be the cause of respiratory distress.[41]

Cooking accidents with overheated oil fumes have been reported to cause significant airflow obstruction.[42] However, cooking with vegetable oil, which is biologically inert, does not have significant adverse effect on the lungs when exposure levels

are kept within the limits recommended by the Occupational Safety and Health Administration and the National Institute for Occupational Safety (NIOSH).[43] Unlike vegetable oil, cooking with certain plant oils such as castor bean, sesame, acacia, and cashew nut have been reported to cause asthma and respiratory irritation such as rhinitis, cough, watery eyes, and wheezing.[43] It is known that frying on a gas or electric stoves may result in the release of polycyclic aromatic hydrocarbons (PAHs), nitrogen dioxide, and particulate matter that may have mutagenic activity and may be a risk factor in lung cancer. A Norwegian study showed that frying on a gas stove, versus frying on an electric stove, resulted in the release of higher concentrations of mutagenic aldehydes and naphthalene. However, the detectable levels of these compounds were below the Norwegian occupational exposure limits for PAHs.[44] In adults with asthma, one study was unable to show an association between gas stove use and FEV1, FEF25-75, cough, wheeze, sputum production, or dyspnea.[45] Despite these negative studies, it is recommended that exposure to cooking fumes be avoided "as much as possible."[45]

HOME HEATING AND VENTILATION AND AIR CLEANING DEVICES

Good ventilation in the home is essential to good respiratory health and dilutes and removes stale air and excessive moisture from the home environment. There are two approaches to ventilating a home: spot ventilation and general ventilation. "Spot ventilation" employs exhaust fans that intermittently remove pollutants in kitchens, laundry rooms, bathrooms, workshops, or home offices. "General ventilation" utilizes fans which run continuously to remove pollutants that are constantly being released into the environment, and not amenable to spot ventilation removal, such as bacteria and viruses, body odors, and moisture. Current recommendations suggest 8–10 air exchanges per hour when utilizing general ventilation.[46]

Because of the air-tight construction methods used in modern homes built within the past 15 years, these dwellings are considered "tight homes." These tight homes are a result of more energy efficient building methods which utilize better windows, high efficiency air conditioners and furnaces, weather stripping on door frames, and more insulation such as cellulose and spray foam.

General ventilation mixes outdoor air with indoor air by two methods: "exhaust-only ventilation" and "supply-and-exhaust ventilation." Exhaust-only home ventilation pulls stale air out of a house through exhaust-only fans such as bathroom or kitchen fans which may run intermittently or continuously at a low speed. This type of one way ventilation results in the need for fresh air, or "make up air" having to enter the house by chance through any available opening such as cracks around an outdoor bulkhead, unused exhaust fans in the house with ducts exiting to the outdoors, opened windows or doors, spaces under indoor doors, a fireplace, or a fresh air intake vent. Although exhaust-only ventilation may reduce odor in a kitchen or moisture in a bathroom, it does not improve the indoor air quality of a new tight house and may actually increase indoor radon levels and levels of stale indoor air.

A second method of home ventilation is "supply-and-exhaust ventilation" which employs continuous exhaust fans to pull stale, humid, or polluted air from inside the house to the outside, in addition to intake fans which draw fresh outside air into the home through existing cooling and heating ducts. Commercially available home "heat recovery ventilation (HRV)," is a type of supply-and-exhaust ventilation which can filter pollen, reduce indoor carbon dioxide levels, and warm or cool incoming fresh outside air before it distributes that fresh air throughout the house. It is generally accepted that supply-and-exhaust ventilation is the preferred method of home ventilation for a tight home or an older home which has undergone an improved energy efficiency upgrade.[46]

In a study of Inuit children in Canada, a comparison was made between households with active HRV or placebo HRV. There was a significant reduction in the odds ratio for wheezing (12.3%) in addition to a decrease in the rate of rhinitis (OR 0.20 at 1 month). Although there was no reduction in the number of health center encounters for the children in the study, the use of HRV was associated with air quality improvement and a reduction in respiratory symptoms.[47]

Even high quality home construction can have unintended consequences. "Back drafting" may occur in tight houses when home appliances such as a central vacuum cleaner system, a clothes dryer, a fireplace, kitchen or bathroom exhaust fans, a gas hot water heater, or a gas furnace suck air from the inside of a tight house to the outside thereby creating negative pressure within the house. If enough negative pressure is created within the house, this process can result in carbon monoxide being pulled back into the home through a fireplace and its chimney. This potential health hazard may be remedied by having a "fresh air intake vent" installed, which can supply "make up air" needed for fuel burning equipment within the home. These vents consist of an intake valve on the outside of the home and two pipes on the inside of the home. One of the inside pipes supplies air to the cold air return of the home's furnace, and the second pipe supplies combustion air for fuel burning appliances within the home.[48] In addition to good ventilation, air purification within the home may improve indoor air quality. Many air purification systems are commercially available and include ozone generators, electrostatic precipitators, ionizers, HEPA filters, and charcoal and zeolite filters.

The allotrope of oxygen (O_2), ozone (O_3), is formed when ultraviolet radiation from the sun splits oxygen atoms forming O_3. Stratospheric ozone is located 6–30 miles above the Earth's surface, and this "ozone layer" protects humans from potentially damaging ultraviolet light from the sun. Ozone closer to the Earth's surface can induce airway inflammation, cough, chest pain, throat irritation, reduce exercise capacity and pulmonary function testing results, and exacerbate asthma and COPD.[49] The EPA lists primary standard levels of indoor ozone as 0.08 ppm averaged over 1 year.[50]

Some indoor home air purifiers, "electrostatic precipitators" or "ionizers," produce ozone not intentionally but as a by-product of their function. These air cleaners electrically charge particles in the air, remove them, and produce low levels of ozone in the process. Some commercially available home air purifiers intentionally utilize ozone to reduce home odors and mold concentrations. These air purifiers are called "ozone generators" and may release potentially toxic levels of ozone. In 2007, after two Consumer Report articles and a class-action lawsuit, one national brand ozone generator home air purifier was taken off of the market for emitting toxic levels of ozone.[51,52] Alternatives to ozone producing air purifiers are HEPA (high efficiency particulate air) filter air purifiers and HEPA vacuum cleaners that utilize a fiber mat made of fiberglass fibers to trap airborne particles such as cooking fumes, spores and pollen, dust and dust mites, and tobacco smoke. A recent study suggested that HEPA air purification may reduce cardiovascular morbidity by reducing short-term particulate matter exposure to subjects.[53] Other portable filtration units utilize zeolite and charcoal filters.

INDOOR MOLD, PET, DUST MITE, AND COCKROACH EXPOSURE

Fungi

Fungi are eukaryotic, parasitic organisms with rigid cell walls which contain chitin. Unlike plants, fungi must absorb all of their nutrients from their environment. By producing a variety of enzymes, fungi may digest and utilize as nutrient materials in the home environment deemed unusable by other organisms. These materials include keratin, cellulose, chitin, and lignin allowing fungi to grow on home materials such as carpeting, drywall and ceiling tiles, and building materials made from organic matter. Although fungi are ubiquitous in air, water, and soil, damp and warm conditions can promote exponential fungal spore germination and growth as reported by many investigators in the aftermath of hurricanes Katrina and Rita in the U.S. Gulf Coast region in 2005.[54]

In general, fungi may be separated into (1) yeast which are unicellular, (2) molds which are multicellular, and (3) mushrooms. Some dimorphic fungi can exist as molds in the environment and yeast in the human body. Most studies that evaluate environmental mold are referring to mold with visible growth and not specific fungal species. Fungal illnesses may be divided into infectious and noninfectious. Although invasive fungal infections are rare in immunocompetent individuals, *Aspergillus* exposure may cause serious pulmonary infections such as pulmonary aspergillosis and aspergillomas in immunocompromised patients.[54]

Symptoms of excess indoor mold exposure include headache, sore throat, non-asthmatic cough, sneezing, and wheezing or cough due to asthma. Energy efficient tight homes may have high indoor temperatures and high humidity promoting dust mite and mold growth.[55] Asthma due to damp conditions and mold exposure may account for up to 21% (confidence interval 12%–29%) of current asthma in the United States.[56] Damp indoor environments and mold exposure have been shown to cause exacerbations of asthma in "sensitized" asthmatics, those who have developed IgE antibodies to allergens, but not in individuals without a previous diagnosis of asthma.[57] Independent of asthma, damp and moldy indoor conditions can also cause cough, wheezing, and upper respiratory symptoms. Other noninfectious respiratory effects known to be caused by mold exposure include hypersensitivity pneumonitis, allergic bronchopulmonary aspergillosis (ABPA), and allergic fungal sinusitis due mainly to dematiaceous fungi, such as those from the genera *Fusarium*, *Helminthosporium*, *Cladosporium herbarum*, *Alternaria alternata*, *Bipolaris*, *Curvularia*, *Exserohilum*, *Drechslera,* and less so *Aspergillus fumigatus*.[57]

Animal Dander

In addition to damp and mold exposure, other household allergens that worsen air quality and asthma symptoms are animal dander, saliva and urine, house dust mites, and cockroaches. Animal allergies usually develop from furred pets such as cats, dogs, rabbits, and guinea pigs, and the allergens are derived mainly from sebaceous gland secretions from the animal's dead skin (animal dander). Animal urine may also contain allergens. Approximately 10% of Americans have some allergy to cats. The most common allergen associated with cat allergies is the Fel d1 protein found in cat saliva and salivary glands. These cat allergens are approximately 2.5 μm in diameter, are suspended in the air, and can penetrate deep into the lung because of their small size. It is important to convey to patients that nonallergenic cats and dogs do not exist. Some cats and dogs are less allergenic than others however.[58] Simple measures such as not having furred pets, restricting furred pets from bedrooms, regular washing of cats and dogs, and HEPA air filtering devices may reduce the allergenic burden of indoor cats and dogs.[58]

Dust Mites

Dust mites, *Dermatophagoides pteronyssinus* and *Dermatophagoides farinae*, are members of the *Acarid* family and represent the most prevalent allergen worldwide. Dust mites most frequently inhabit homes in humid and temperate climates, but are not usually a significant problem at high altitudes. As with mold, tight home construction may lead to higher indoor temperatures and humidity and increase a home's house dust mite burden. Although dust mites can be found in bedroom carpeting and upholstered furniture, bed mattresses are the most common source of dust mites where as many as 100,000–10 million mites might live and feed on dead human skin (dander). It is not the dust mite itself, but rather the fecal particles, that are the most allergenic. It is estimated that approximately 26% of Americans have dust mite allergies.[59] Environmental controls to reduce the home dust mite allergy burden are listed in Table 57.2.[60]

TABLE 57.2
Environmental Dust Mite Control Measures for the Home

Use of hypo-allergenic, non-feather pillows
Use of impermeable pillow and mattress covers
Removal of rugs from rooms
Frequent vacuuming
Laundering bedding in hot water
Remove clutter and stuffed animals from bedrooms
Eliminate cloth upholstered furniture

Cockroaches

Cockroaches have been on earth for more than 300 million years and can be found worldwide with approximately 3500 species. In the United States there are some 55 species. Cockroach infestation is a major inner city problem for many reasons, and high levels of cockroach antigens (Bla g 1 and Bla g 2) have been found in urban schools, daycare centers, and substandard housing. Much like dust mites, the fecal particles of the cockroach are the source of the allergen. Uncovered food, damp, warm conditions, poor sanitation, and crowding all promote cockroach infestation.[61] Children who experience cockroach antigen exposure can get sensitized and exhibit positive skin test responses to cockroach allergen. Rosenstreich showed that children who were exposed and sensitized to cockroach antigen in high levels (>8 U/g) could develop wheezing and asthma and have a higher asthma morbidity, more medical visits, and more hospitalizations due to asthma.[62] Several techniques have been recommended to reduce cockroach allergen exposure and include environmental controls of humidity, ventilation and temperature, improved indoor sanitation, chemical and nonchemical extermination, and enforcement of public housing codes.[61]

HOME HOBBIES AND GARDENING

Home hobbies and gardening are often overlooked, as a potential cause for respiratory illnesses, even by experienced clinicians. This is mainly because of the rarity of such occurrences. Nevertheless, identifying and eliminating such exposure is critical when evaluating such illnesses. It is a common misconception that men are more likely to suffer from such exposure, but research suggests that the role of household exposure as a risk factor for adverse respiratory effects is as important in women.[63] Not infrequently, multiple family members in the same household could be exposed to a similar toxin leading to lung injury. An exhaustive list of such activities and the offending agents is not practical. However, in terms of respiratory disease, avocations of relevance include painting, metal works including metal refining, wood working, use of synthetic polymers and adhesives, auto-repair chemicals textile work to name a few. For example, severe lung injury has been reported from home gold refining work with mercury amalgams.[64] Home plumbing repair has been reported to cause exposure to hydrogen sulfide, which is a mucous membrane and respiratory tract irritant; pulmonary edema, which may be immediate or delayed, can occur after exposure to high concentrations. Agricultural products for gardening, including herbicides and plant allergens, are another source for respiratory ailments. For example, the herbicide paraquat is selectively toxic to the lungs and has been shown in many studies on agricultural workers across the world.[65]

SUMMARY

Excellent indoor air quality is vital to excellent health. This chapter has briefly outlined some areas to address in the home to improve indoor air quality. Keeping pollution out of your home by checking radon levels, not allowing smoking indoors, reducing conditions which promote mold growth, dust mites and animal dander, monitoring carbon monoxide levels, providing adequate ventilation, and using chemical products with care are just a few examples that can improve the indoor air you breathe. Since we spend most of our lifetime indoors, continued lifelong awareness and elimination of potential indoor environmental hazards is essential for our long-term respiratory well-being.

INTRODUCTION

Nutritional and performance-enhancing supplement use is growing in popularity among athletes and nonathletes of all ages [1–6]. Although the exact prevalence of their use is unknown, limited studies show that the number seems to be significant [1–9]. The Food and Drug Administration (FDA) regulates nutritional supplements under the Dietary Supplement Health and Education Act of 1994 (DSHEA), instead of as "conventional" foods and drug products (prescription and over-the-counter) [10]. As a result of the DSHEA, manufacturing and use of these supplements have increased dramatically in the United States, with estimated annual sales of $20 billion [2,4,5]. Under the DSHEA, the manufacturer is responsible for safety and accuracy of the label information of a dietary supplement before it is marketed [10]. In reality, the content of a supplement is not always consistent with the claimed label. The FDA monitors the post-marketing safety of the supplements. Due to the lack of scientific evidence, the effectiveness of most supplements is unknown [1–8]. Marketing strategy for the efficacy of a supplement is usually based on individual testimony, especially from famous people and athletes. Most medical and sports organizations are against using drugs to enhance human athletic performance [1,11]. Table 58.1 summarizes the effectiveness, adverse effects, and legal aspects of common sports supplements.

ANABOLIC ANDROGENIC STEROIDS

Anabolic androgenic steroids (AAS) are used to increase strength and lean muscle mass [2,3,6–8]. This may enhance performance or aid in recovery after exercise [12–20]. Steroid supplements are synthetic derivatives that mimic the effects of the male sex hormones testosterone and dihydrotestosterone. These hormones exert their effects on many different body tissues including muscle, bone, kidneys, liver, hematologic system, hair, immune system, and central nervous system. This is thought to be done by several different mechanisms including modulating androgen receptor expression by intracellular metabolism and physical alteration of the androgen receptor, as well as anti-catabolic activity via inhibition of glucocorticoid (stress hormone) receptor expression [13,20]. In the muscle tissue, this results in increased muscle mass by increasing muscle protein synthesis (promotes anabolism) and may also reduce recovery time by blocking the effects of stress hormones on muscle tissue (inhibits catabolism).

There is a paucity of controlled studies on the effects of AAS. This is likely due to a combination of their use being banned in almost all athletic realms, the fact that many athletes who supplement with steroids are also concurrently using other substances, and the severe side effects that anabolic steroids produce. The available literature demonstrates that short-term use of anabolic steroids by athletes can increase both strength and bodyweight [4,19]. Strength gains of about 5%–20% and 2–5 kg of increased bodyweight have

TABLE 58.1
Effectiveness, Adverse Effects, and Regulation of Common Sports Supplements

Supplement	Claimed Effect	Evidence for Efficacy	Side Effects[a]	Regulations
Anabolic androgenic steroids	↑muscle mass, ↑lean body mass, ↑strength	Effective	Significant on multiple organs	Prohibited by IOC and NCAA
Dehydroepiandrosterone	↑muscle mass, ↑lean body mass, ↑strength	No evidence	Significant	Prohibited by IOC and NCAA
Human growth hormone	↑muscle protein synthesis, ↑lean body mass, ↑strength	Very limited	Significant on multiple organs	Prohibited by IOC and NCAA
Creatine	↑muscle mass, ↑strength, ↑power	Limited (↑anaerobic exercise capacity)	Minimal	None
Beta-hydroxy beta-methylbutyrate	↑muscle mass, ↑strength	No evidence	Minimal (lack of reports)	None
Amphetamine	↑focus, ↑alertness, ↑energy, ↓fatigue	Limited, studies mainly in sleep-deprived individuals	Significant	Prohibited by IOC and NCAA[b]
Methylphenidate	↑focus, ↑alertness, ↑energy, ↓fatigue	Very limited	Significant	Prohibited by IOC and NCAA[b]
Ephedrine/pseudoephedrine	↑energy, ↓fatigue	No evidence	Significant	Prohibited by IOC and NCAA
Blood doping	↑endurance, ↑O_2 delivery	Effective	Significant	Prohibited by IOC and NCAA
Caffeine	↑energy, ↑strength, ↓fatigue	Most likely effective	Minimal	Prohibited by IOC and NCAA (urinary level > 12 mcg/mL and 15 mcg/mL, respectively)
Energy drinks	↑energy, ↓fatigue	No evidence	Minimal (lack of reports)	Depends on ingredients
Carbohydrate-electrolyte beverages	Improve performance, ↑endurance	No evidence	Minimal (lack of reports)	None
Sodium bicarbonate	↑endurance, ↓fatigue	No evidence	Minimal (lack of reports)	None
Chromium	↓body fat, ↑muscle mass, improve performance	No evidence	Minimal (lack of reports)	None

[a] For more information refer to the text; [b] except when medically necessary.

been observed. This may be attributed to an increase in lean body mass. Currently, there is limited evidence to support that anabolic steroids aid in muscle recovery. There is no evidence to support reduction in overall fat mass or an increase in endurance performance from anabolic steroids.

Some acute adverse effects of anabolic steroids include fluid retention, headaches, gastrointestinal (GI) upset, jaundice, dysmenorrhea, and hypertension [2,3,6,21]. Long-term use has been linked to premature mortality (especially from cardiovascular death and suicide), cardiovascular disease (hypertension, myocardial infarction, stroke), decreased HDL levels, aggressive behavior ("roid rage"), suppressed spermatogenesis and testicular atrophy, liver damage, predisposition to tendon injury/rupture, acne, irreversible gynecomastia in males, and virilization in women.

Anabolic steroids are illegal at all times (in and out of competition) according to athletic regulatory agencies such as the World Anti-Doping Agency (WADA), International Olympic Committee (IOC), and National Collegiate Athletic Association (NCAA) due to their strength enhancement and numerous dangerous side effects [22,23]. Several new anabolic substances have being created that may evade current techniques of detection. Therefore, enhanced methods of detection are being explored, such as gas or liquid chromatography attached to a variety of mass spectroscopy instruments.

DEHYDROEPIANDROSTERONE

Dehydroepiandrosterone (DHEA) is believed to enhance performance by increasing muscle mass, strength, and power while decreasing fat mass [8,24–26]. It is one of the most abundant steroids in the human body. The majority is synthesized in the zona reticularis of the adrenal cortex, with the remaining 5% produced via the gonads. Peak DHEA levels in the body are present during early adulthood and then slowly decline throughout the remainder of life. DHEA has androgenic effects mediated by its conversion to testosterone and dihydrotestosterone. Administration of exogenous DHEA in humans produces significant increases in the circulating levels of these sex steroids, which have anabolic effects in the body (see "Anabolic Androgenic Steroids").

Studies of DHEA have not demonstrated any significant effects on performance enhancement in athletics [8]. This is

likely because even though endogenous DHEA is a precursor of testosterone and dihydrotestosterone, DHEA supplementation does not result in a significant elevation in testosterone in the body. Consequently, there is no change in regards to muscle mass, body fat composition, power, or strength. At higher doses of daily DHEA supplementation, there are some transient elevations in serum testosterone levels; however, these levels return to baseline by 12 weeks. The higher DHEA dosing also does not correspond with increased lean muscle mass or strength. On the other hand, DHEA supplementation does appear to elevate circulating levels of estrogens, primarily via peripheral aromatization. This has shown no effect on athletic performance. Interestingly though, almost all of these studies regarding estrogens have primarily focused male subjects. Therefore, this effect of DHEA supplementation causing elevated estrogens in female athletes has yet to be adequately evaluated.

Adverse effects of DHEA supplementation are not well described as few long-term studies have been done [6,8]. The most common reported side effects have been gynecomastia in males and virilization in females. In both sexes, there is evidence of decreased HDL levels and increased risk of coronary artery disease. Some theoretical but currently unsubstantiated adverse effects caused by elevated hormone levels may include increased risk of hormone-related cancers (i.e., breast and prostate), liver damage, diabetes, and aggressive behavior.

Even though there are no proven ergogenic benefits of DHEA supplementation, there is concern that DHEA is too similar to anabolic androgenic supplements as it is a precursor to dihydrotestosterone and testosterone. As a result, DHEA is classified in a similar manner as anabolic androgenic steroids and is deemed illegal at all times (in and out of competition) according to athletic regulatory agencies such as the WADA and NCAA [22,23]. Current testing for DHEA is not adequate and revisions need to be made in order to properly detect this substance.

HUMAN GROWTH HORMONE

Human growth hormone (HGH) is used to enhance athletic performance mainly by increasing muscle mass while decreasing fat mass [2,3,8,27–30]. It may also be used to decrease recovery time. HGH is a protein-based peptide hormone that has many anabolic effects throughout the body. Normal functions of HGH include increased height during childhood, increased bone mineralization, increased protein synthesis, increased lipolysis, growth of internal organs, promotion of liver gluconeogenesis, and stimulation of the immune system.

The effect of growth hormone on physical performance in healthy adults has not been extensively studied [27–30]. Current limited evidence shows that growth hormone does not significantly improve muscle strength and power, does not increase aerobic exercise capacity, but may improve anaerobic exercise capacity. There is some anecdotal evidence that HGH excess may increase tolerance for hard training, shorten recovery time after exercise, and accelerate recovery after soft-tissue injury.

Acute side effects from HGH may include edema, "pins and needles" sensation, carpal tunnel syndrome, arthralgias, sweating, fatigue, and dizziness. More significant side effects may arise with chronic levels of excess growth hormone, as demonstrated by patients who develop acromegaly. They often present with complications such as diabetes, left ventricular hypertrophy, and hypertension and have an increased risk of malignant neoplasms. In those with acromegaly, there is a twofold increase in mortality rate and a life expectancy decrease of 10 years compared to the general population. These effects may also be increased with simultaneous use of anabolic steroid supplements.

HGH use is prohibited by the WADA and NCAA in and out of competition [22,23]. In the United States, HGH is available only by prescription and its licit uses are narrowly defined including growth hormone deficiencies, childhood metabolic disorders, and wasting syndromes (such as in HIV/AIDS). Any off-label use, such as for athletics, is deemed illicit.

CREATINE

Creatine is claimed to enhance performance by providing increased power during anaerobic, short-duration, high-intensity activity, and enhancing muscle mass [1,31–36].

Creatine is an amine that is synthesized normally in the human body in the liver, pancreas, and kidney. It supplies energy to all cells, but primarily skeletal muscle, by increasing the formation of ATP via regeneration from ADP and transferring ATP to utilization sites. Creatine supplementation aims at saturating these bodily stores to maximize its function [2,3,5,8]. Exogenous creatine is not degraded during digestion and approximately 99% is either taken up by muscle or excreted in the urine. Studies consistently indicate that creatine supplementation increases muscle creatine and phosphocreatine concentrations from 15% to 40%. It has also been shown to enhance anaerobic exercise capacity, thereby allowing for improvements in muscle mass, strength, and power. There may be some variation in responsiveness to creatine among athletes, however, as up to 25% of athletes may already have saturated creatine stores. Therefore, the demonstrated performance-enhancing effects may be more prominent in certain individuals with lower baseline stores.

The only clinically significant side effect that has been demonstrated in the literature is weight gain (which may often be a desired effect in athletes). There have been some case reports of side effects that have not been validated in large-scale studies. These include GI distress, muscle cramping, dizziness, propensity for muscle injury (i.e., tears), renal injury, and inhibited insulin production.

Creatine is allowed by the WADA, NCAA, and most professional sports [22,23]. Even so, the NCAA does not allow colleges and universities to supply creatine to their students with school funds. Students are permitted to buy creatine on their own and the NCAA has no plans to ban creatine unless

medical evidence indicates that it is harmful [23]. Also with current testing methods, detection of supplemental creatine is not possible as it is normally synthesized in the body and any excess is excreted in the urine.

BETA-HYDROXY BETA-METHYLBUTYRATE

Beta-hydroxy beta-methylbutyrate (HMB) is claimed to improve performance by increasing lean body mass and strength as well as promoting recovery in trained athletes [1,2,5]. HMB is a by-product of leucine (amino acid) metabolism and is a cholesterol precursor [37,38]. It is believed that it produces its effects on athletic performance by decreasing the catabolism of muscle protein and promoting muscle mass increase via its role as a precursor of muscle cell cholesterol, thereby providing substrate for muscle cell membrane formation. HMB is produced in small amounts endogenously and dietary sources include catfish and citrus fruits.

Research on HMB has shown some benefit in studies done on various small populations. In 2009, a meta-analysis of nine different studies was done which showed that the average strength increase and fat mass decrease with HMB supplementation was trivial [38]. When broken down into "untrained" and "trained" groups, there was a small increase in strength in the untrained group while there was no significant increase in the trained group. There is need for further large-scale and longer-term studies in order to investigate the true effectiveness of HMB and explore why the biggest increase in strength was present in untrained athletes.

Research on adverse effects of HMB is also limited in quantity and study length, but no specific problems have been proven to this point [2,5,37,38]. One 6-week study showed no adverse effects of HMB on complete blood count, lipid panel, testosterone, cortisol, electrolytes, urea, glucose, sperm count/motility, or psychologic state. Due to the lack of long-term studies, adverse effects of continued HMB supplementation are unknown. As there have been no definitive ergogenic effects of HMB and no reported side effects, it is currently allowed for use by the WADA, NCAA, and other organizations both in and out of competition. There needs to be more research into both efficacy and adverse effects to determine if HMB should be allowed as a sports supplement.

AMPHETAMINE

Amphetamine is believed to enhance performance through a strong stimulant effect which increases focus, alertness, and energy as well as decreases fatigue [39,40]. Amphetamine was originally introduced as a synthetic analogue of ephedrine for treatment of asthmatic and allergic reactions. It is structurally similar to norepinephrine and stimulates further norepinephrine release in the body, therefore having a stimulant effect on the sympathetic nervous system. In addition, amphetamine acts to increase levels of dopamine and serotonin neurotransmitters in the central nervous system, having a significant effect on the brain's reward pathways. Amphetamine may also be a major or minor metabolite of many other stimulants. Amphetamine's effect on well-rested subjects is unclear as it has mostly been tested in sleep-deprived individuals [40,41]. It may possibly allow more rapid learning of new tasks and provide increased physical energy, confidence, and well-being. In addition, amphetamine may improve short-term power performance, possibly through tolerance of longer periods of anaerobic metabolism; however, controlled data are again minimal.

Short-term effects of amphetamine may consist of tachycardia, flushing, hyperactivity, anorexia, headache, dizziness, insomnia, palpitations, tremors, euphoria, aggression, and hypo- or hypertension. Chronic adverse effects can include acne, psychosis, dependence, violent behavior, anxiety, and brain damage. All amphetamines are banned by the WADA and NCAA during competition, except when deemed medically necessary. The WADA may grant athletes a Therapeutic Use Exemption (TUE) [41–44]. The athlete must submit paperwork and then this is evaluated by a group of independent physicians, specializing in the area of concern for that patient, called a Therapeutic Use Exemption Committee (TUEC). The TUEC will determine whether or not the medication is necessary and if it would provide an unfair advantage over fellow competitors. The NCAA permits amphetamines during competition only with substantial and current documentation of the medical indication for their use. It is only legal if this documentation is provided before an athlete has a positive test. Professional sports also allow exemptions for use of stimulants with physician documentation for their medical necessity. This appears to be a less rigorous process in professional sports compared to the WADA and NCAA. Allowance of exemptions for this medication (and other stimulants) may lead to over-prescription in athletes. For instance, in U.S. professional baseball, the number of therapeutic exemptions for the use of stimulants to treat ADHD increased almost fourfold in 2007 after stimulants were "banned" in 2006 [39]. Consequently, the rate of ADHD diagnosis in professional baseball players is about five to eight times higher than in the general U.S. adult population [39].

METHYLPHENIDATE

Methylphenidate is thought to enhance performance by providing stimulant effect and therefore increasing focus, energy, and cognition [44]. Methylphenidate stimulates dopamine and norepinephrine release and also acts as a reuptake inhibitor. It therefore exerts its effects as a central nervous system and sympathetic stimulant [44]. Due to its dopaminergic action, methylphenidate also has an impact on feelings of pleasure and reward. These increases on norepinephrine and dopamine levels appear to be less significant than those with amphetamine. The efficacy of methylphenidate has not been extensively studied in relation to athletics, but does have proven benefits in relation to focus and concentration [39]. For instance, methylphenidate has been shown to reduce driving errors in adults with ADHD. Therefore, it is possible that similar improvement in concentration and

reduction of errors may be present on the playing field in athletes who take methylphenidate; however, further investigation is warranted. The short-term side effects of methylphenidate include nervousness, abdominal pain, insomnia, tachycardia, irritability, diaphoresis, headaches, dizziness, and palpitations [43–45]. Long-term effects are not as well described and frequently debated, but may include psychosis, medication dependence, and depression. Regulation of methylphenidate is similar to that of amphetamines [22,23,45,46].

EPHEDRINE/PSEUDOEPHEDRINE

Ephedrine and pseudoephedrine are claimed to enhance performance through stimulant effect, thereby improving energy levels, concentration, and alertness and decreasing fatigue [39,47–49]. Ephedrine and pseudoephedrine act as sympathomimetic amines. The principal mechanism of action is stimulation of endogenous norepinephrine from storage vesicles in presynaptic neurons. This results in a stimulant effect of the sympathetic nervous system [2,3,6,8]. The majority of literature shows no effect of ephedrine or pseudoephedrine on athletic performance, including strength, oxygen uptake, or time to exhaustion [2,3,6,8]. Two studies do show minimal effect on performance [48]. The first shows increased knee extension strength when using three times the normal dose of pseudoephedrine and the second shows improved muscle endurance in the first of three repetitions when using compounds containing both caffeine and ephedrine. Thus, there are no good large-scale data to conclude that ephedrine or pseudoephedrine have significant ergogenic effects.

Acute adverse effects of ephedrine and pseudoephedrine may include tachycardia, anorexia, nausea, irritability, flushing, diaphoresis, insomnia, mild euphoria, headache, and dizziness [2,3,6,8]. Effects associated with longer-term use can be acne, psychosis, cardiac arrhythmias, heat stroke, and aggressive/violent behavior. Ephedrine and methylephedrine are prohibited in competition by the WADA when concentration in the urine is greater than 10 μg/mL [22]. Pseudoephedrine is prohibited when its concentration is greater than 150 μg/mL. The NCAA has banned use of ephedrine completely, but does allow use of pseudoephedrine in competition [23]. There are no regulations on urine concentration of pseudoephedrine in NCAA competition.

BLOOD DOPING

Blood doping enhances athletic performance by increasing oxygen transport, thereby improving endurance capacity [50–52]. The term blood doping refers to any method that aims to increase red cell mass and enhance oxygen transport capacity [2,8]. Previously, this was mainly done via blood transfusions but current doping strategies usually involve erythropoiesis-stimulating agents (i.e., erythropoietin), so this will mainly be described here. Erythropoietin (EPO) increases the arterial oxygen content by increasing red blood cell mass and decreasing plasma volume. This results in an increased capacity for the body to tolerate endurance activities (via increased VO_2 max). EPO also decreases plasma renin and aldosterone levels as well as the proximal renal tubular reabsorption rate. This triggers a feedback mechanism that causes a fall in glomerular filtration rate and diminishes intrarenal oxygen consumption, resulting in suppression of endogenous erythropoietin. There are also some other possible non-erythropoietic ergogenic effects of EPO that have been postulated, but not confirmed, including angiogenesis, shift in muscle fiber type/composition, cognitive enhancement, and anti-apoptotic effects that may be linked to antioxidant activity. The scientific literature clearly demonstrates that exogenous EPO administration causes a significant increase in submaximal performance with prolongation of time to exhaustion during exercise [2,8,50–52]. A study by Thomsen et al. in 2007 found that after 4–11 weeks of treatment with recombinant human erythropoietin (rHuEPO), subjects increased submaximal exercise performance (at 80% of VO_2 max) by 54%. As described earlier, this is mostly due to increase in VO_2 max; however, it appears that this highly significant exercise improvement cannot be explained by the VO_2 max alone. Therefore, other non-erythropoietic effects of exogenous EPO should be explored. Adverse effects of exogenous erythropoietin may include elevated arterial blood pressure, increased cardiac stress, deep vein thrombosis, pulmonary embolism, and stroke [2,5,8]. Long-term EPO administration may also lead to autoimmune disease. If blood transfusions are used for doping, there is also a risk of infection (i.e., HIV, hepatitis) or transfusion reaction.

Blood doping, including both transfusions and erythropoiesis-stimulating agents, is prohibited at all times by the WADA and NCAA [22,23]. Urine testing for exogenous EPO has been present for several years. This issue has been most prominent over recent years in international cycling events, resulting in numerous disqualifications for positive tests and significant media attention. Continued strong enforcement of these rules and regulations is necessary as the ergogenic effects of blood doping appear to be quite substantial.

CAFFEINE

Caffeine is used to increase endurance and to enhance performance. Caffeine is classified as a stimulant; it can both increase alertness and delay fatigue [1,2,8,33,53,54]. There are claims that caffeine can increase the utilization of fat (adipose tissue) as an exercise fuel and spare muscle glycogen stores. Caffeine is a substance that occurs naturally in the leaves, nuts, and seeds of a number of plants. It has various effects depending on the particular body tissue acting as the substrate, as well as interindividual variability due to a combination of genetic and environmental factors. The average time to peak serum concentration is approximately 1 h, and half-life is about 3–7 h, although there are variations between individuals. Caffeine is a central nervous system stimulant, therefore altering perceptions of effort and fatigue. There are many different cellular actions that likely contribute to the observed effects of caffeine. These include potentiation of muscle contractility by causing sarcoplasmic

reticulum calcium release, inhibition of phosphodiesterase isoenzymes and concomitant cyclic monophosphate accumulation, inhibition of glycogen phosphorylase enzymes in liver and muscle, nonselective adenosine receptor antagonism, and stimulation of the cellular membrane sodium/potassium pump [53,54]. The most physiologically significant mechanism likely relates to adenosine receptor antagonism, although the precise mechanism supporting its ergogenic properties is unclear. Major dietary sources of caffeine typically provide 30–100 mg per serving. Some non-prescription medications contain 100–200 mcg of caffeine per tablet. Research has shown that caffeine enhances endurance and provides a small but notable enhancement of performance over a range of exercise protocols. Benefits have been seen with small to moderate levels of caffeine (1–3 mg/kg) taken before, throughout, and near the end of an exercise program. There have not been additional performance benefits shown with increases in the caffeine dose above 3 mg/kg. In trials, increased performance was noted at urinary caffeine concentrations less than the limit of 12 mcg/mL allowed by the IOC. Anxiety, irritability, tremulousness, muscle twitching, insomnia, and headaches. Dependence and withdrawal occur due to central nervous system effects [2,8]. Caffeine was removed from the IOC list of banned substances in 2004 and is now a "controlled or restricted substance." At this time, the upper limit for urinary excretion allowed by the IOC is 12 mcg/mL [22]. The NCAA allows up to 15 mcg/mL [23].

ENERGY DRINKS

Energy drinks have a variety of ingredients; therefore, claims of benefits differ according to the particular product and its corresponding marketing [1,55–58]. Energy drinks are often found displayed next to sports electrolyte drinks, which often misleads the purchaser into believing the products have similar actions. Athletes perceive energy drinks as a quick way to consume extra energy to fight fatigue and increase endurance. Certain energy drinks also contain vitamins, minerals, herbs, and other nutrients. They are used by some athletes in an attempt to burn fat and increase lean muscle mass. The primary ingredient in most "energy blends" is caffeine (reviewed separately). The most common other ingredients include taurine, guarana, L-carnitine, glucuronolactone, and B vitamins. Energy drinks typically provide a large carbohydrate (usually more than 25 g/oz) load beyond the amount generally recommended for physically active individuals. This amount of carbohydrate can decrease the rate of fluid absorption into the bloodstream secondary to osmotic effects, impeding rehydration during exercise. Some energy drinks have been found to have thermogenic effects as well. With regard to some of the specific ingredients of energy drinks, taurine is known to modulate skeletal muscle contractile function, and may modify exercise-induced DNA damage. L-carnitine has been shown to play a decisive role in preventing cellular damage. There is little research that has been done regarding the interactions of the various ingredients of energy drinks in the human body; therefore, the effects of these are poorly understood at this time. The effectiveness of energy drinks as performance enhancers remains unproven [1,58]. Most of the ingredients are categorized as "dietary supplements," and fall under the DSHEA. Therefore, they are not subject to the strict requirements for safety and efficacy data prior to human use. There are some studies showing limited evidence of benefits of both taurine and L-carnitine supplementation in improving exercise capacity and performance. However, the amounts of these substances found in popular energy drinks are often below the amounts expected to deliver therapeutic benefits. There are limited data on the outcomes of combining the additives in a single beverage. In studies, energy drinks have been associated with increased blood pressure and tachycardia. There are also risks of palpitations, restlessness, irritability, and dehydration. The large carbohydrate load found in energy drinks can cause GI distress.

CARBOHYDRATE-ELECTROLYTE BEVERAGES

Carbohydrate-electrolyte beverages aid in the replacement of fluid lost during exercise. Specifically, studies have shown benefits in high-intensity exercise and endurance events [58–60]. Evidence also indicates that use of carbohydrate-electrolyte beverages can improve athletic performance. Beverages contain electrolytes including sodium (10–25 mmol/L) and potassium (3–5 mmol/L) in a carbohydrate rich fluid (5%–7% carbohydrate). Compared to water alone, with carbohydrate-electrolyte beverages there is an increased uptake of water from the intestine into the blood. This effect occurs at a total carbohydrate concentration of approximately 5%–7%. Lower concentrations provide less performance benefit, and higher concentrations can actually interfere with rehydration. This aids in the replacement of ongoing fluid losses during sports. The sodium in the beverages also acts to stimulate thirst as well as to increase water absorption by the kidneys. Many beverages also contain calcium, magnesium, and other electrolytes, which play a relatively smaller role in terms of rehydration. Studies have shown that when carbohydrate-electrolyte beverages are consumed during activity, there is an improvement in times for a 20-m sprint as well as a delay in fatigue. Other studies conducted in soccer players have shown an increase in overall running distance and improved performance during the second half of games in distance run at speed. To obtain the maximum benefit, athletes should periodically consume carbohydrate-electrolyte beverages to replace fluid lost during activity [58–60]. There have been no reported side effects when properly formulated carbohydrate-electrolyte beverages are consumed.

SODIUM BICARBONATE

Sodium bicarbonate is claimed to improve endurance running, cycling, and swimming athletic performances [1,61,62]. It is said to decrease race times in 400–1500 m sprints, and delay exhaustion, demonstrated by improved performance during the second halves of prolonged intermittent cycling

events. The effect of sodium bicarbonate is to buffer the blood from the buildup of lactic acid that occurs with exercise due to release from muscle cells during anaerobic glycolysis [2,61,62]. Lactic acidosis contributes to fatigue via inhibition of enzymes used for the production of energy and reduction of muscle fiber contractility. Sodium bicarbonate reduces the level of blood and muscle acidity, therefore decreasing these effects of lactic acid. There is conflicting evidence regarding the efficacy across studies [1,2,61,62]. There is some evidence to show that bicarbonate supplementation may have benefits for high-intensity events of up to an hour in length as well as intermittent high-intensity team sports. Few adverse effects have been reported; GI distress (diarrhea, bloating, belching) is the most common. Supplementation is not currently prohibited by WADA or NCAA [22,23].

CHROMIUM

Chromium (as chromium picolonate) is used for weight loss and has been used by athletes to assist with fat loss, increase muscle mass, and enhance performance [2,5,35]. There is also suggestion that chromium decreases insulin resistance, particularly in diabetics. Chromium is thought to play a role in normal carbohydrate metabolism by potentiating the action of insulin. Chromium may increase insulin binding to cells and insulin receptor number, as well as activate insulin receptor kinase, leading to increased insulin sensitivity. Research has not supported claims of performance or endurance enhancement with chromium supplementation [2,5]. In a small study, there was no increase in muscle strength noted over a 6-week period of supplementation. Similarly, there has not been any evidence that chromium effects weight loss or body composition. At this time, reviews of meta-analyses have not shown a significant association between chromium and insulin resistance. There has been concern over potential serious side effects associated with chromium use. Previous studies indicated a potential for genotoxicity; however, this claim has not been well supported. Other possible side effects include liver and renal dysfunction, rhabdomyolysis, and gastrointestinal complaints. Chromium interferes with the metabolism of iron as well as zinc absorption. Chromium supplements are not currently regulated. Older commercial formulas containing chromium with ephedrine were banned with the regulation of ephedrine [22,23].

INTRODUCTION

Physical activity is paramount in society. Children participate in recreational activities and organized sports to stay active and engage in social activities. Adults exercise to improve health, lose weight, and stave off illness. The geriatric population may use activity to maintain their independence and to help manage chronic medical conditions. Physical activity has become a vehicle to improve the quality of life. Unfortunately, the risk of injury and illness associated with exercise and sports increases as people become more physically active.

Injury prevention has become a focus in the medical literature in recent years. Besides diagnosing and treating injuries, health care professionals can and should promote injury prevention. Dedicated research and initiatives have been undertaken to promote prevention. Over the past decade, several conferences, including three international meetings (the World Congress on Sport Injury Prevention), have been held to discuss current strategies for keeping athletes on the field and for keeping people active and healthy. A number of peer-reviewed articles, along with a specific journal, *Injury Prevention*, have been published to provide current updates on injury prevention. Additionally, several organizations have been created to help train active people on how to properly condition and participate in various sports. The shift toward prevention may help save expense and time loss associated with injuries.

Before identifying which injury prevention strategies may be effective, risk factors and injury-promoting behaviors need to be examined. These factors can be divided into extrinsic and intrinsic categories [28,38]. Examples of extrinsic risk factors are training, environment, and equipment [24,25]. Training "errors" may involve inadequate conditioning, improper neuromuscular balance, or overtraining. Environmental conditions and playing surfaces are factors that can place a person at risk for injury. Consideration for equipment such as braces and footwear needs to be given when evaluating for injuries. Intrinsic risk factors include age, gender, current health status, and comorbid medical conditions, and they can be primary or secondary causes of injury.

Injury prevention also includes motor vehicle safety, smoking cessation, home safety, fire precautions, and firearm safety. Although these are important factors and critical to injury prevention, they are beyond the scope of this chapter (see Chapters 121 through 128). This chapter discusses injury

prevention and important medical and musculoskeletal conditions by age group, specifically in the pediatric, adult, and geriatric populations.

PEDIATRIC

Warm-Up

A common approach is to begin exercise with a proper warm-up. This is a set period of time in which a person prepares for exercise in an attempt to enhance the upcoming event. A proper warm-up is traditionally composed of three phases. Initially, a period of aerobic exercise is performed to increase body temperature and shunt blood to the muscles, followed by nonspecific stretching, and ending with a set of functional activities that mimic sport-specific movements [10]. Although stretching is mentioned as part of the warm-up, this component is addressed individually in the following section.

The current medical evidence is controversial in regard to the relationship between a thorough "warm-up" prior to exercise and injury prevention. A number of studies point in favor of using a warm-up as a way to decrease risk of acute injury, including strains and sprains. However, even though a proper warm-up may prevent acute traumatic injuries, some studies demonstrate that a formal warm-up may not have a definitive effect on reducing overall injury risk [10,27]. There is evidence that performing an abbreviated warm-up after a rest period, such as halftime, has been found to reduce the number of acute strains and sprains that occur in the second half of a competition. Two additional benefits from a warm-up, however, can include a decrease in muscle soreness along with improvement in exercise performance [37].

Effective time for warm-up ranges from 3 to 4 min, with the amount of time tailored to time spent in actual physical exercise [10]. Additionally, the intensity of the warm-up needs to be set on an individual level to allow for maximum benefit without risking fatigue and a detrimental effect on performance.

Stretching

A universal component of exercise is stretching. Stretching has been a facet of physical education class, organized sports, and individual exercise regimens for decades. Stretching may have two benefits—reducing injury and improving performance—however, this is still debated in the medical literature.

Before discussing how muscle stretching plays a role in injury prevention, an important distinction should be clarified. Stretching and flexibility are two different entities that coexist, as stretching affects flexibility [27,35,37]. Stretching is an extrinsic factor performed to lengthen muscle tissue, while flexibility is an intrinsic factor affecting joint mobility [27,37]. Stretching decreases passive resistance, thereby increasing muscle compliance and decreasing muscle stiffness [27,35]. The increased muscle compliance allows a muscle to work more efficiently and decreases the susceptibility to muscle strain. The decrease in muscle stiffness is the goal of preperformance stretching.

Flexibility affects the functional range motion of a joint. Various forms of stretching, including active, passive, static, ballistic, and dynamic have been employed to improve flexibility. Most people use static stretching as the method of choice. Stretching does provide short-term improvement in flexibility [37]; however, several control studies have documented that stretching has no effect in preventing injuries other than muscle strains [28,35,37]. One reason that stretching is not effective is because most injuries occur within the normal range of motion [35]. Additionally, stretching has not been found to decrease postexercise soreness [37].

A concern associated with passive stretching is that it may lead to an acute loss of strength to the lengthened muscle. In contrast, there is no strength loss with dynamic stretching. Not only does the loss of strength negatively affect injury prevention, it also hampers muscle performance. Additionally, stretching can lead to a hyperflexible state, which can also compromise muscle performance [27].

Even though stretching has not definitively demonstrated a protective effect or a reduction in exercise-related injuries [35,37], several recommendations can be made to ensure that proper stretching technique is observed. Stretch muscle groups that are at risk for the sport-specific activity. Although there is no specific time threshold for holding a stretch, the longer the duration a stretch is held (at least 60 s), the more prolonged the effect of the stretch [27]. Along with passive stretching, incorporate dynamic stretching and drills to help maintain strength that is lost with stretching.

Anterior Cruciate Ligament

Anterior cruciate ligament (ACL) injuries represent one of the more prevalent and devastating injuries young athletes experience in all athletics. Unfortunately, female athletes experience noncontact ACL injuries at a rate of four to six times more often than their male counterparts [20]. Current research is being focused on why this injury befalls women at such an epidemic rate and the reasons appear multifactorial. Intrinsic and extrinsic factors are being investigated; research has demonstrated three extrinsic variables as risk factors. These risk factors include (1) greater knee extension and valgus movement during the landing phase of jump stopping, (2) less knee flexion combined with more knee and hip internal rotation with single leg jumping, and (3) primary use of quadriceps, with less hamstring and gastrocnemius muscle activity when stabilizing the knee [20]. Intrinsic factors to female ACL injuries may include hormonal receptors on the ACL leading to increased laxity, a narrow femoral condylar notch, and other gender-specific biomechanical factors such as a relatively wider pelvis.

ACL injury prevention strategies have focused on the modifiable extrinsic risk factors. Traditional stretching of the quadriceps muscles along with hamstring and gastrocnemius strengthening is targeted to help relieve the anterior shearing

effect of the tibia on the femur. Once the anterior and posterior muscles are balanced, the focus should be on neuromuscular control of the core and lower leg [20]. This factor is trained with plyometrics and sport-specific agilities. Specific training with box jumps, single leg landing, and single leg bounding will help reinforce the athlete's core and limb control. Additionally, education and training on stopping with several small steps instead of one large step or rounding off curves instead of cutting sharply will help limit the amount of lower leg internal rotation.

Several formal programs have been implemented with success in female basketball and soccer programs. All successful ACL prevention programs contain aspects of the aforementioned tools. Considering that at least 6 weeks is needed to increase motor recruitment, the training programs should commence at least 6 weeks prior to intense contact activity [20]. Additionally, for the program to be effective there needs to be a high level of compliance and commitment on the part of the athlete and, if there is a team involved, the coaching staff.

Epiphyseal and Apophyseal Injuries

During childhood development, growth occurs at two different sites. Epiphyseal growth centers are sites of long bone growth and respond to pressure. These centers contribute to height and length. In contrast, apophyseal growth centers are secondary growth sites where tendons attach and are affected by traction. Because of rapid changes in bone and muscle tissues, a child's bone physiology is different than an adult and responds differently to applied forces. Increased levels of intensity and repetitive loading can have a negative effect on these growth centers. Injury to physeal sites can lead to pain, interrupted growth, or altered joint mechanics.

The two most common physeal sites of injury are located in the upper extremity, the elbow and the shoulder. Injury to proximal humeral head, "little league shoulder," results from repetitive traction and rotational forces across the growth center. The pediatric elbow is at risk for two injuries related to overuse—a traction injury, "little league elbow," and osteochondritis dessicans, a result of repetitive compression injury. Both affect the medial aspect of the elbow. Because of the large number of adolescents who participate in overhead throwing or racket sports and are affected by these conditions, injury prevention has become a primary focus when discussing these conditions.

Prevention of pediatric elbow and shoulder overuse issues also focuses on two aspects: intrinsic and extrinsic factors [34]. Intrinsic prevention strategies include balancing appropriate strength and flexibility to reduce imbalances at the scapula, hip, and trunk [6]. One key risk factor is glenohumeral internal rotation deficit (GIRD). Two stretches that are helpful in reducing GIRD are the "sleeper stretch" (external rotators of the shoulder) and the "open book stretch" (pectoralis minor) [34]. Strengthening exercises to target weak scapular stabilizer muscles, serratus anterior, rhomboid, trapezius, and posterior deltoid muscles, will help muscular imbalances. Additionally, focusing on hip and trunk muscles will help reduce muscle fatigue. Both improved joint range of motion and increased strength will aid in proper mechanics. Lastly, establishing conditioning programs that are sports specific will build muscle endurance while maintaining a high level of compliance.

Injury prevention is directed toward extrinsic risk factors including pitch count and pitch type. Guidelines for little league pitchers include throwing no more than 80 pitches per game or 800 pitches in a season [34]. Guidelines have been established for a set number of days off after throwing a set number of pitches. Examples of pitch selection recommendations include only throwing fastballs until age 8 and not throwing a curve ball until age 14 [34].

Concussion

Concussion is a pathophysiological process affecting the brain, introduced by traumatic biomechanical forces. In addition to the acute injury, the possibility of developing post-concussion syndrome is of significant concern. Due to the seriousness of the injury and the potential for tragic and long-lasting effects, health care professionals have made this a focus for the past several years in sports medicine. In recent years, many U.S. states have enacted laws about concussion recognition and education for high school athletes, and the NCAA and the four major professional leagues have created policies to protect their athletes from sustaining a concussion or the sequelae related to this condition.

Significant research effort and resources have been dedicated to concussion prevention, both primary and secondary. The prevention strategies have focused on two aspects: protective equipment and rules [26]. Protective equipment designed to prevent concussion includes helmets and mouth guards; thus far, newer models in helmets and mouth guards have not definitively demonstrated an increased effectiveness in concussion prevention [26]. Helmets have been found to reduce impact forces directed to the skull and face. This reduction in force translates to a reduced incidence in skull fractures and facial injuries. However, because of the movement of the neck and the movement of the brain inside the skull, countercoup injuries can still occur. Mouth guards help protect from dental and orofacial injuries, but no reduction in brain trauma has been demonstrated.

Rule changes and education has had a more profound effect on concussion prevention compared to other interventions. Starting with adolescent football, teaching athletes to tackle with their head up has helped reduce neck and head injuries [26]. Enforcing rules of making head-to-head contact illegal has reduced the incidence of head injuries [26].

To help protect athletes diagnosed with a concussion, several measures have been put in place to prevent second impact syndrome. Guidelines have been created to assist with management and return-to-play issues. Neuropsychological testing provides objective data to help evaluate cognitive function [26]. Comparing post-injury results to either baseline results or national standards combined with physical

assessment helps health professionals prevent athletes from returning to activity too soon and being at risk for second impact syndrome. Once a concussion has resolved, a specific return-to-play progression [26] has been established to gradually return an athlete to competition through a series of more demanding tasks. The step-by-step protocol allows an athlete to increase activity while being closely monitored. The controlled return helps prevent exposing an athlete to sustaining a second concussion before the resolution of the first concussion.

Exercise-Induced Asthma

Asthma can take on many forms and have many triggers. Exercise-induced asthma is the transient narrowing of the airways that occurs after vigorous exercise. It is not possible to prevent asthma; however, strategies can be employed to reduce the risk of asthma-related problems associated with exercise and allow for peak performance. Identifying asthma-related triggers and proper use of medication are two necessary preventions that aid in this cause.

As derived from the name, exercise is the prime trigger for exercise-induced asthma. However, environmental triggers can worsen an exacerbation. If present, seasonal allergies need to be identified and can be treated with medication or desensitization. Cold air and aerosolized chemical products, for example, chlorine, can exacerbate attacks in some asthmatics. Even though it can be difficult to control for these factors, taking steps to warm and humidify air or enable proper ventilation can aid with close monitoring.

Medication treatment is the gold standard in preventing exercise-induced asthma issues. The most widely used medication is inhaled short-acting β_2–agonists [7]. Considering that most attacks of exercise-induced asthma occur after exercising for 20–30 min, taking these medications 10–15 min prior to activity is very effective. The maximum effect of this drug occurs 20 min after inhalation and remains effective for roughly 4 h [7]. If a bout of exercise is longer than 4 h, this medication may need to be repeated. In contrast, long-acting β_2–agonists can be used, which will provide longer coverage; however, tolerance has been observed after repeated dosing, decreasing its protective effect. Additionally, there is recent concern that regular use of long-acting β_2–agonists can increase the risk of severe cardiovascular side effects [7].

Alternative medications are available for the prevention of exercise-induced asthma exacerbations. Ipratropium bromide is another inhaled medication that has protective benefit; however, this medication has been found to be more beneficial when combined with β_2–agonists [7]. Inhaled corticosteroids and leukotriene antagonists are both effective in managing exercise-induced asthma [1] and may even help increase the protective effect of β_2–agonists. These medications are typically used in asthmatics that need additional help in controlling their symptoms. However, considering the systemic effects, the risk versus reward profile needs to be weighed.

Because some asthma medications can affect performance, the goal is to prevent asthma exacerbations and to reduce the impact of exercise-induced asthma on athletics, not to gain an advantage in performance. Prior to starting a medication, appropriate testing should be performed to determine if a medication is needed. Once the need is established, the athlete and health care professional need to ensure that all the rules are followed for the sport's governing body in the use of the desired medication.

Sudden Cardiac Death

Many people use exercise as a way to improve overall health and specifically cardiovascular condition. On the opposite end of the spectrum is sudden cardiac death related to exercise. Due to the all-encompassing nature of sudden cardiac death and its widespread effect on all involved parties, prevention has become paramount. There are various causes of sudden cardiac death, with certain conditions demonstrating prevalence at various stages of life. Adolescents are at increased risk of commotio cordis, young adults have a higher incidence of hypertrophic cardiomyopathy, while older adults are more prone to coronary artery disease. Whatever the etiology, the goal is to identify people at risk and prevent occurrence.

A major tool for prevention of sudden cardiac death is the preparticipation evaluation. The evaluation includes standardized questions and examination techniques to target patients who are at risk. Because of the difficulty in identifying abnormalities, often the history is more important than the exam. Specifically, all participants need to be questioned about a history of cardiac abnormalities or a family history of cardiac problems [8,12]. Further clarification of family history including sudden death, cardiac abnormalities, or myocardial infarction in family members younger than age 50 needs to be detailed [8,12]. A personal history of chest pain or shortness of breath that occurs during exercise along with syncope (or near syncope) during exercise needs to be questioned [8,12]. Any report of previous cardiac testing should be explained. The cardiovascular physical exam includes blood pressure measurement, auscultation of the heart, palpation of the pulses, and examination for clinical features of Marfan Syndrome. When performing cardiac auscultation, the heart should be evaluated in two positions while using maneuvers (inhalation, valsalva, and squatting); these maneuvers will aid in the detection of murmurs and will help distinguish between benign and pathologic murmurs. Any abnormal murmur warrants further evaluation.

A controversial and much debated topic is the use of screening electrocardiogram (ECG) and echocardiogram when performing the preparticipation evaluation in the asymptomatic adolescent athletes with no concerning family history of sudden cardiac death. The use of these tests is commonplace when an abnormality is identified during a preparticipation evaluation and a diagnostic evaluation is indicated, but not as a screening tool [3] for asymptomatic individuals. Some health care professionals believe that the preparticipation ECG would help identify underlying cardiac

disease; however, the concern for a high number of false-positives is among several reasons that the American College of Cardiology is not currently recommending use of screening ECGs in this population.

A rare cause of sudden cardiac death is commotio cordis. This condition results from a direct blow to the precordial chest area that results in a cardiac arrhythmia [4,22]. What makes this condition difficult to prevent is that it occurs in individuals with no history of cardiac dysfunction. Despite the difficulties in preventing this condition, investigation into two areas has produced mixed results. Because the condition revolves around direct trauma to the chest, both the chest protector and the projectile have been checked. Numerous research studies have failed to demonstrate the protective nature of chest protectors across multiple sports [4,9]. The failure of the chest protection results from either improper fitting or insufficient padding [4,9]. In contrast, the density of the projectile has provided a mechanism for prevention. Softer core balls or safety balls have been found to result in a lower risk of a commotio cordis event [4].

YOUNG ADULT/MIDDLE AGE

Heat-Related Illness

Summertime is a great time for participation in sports and exercise. Long days, bright sun, and warm temperatures create a perfect combination for people to go outside. However, prevention of heat illness and injury has to be a concern. Heat illness can present in various forms from heat edema and cramps to heat exhaustion and stroke. The symptoms can be mild to life threatening. Observing a few prevention strategies can reduce risk and allow for safe participation. In addition, heat-related illness is a condition relevant to all age groups and should be included in any discussion of preventable injuries in the pediatric and elderly populations.

Before heading outdoors, knowing the temperature and humidity can help determine if it is safe to exercise. Elevated temperature correlates with the amount of heat in the air, while humidity determines the amount of moisture. Together, temperature and humidity create the heat index. The air temperature will raise skin temperature and the body will attempt to cool through sweating. High humidity makes it difficult for the body to cool itself and more susceptible to heat illness. Since temperature alone cannot predict risk, wet and dry bulb thermometers and heat graphs have been used to determine safe zones for exercise. Using caution in temperatures above 85°F and 15% humidity is wise [18].

Continued exercise in anticipated warm temperatures makes acclimatization important to reduce risk and an important concept to discuss. Heat acclimatization involves the gradual increase of exposure to elevated temperatures with gradually increased workloads over days to allow the body to adapt to the environment. It takes 10–14 days to become fully acclimatized to a hot environment. Additionally, because of child's small mass, it may take even longer for a child to acclimatize [18]. Reducing workload to 50% on day 1 and gradually increasing over the next 2 weeks is critical. Safe acclimatization also involves gradually increasing exposure time; shorter training sessions and less protective equipment in the early stages of the progression. Finally, avoiding exposure in the hottest part of the day, from 11 am to 4 pm, may reduce risk and help prevent heat-related injury [18].

Two additional precautions include clothing and fluid hydration. Ideal clothing for exercising in a high heat index environment includes lightweight and light-colored clothing [18]. This allows for less heat absorption and improved body cooling. Fluid hydration is critical to preventing heat injury. Fluid intake prior to exercise at a minimum should be 500 mL [18]. Over the course of exercise 150–300 mL of fluid should be consumed frequently [18], approximately every 15 min during moderate to strenuous exercise. Finally, at the completion of exercise, drinking fluids is paramount over the next hour to replace what was lost. Ideal intake should consist of water and carbohydrate sport drinks, while carbonated beverages and alcohol should be avoided. Dehydration will have a negative effect on performance, and by the time thirst is perceived, the individual is already dehydrated.

Medical: Hypertension and Diabetes

Hypertension and diabetes are two of the most prevalent medical conditions affecting adults and geriatric patients. Either of these conditions can cause significant morbidity. Additionally, diabetes can potentiate the effects of hypertension because of the effect it has on blood vessels. To help limit the devastating effects of the aforementioned conditions and help prevent complications, regular exercise is strongly recommended.

Through various trials, regular exercise has been found to reduce both systolic and diastolic pressures in hypertensive patients both with and without diabetes. Exercise results in weight loss and redistribution of fat stores, leading to improved blood pressure control [5,36]. Two additional physiological responses to exercise include improved glucose tolerance and enhanced skeletal muscle insulin sensitivity [36].

Even with the effects of hypertension and diabetes, the level of exercises needed for an appreciable gain is attainable by most affected individuals. Aerobic activity can include walking, cycling, and swimming ideally maintained for 30–45 min [5,36]. Because of the negative effect that hypertension and diabetes have on the heart, heart rate is the primary guide for intensity. A target heart rate of 55%–80% of the maximum rate is the goal [36]. Resistance training should focus on the core muscle groups. Selecting 8–10 exercises and performing one set of 10 repetitions is sufficient. The American College of Sports Medicine recommends 150 min of moderately strenuous exercise per week (30 min five times a week) for all adults, as regular weight training resistance exercises. Moderately strenuous exercise can be any activity that continuously increases the heart rate and is at a level of effort that an individual could talk to a partner while exercising but would find it difficult to sing.

Exercise is an effective and critical part of the treatment of hypertension and diabetes. It may also play a role in the prevention of these conditions as well as the development of complications from these conditions (secondary prevention role). Hypertension and diabetes are two excellent examples of how exercise is really "medicine" to help individuals stay healthy and well. There are a number of other medical conditions that regular exercise also can play a key role in management including but not limited to heart disease, stroke, hyperlipidemia, depression, fibromyalgia, arthritis, and even some cancers.

Muscle and Tendon Injury

Muscle and tendon injuries represent some of the most common injuries experienced during physical activity. Both muscles and tendons are contracting tissues that respond to movement by stretching to lengthen and contracting to shorten. Injury occurs when force exceeds the elastic properties of the tissue. Acute muscle injuries are strains and one of the most commonly strained muscles is the hamstring. In comparison, tendons can be strained from one sentinel event or overused from repetitive trauma leading to tendinitis. Both of these injury types occur at the Achilles tendon and can be very debilitating. In contrast to acute injuries, chronic tendon injuries, tendinosis, occurs from overuse without proper healing, leading to disorganized and dysfunctional physiology. Because of the long-lasting effects and often difficulty in treatment, preventing muscle and tendon issues has become paramount for people engaging in physical activity.

Hamstring injuries are a good example of both the acute and chronic musculotendinous issues that can occur in this population. Hamstring injuries occur in many settings, but sports that have an emphasis on sprinting, including track, football, and rugby, place the athletes at the greatest risk. Additionally, dancers and water skiing participants are also vulnerable because of the extreme stretching that can occur. When a hamstring injury occurs, a tremendous amount of time can be lost; to combat this, prevention is important. Contrary to popular thought, stretching has not proven to be an effective strategy. However, increasing flexibility at the hip joint can be important to help balance forces of the opposing muscles, quadriceps and hip flexors [15,31]. Additionally, performing a warm-up prior to intense exercise allows the hamstring to lengthen and become conditioned. Greater force is needed to subject a preconditioned muscle to injury. A second preventive strategy is focusing on neuromuscular exercises involving the lumbopelvic region [15]. Examples of these exercises include high knee kicks, bounding, and single leg supports. These exercises improve lower extremity control and pelvic balance. An important intervention is the addition of routine eccentric hamstring exercises [15,31]. Performing eccentric exercises has multiple benefits: (1) muscle hypertrophy and greater surface area, (2) develop strength along the entire length of the muscle, (3) increase spring quality of the muscle, (4) overcome the strength deficit created by the stronger quadriceps muscle, and (5) mimic the force needed to overcome the explosive forces from activities that usually cause the injury [19].

If an athlete does sustain a hamstring injury, care needs to be taken to ensure that a reinjury is prevented. Once an athlete demonstrates full range of motion, full strength, and ability to perform all functional activities, a return to sport is usually granted. Similar to the aforementioned prevention interventions, balancing pelvic tilt created by the iliopsoas and quadriceps muscles is critical to reducing a pathological stretch at the hamstring muscles [15].

When treating tendon injuries, many of the same strategies can be employed, specifically, eccentric exercises that increase fibroblast activity and lead to tendon hypertrophy and increased tendon strength [19]. The increased size and strength allow tendons to become more compliant to stress and reduce individual fiber fatigue. Additional prevention tactics include delaying the use of nonsteroidal anti-inflammatory medications until day 3 of an acute injury [31]. This will prevent interfering with the body's natural healing process of repair and remolding for regenerating muscle tissue. Consider avoiding medications that may make tendons susceptible to injury, including fluoroquinolone antibiotics and corticosteroids [14]. One final preventative strategy directed toward Achilles tendinopathy is using orthotics to correct pathological foot malalignments, which contribute to injury [14].

The preceding section focused on two muscle–tendon units, but all the techniques translate to other muscles and tendons throughout the body including rotator cuff, medial and lateral epicondylitis, and patellar tendinopathy.

Joint Health: Arthritis and Cartilage

One of the most common and disabling musculoskeletal conditions faced by adults is arthritis. The Arthritis Foundation states that one in five adult Americans have some form of arthritis or an arthritis-related condition and that in the next 10 years, this figure will be one in four. Osteoarthritis is far and away the most common type of the over 100 subtypes of arthritis. Osteoarthritis has become easier to recognize, and over the years, health care professionals have refined the treatment of this condition. However, with the high prevalence of osteoarthritis, prevention has been difficult. Arthritis is typically a result of routine use and more often overuse. The overuse can be a result of work or exercise but unfortunately both lead to a common disabling result.

A common reason for early-onset osteoarthritis is injury [32]. This chapter has gone into great detail on how to prevent injury, but sometimes injuries are unavoidable. When dealing with an injury, prompt recognition and treatment will decrease the risk of later developing arthritis. Structured rehabilitation can help strengthen and correct muscle imbalances that become altered after an injury. There is a lot of research currently being devoted to developing ways to restore articular cartilage, damage to which is one of the end results of arthritis in the joint.

Technology and research has also played a role in helping to reduce injuries and subsequent development of osteoarthritis of the knee. The use of prophylactic bracing of the knee in football has seen reduction in ligament injuries of the knee [32]. Additionally, softer playing surfaces and surfaces that reduce shoe–surface friction have been found to decrease joint shearing forces [32]. These interventions help preserve the native biomechanical function and reduce excessive wear on the knee joint.

Exercise is the best way to maintain joint function and optimize joint function [30]. Both resistance training and cardiovascular training play a role in osteoarthritis prevention. Through exercise, bone mass and muscle strength are increased [32]. The increased mass leads to a large surface area and the increased muscle mass helps offload the bone and put more stress on the muscles. The abusive shearing forces are spread over a larger area and not focused on the venerable joint. Cardiovascular training helps control body weight, decreasing the total mass that is passed onto weight-bearing joints. Additionally, cardiovascular training also increases muscle endurance, which helps limit muscle fatigue. With less fatigue, the joint is protected during extended bouts of exercise. In many cases, osteoarthritis cannot be fully prevented, but if the deteriorating effects can be minimalized, pain can be reduced and function can be maintained. It is often said in sports medicine that movement (of the joint) is life; in fact, joint movement may help the joint secrete its own natural lubricant, thereby improving comfort and preserving function.

OLDER ADULTS

Wellness

As people age, the body changes and many older people experience increased body weight and slowed metabolism that lead to obesity. While gaining weight, there is often a loss of strength and endurance. The combination of obesity and decline in muscle performance often result in decreased mobility, loss of independence, and overall physical decline [40–42]. To help prevent this decline and maintain function, proper diet and exercise need to be a mainstay in the daily life of geriatric individuals.

Obesity is associated with a decrease in function as it becomes difficult to carry increased weight. The limited function and movement can reciprocally lead to a decrease in energy expenditure [42]. With a lower basal caloric need, intake needs to be adjusted accordingly. A balanced diet is recommended with less focus on fats and carbohydrates to prevent glycogen storage. Along with adequate calorie intake, proper hydration is also necessary.

Older people who engage in physical exercise enjoy multiple benefits. Along with helping to increase muscle strength and endurance, physical exercise helps maintain weight, improve balance, and increase gait velocity [40]. The benefits of exercise have an effect on medical conditions as it decreases joint stiffness and pain associated with osteoarthritis and prevents bone loss seen in osteoporosis [41]. To accomplish these goals, exercise should include a combination of both cardiovascular and resistance training. Moderate intensity cardiovascular exercise of at least 30 min five times a week is ideal for cardiovascular training [11,13,43]. If five times a week is not possible due to health or other circumstances, any amount of regular exercise is recommended. An ideal resistance training program will incorporate six to eight exercises covering all major muscle groups. To reduce redundancy, the exercises should be varied over the course of the week. To increase intensity of the resistance workout and limit risk, additional weight or a second set can be added, instead of increasing repetitions or decreasing rest time between exercises. It is recommended in this population that the individual consult their health care provider before starting a new exercise program; the health care provider may consider some evaluation to help ensure safe participation in sports and exercise.

To maximize health and wellness, the combination of physical exercise and diet control has been determined to be more effective than either alone [41]. Moderate intensity cardiovascular training with resistance training targeting major muscle groups on all days of the week is recommended and it has been determined that performing both in one session does not negatively impact the effects that would be observed by only performing one type of exercise on a given day.

Medical: Cardiovascular and Cerebral Vascular Disease

Many older Americans suffer from cardiovascular disease and cerebral vascular disease leading to premature death. Physical activity has been proven to reduce the risk of these conditions in multiple studies and has been found effective for both genders as well as various ethnicities [11,13]. The protective measures for cardiovascular and cerebral vascular events is a result of physical activity helping to control obesity, blood pressure, and increased blood sugar (diabetes).

At a minimum, the guidelines established by the Centers for Disease Control and Prevention recommend moderate exercise of at least 30 min on most days of the week [11,13]. Both aerobic exercise and strength training have proven benefit and should be considered in an exercise program. If a person is unable to perform moderate exercise, even light activities have proven benefit. However, more intense forms of exercise and longer duration have provided additional benefits.

Congestive Heart Failure

Congestive heart failure can also be affected by exercise. Moderate intensity aerobic and resistance training improved heart function by increasing early diastolic filling at rest and exercise. Additionally, exercise can increase left ventricular mass and increase oxygen uptake, thus preventing further deteriorating heart failure.

Bone Health

The most common bone disease diagnosis is osteoporosis. This condition affects both men and women and is viewed as an age-related condition. This condition results from low bone mass and leads to decreased bone strength and deterioration eventually resulting in bone fragility. The loss of bone mass is secondary bone reabsorption rates greater than bone replacement. Bone fragility can result in falls, fractures, and disability. Because of the significant consequences, prevention of osteoporosis is a necessity.

One key to prevention is screening. Guidelines have been established on when to screen people for the condition. Current recommendations include screening all women aged 65 years old or greater and younger women and men with risk factors [21,39]. However, prevention can begin long before screening occurs.

Early risk prevention for osteoporosis can begin at childhood and continue through adult years. Routine physical exercise, especially resistance training increases bone density and strength [17,19]. The strain on a bone from muscle pull during exercise forces the bone to adapt with equal force. Weight-bearing physical activity helps protect the spine and lower extremities, two areas that are susceptible to fracture from weakened bones. A second early intervention is dietary supplementation with calcium and vitamin D. Calcium is the building block of bone and vitamin D is needed for calcium to become active. In childhood, calcium stores can be increased with supplementation; however, calcium absorption decreases with advancing age. Once a person is over age 30, the supplemental calcium makes calcium more available for the body and less needs to be leached from bone for other vital functions. Current recommendation advises that supplemental calcium should be 500–1200 mg/day along with 800 IU/day of vitamin D [21,23].

Along with non-pharmacological interventions, prescription medications play a role in prevention. The most common prescribed agents are bisphosphonates. These medications work by inhibiting the action of osteoclasts, cells that break down bone tissue. Current recommendations include using these medications for only 5 years when low bone density is discovered [29]. Other agents that can be prescribed include raloxifene, nasal calcitonin, and teriparatide. Previously, hormone replacement therapy was used effectively. The effect of increasing estrogen provided a protective mechanism for bone health; however, because of cardiac and cancer concerns, the use of hormone therapy has fallen out of favor [23].

Fall Prevention

Closely related to bone health is fall prevention. Falls in the elderly are very common and represent the leading cause of accidental death. Besides death, falls place a person at risk for fracture, head injury, and prolonged disability. Due to the high risk of morbidity and mortality associated with falls and the subsequent high cost, fall prevention is crucial. Risk factors for falls can be divided into intrinsic and extrinsic causes. Thankfully, many of the fall risk factors have a preventable solution.

Intrinsic risk factors include gait and balance impairment, along with muscle weakness. Routine physical exercise can help prevent this deterioration [16,17]. Exercise helps strengthening muscles and bones. Additionally, exercise helps train proprioception [17]. Specifically, eccentric exercises help with restoring strength as a muscle lengthens [19]. This is critical for descending stairs—a common place where falls occur. A second major intrinsic risk factor is deteriorating medical health. Medical illness, impaired vision, medications, orthostasis, and dementia can all precipitate a fall. Routine follow-up with a physician for close monitoring and management is necessary. Finally, poor nutrition and vitamin deficiencies need to be considered and treated. A healthy diet provides not only needed calories for energy but also needed vitamins for overall well-being. One specific vitamin deficiency that can have deleterious effects and is implicated in falls is vitamin D deficiency. Appropriate vitamin D levels have been linked to bone, muscle, and nervous system health. Vitamin D supplementation is necessary to help strengthen bone, aid in muscle function, and provide postural balance and gait propulsion [2].

Extrinsic risk factors include environmental hazards and proper footwear. Performing a home inspection could identify misaligned floors, clutter, or inadequate lighting [33]. Injury prevention includes fixing cracked walkways and installing handrails [33]. Inside the home, picking up clutter, burying electrical cords, and securing rugs will help eliminate objects that can be tripped over. Additionally, using nonslip mats and installing hand grabs in a bathroom will limit accidental slips [33]. Proper shoes with good traction and an evenly worn sole will provide stability and balance [33]. Not all falls are preventable, but applying the aforementioned interventions can reduce the risk of an avoidable fall.

CONCLUSION

This chapter discussed injury prevention principles and strategies, and reviewed specific conditions and injuries by age groups. These issues ranged from the prevention of ACL injuries, sudden cardiac death, concussions, heat illness, tendinopathy, and arthritis. The role of exercise was also discussed. Exercise can and should be used to treat heart disease, diabetes, hypertension, depression, and cancer. It is worth repeating that the American College of Sports Medicine recommends moderately strenuous exercise 30 min a day 5 days a week for all adults, and there is a growing body of evidence to support this role of exercise in promoting and maintaining health and wellness.

Prevention of injury plays a significant role in sports medicine and exercise science. In the clinical setting, health care providers say that “prevention is the best medicine.” Prevention may be primary or secondary in nature. Primary prevention is preventing a condition from occurring, and secondary prevention is once a condition is established preventing further progression or complications. Injury prevention,

therefore, plays a critical role in health promotion. Injury prevention is ultimately about keeping individuals and communities active, preventing disease and its complications, and promoting health and wellness for everyone.

INTRODUCTION

Organized athletic participation in the United States has seen an 800% rise in the volume of female athletes at every level, since the passage of Title IX in 1972.[1] As a result, there has been increased understanding of the female athlete triad. The first published recognition of the effects exercise has on reproductive function took place in ballet dancers in 1980.[1] The relationship between disordered eating, amenorrhea, and osteoporosis was first formally defined as the female athlete triad in 1993.[2] In 2007, the American College of Sports Medicine (ACSM) updated a 1997 published position stand on the triad.[3] In this statement, an emphasis is placed on decreased energy availability, with or without a diagnosed eating disorder, as the initiating factor in athletes that can lead to abnormalities in menstruation, which in turn play a key role on bone health.

The ACSM stresses the importance in understanding each part of the triad as a spectrum from healthy to disease, with potential effects of even mild deviations.[4] This may be seen in athletes with mild disordered eating, a subclinical menstrual disorder, and have a slightly higher risk of stress fracture. At the other end of the spectrum would be athletes diagnosed with anorexia or bulimia, chronic amenorrhea, and osteoporosis.[5] Throughout the spectrum, athletes are putting themselves at risk and should be evaluated and treated accordingly.

DEFINITIONS AND EPIDEMIOLOGY

The prevalence of disordered eating is difficult to measure secondary to the wide variation in case definitions. Studies have shown prevalence to be anywhere from 0% to 50%.[6] However, two large studies using the *Diagnostic and Statistical Manual of Mental Disorders* as criteria estimated 25%–31% of elite athletes compared to 5%–9% of the general population to have criteria meeting a diagnosis of female athlete triad.[7,8] But, given the shift in defining female athlete triad as a decrease in energy availability as opposed to clinical disordered eating, comparing the prevalence of decreased energy availability in athletes and the general population would be a more accurate distinction. Some studies have defined decreased energy availability as less than 45 kcal/kg lean body mass/day, while others use less than 30 kcal/kg. A study looking at 80 varsity high school athletes and 80 sedentary control students found decreased energy availability, defined as less than 45 kcal/kg, in 36% of the athletes and 39% of the sedentary controls.[9] These findings suggest that low energy availability, and the complications of that deficit, may not be unique to athletes, but rather all adolescent females. Additional studies are needed to truly determine if a difference exists between athletes and controls, and the implications of these findings.

Menstrual function ranges from eumenorrhea to amenorrhea. Primary amenorrhea is defined as failure to menstruate by age 15, which has been lowered from age 16 due to a trend toward earlier age at menarche. Secondary amenorrhea is seen in women with previously normal menstrual cycles that later develop an absence lasting more than 3 months. Within that spectrum, oligomenorrhea involves less than 9 cycles/year.

In the general population, the prevalence of primary amenorrhea is less than 1%,[10] while the prevalence of secondary amenorrhea not due to pregnancy, lactation, or menopause is approximately 3%–4%.[11,12] In athletes, primary amenorrhea has been reported to be 22% in cheerleading, diving, and gymnastics. Reported prevalence of secondary amenorrhea in athletes is variable based on multiple factors

such as sport, level, and age. Studies have documented rates ranging from 26% among U.S. collegiate athletes from seven different sports,[13] to 65% in distance runners and 69% in dancers.[14,15] Perhaps even more important is the estimated menstrual abnormalities along the spectrum of departures from normal menstruation. One study noted among eumenorrheic recreational athletes, 78% were found to have luteal deficiency or anovulation during at least one out of three menstrual cycles.[16]

Similar to energy availability and menstrual dysfunction, bone strength also occurs along a spectrum. Osteoporosis, commonly seen in postmenopausal women, is the most severe form of low bone mineral density (BMD). The World Health Organization (WHO) Classification of Osteoporosis bases BMD on dual energy x-ray absorptiometry (DXA) measurements to a reference young adult population (T-score). In contrast, the Z-score is a comparison of the patient's bone mineral density to an age-matched population. Currently, there is no consensus on the terminology and cutoffs for classification among the International Olympic Committee (IOC), the International Society of Clinical Densitometry (ISCD), and the ACSM when classifying BMD in premenopausal women.[4,17,18]

Organization	Normal BMD	Osteopenia (Low BMD)	Osteoporosis
WHO[a]	T-score within 1 standard deviation (SD) or less of reference population	T-score 1–2.5 SDs below reference population	T-score more than 2.5 SDs below reference population[b]
ISCD	Z-score above −2.0[19]	Z-scores below −2.0	—
ACSM	—	Z-score −1.0 and −2.0[c]	Z-score ≤ −2.0

[a] Diagnosis in postmenopausal women.
[b] In the presence of one or more fragility fractures.
[c] Along with history of nutritional deficiencies, hypoestrogenism, stress fractures, or other secondary clinical risk for fracture (chronic malnutrition, eating disorders, hypogonadism, glucocorticoid exposure, and previous fracture).[3]

A complication to determining the prevalence of low BMD in athletes is that many healthy athletes in weight-bearing sports typically have a BMD 5%–30% higher than sedentary controls. This suggests any decrease in BMD on standard testing to actually be evidence of more advanced bone weakness in athletes versus nonathletes.[19–21] However, one systematic review using the WHO Classification for comparison of BMD, found that T-scores less than −2.5 were found in 0%–13% of female athletes compared to 2.3% in the normal population. But T-scores of −1.0 to −2.5 were found in 22%–50% of athletes compared to 12% in the normal population.[22]

Few studies estimate the prevalence of all three components of the female athlete triad, most have shown that while many athletes may experience one or two of the components of the triad, few will actually display all three. In one study that evaluated 112 U.S. college athletes, 10 athletes (8.9%) met criteria for a combination of two disorders, whereas only one athlete (0.9%) met criteria for all three disorders. It is important to note that in this study, within the testing for low BMD, if a Z-score cutoff of −1.0 was used for low BMD, then three athletes (2.7%) met criteria for all components of the triad.[13] Another study of 170 high school athletes found that 10 athletes (5.9%) met criteria for 2 components of the triad, whereas 2 (1.2%) met all 3 components.[23]

PATHOPHYSIOLOGY

Clinical eating disorders include anorexia nervosa, bulimia nervosa, and disordered eating not otherwise specified. Several predisposing factors for clinical eating disorders have been identified; dieting is the most common factor. Dieting at moderate or severe levels leads to 5 times and 18 times increased risk of a diagnosed clinical eating disorder 6 months later.[24] Other factors include low self-esteem and self-control. It is also important to recognize clinical eating disorders are often accompanied by comorbid psychological conditions, including depression, anxiety disorder, and obsessive-compulsive disorder.[25] And finally, there is also mounting evidence for a genetic component to eating disorders.[26,27]

The etiology of low energy availability in athletes is less clear. Athletes may attempt to lose weight or body fat for the benefit of their athletic performance. This may consist of knowingly restricting caloric intake or an unintentional lack of adjusting caloric intake to correspond with increased energy expenditure.[18] Nutritional guidance helps to show athletes how to eat accordingly to replace energy expenditure as opposed to in response to hunger, studies have shown that although decreased dietary intake does increase hunger, exercise that results in equal energy deficit does not increase hunger.[3,28]

When net energy availability is insufficient, the body's natural response to promote survival is to reduce the amount of energy used for growth and reproduction. In females with insufficient net energy, there is a disruption in the pulsatile secretion of gonadotropic-releasing hormone from the hypothalamus, thus causing a disruption in pulsatile secretion of luteinizing hormone (LH) from the pituitary. This results in a functional hypogonadotropic hypothalamic amenorrhea or dysmenorrhea in athletes, although the specific pathway of this disruption is yet to be identified.[3] This can occur even after just 5 days of low energy availability.[29] LH pulsatility is abruptly disrupted when energy availability drops below 30 kcal/kg lean body mass/day, as opposed to a linear relationship between LH pulsatility and energy availability.[30] Furthermore, neither low body weight nor the act of exercising itself can explain the disruption of LH pulsatility in athletes, suggesting that LH pulsatility depends more importantly on energy availability.[31]

Functional hypothalamic amenorrhea appears to also have a genetic component, and several genes may add to the

susceptibility of certain females to the functional changes in GnRH secretion.[32] There has also been some evidence that the hormone leptin may serve as a signal to the hypothalamus regarding energy availability, in one study treatment of amenorrheic athletes with recombinant human leptin restored menstrual cycles.[33] Several other hormones, including insulin, insulin-like growth factor-I, cortisol, and growth hormone are also being investigated regarding possible signaling roles, although their role is currently unclear.[34]

In postmenopausal women, the most important contributor to low bone mass and osteoporosis is estrogen deficiency, related to estrogen's suppression of osteoclast activity.[35] The relative estrogen deficiency in athletes with amenorrhea contributes to the increased osteoclast activity, although this is only partially responsible for low bone mass in amenorrheic athletes. This is demonstrated best by a lack of normalization of BMD even after years of estrogen replacement.[36,37] Undernutrition has also been shown to reduce the rate of bone formation.[38] One randomized trial placed women into either a dieting group or exercising group with the goal energy availability to be below 30 kcal/kg lean body mass/day. Within 5 days blood markers of bone formation were noted to be decreased, and bone resorption increased.[39] Other factors that affect bone acquisition include leptin, growth hormone, and insulin-like growth factor, and have been discussed in the literature as being affected by low energy availability, further explaining a mechanism by which low energy availability can translate into low bone mineral density.

The statement "Senile osteoporosis is a pediatric disease" alludes to the concept that failure to achieve peak bone mass during adolescence and young adulthood often leads to osteoporosis and increased fracture risk later in life.[40] Most women achieve peak bone mass during their 20s, and while the majority of variability in peak bone mass is determined by genetics, the remaining 30%–40% of variability can be attributed to environmental factors including diet and exercise.[41] This important understanding in the pathophysiology of osteoporosis in postmenopausal women again underscores the need to prevent or treat low energy availability, amenorrhea, and low bone density that can occur in young women.

SCREENING AND DIAGNOSIS

History

The opportunity to screen for the female athlete triad, or one of its components, occurs most frequently at pre-participation physical exams or annual health checkups. However, other visits that may prompt evaluation for the triad may include menstrual abnormalities, stress fractures, or recurrent injuries. Important information to ascertain includes dietary practices, changes in weight or weight fluctuations, exercise practices, feelings of being overweight or underweight, medication history, menstrual history, current menstrual status, and prior stress fractures. There are also screening questionnaires for disordered eating that clinicians may consider using with routine physical exams, including the Bright Futures guidelines and the SCOFF questionnaire (currently validated only in adults).[42,43]

Physical Exam

Exam findings to suggest components of the triad include bradycardia, orthostatic hypotension, cold hands and feet, hypothermia, hypercarotenemia, lanugo hair or thinning scalp hair, oral ulcerations, dental enamel erosions, and parotid gland enlargement. Pelvic exam may reveal atrophy related to hypoestrogenism. ECG, if obtained, may show prolonged QT interval if the patient has a clinical eating disorder. Often, the physical exam will be normal, which should not rule out the presence of any aspect of the triad.[44]

Laboratory Testing and Imaging

For athletes with disordered eating, lab testing should include complete blood count, serum electrolytes, calcium, magnesium, glucose, liver function tests, thyroid function tests, and urinalysis.

In patients with amenorrhea, additional studies should include urine pregnancy test, serum LH and FSH, LH/FSH ratio, and serum prolactin to rule out other causes of secondary amenorrhea, since functional hypothalamic amenorrhea is a diagnosis of exclusion.[42] If these are normal, serum estradiol or a progesterone challenge test can be performed to assess estrogen indirectly (administration of medroxyprogesterone acetate 10 mg once daily for 7–10 days). In functional hypothalamic amenorrhea, the patient would be expected to have a withdrawal bleed and low FSH and LH levels.[45]

Other studies to consider include screening for celiac disease, erythrocyte-sedimentation rate, MRI of the brain, and upper and lower gastrointestinal studies if there is uncertainty about the diagnosis.[42]

The International Society for Clinical Densitometry (ISCD) proposes that bone mineral density testing should be completed in premenopausal women who have a fragility fracture or a disease, condition, or medication associated with low bone mass or bone loss, or in any patient that pharmacologic therapy for the management of osteoporosis is being given or being considered. The current ACSM position stand recommends a bone mineral density assessment by DXA in any female with a history of hypoestrogenism, disordered eating or eating disorder for 6 months or more, and/or a history of stress fractures or fractures from minimal trauma. Additionally, re-evaluation is recommended after 12 months for any persistent female athlete triad disorder.[3]

PREVENTION AND TREATMENT

Prevention

Education is the key to prevention of the female athlete triad, with an emphasis on understanding energy availability, nutritional intake, and balancing intake with energy output.[3,39]

Adolescents, involved in athletics or not, are at risk for low energy availability, menstrual dysfunction, and low bone mineral density, suggesting that all adolescent females may benefit from education on these topics.[9] Specific teaching on daily caloric needs, caloric expenditure with activities, and intake of nutrients, especially calcium and vitamin D, is important. Those that have low energy availability because of a lack of awareness will benefit most from nutritional counseling. Furthermore, it should be stressed to athletes that amenorrhea is not a normal response to exercise and should be evaluated by a physician. The risks of impaired bone mineral density accrual, osteoporosis, and stress fractures should also be communicated to adolescent and young adult females.

For athletes, a multidisciplinary team approach to education is ideal, to include parents, physician, coach, registered dietician, athletic trainer, and mental health provider.[46] Societal and media-related pressures to be thin may play a role in disordered eating.[9] These pressures are compounded in specific sports where performance may be perceived to be enhanced by decreased body fat or weight. The decision to try to lose weight should not be based on a coach's recommendation, and the coach should not play a role in determining the athlete's ideal weight. Rather, any athlete that has concerns about her weight should be evaluated by a nutritionist, with an estimation of daily energy availability and intake of nutrients, followed by further testing as indicated and a discussion between the athlete and health care providers. If a decision is made that the athlete may safely make changes in diet and/or training to try to improve athletic performance, then the athlete should be followed up closely after the goal weight or body composition is reached.[18]

Treatment

The primary goal in therapy is to increase energy availability by modifying diet to at least 30 kcal/kg lean body mass/day and exercise behavior in order to have normal LH pulsatility and restore normal menstrual cycles.[30] With a reversal of amenorrhea, one study showed an 11% increase in bone mineral density, although not necessarily back to normal.[47] Another study in which participants underwent nutritional therapy with regain back to 90% of ideal body weight, increases in spine and hip BMD of 4.38% and 3.77%, were seen after 2.2 months.[48] In a study examining anorexia nervosa patients, those that improved weight and resumed menses showed a mean annual increase in bone mineral density of 3.1% at the posteroposterior spine and 1.8% at the hip.[49] From these studies, results show resumption of menses was most important for improved, spine BMD, whereas weight recovery was most important to the hip. Taken together the conclusion is "nutritional recovery, leading to recurrence of menses and reflected by an increased body mass index, is the best predictor of improved bone mineral density in these patients."[50]

Nutritional counseling is vital to restoring energy availability, including evaluation of the patient's current intake and daily output with training and the steps necessary to reach daily goals. Nutrition counseling should include recommendations on intake of calcium and vitamin D, which should be achieved by supplementation if not reached with dietary intake. For athletes that do not routinely meet these goals or are resistant to counseling or monitoring, restrictions on practice or competition may be necessary and enforced with a written contract.[3]

Treatment with hormone replacement therapy has provided mixed results. A systematic review found "fair" evidence of oral contraceptives showing a positive effect on bone mineral density in oligo/amenorrheic premenopausal women. Limited evidence of a positive effect is seen in anorexic premenopausal women with amenorrhea, with two studies showing a positive effect and five studies showing no effect.[51] Despite this trend toward improvement in bone mineral density, oral contraceptives are unlikely to fully reverse any deficiencies in bone mineral density in hypothalamic amenorrheic women, since "restoration of regular menstrual cycles with OCPs will not normalize the metabolic factors that impair bone formation, health, and performance."[3]

While there does not seem to be a negative effect of oral contraceptives on bone mineral density, it is important to note that hormone replacement therapy-induced menses may make it difficult for health care providers to determine the status of energy availability.[5] The decision to treat with oral contraceptives should be made on an individual basis, while keeping lifestyle and hormonal factors in mind. These factors may include desire for contraception or a failure to regain menses despite conservative measures.[51]

Bisphosphonates are approved only in the treatment of postmenopausal osteoporosis; they are not approved and should not be used in young women of reproductive age. There is a lack of safety data in this population. Furthermore, bisphosphonates are known to cross the placenta, and reside in a woman's bone for many years, potentially causing adverse effects on a fetus even several years after administration.[3,51] Bisphosphonates have been shown to be effective in patients with anorexia nervosa, increasing femoral neck and lumbar spine bone mineral density, but without long-term safety data they should not be used in young women.[52,53]

CONCLUSION

The female athlete triad, consisting of low energy availability with or without eating disorders, menstrual abnormalities, and decreased bone mineral density for age, has continued to evolve as the understanding of prevalence, pathophysiology, and treatment for these linked disorders has progressed. With an emphasis on the understanding of energy availability and its role within the framework of the female athlete triad, health care providers can help athletes to help prevent or minimize potentially significant health risks.

The goal of this chapter is to present rehabilitation principles and common therapeutic interventions, and the role they play in the management of acute and chronic injuries. A common approach to injury management for many athletes is to rest from sport, take anti-inflammatories, and return to the pre-injury level of activity when pain decreases. This approach may be effective in cases where there is a mild well-defined injury, but risk factors that may have caused the original injury are rarely addressed. Reoccurrence is a common complication, and an acute injury often becomes chronic with the healing potential of the tissue compromised. Perhaps a more appropriate approach to injury management is to apply rehabilitation principles to improve tissue healing potential, reduce the risk factors associated with the injury, and provide training guidelines and assessment for the readiness to return to activity/sport. The goal of this approach is to return the athlete to pre-injury activity levels while minimizing the risk of re-injury.

REHABILITATION CONSIDERATIONS AND THERAPEUTIC INTERVENTIONS

The timeline for returning to sport is dependent on many factors including the extent of injury, healing properties of the respective tissue, and demands of the activity involved. There are many tools and techniques used to address the specific needs and goals of a rehabilitation program. When prescribing physical therapy, it is helpful to understand rehabilitation principles and the interventions appropriate for the given injury. The interventions chosen to address specific injuries are based on theoretical knowledge, evidence-based research, and the practical experience of the clinician. Common interventions by category are presented in Table 61.1.

REHABILITATION CONSIDERATIONS

Regardless of the injury, development of an effective rehabilitation program must include the assessment of the following elements: pain and edema, functional range of motion and strength, neuromuscular control, biomechanical efficiency, training habits, and sport-specific fitness levels [1].

Pain and Edema

Limiting effusion and edema is one of the primary goals in the acute phase of injury. Excessive or prolonged edema can cause secondary cell death creating a more extensive injury, increased tissue pressure, pain, and a reflex inhibition of the associated musculature [2]. Pain control is necessary to enable normal neuromotor recruitment, prevent reflexive muscle spasm, and advance through all phases of rehabilitation.

Therapy interventions used to assist venous and lymphatic function to reduce swelling and pain include modalities (Table 61.2), therapeutic exercise, and manual therapy techniques. Although modalities are commonly used in the management of acute and chronic injury, conflicting evidence

TABLE 61.1
Common Rehabilitation Interventions

Modalities	Ultrasound, phonophoresis, iontophoresis, electrical stimulation, cold, and heat therapy
Therapeutic exercise	Specific exercise interventions to restore bilateral symmetry and function include: ROM, flexibility, neuromotor re-education, strength training, plyometric training, endurance training
Manual therapy	Hands-on techniques to restore mobility of the joint and soft tissues, and modulate neural input include joint mobilization, soft tissue mobilization, myofascial release, trigger point therapy techniques, neural mobilization
Biomechanical analysis	Analysis of motion to identify pathomechanics and optimize mechanics of specific movements including gait training, running, throwing, and jumping
Program planning	Development of a home exercise program (HEP) and structured training program to define a logical progression of training and recovery in order to reduce the risk of re-injury upon return to sport

TABLE 61.2
Therapeutic Modalities

Modality	Therapeutic Effect
Cold	Decrease pain, inflammation, edema Ice massage: 5–7 min; ice pack: 15–20 min *Acute* every hour or multiple times/day; *Post rehab*: 15–20 min
Heat	Increase blood flow; tissue extensibility, and muscle relaxation; decrease pain; 15–20 min, after first 48 h
Heat/cold contrast	Increase blood flow; mobilize chronic edema Hot:cold ratio = 3:1
Ultrasound	Deep tissue heating; decrease pain; decrease inflammation; decrease chronic edema
Phonophoresis (ultrasound used to drive medication into tissue)	Hydrocortisone cream commonly used Decrease inflammation, swelling, and pain
Iontophoresis (delivery of medication via electrical current)	Corticosteroids commonly used Decrease inflammation, swelling, and pain
Electrical stimulation	Decrease pain; muscle contraction and re-education, decrease swelling

exists regarding their efficacy in the role of recovery [3–5]. Appropriate therapeutic exercises include passive and active ROM activities, such as sub-maximal muscle contractions, and light resistance cycling. Manual therapy techniques include gentle soft tissue and joint mobilization.

JOINT STABILITY AND MOBILITY

Joint mobility can be defined as the range a joint can move through before being restricted by the surrounding ligaments, joint capsule, musculature, and bony anatomy. Assessment of mobility is measured in degrees of range of motion (ROM). *Active ROM* (*AROM*) is the active movement of a joint by the muscles controlling the joint. *Passive ROM* (*PROM*) is the passive movement of a joint by an external source or gravity, and without muscular contraction. Both may be limited following injury secondary to pain, joint or muscle tightness, and muscle spasm. Therapeutic interventions including active and passive stretching exercises, joint and soft tissue mobilization techniques, and modalities to enhance tissue flexibility are employed to restore functional mobility.

Joint stability is the ability to maintain necessary joint congruency and alignment to reduce friction and wear of the joint, and control active movement of the joint. *Static stability* depends on passive restrictions to movement and includes the bony anatomy, ligaments, joint capsule, and cartilaginous structures. *Dynamic stability* depends on the strength, endurance, and neuromuscular recruitment of the joint and core stabilizing musculature to stabilize the joint with active movement and increased joint loads.

CLINICAL EXAMPLE: THE IMPORTANCE OF MOBILITY AND STABILITY IN SHOULDER FUNCTION

The shoulder joint has a large capacity for motion secondary to its anatomical configuration, but stability of the joint is dependent on the static and dynamic stabilizers. The glenoid labrum, glenohumeral ligaments, and joint capsule provide passive joint stability, while the rotator cuff and scapular stabilizers provide dynamic stability and control [6,7].

In dislocation or subluxation injuries, the ligaments and capsule of the joint are overstretched with a resulting loss of static joint congruency, and an increasing reliance on the dynamic stabilizers. Dynamic stability and function of the shoulder depends significantly on the strength, endurance, and coordination of the surrounding musculature. The *scapular stabilizers* link the scapula directly to the trunk of the body and include the rhomboids, upper, middle, and lower trapezius, and the serratus anterior. Their role is to provide the humerus with a stable platform from which it can efficiently operate. When the arm is elevated above 90°, the scapula has to upwardly rotate to prevent impingement of the humerus against the acromion. This requires a coordinated force couple of the upper trap, lower trap, and serratus anterior(Figure 61.1). *Scapular dyskinesia* is an alteration in the normal position or motion of the scapula during coupled scapulo-humeral movements and is a result of weakness or fatigue.

(continued)

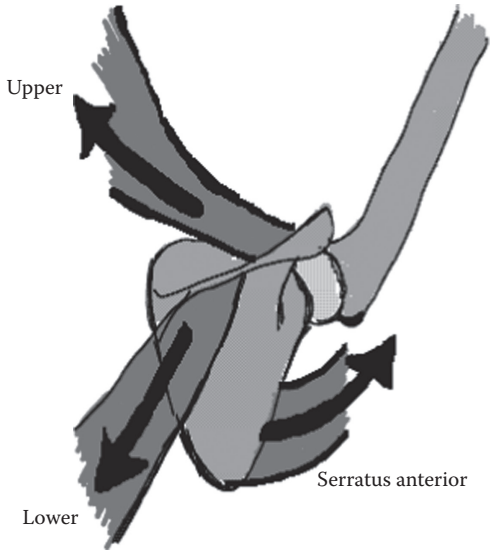

FIGURE 61.1 Muscular force couple for upward rotation of the scapula.

The *glenohumeral stabilizers* consist of the rotator cuff musculature (infraspinatus, supraspinatus, teres minor, subscapularis). Because of their length, alignment, and proximity to the joint, these muscles have an excellent biomechanical advantage to provide compression and stability to the humeral head. This is necessary to keep the humeral head centered in the glenoid and prevent superior migration as the arm is taken into an elevated position (Figure 61.2).

The scapular stabilizers and rotator cuff must work in coordination for efficient shoulder function, and common rehabilitation exercises for both are presented in Figures 61.3 through 61.6 [8–10].

Neuromuscular Activation and Control

Neuromuscular inhibition is common in an acute injury secondary to pain or swelling. It is also present in injuries of a chronic nature secondary to pain, tightness, decreased proprioceptive feedback, or apprehension. Persistent muscle imbalances may result in altered motor control and mechanics, and increased risk for injury. Re-establishing efficient neuromuscular recruitment patterns is essential for restoring symmetrical balance, proprioception, and strength post injury [11].

Therapeutic exercise programs should incorporate closed chain exercises to stimulate articular receptors, and muscle co-contraction to enhance joint stability. *Balance, proprioception, and core stability* training is necessary to increase the ability to sense and control joint movement and position. It is also required to maintain balance and a stable base, despite forces generated from other body parts during athletic maneuvers [1,11–13]. Reactive neuromuscular training enhances reflexive stabilization. Strength and plyometric exercises have been shown to decrease the response time and develop reactive strategies to increased or unexpected joint

CLINICAL APPLICATION: NEUROMUSCULAR TRAINING TO REDUCE ACL INJURY

ACL injuries are very prominent in young athletes, especially females. The rate of injury is as common as 1/10 college athletes and 1/50 high school participants [11,13,14]. Common risk factors that may affect incidence of injury are landing in a valgus knee position, decreased trunk stability and awareness, poor knee flexion or straight-leg landing, quadriceps dominance, and imbalances between sides. Many programs have

(continued)

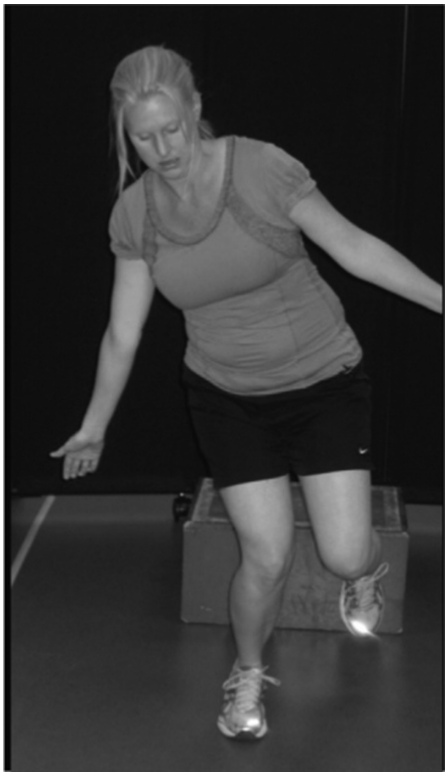

FIGURE 61.7 Valgus landing and center of mass outside base of support. Common presentation of poor body awareness and control, and inability to absorb and direct ground impact forces.

FIGURE 61.8 Good alignment with athletic stance landing position.

(continued)

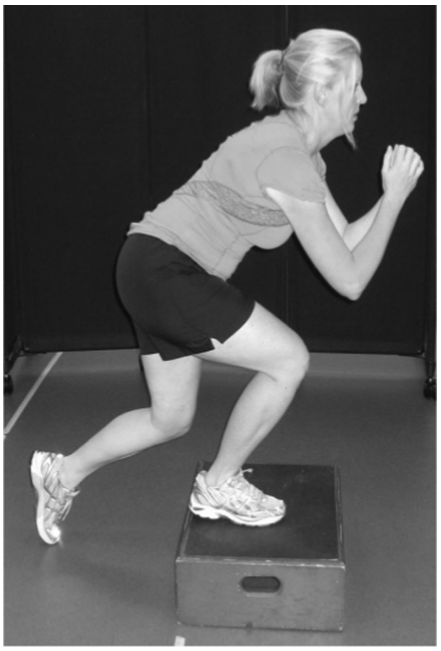

FIGURE 61.9 Step back exercise emphasizes strengthening in good lower extremity alignment with a bias of gluteal and hamstring recruitment.

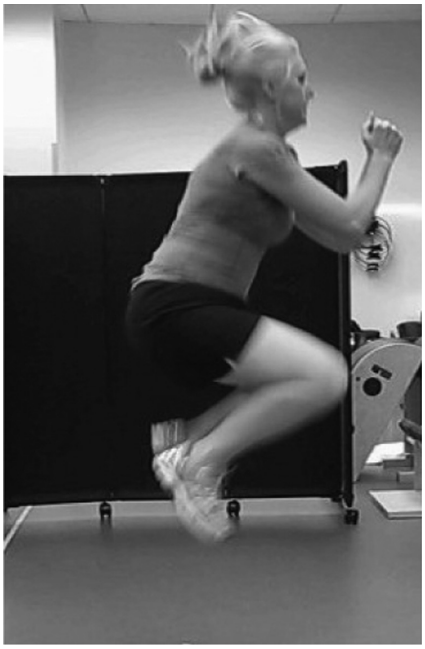

FIGURE 61.10 Tuck jump-plyometric rebound exercise to decrease ground response time and develop reactive strategies.

been developed which address the risk factors for ACL injury, and a common component of all programs is neuromuscular training. Programs to reduce injury focus on techniques that emphasize strong athletic positioning and body control, while eliminating excessive side to side motion. The programs are based on biofeedback and emphasize correct posture, body alignment,

(continued)

core stability, soft landings, and appropriate recoil in jumping. Proper neuromuscular training has been shown to reduce impact and decreases peak landing forces, thus lowering the injury risk in female athletes. The decrease may be due to increased dynamic stability of the knee through training (Figures 61.7 through 61.10) [14,15].

loads [11]. The goal of training is to progress from conscious to unconscious control of movement patterns and strategies.

Strength: is the ability to produce, resist, or control force, and is dependent on how well the nervous system recruits muscle fibers, as well as on the size and number of muscle fibers recruited. It is an important factor in injury prevention and return to play, and there is a critical level of strength needed to reduce the risk of injury or restore function which is determined by the demands of the sport. Strengthening major muscle groups throughout the ROM and demonstrating muscular power are components of *functional strength training*, and should focus on symmetry between limbs and between agonist/antagonist [10,13,16] (Table 61.3).

Biomechanics of activity: Subtle alteration in normal mechanics may have a profound effect, especially with repetitive movements over a period of time. It is important to evaluate and recognize pathological biomechanics that will lead to increased stress and subsequent tissue injury [17–20]. Evaluation of running form can identify loading patterns that have a high correlation to injury at the foot or ankle. Appraisal of landing mechanics can identify positions that correlate with increased risk of patella-femoral problems or ACL injury in the female population, and assessment of throwing mechanics can identify patterns that correlate with increased risk of injury to the shoulder or elbow.

Training modifications: Training modifications are necessary for most athletes returning to activity following injury. Structured programming should modify training by adjusting volume, load, and intensity to prevent interruption of the healing process. Integrating cross-training, multi-planar strengthening techniques, and activity diversification is an effective way to prevent tissue overload as programs addressing these factors have been shown to decrease rate of re-injury [21,22].

Return to sport: Return to sport is the final stage of rehabilitation for an athlete. Progressive increase of the load demands on the body while protecting it from injury is the main goal of return to sport programs. Training should gradually introduce more aggressive movements throughout unrestricted range of motion, and include the combination of balance, weights, plyometrics, agility, and sport-specific patterns or skills [23]. Sport-specific requirements of strength, endurance, speed, load, and flexibility determine readiness to play, and should meet predetermined criteria based on the imposed demands of the sporting activity [14,24–28].

TABLE 61.3
Training Definitions

Term	Definition	Clinical Example
Concentric	Contraction with muscle shortening	Ascent from a squatting position
Eccentric	Contraction with muscle lengthening "Negative or Braking" contraction	Decent into a squatting position
Open kinetic chain	Distal limb moves through space	Seated knee extension, bicep curl
Closed kinetic chain	Distal limb fixed	Squat, Step-up, push-up
Proprioception	Awareness of body position and movement	Wobble board, balance perturbations
Plyometrics	Exercise involving repeated rapid stretching and contracting of muscles to increase shock absorbing capabilities, neuromuscular coordination, and quickness	Rebound jumps, tuck jumps, overhead throws
Core stability	Muscles that contract to stabilize the spine, pelvis, and shoulder girdle and create a solid base of support for powerful movements of the extremities	Front bridges, side bridge, back bridge
Multi-planar	Are multi-joint, closed chain exercises in the sagittal, frontal, and transverse planes for the purpose to increase strength and stability in functional movement patterns and decreases repetitive stress in the primary plane of motion	Multi-planar matrix lunges, woodchops, dot drills

Functional fitness: Needs to be attained prior to unrestricted return to sport. Cardiovascular and muscular endurance detraining occurs at a more rapid rate than muscle atrophy, and athletes who do not maintain cardiovascular fitness are more likely to sustain another injury when returning to their sport [29]. The intensity of cardiovascular re-training should be sport specific, and the training load progressed to a level equal to or higher than the athlete's actual sport.

Determinants of Rehabilitation Progression

The initiation and progression of a rehabilitation program is primarily based on the healing properties of the involved tissues. Therapeutic interventions with specific criteria for progression are applied to optimize healing potential and minimize the risk of re-injury. The timeline for returning to sport is dependent on many factors including the extent of injury, healing properties of the respective tissue, and demands of the activity involved.

Tissue injury occurs by one of two mechanisms. *Macrotraumatic* injuries involve any single stress to the tissue beyond its tensile limit. These are typically acute injures with a specific history of insult. Examples of these types of injuries are fractures and acute musculoskeletal sprains or strains. *Microtraumatic* injuries occur in response to repeated stresses within the tensile limit of the tissue but with an insufficient recovery time between stress applications. These injuries tend to be more vague in exact onset and are usually described as a more chronic and persistent type of injury. Examples of these types of injuries include tendonitis, bursitis, and stress fractures [2].

Tissue vascularity is a critical component to healing. Avascular tissues have a longer healing time and often cannot

TABLE 61.4
Healing Characteristics of Specific Tissue

Tissue	Healing Considerations
Bone	Good vascularity. Overall healing potential is affected by age, severity, and site of the fracture. Healing usually requires immobilization for 4–8 weeks, with the gradual application of load following that to allow tissue adaptation to the stress applied
Tendon	Limited vascularity. The musculotendinous junction and bone/tendon interface vascularity is greater than that of the free tendon. 4–6 weeks of relative rest or immobilization is required for healing
Ligament	Limited vascularity. Frequently the structural strength of the scar produced is inadequate for strong approximation of the ruptured ligament. Immobilization for 6 weeks with many months of remodeling are necessary to restore full strength
Articular cartilage	Avascular. Limited capacity to heal
Menisci/fibrocartilage	Healing depends on pattern of blood supply. The periphery of the meniscus has adequate blood supply for healing and requires 4–6 weeks of restricted movement and weight bearing to heal. The inner portion of the meniscus is avascular and has poor healing potential
Nerves	Nerve cells can regenerate significantly if the injury does not affect the cell body. The closer the injury is to the cell body, the longer the healing time. The axon proximal to the cut begins regenerative process, and scar formation can obstruct regeneration. Healing occurs at a rate of 3–4 mm/day
Muscle	Vascular. Healing is affected by extent and location of injury. Re-injury is frequent due to altered neuromuscular input, and return to activity before tensile strength is regained. Healing occurs from 1 week to many months

produce a functional healing response or a strong scar. Other factors that may impede healing are excessive bleeding and edema, poor approximation of injured tissue, extensive tissue trauma, infection, advanced age, and an interruption of the inflammatory response [2]. (See Table 61.4 for healing consideration for specific tissues.)

Although different types of tissue have specific healing characteristics that determine rehab progression time frames, in general all go through three primary phases of a healing continuum with correlated stages of rehabilitation [30–39].

PHASES OF TISSUE HEALING AND REHABILITATION

Destruction/Inflammatory Response Phase

This is the acute response to injury and characterized by cell rupture and death. The initiation of an inflammatory response sets off a cascade of metabolic changes and formation of a hematoma resulting in a localization of the injured area. This phase is essential to an effective healing process and lasts approximately 2–5 days depending on the extent of the injury.

Phase 1 Rehabilitation: The goals of this stage are to do the following:

1. *Minimize pain, and limit edema*: Prevent neuromuscular inhibition and secondary cell death.
2. *Protect the scar formation*: Aggressive mobilization during this phase can result in rerupture of the healing tissues, and ultimately increased scarring.
3. *Minimize atrophy and maintain neuromuscular control*.
4. *Reduce associated muscle spasm*: Decrease pain and neuromuscular inhibition.

R.I.C.E

The first 24–48 h to prevent prolonged inflammation and excessive scarring [30,31,40].

Rest: Immobilization and non-weightbearing or non-loading of the injured extremity with use of crutches, braces, or splints

Ice: 15–20 min with cold pack several times a day to control swelling and pain

Compression: Wrap to decrease the pressure gradient between vessels and tissue, and assist lymphatic drainage

Elevation: Elevation of the injured body part above the level of the heart also promotes decreased blood flow and helps with absorption into the lymphatic system, reducing the amount of edema

Repair Phase

Important events of this phase are the phagocytosis of the necrotic tissue, tissue regeneration and revascularization, and production of a connective tissue scar. This process starts within a few hours of injury and can continue for 4–6 weeks again depending on the type of tissue injured and the extent of the injury.

Phase 2 Rehabilitation: The goals of this stage are to do the following:

1. *Stimulate the healing tissue*: To adapt and grow to the stress demands that will be placed on it. Gradual and specific application of stress will stimulate the tissue to increase structural strength, prevent inadequate scar formation, and reduce the likelihood of re-injury when functional load of sport is applied [30,31,40].
2. *Progress ROM and strength*: Based on patient tolerance and rate of improvement.
3. *Restore neuromuscular control*.
4. *Gradual re-introduction of functional*: Activity limited by pain.

Remodeling Phase

This phase consists of reorganization and remodeling of the scar tissue, and recovery of the functional capacity as the tensile strength of the scar increases. This process can take from a few weeks to months or years depending on the extent of the scar and the type of tissue involved.

Phase 3 Rehabilitation: The focus of this phase is to prepare the athlete for a safe return to sport:

1. Perform more aggressive movements through full unrestricted range of motion.
2. Restore functional and bilaterally symmetrical strength.
3. Sport-specific conditioning and training to prepare the athlete for return to sport.
4. Regain sport-specific skills.

SPECIFIC REHABILITATION INTERVENTIONS FOR CHRONIC INJURIES

What if the normal healing response is interrupted or dysfunctional? Many injuries of a chronic nature do not have a well-defined injury mechanism and do not follow the typical phases of healing. Although the exact mechanism of injury varies, repetitive stress, and overuse with lack of recovery time often play a key role in the development of these types of injuries [35–39,41–46]. With chronic inflammation there is a failure of the healing response, and poor tissue reorganization. The body is unable to keep up with

CLINICAL EXAMPLE: MANAGEMENT OF ACUTE ANKLE SPRAINS

Phase 1: Inflammatory, Acute Phase: The goal of this phase is to reduce pain and inflammation, and set up an optimal healing environment.

Relative rest	Remove the athlete from painful and irritating activities. Rest by non-weightbearing or unloading the effected ankle with crutch until the athlete can walk without a limp. A CAM walking boot is often used in this phase to immobilize the injured ankle. Continue modified conditioning program that does not involve the lower extremities
Decrease inflammation, swelling, and pain	R.I.C.E—Ice 20 min several times per day. Modalities such as electrical stimulation may be used to control pain and superficial swelling
Therapeutic exercise	Gentle ankle AROM within pain-free range. Toe gripping and spreading. General body maintenance exercises that do not stress the ankle
Manual therapy	Avoid aggressive soft tissue mobilization that may disrupt scar formation
Criteria for progression	Minimal pain at rest, ambulation without assistive device or limp

Phase 2: Restoration of Function: The goal of this phase is to restore normal biomechanics to the ankle joint, promote functional/dynamic mobility; Correct ROM limitations

Control pain and swelling	Compression, ice, and modalities to limit edema and pain. Sporting activity is limited as patient restores function to the joint
Therapeutic exercise	Restore full ROM through active and passive stretches Progressive strengthening of ankle musculature through pain-free ROM including calf raises, elastic band resisted exercises in eversion, inversion, plantarflexion, and dorsiflexion Balance and proprioception progressions: Single leg stance exercises starting on a stable surface with progression to unstable surfaces. Increase exercise challenge: eyes closed, barefoot, movement of opposite extremities, balance perturbations Maintain cardiovascular fitness with conditioning programs on bike, elliptical, and aqua-jogging as tolerated
Manual therapy	Gentle joint mobilization of foot and ankle to restore ROM Gentle soft tissue mobilization to decrease swelling
Criteria for progression	Full pain-free ROM, 5/5 pain-free manual muscle test of all ankle motions, pain-free initiation of sport-specific activities, minimal and controlled swelling following activity

Phase 3: Return to Sport: Goal is to return to full participation without reoccurrence of injury

Continued interventions	Bracing or taping for practice and sport to increase proprioception and stability Modalities as needed to control swelling and post workout discomfort
Training progressions	Progress training to include a more functional load, volume, and speed with parameters for advancement (return to running, jumping, kicking). Initially allow for long recovery, progressing to shorter recovery to advance to more sport-like scenario. Focus is given to equalizing ground reaction forces, improving confidence and stability with change in direction, and perfecting biomechanics. Activities incorporate cutting, agility drills, plyometrics, and power drills
Criteria for return to play	5/5 manual muscle test with repeated contraction, bilateral balance symmetry, sport-specific tasks (running, cutting, jumping) without pain or stiffness. Meet pre-injury or baseline fitness criteria

repair of the damage created from repetitive micro-trauma to tendons and muscles. Genetic predisposition, increased age, and tissue strength less than the task demands may also play a role in these types of injuries [35].

The rehabilitation goals for these types of injuries are to try to stimulate a healing response and limit repetitive stress to the injured tissue. Rehabilitation focuses on restoring functional mobility, strength, and stability, correcting faulty biomechanics associated with tissue overload, and creating a training plan to limit stress and increase recovery potential [47–50].

Components of a rehabilitation program to address chronic injuries include the following: (1) stimulation of a healing response; (2) correction of faulty biomechanics; (3) restoration of functional mobility, stability, and strength; and (4) modification of training programs to limit repetitive stress to the injured tissue.

CLINICAL EXAMPLE: ECCENTRIC TRAINING IN ACHILLES TENDINOPATHY

Achilles tendinopathy is a common overuse injury in athletes [51]. The term *tendinopathy* is used to describe a non-specific dysfunction of a tendon that occurs in response to an unaccustomed activity or stress. Further delineation of tendinopathies requires histological analysis of the involved tissue. *Tendonitis* is a dysfunction that involves an inflammatory process in the tendon or associated structures. *Tendinosis*, in contrast, is characterized by an absence of inflammatory cells, and a degradation of the tendon tissue with infiltration of abnormal nerve and vascular tissue [52–56].

While therapeutic interventions aimed at reducing inflammation may be helpful in reducing pain and inflammation in tissues surrounding the tendon, they are of limited benefit where there is a lack of inflammatory response in the tendon itself. The focus of rehabilitation in these cases is to stimulate a tendon-healing response. Mechano-transduction is the process of a cell converting mechanical stimuli into biochemical signals. Tendons adapt their metabolism and structural properties to meet mechanical forces applied. This is the reason *eccentric strengthening* programs are commonly used to elicit a remodeling response in tendinopathies [57–62].

There are many eccentric training programs presented in the literature [63–72] for the treatment of Achilles tendinopathies. The program presented next is illustrative of a common eccentric program:

ECCENTRIC TRAINING PROGRAM FOR ACHILLES TENDINOPATHY

Calf muscle soreness, and increased pain in the Achilles insertion, could appear during the first weeks of eccentric training

General instructions: Lift both heels off of the floor to a position of full plantarflexion. Transfer weight to injured leg and slowly lower heel down to the floor on a 3 count. (This can also be done with heels of the edge of a stair for more ROM.)

Program execution: 15 reps:2×/day, progressing to 2–3 sets of 15 reps:2×/day
7 days/week, × 12 weeks

Program progression: Increase load by adding dumbbells or weight in a backpack when there is no increased pain immediately after exercise or the following morning.

SUMMARY

The ultimate goal of rehabilitation is to return the athlete to sport as quickly as possible without recurrence of injury. Understanding the phases of healing as well as the therapeutic interventions and principles can assist the practitioner in determining a logical progression through the rehabilitation program. Specific criteria for advancement are the best strategy to minimize risk, but it is important to clarify that release from a rehabilitation program and return to sport does not necessarily correspond with full healing of the injury, and precautions may exist for the athlete [22,24].

The field of exercise physiology is an important part of an integrative sports medicine.

More and more athletes are competitive worldwide, regardless of the level of competition, age, or gender. From professional to recreational athletes, competitions in many different sports worldwide keep breaking records of audience and participation every year. We live in a very competitive society where competition is always present. Exercise physiology is part of integrative sports medicine programs in many professional and elite sport teams worldwide where the improvement and optimization of performance is the ultimate goal of any athlete and team and as important as the recovery and return to play after injury.

For recreational athletes, improvement in performance is a major goal as well. Hundreds of thousands of recreational athletes worldwide have become competitive athletes of their own. They enter many competitions with the purpose of improving their personal record, beating the opposite team, or just beating the next-door neighbor. Although not yet very well established in the United States, for recreational athletes, the field of exercise physiology has a very large potential and application in order to help this population in achieving their goals and optimizing their time.

The goal of this chapter is to present the audience with different approaches in the field of exercise physiology that are being applied nowadays to both elite and recreational athletes through different methodologies like physiological testing, training monitoring, nutrition, and prevention and detection of overtraining where the scientific approach and rationale are essential for the application of these methodologies.

PHYSIOLOGY OF THE PERFORMANCE ATHLETE: CENTRAL ADAPTATIONS VERSUS LOCAL ADAPTATIONS

The human body is the most fascinating and complex machine that has ever been built. It is so complex to understand that after centuries of study we still don't fully understand many processes happening in the human body. During exercise many physiological and metabolic process occur simultaneously and the study of these physiological and metabolic processes has occupied a vast space in many scientific studies. The field of exercise physiology is an evolving field and many concepts and knowledge have evolved from the first scientific studies in exercise physiology back in the eighteenth century to the present time. Central adaptations to exercise based on the cardiovascular and respiratory system were the main physiological parameters measured and understood for many years. The scientific advances in technology, infrastructures, and knowledge of the last part of the twentieth century have allowed us to know much more about exercise bioenergetics as well as the physiological and metabolic adaptations to exercise at the cellular level such as the muscle and enzymatic responses and adaptation to exercise, muscle fiber recruitment patterns, the regulation and utilization of energy substrates, and in general, the muscle metabolic integration of the athlete. The capacity of an athlete to exercise depends on the ability to convert chemical energy into mechanical energy, so ultimately all the events happening at the cellular level are crucial for skeletal muscle during exercise. Modern exercise physiology has in a way become exercise biochemistry due to all the knowledge that we have nowadays of the events happening at the cellular level during exercise. For example, we know now that the central adaptations to exercise (cardiorespiratory) are very similar among athletes of similar levels of competition, but we know that the local adaptations at the cellular level are the ones that set athletes apart during the competition.

MAXIMAL OXYGEN CONSUMPTION

Maximal oxygen consumption (VO_{2max}) is the main parameter representing central adaptations to exercise. VO_{2max} is the maximum capacity that the body has to transport and use oxygen during exercise. It is the major cardiorespiratory parameter used to measure physical fitness and aerobic capacity. Oxygen consumption during exercise was first measured by French chemist Antoine Lavoisier in 1873 [1], and ever since the measurement of O_2 consumption during exercise has been of great interest in the field of exercise physiology. VO_{2max} has been used for many years as the best assessment of cardiorespiratory fitness. The relatively easy measurement of VO_{2max} through indirect calorimetry with commercially available "metabolic carts" since the 1970s has made the "VO_{2max} test" very popular worldwide as a way to assess the fitness level of an athlete and is even used to predict performance and prescribe training zones and programs for athletes. However, it is well known that VO_{2max} is a poor indicator of performance [2]. Many exercise physiology laboratories worldwide can observe how athletes improve their records and performances over the years in spite of not improving their VO_{2max}. However, in these athletes, it is easy to observe improvements in lactate metabolism or fat and carbohydrate (CHO) metabolism during exercise, which means that the physiological and metabolic parameters that elicit an improvement in performance in these athletes are local, at the cellular level. Therefore, in modern exercise physiology it should be important to study and identify the metabolic responses to exercise at the cellular level like lactate metabolism or fat and CHO metabolism during exercise.

Local Adaptations Start in Skeletal Muscle: The Muscle Contraction

Skeletal muscles are surrounded by a layer of connective tissue, called epimysium, which attaches to the bone through the tendon. Each muscle is composed of fascicles and each fascicle is made of a bunch of muscle cells, called muscle fibers. Each muscle fiber is long and has multiple nuclei and specialized organelles. Each muscle fiber contains multiple myofibrils where muscle contraction ultimately happens. Myofibrils contain contractile proteins organized in

thin filaments (actin) and thick filaments (myosin), which repeat many times along the length of a myofibril in sections called sarcomeres. Muscles contract by sliding the actin and myosin filaments along each other and sarcomeres shorten. Adenosine-5′-triphosphate (ATP) is the compound necessary for muscle contraction. The binding of ATP dissociates myosin from actin. ATP hydrolysis results in a change in configuration that displaces the myosin head group. This change in configuration is followed by the binding of the myosin head to a new position on the actin filament and then the release of adenosine diphosphate (ADP) and phosphate (P_i.). When the myosin head returns to its original conformation, the actin filament slides, and this causes muscle contraction. This process also requires calcium (Ca^{++}), which is released from the sarcoplasmic reticulum. There is a protein called tropomyosin that prevents myosin from binding actin when muscle contraction is not needed. Tropomyosin exists on top of actin filament and has a regulatory protein called Troponin C. When an action potential generated by a motor unit arrives at the muscle, calcium is released from the sarcoplasmic reticulum and binds to troponin C. This "unlocks" tropomyosin from actin, allowing the myosin head to bind actin for the initiation of muscle contraction.

MUSCLE FIBERS

Skeletal muscle has three kinds of muscle fibers: slow twitch/red/oxidative muscle fibers also called Type I and fast twitch/white/glycolytic muscle fibers divided in two subgroups called Type IIa and IIb. Muscle fiber contraction obeys a sequential recruitment pattern where Type I muscle fibers are the first ones to be recruited, followed by Type IIa and finally Type IIb [3–5]. Each muscle fiber has different biochemical properties and behavior during exercise. The knowledge of the histological properties of these muscle fibers has been crucial to understanding muscle physiology.

Type I Muscle Fibers

These muscle fibers are also called slow twitch, slow oxidative, and red fibers. They have a high mitochondrial density and oxidative enzymes. Of all the muscle fibers, Type I's have the highest capacity to oxidize free fatty acids (FFAs) from subcutaneous adipose tissue and intramuscular triglycerides (IMTGs). They have the slowest contraction time of all fibers as well as the lowest force production. However, they have the highest resistance to fatigue. These muscle fibers are suited to endurance events and endurance athletes have the highest proportion of these muscle fibers.

Type IIa Muscle Fibers

Also called fast oxidative glycolytic or fast red, Type IIa muscle fibers have a high glycolytic capacity and somehow a good or intermediate oxidative capacity, although the latter is not as much as in Type I muscle fibers. Mitochondrial density is also considerably less than Type I fibers. Fat oxidation is less than in Type I muscle fibers and glucose oxidation is higher. Contraction time is fast, force production is high, and resistance to fatigue is intermediate. Type IIa muscle fibers are crucial for most athletes and sports, including endurance sports, as although the endurance aspect is very important, almost all competitions are decided at high intensities and therefore in the glycolytic state where these muscle fibers are the major players.

Type IIb Muscle Fibers

Finally, these muscle fibers, also called fast glycolytic or fast white, have the fastest contraction time of all fibers as well as the highest contraction force. Mitochondrial density is quite poor in these muscle fibers; therefore, lypolysis and aerobic glycolysis will be very low. The anaerobic component through anaerobic glycolysis and stored phosphocreatine (PC) and ATP of these muscle fibers is the dominant metabolic pathway. Type IIb muscle fibers are very important in athletic events of very short duration and very high intensity such as sprinting or 400 m.

BASIC EXERCISE BIOENERGETICS

The capacity of an athlete to exercise ultimately depends on the ability to transform chemical energy into mechanical energy. For this, skeletal muscle needs to synthesize ATP for muscle contraction. ATP is a nucleotide responsible for the energy processes in human cells. It is often called the "molecular unit of currency" for the cells. ATP is indispensable for muscle contraction so ATP needs to be synthesized constantly during exercise. ATP generation is achieved by two mechanisms: anaerobic and aerobic metabolism and through fats and CHOs mainly, with some contribution from amino acids. Fats and CHO are stored in skeletal muscle and in the case of fat it is stored primarily in the adipose tissue but also in skeletal muscle and in the liver. Each energy system and substrate will be activated depending on the metabolic and physiological stress, contractile necessities for ATP generation of the muscle (exercise intensity), and the fiber recruitment pattern. The process of ATP generation and activation of different energy process for muscle contraction is a complex mechanism that needs the regulation and coordination of different systems including the cardiovascular, respiratory, nervous, and endocrine systems, which ultimately will elicit different actions on skeletal muscle and its muscle fibers where all the of different physiological systems come into action in the cytosol and mitochondria of these muscle fibers. A large majority and range of exercise intensities can generate ATP through aerobic metabolism also called oxidative phosphorylation. Fat and CHO generate ATP during aerobic exercise. Depending on the level of fitness of an individual, fat can sustain the biggest part of ATP generation aerobically up to 55%–75% of VO_{2max} intensity, although CHO is also used at small rates during low and moderate exercise intensities. Beyond this point, ATP generation needs to be faster in order

to keep up with a higher frequency and power in muscle contraction and CHO will become the major energy used by skeletal muscle up to 100% of VO_{2max}. When exercise intensities are very high and maximal or close to maximal and therefore above 100% of VO_{2max}, ATP cannot be generated by the aerobic mechanism so the ATP needs to be generated through the anaerobic mechanism also called substrate phosphorylation.

ANAEROBIC METABOLISM DURING EXERCISE

At exercise intensities of 100% of VO_{2max} and more, ATP cannot be synthesized through aerobic mechanisms so anaerobic metabolism is necessary for its regeneration. Anaerobic metabolism has a very high rate of ATP synthesis. In skeletal muscle there is always a small amount of stored ATP ready to provide energy to muscle fibers. ATP is hydrolyzed (broken down) to ADP to produce energy for muscle contraction by an enzyme called ATPase in the myosin head of myofibrils. The human body has a remarkable capacity to restore ATP storage and production under any circumstance. The main sources for anaerobic ATP synthesis are PC and the anaerobic glycolysis. These two sources together can generate ATP up to six times higher than aerobic metabolism.

CP is a high energy compound that is stored in muscles about five to six times more than ATP. When ATP is hydrolyzed, ADP is produced and then binds CP to regenerate ATP (Fig):

$$\text{Creatine phosphate} + \text{ADP} + \text{H}^+ \underset{\text{Creatine kinase}}{\rightleftharpoons} \text{ATP} + \text{creatine}$$

Thus, anaerobic metabolism has a very high and fast rate of ATP synthesis, but it can only be maintained for very short periods of time (seconds to 1–3 min) due to PC depletion and accumulation of by-products from anaerobic metabolism, which interfere with muscle contraction.

Anaerobic glycolysis is the third source for anaerobic ATP synthesis. The amount of ATP yield by anaerobic glycolysis is 3 mmol of ATP per each mmol of glucose derived from glycogen as opposed to 38–39 mmol of ATP from aerobic CHO metabolism. However, the rate of ATP synthesis through anaerobic metabolism is about two times faster than the aerobic metabolism. In skeletal muscle most of the anaerobic CHO comes from glycogen stored in the muscles. Glycogen cannot be used for energy purposes so it needs to be broken down to glucose. This process is called glycogenolysis and it is larger in Type II muscle fibers that have more glycogen content and glycolytic enzymes than Type I muscle fibers. The process of glucose oxidation to obtain ATP is called glycolysis. The end product of glycolysis is pyruvate, which enters the citric acid cycle to further produce aerobic ATP. As described earlier, the aerobic metabolism of CHO produces 38–39 ATPs when anaerobic glycolysis produces 2 ATP although faster than aerobic metabolism. For many years it has been thought that lactate was the end product of anaerobic glycolysis. In fact, the anaerobic versus aerobic glycolysis has been a source of great debate and, probably, misunderstanding for many years. Important scientists like Louis Pasteur and AV Hill described the terms of aerobic and anaerobic a long time ago. It was observed that when glycolysis happened in the presence of oxygen, there was no lactic acid formation so pyruvate would be finally oxidized in the mitochondria for ATP production. It was also observed that when glycolysis happened without oxygen, there was lactic acid formation which led to the conclusion that lactate production was anaerobic [6,7]. However, and thanks to most of the work that Dr. George Brooks has conducted during the last 30 years, we know that lactic acid formation can perfectly occur under plenty of aerobic conditions and that lactic acid formation is more a result of excessive glycolytic flux in the cytosol. In fact, glycolysis per se (before pyruvate oxidation) is a process occurring in the cytosol, so no O_2 is required. The term anaerobic is probably an archaic term. When exercise is very intense, Type II muscle fibers are fully recruited as the contractile velocity and power requires it. Type II muscle fibers are highly glycolytic, which alone with a high adrenergic activation will elicit a high glycogenolitic response, resulting in a very high glycolytic flux in the cytosol and a large amount of pyruvate formation. In order to complete pyruvate oxidation in the mitochondria, it needs to be converted to acetyl-CoA (coenzyme A). This process is performed by an enzyme called pyruvate dehydrogenase (PDH), which saturates quickly when pyruvate formation is very elevated and cannot handle with all the pyruvate being formed when there is a very high rate of glycolysis like that observed in high exercise intensities. When this situation happens, pyruvate is reduced to lactate by an enzyme called lactate dehydrogenase (LDH). The provision of ATP by this process is faster but not necessarily anaerobic as this can perfectly happen under fully aerobic conditions. Thus, although the terms anaerobic and aerobic glycolysis are still widely used, it would probably be more appropriate to use the terms fast or slow glycolysis.

AEROBIC METABOLISM DURING EXERCISE

As described earlier, any provision of energy in the muscle at intensities below 100% of VO_{2max} is achieved through aerobic means (with oxygen), also called oxidative phosphorylation. CHO, fats, and protein are oxidized this way in order to generate ATP for muscle contraction.

CARBOHYDRATE METABOLISM DURING EXERCISE

CHO metabolism is of great importance during exercise, especially during high exercise intensity where it is the predominant energy substrate for skeletal muscle. Glycogen is the storage form of glucose and CHOs in animals and humans. CHOs are a very limited source of energy accounting for only about 1%–2% of total bodily energy stores [8]. Furthermore, about 80% of total CHO is stored in skeletal muscle; about 14% is stored in the liver and about 6% in blood in the form of glucose, so this would represent

about 300–400 g of glycogen stored in muscle and about 70–100 g stored in the liver [9,10]. Glycogen cannot be utilized for energy purposes by muscle, so it needs to be broken down to glucose 1-phosphate by the enzyme phosphorylase, which is the process called glycogenolysis. The process of glucose utilization is called glycolysis, which accounts for 15%–20% of peripheral glucose utilization in skeletal muscle at rest. At an exercise intensity of 55%–60% VO_{2max}, glucose utilization by skeletal muscle increases to about 80%–85% of whole-body disposal [11]. Thus, muscle glycogen is crucial for ATP synthesis during exercise. Proper glycogen storages are of great importance for athletic performance. Multiple studies show that fatigue and decrease in performance are often associated with glycogen depletion and that athletes who have low CHO diets or low glycogen storages will suffer a decrease in exercise capacity [12–18] as well as an increase in risk for overtraining [9,10,19]. McArdle's disease patients lack phosphorylase enzyme, impairing glycogen utilization and thus drastically decreasing athletic performance [20].

The rate of ATP synthesis is parallel to the exercise intensity. Glycolysis occurs mainly in the cytosol and this process can be aerobic through the complete oxidation of pyruvate (oxidative phosphorylation in the mitochondria) or anaerobic (substrate phosphorylation in the cytosol). Exercise intensity determines the substrate demands of skeletal muscle to generate ATP. During exercise, skeletal muscles use primarily fat and CHO for energy purposes, and at low exercise intensities, fat is the preferred substrate although there is always some glucose oxidation. At higher exercise intensities of about 50%–60% of VO_{2max}, ATP synthesis demand increases and fat cannot entirely meet the rate of ATP synthesis so glucose oxidation increases. Furthermore, at higher exercise intensities, fat cannot synthesize ATP fast enough for the contractile demands of skeletal muscle fibers. Although the oxidation of fat yields a much higher amount of ATP, glucose utilization is much faster, therefore necessary for ATP synthesis.

Exercise intensity is the main regulator for skeletal muscle CHO utilization and the mechanisms responsible for CHO utilization during exercise involve hormonal and local factors as well as glycogen availability. Epinephrine (adrenaline) is the main hormone involved in CHO metabolism during exercise. B-adrenergic activity increases with exercise intensity. Phosphorylase is the enzyme responsible for glycogen breakdown to glucose and it is regulated by epinephrine. The release of epinephrine from the adrenal medulla is directly proportional to exercise intensity. Epinephrine stimulates muscle glycogenolysis by increasing phosphorylase activity; thus, it is a major regulator of CHO metabolism during exercise. Availability of FFAs during exercise is also closely regulated by epinephrine. During high exercise intensities, epinephrine reduces the blood flow to adipose tissue, eliciting a constricting effect on adipose tissue, thereby reducing plasma FFA availability to the muscles during high intensity exercise [21,22]. Local factors regulating CHO utilization during exercise involve the activation of phosphorylase by an increase in cytosolic calcium during excitation–contraction coupling [23]. Muscle contraction also stimulates sarcolemmal translocation of glucose transporters, GLUT4 isoform, which makes glucose uptake by muscle non-insulin dependent during exercise. The muscle fiber composition and activation patterns play an important role as well. During high exercise intensities, contraction time is lower, shortening velocity is higher, and power production is higher as well, so Type II muscle fibers are recruited at these exercise intensities [5]. Since Type II muscle fibers have a higher glycogenolyic capacity and lower mitochondrial density, glucose utilization in these fibers will prevail over fat.

Exercise duration also plays an important role in CHO metabolism during exercise. Since glycogen storage capacity is about 500 g in muscle and liver, the length of the exercise activity will be very important for the regulation of CHO metabolism. Glucose uptake in skeletal muscle is dependent on glycogen content [24] and hypoglycemia during exercise can be prevented by the sufficient intake of CHO [25]. Exercise duration is intimately related to glycogen storages as low glycogen storages during endurance events are associated with hypoglycemia, fatigue, and decrease of performance [12–18].

LIPID METABOLISM DURING EXERCISE

Lipids are a very important energy source during endurance exercise. Although ATP generation for muscle contraction from lipids is slower than that from CHO sources, the amount of ATP produced by lipids is far higher than that from CHO, which makes lipids the fuel of choice by skeletal muscle during endurance exercise and will spare glycogen. The main source for lipid metabolism is subcutaneous tissue. Even the leanest athletes have more than 100,000 kcal of potential energy in their adipose tissue. Lipid metabolism during exercise is a highly coordinated and integrated process starting at the adipose tissue and ending at the mitochondria in skeletal muscle. This process involves mobilization or breakdown of adipose tissue, circulation from adipose tissue to skeletal muscle, uptake, and final mitochondrial oxidation in skeletal muscle. Lipolysis is the first step in lipid metabolism and it is the breakdown of adipose tissue as well as IMTG. Triglycerides in the adipose tissue and muscle are broken down into FFAs and glycerol by hormone-sensitive lipase (HSL). Hormonal control of lypolysis is tightly regulated by several hormones, especially catecholamines (epinephrine and norepinephrine), which are probably the major hormones regulating lipolysis. Catecholamines bind to both β-adrenergic and α_2-adrenergic receptors on the fat cell (adipocyte) membrane. This activates a cascade of cellular signals which starts by the activation of adenylate cyclase (AC) which increases cyclic adenosine monophosphate (cAMP) which activates cAMP-dependent protein kinase which ultimately phosphorylates HSL which finally elicits lipolysis. At rest, low level of plasma catecholamines bind to α_2 receptors, eliciting an inhibitory effect

on lypolysis, while during exercise, plasma catecholamines increase and stimulate β-adrenergic receptors, stimulating lypolysis [26]. However, during very high exercise intensities, catecholamines have an inhibitory effect on lypolysis probably by causing a constriction in capillarization and blood flow to adipose tissue [21,22] and eliciting potent glycogenolytic effects. Although there seem to be different catecholamine thresholds for both lipolysis and glycogenolysis [27], the exact mechanisms and catecholamine concentrations to elicit either lipolytic or glycogenolytic effects are not entirely understood.

Insulin also regulates lipolysis, although its effects during exercise are not as profound as when at rest or as powerful as catecholamines during exercise. At rest, insulin inhibits lipolysis [28–30], but during exercise insulin secretion decreases, allowing higher lipolytic activity [31].

Upon adipose tissue lipolysis, FFA must be transported to skeletal muscle. Adipose tissue blood flow (ATBF) is of great importance for FFA circulation as it delivers catecholamines to adipose tissue for lipolysis as well as albumin to transport FFA to skeletal muscle where the uptake of FFA is mediated by a sarcolemma, specific receptor, sarcolemmal fatty acid binding protein (S-FABP), which together with another FABP facilitates the transport of fatty acids throughout the cell for beta oxidation and generation of acetyl-CoA for TCA oxidation. Once in the cytosol, FFA needs to be activated to fatty acyl-CoA ester. FFA is attached to CoA, which forms fatty acyl-CoA, which then is transported across the outer mitochondrial membrane by carnitine-palmitoyl transferase I (CPT-I), and finally transported to the mitochondrial matrix by carnitine. Once inside the mitochondrial matrix, fatty acids undergo β-oxidation where fatty acyl-CoA is degraded to acetyl-CoA, which can then enter the citric acid cycle. During this process, NADH and $FADH_2$ are generated for ATP production through the electron transport chain.

Skeletal muscle also contains small lipid droplets called IMTGs, which are stored in the cytoplasm of skeletal muscle cells close to the mitochondria. Depending on different circumstances such as endurance exercise and low glycogen content, IMTG can play an important role in the contribution to lipid metabolism during exercise [32], which depending on the exercise duration and glycogen availability, can contribute to a great extent to lipid metabolism during exercise.

PROTEIN METABOLISM

Although not considered a major contributor to energy during exercise, the metabolism of proteins during exercise can be important, especially depending on the exercise intensity, type, duration, and nutritional status of the athlete. Proteins are made up of amino acids and there are over 20 amino acids divided in two groups: nonessential, which are those that can be synthesized in the body, and essential, those ones that need to be obtained from the diet. Amino acid metabolism is a sum of very complex and different mechanisms whose explanation goes beyond the nature of this chapter. Amino acids are basically characterized by having an amino group $(-NH_3^+)$ as part of their chemical structure. Before amino acids can be used in the body, the nitrogen group from the amino acid must be removed by two processes: oxidative deamination and transamination. Oxidative deamination is a reversible mitochondrial reaction triggered by glutamate dehydrogenase on the mitochondrial matrix and involves and generates intermediates for the TCA cycle as well as NADH for ATP production through the electron chain transport. The other process involved in amino acid metabolism is transamination, which transfers the amine group from an amino acid to a keto acid of the same amino acid. This reaction is achieved by a type of enzymes called transaminases. Glutamate-pyruvate transaminase (GPT/ALT), involved in alanine metabolism, and glutamate-oxaloacetate (GOT/AST), involved in aspartate metabolism, are two major transaminases in the body. Both of these reactions involve the production of α-ketoglutarate, an important intermediate for the TCA cycle. Carbon skeletons of amino acids are used to generate energy via different mechanisms, and depending on the final fate of these carbon skeletons, amino acids are grouped in glucogenic amino acids and ketogenic acids. Glucogenic amino acids degrade their carbon skeletons to pyruvate or TCA intermediates as a precursor for gluconeogenesis. Ketogenic amino acids cannot be converted to glucose but can be degraded to acetyl-CoA or acetoacetate and be used for energy production through the TCA cycle or converted to ketone bodies or fatty acids.

There are several amino acids that play an active role during exercise activity. Amino acids may provide between 3% and 10% of the total energy during exercise, depending on exercise intensity and duration [33–37]. These percentages may not be very high but may play a very important role in exercise performance. In exercises when glycogen levels are low the contributions to energy by amino acids will be greater [38]. Alanine is an important glucogenic amino acid, especially during endurance exercise and it is synthesized in the muscle and then exported to the liver to be converted to glucose through what is called the glucose-alamine cycle [33]. Branched-chain amino acids (BCAA) may also play an important part during exercise. Leucine, isoleucine, and valine make up the BCAA. Leucine is a ketogenic amino acid, isoleucine is both ketogenic and glucogenic, whereas valine is a glucogenic amino acid. BCAA seem to be the kind of amino acids most used by the muscle during exercise. Since these amino acids are building blocks of the muscle, an excessive utilization, as what happens during intense and long exercise, along with decreased glycogen content may lead to an excessive muscle breakdown and a catabolic situation for the muscles, which causes muscle damage and would be detrimental for performance. Therefore, a BCAA supplementation during endurance exercise may have some sparing effects on endogenous muscle BCAA utilization and, therefore, decrease the possibilities of muscle damage [39].

In general, amino acid metabolism, although accounting for a small percentage of total ATP synthesis during exercise, may play an important role in the intermediate metabolism and performance as well as recovery after training/competition.

LACTATE METABOLISM

Lactate is the by-product of the utilization of glucose (glycolysis). During glycolysis, lactic acid is formed, and under normal physiological pH, it rapidly dissociates to lactate and a hydrogen ion (H^+). It was for a long time believed to be just a waste product and the result of anaerobic glycolysis as a result of lack of O_2 [6,7,40]. However, the work done by some researchers at the end of the twentieth century, especially by Dr. George Brooks, showed that lactate production is not only the natural by-product of glycolysis but also a very important metabolite and regulator of the intermediate metabolism and even could be considered a "lactormone" due to its hormone-like properties [41–43]. During high intensity exercises (those typical of competition) ATP generation demands increase and glucose becomes the predominant muscle substrate for ATP generation. The higher the glucose flux into the cell, the higher the lactate production. As a matter of fact, lactate production is necessary for the continuation of glycolysis.

Lactate has two key functions in glycolysis. The first one is the equilibrium of the cytoplasmic redox status (NADH/NAD^+). During anaerobic glycolysis or excess glycolytic flux, pyruvate is reduced by LDH to lactate plus NAD^+ (nicotinamide adenine dinucleotide), which restores cytoplasmic NAD^+ for the continuation of the oxidation of glyceraldehyde 3-phosphate to 1,3-biphosphoglycerate, so during these circumstances, lactate is a key player for the continuation of glycolysis. The second important function of lactate is to release the saturation of the enzyme PDH. When the rate of pyruvate formation due to excessive glycolytic flux exceeds the rate of oxidation by the enzyme PDH lactate is then formed [44–46]. Pyruvate then will be reduced to lactate by LDH whose equilibrium constant (K_{eq}) favors lactate over pyruvate; therefore, small increases in pyruvate concentration will result in increases in lactate concentration during higher exercise intensities when glycolytic flux elicits a high production of pyruvate that exceeds the oxidative activity of PDH [46].

During intense exercise, lactate production is many times higher than that of resting levels and the equimolar release of H^+ can cause, in spite of a cellular important buffer capacity mediated by bicarbonate (HCO_3^-), an important reduction of muscle pH of 0.4–0.5 or 0.8–0.9 points as it has been observed [47–49]. This excessive accumulation of H^+, not only from lactate but also from ATP hydrolysis due to muscle contraction and calcium reuptake in the sarcoplasmic reticulum, may decrease muscle pH and can cause an important decrease in peak twitch force, a decrease in ATPase per active myosin head during contraction, and a decrease in maximum shortening velocity [50,51]. On the other hand, it is also possible that H^+ competes with Ca^{++} for troponin C binding site interfering with muscle contraction [48,51,52]. It is also possible that H^+ inhibits calcium release from sarcoplasmic reticulum [51,53] as well as may decrease the reuptake of Ca^{++} in the sarcoplasmic reticulum [51,52,54].

Recently, several authors have suggested that lactate is not involved in muscle acidosis associated with high intensity exercise and that, in fact, lactate delays and buffers acidosis, acting as a protective mechanism for muscle contraction [54]. According to this hypothesis, those athletes producing the most lactate would have an advantage during the competition. So the debate is open as to whether lactate is involved in muscle acidosis or assists in acidosis buffering. Whether one or the other is true would still need to be fully elucidated. The fact is that lactate is an excellent biomarker for muscle metabolic stress. What we also know today is that the better the competitive level of an endurance athlete and the better trained that athlete is, the less is the lactate accumulation that is observed [55–61], which is due to an enhanced lactate clearance capacity [43]. According to San Millán et al., world-class professional cyclists accumulate less blood lactate than the rest of their professional peers who at the same time accumulate less blood lactate than the amateur cyclists who accumulate less lactate than the juniors. These data clearly show that the better the performance level of a cyclist, the lower the blood lactate concentration at the same relative exercise intensity [62].

Lactate testing is probably the best method that we have to predict performance in endurance events [63,64], it is probably the parameter that discriminates the most between different levels of athletic performance [62] and it can also be a very good parameter to prescribe exercise training zones and training programs for athletes [64,65]. Lactate analysis can give us a lot of information on muscle metabolism during exercise where we can indirectly assess mitochondria density and oxidative enzyme function, substrate utilization or muscle fiber recruitment patterns. Lactate clearance capacity is of great importance for competitive athletes.

TRAINING ADAPTATIONS TO EXERCISE

The physiological adaptations to training are very important and can elicit profound improvements in athletic performance. The main goal of all these adaptations is to increase the body's efficiency during exercise. The body improves many physiological functions and metabolic pathways in order to become more efficient. The main adaptations to training result in the improved efficiency of both central (cardiorespiratory adaptations) and local responses (skeletal muscle structure and metabolism) to exercise.

Central Adaptations to Exercise

One of the main adaptations of training is an increased O_2 delivery to the muscles. This increased O_2 capacity is the result of a coordinated response and improvement of different cardiorespiratory functions (heart, lungs, and blood vessels). An increase in cardiac output (CO) is one of the principal cardiorespiratory respiratory adaptations and elicits an increased delivery of O_2 to the skeletal muscle. CO is the product of heart rate times the stroke volume, and an increase in stroke volume is the main contributor for an increase in CO, which will ultimately increase VO_{2max}. An increase in capillarization to the contracting muscles is another major

adaptation to training. Muscles increase the capillarization and therefore their blood supply during exercise. Other cardiorespiratory adaptations to exercise pertain to blood flow redistribution from tissues that don't need much blood during exercise so that contractile skeletal muscle can have an increased blood flow supply. Decreased blood flow to the kidneys and other viscera, spleen vasoconstriction, as well as increased blood flow to the coronary arteries and skeletal muscles are the main blood flow redistribution adaptations to exercise. An increase in blood flow to the skin is a very common adaptation as well in order to improve the capacity to dissipate heat.

Local Adaptations to Exercise

We know a lot more about cellular metabolism during exercise and the local adaptations are for the most part the most important adaptations as a result of training. These local adaptations to exercise training happen at the skeletal muscle level with structural changes and arrangements and elicit important changes in mitochondrial density and oxidative and glycolytic enzymes eliciting profound changes in substrate utilization during exercise.

Skeletal Muscle Fiber Changes

Muscle fibers can change the histological and biochemical characteristics toward more oxidative behavior due to training, which will increase fatty acid oxidation and increase lactate oxidation to pyruvate. Highly glycolytic muscle fibers acquire biochemical behaviors more typical of oxidative muscle fiber by increasing the content of oxidative enzymes and mitochondrial density as observed in different studies [4,66–70].

Type IIb muscle fibers can behave more like Type IIa's and the latter ones more like a Type I, improving their oxidative capacity.

Adaptations to Training at the Cellular Level and Substrate Utilization

There are important adaptations to training at the cellular level as well as in fat and CHO metabolism. After training, glycolytic flux is decreased at same relative intensities. There is a decrease in glycogenolysis and therefore a reduction of energy requirements derived from glucose. This observation was already discussed by Christensen and Hansen [71], and with the progress of science, it has been shown in numerous studies that glucose utilization, and thus the glycolytic flux, decreases with endurance training [12,57,72–77] and even can be higher in well-trained athletes at higher exercise intensities where blood lactate accumulation will still be lower due to a higher lactate oxidation [55,61]. An enhanced glycolytic capacity at high exercise intensities would ensure a higher level of performance of an athlete at those intensities.

Mitochondrial density and oxidative enzymes can largely increase with training, which will have an important impact on fat utilization. Endurance training can double the mitochondrial capacity to oxidize FFA and pyruvate [66,67,76,78,79]. Increases of up to 60% in mitochondrial content have been observed [66,80] as well as important increases in the activity of oxidative enzyme citrate synthase [81,82].

One of the most important adaptations observed in athletes is the decrease in blood lactate levels observed after training as well as lower glucose utilization and higher fat utilization, respectively. The increase in mitochondrial density increases the oxidation of cytosolic pyruvate via PDH and the intracellular lactate system through which will increase lactate clearance capacity through an increase in mitochondrial lactate dehydrogenase (mLDH) [45,83]. LDH is involved in the reversible reaction of oxidation of lactate to pyruvate and reduction of pyruvate to lactate. LDH-M isoform is more prone to a reduction of pyruvate to lactate where the LDH-H isoform is more prone to oxidation of lactate to pyruvate. Endurance training decreases LDH-M, so less lactate production will result [84,85], and increases LDH-H isoform.

Endurance training also has a great impact on specific lactate transporters called metacarboxylates (MCTs) that facilitate lactate transport in and out of the muscle cell. There are two major isoforms of MCTs in skeletal muscle. MCT1 are highly expressed in oxidative muscle fibers (Type 1) and involved in lactate transport inside the cell and into the mitochondria for later oxidation. Endurance training increases MCT 1 expression [85,86] which would result in a higher lactate clearance capacity. MCT 4 isoforms are expressed mainly in glycolytic fibers and are involved in lactate transport out of the cell from glycolytic fibers to more oxidative fibers and increases with endurance training [43,85–87], increasing lactate clearance capacity by facilitating lactate transport to oxidative cells.

PHYSIOLOGICAL TESTING AND MONITORING OF THE ATHLETE

All the knowledge described earlier is of little use if we don't correctly apply it to athletes. Unfortunately, many times the impressive work and knowledge of brilliant researches stay in a scientific journal as they are either not applied or incorrectly applied to the athletes who could really get an advantage to optimize their performance, whatever the level of performance is. When the scientific approach is not applied, "urban legends" grow where athletes train based on misleading information or many times just "by the feeling." In today's society, most fields are based on scientific research and evidence but, in general, many athletes lack that scientific approach to training and preparation despite using the most advanced equipment. The fastest bicycle, running shoes, or skies represent just a minimal ("marginal") gain when it comes to performance and in most situations not even that, as most athletes nowadays have the same access to the same fast, top equipment … so those marginal gains could represent zero or no gain. However, and despite spending thousands

of dollars in those "marginal gains" through using the best equipment, many athletes never find out how they can optimize their performance by training better and smarter or using their heart rate monitor more efficiently or eating properly. This kind of gains and improvements in performance regardless of the level of activity are far larger and more important than the "marginal gains," and the proper application of the scientific approach can result in dramatic improvements and optimization of performance.

THE SCIENTIFIC APPROACH

Science is derived from the Latin word "Scientia," which means knowledge, so the scientific approach should always be applied. There are many effectors of athletic performance (Fig-); a thorough evaluation of these effectors should be performed and for this, the knowledge of the physiological parameters of the athlete is essential in order to obtain maximum optimization of performance. An integrative approach in exercise physiology should be able to control different effectors of performance such as physiological parameters, training, monitoring, and nutrition.

PHYSIOLOGICAL TESTING: COACHING 101

The only way where athletes engaged in any sports and activity level can have a customized, individual training program is by knowing how their bodies respond to exercise. Therefore, performing a physiological test in order to know the many different parameters that can be improved and then design the right training and individual training program should be the first step before starting a training program or working with a coach. We live in the Internet era where many athletes hire coaching services from "cybercoaches" who most of the times just email "copy and paste" training programs without either knowing the athlete in person or knowing his or her physiological parameters in order to prescribe an individual training program. The "cyberspace-prescribed" coaching service could be quite detrimental for performance as for the most part it is just a "hit and miss" service missing the most basic information on an athlete's physiology or "engine" whatever the level of competition could be. Many times coaches tend to prescribe generalized training programs and routines using training zones, intensities, and durations based on generalized formulas and standard training programs. However, in order to optimize performance, it is necessary to individualize training programs as much as possible. In order to achieve this, it is essential to obtain the knowledge of the individual physiological and metabolic parameters of each athlete through physiological testing.

The best coaches in the world are characterized by their strict methodologies and scientific application when it comes to coaching as well as preparation and for this they know very well that knowing an athlete's physiological parameters and responses to exercise permits them to prescribe the most adequate, individual, and correct training program in order to maximize performance. So for the best coaches, physiological testing in the field and in exercise laboratories is a constant partner and ally when it comes to improving the performance of their athletes. In the United States, there are many exercise laboratories in universities and sports medicine clinics opening their doors not only to elite athletes but also to recreational ones. Unfortunately, many recreational athletes are not aware of this or may think that physiological testing only pertains to the elite/professional athlete. The fact is that whether an athlete wants to run a marathon for the first time, improve the PR in a triathlon competition, or win the Tour de France, the optimization of performance should start by performing physiological testing in order to have an adequate, individualized, and optimized training.

There are several important parameters that can be obtained through physiological testing:

- VO_{2max}
- Lactate metabolism
- Fat metabolism
- CHO metabolism
- Metabolic efficiency
- Power
- Speed
- Strength

The measurement of all these parameters puts into application all the knowledge, as described in the first part of this chapter, of the individual physiological and metabolic responses to exercise of an athlete. A professional exercise physiologist should be able to measure in the exercise physiology laboratory most or all of the parameters that have been presented in the first part of this chapter in order to provide the best information such as individual training zones in order to prescribe the most adequate training program for an athlete or working in conjunction with coaches to provide them with individual physiological information of their athletes so that they (coaches) can work better with their athletes and with more scientific information.

Physiological Testing in Laboratory and Field Tests

Physiological testing can be performed in the laboratory as well as in the field. The majority of universities and sports medicine clinics have nowadays very well-equipped laboratories run by professional exercise physiologists, opening the doors to the community and recreational athletes, so athletes of any level should not be shy to go to an exercise laboratory in order to get tested. There are two possibilities of physiological testing: laboratory tests and field tests. A physiological test in a laboratory is probably the best way to measure physiological parameters.

LABORATORY TESTS

As the name indicates, they are physiological tests performed in the laboratory. The great advantage of performing a test in the laboratory is that the environmental conditions are always controlled and always the same, so an athlete can repeat the

test later on in the year or the following year to measure the progress and improvement and maybe change or tweak the training zones prescribed and yet be sure that the environmental conditions are identical. Another important aspect is that exercise physiology laboratories use very delicate and many times big and heavy equipment to measure different metabolic and physiological parameters and the portability outside the lab can very difficult sometimes.

FIELD TESTS

Field tests have the advantage of being performed on the same ground where competition or physical activity happens. This way it is possible to reproduce very similar performing conditions for an athlete. The main disadvantage of field tests is that repeatability is not possible when tests are done outdoors as the environmental conditions cannot be replicated as in the laboratory and these environmental conditions (wind, rain, heat, cold, etc.) would affect the results of the tests. The other disadvantage of field tests is that heavy and delicate laboratory equipment cannot be used or transported outside the laboratory, so we can lose valuable physiological and valuable data. There is some portable equipment such as small handheld lactate analyzers but these may not be very accurate when compared to laboratory analyzers and, therefore, we may be losing precision and therefore accurate information, which can be crucial in order to establish training zones and individualized training programs. All in all, field testing is quite useful to complement and confirm, in real athletic event conditions, the data obtained in the laboratory.

In summary, physiological testing is of great importance for any athlete regardless of the sport and the level of competition in order to measure physiological and metabolic responses to exercise to assess performance potential but mostly important to prescribe an individualized training program to optimize performance.

MONITORING OF THE ATHLETE

Over the years, many books and articles have been written regarding different training methodologies. Although the many different training methodologies, theories, applications, and results are beyond the scope of this chapter, it seems that as per what we can read from the literature on training, most training methodologies seem to work. There is a general assumption among many athletes and coaches that training per se will always improve performance. In team sports, there is a general assumption that form improves during the season when the reality is that many times athletes and teams deteriorate during the season and they tend to "take a dive" toward the end of their competition year. The fact is that even at the highest level of competition, little is done, in general, to monitor athletes to make sure they are assimilating training and competition in order to avoid overtraining and fatigue. As an example, the majority of professional teams monitor every single ticket they sell, every single t-shirt they sell, and even every single soda or popcorn they sell. However, many teams of professional sports don't monitor the most important part of the entire show—the engine of their players. Strenuous competition throughout the season elicits important physiological and metabolic stress on players' bodies, and the evaluation of how well or how bad they are dealing with recovery from training and competition should be critical in order to improve or at least preserve performance throughout the season and avoid overtraining that could have catastrophic consequences for the performance of the team and therefore important negative economical consequences. From the individual standpoint, individual athletes also need to monitor how well they assimilate training and, if it applies, competition. Most recreational athletes have evolved to competitive athletes and they have real 40 h/week jobs, traveling, families, etc. and they are at a high risk of overtraining. Many of them are often tired and fatigued and most think that it is a normal state of being an athlete or they may think that they just need to toughen up and shake off that fatigue and tiredness when the fact is that they may be quite overtrained and they don't even know.

This part of the chapter will deal with the scientific approach to monitor the physiological status of an athlete in order to prevent or at least detect overtraining situations. Several methodologies are of great importance and value for many athletes, coaches, physiologists, and physicians.

Physiological Testing for Monitoring Purposes

Through physiological testing throughout the season, it is possible to identify and quantify the improvement in physiological parameters and therefore performance or athletic form. There are many training methodologies but none of them are an exact science so it is possible that the training methodology that works best for one athlete may be detrimental for another as it may cause too much training overload. The best way to quantify how much an athlete is improving or deteriorating throughout the season is to perform physiological testing on athletes throughout the season. Many times, if repeatability conditions permit, field tests at their training facilities may work so they can avoid several visits to the laboratory. Top coaches of both individual and team sports find this physiological testing very useful in order to identify the elements that are going wrong and interfering with performance and then have the possibility to correct them in order to restore performance. In team sports, many head coaches need to improve the vision of monitoring their athletes, as many don't know what it is. Ironically, in many cases, this turns against them when they are fired after the performance of the team has plummeted in the second half of the season as there is no monitoring of their athletes and nobody is able to identify that players are fatigued and overtrained. Therefore, blame will be put on the head coach for technical/tactical underperformance of the team when the reality could be that players are trying to execute the correct technical and tactical aspects directed by the head coach but they are just too fatigued and overtrained, and unfortunately this is completely undiagnosed in many situations. Individual or recreational athletes may be deteriorating and obtaining

very poor results. For example, it is not uncommon to see an athlete attempting his/her first marathon or triathlon quit the sport after a very hard time during the race or during training leading to the race. They may think that they are not good enough for the sport they like when the truth is that they were fatigued and overtrained and therefore could not perform at the desired level.

MONITORING FOR OVERTRAINING

Overtraining is a great unknown among athletes. Overtraining affects many athletes and many are not aware of the condition. There are a few definitions of overtraining, but we can define it as an accumulation of training and nontraining stress resulting in a decrement in performance capacity. Another term commonly used is overreaching, which is a form of short-term overtraining. Normally, overreaching or short-term overtraining is undetected by the athlete and becomes long-term or chronic overtraining, which interferes with performance.

CAUSES OF OVERTRAINING

There are different causes of overtraining, but the following is a list of the most common causes for overtraining.

Excessive Training

Many athletes train more than what they can assimilate. In many cases athletes, coaches, and trainers don't know how much training an athlete can assimilate. As explained earlier, physiological testing can identify and quantify the proper dose of training of an athlete, which can be very helpful to avoid overtraining due to excessive training.

Poor Recovery and Assimilation

There are two main principles of training: overload and supercompensation. The overload principle pertains to the training phase, which elicits a physiological stress on the body and many times a catabolic (destructive) effect. That overload on the body is followed by a supercompensation, which is the regeneration phase of the training where the body regenerates, supercompensates, and gets stronger so increases adaptation to training and results in an increase in form and performance. This is an anabolic (constructive) process that is achieved by proper recovery. Many times, the recovery component is absent or not enough to elicit a regeneration and supercompensation and eventually overtraining will strike. Professional and elite athletes are very prone to this misbalance between training and recovery. In many situations the physiological stress of training or competition is too much and recovery may not be that well adjusted so overtraining occurs. In recreational athletes, this is a very common way to get overtrained as many don't pay enough attention to recovery (or they can't). Many recreational athletes have full-time jobs with busy schedules, travel, stress, etc. and they may jump on the bike for 1:30 h at lunch time and right after that continue their workday, which may be too physical, intellectual, or both so recovery will be inadequate or sometimes absent, eventually resulting in an overtraining condition.

Improper Nutrition

Nutrition is a key part of the training regime of any athlete. Not ingesting enough amounts of calories (kcalories—kcal) can result in a lack of important macro- and micronutrients. This is especially true when it comes to CHOs. Modern societies tend to "demonize" CHO and there are multiple books and diets out there claiming that high protein and or high fat diets with important restriction of CHO are the appropriate way for an athlete to lose weight and have a healthy diet. However, most of these books and diets lack scientific evidence. This is especially true for athletes who restrict CHO as the massive amount of scientific evidence clearly shows that a good CHO diet is crucial to maintain performance. As previously discussed in this chapter, multiple studies show that fatigue and decrease in performance is associated with low CHO diets causing glycogen depletion [12–18] and how low glycogen levels may cause overtraining [9,10,19]. Since glycogen storage capacity is very limited, many high-performance athletes may find it difficult to even keep up with CHO intake and therefore have some patterns of glycogen depletion [88–90].

When glycogen levels are low or there is a glycogen depletion, the muscle increases the utilization of protein and amino acid utilization as a gluconeogenic precursor increases [37,38]. Since protein and amino acids are the building blocks of muscle, the latter one may enter a catabolic situation (muscle breakdown) as the muscle may "eat itself to feed itself" by increasing the amount of protein and amino acids used for energy purposes. This situation may lead to muscle damage and, furthermore, this may lead to chronic overtraining as it has been shown that muscle damage limits and interferes with glycogen storage and synthesis [91,92], so even with a high CHO diet, it would be difficult to maintain glycogen storages and therefore enter a vicious circle that may lead to overtraining and decrease in performance.

Psychological Stress

Athletes may experience two different kinds of psychological stress. Elite athletes typically develop a psychological stress derived from the high psychological and physiological demand of training and competition. Recreational athletes may develop a different kind of stress derived from their busy schedules from a full-time job and the difficulty to train around their schedules. Many may be the effects of stress on performance and although the physiological issues derived from psychological stress and how it affects performance are beyond the scope of this chapter, there are many studies linking different kinds of psychological stress with overtraining [93].

MONITORING OVERTRAINING: THE ANSWER IS IN THE BLOOD

There are many indirect parameters to assess overtraining [94–97], but they may not be very sensitive and are difficult to quantify and interpret. Examining direct biomarkers of overtraining from the blood is a very useful tool and weapon to prevent and detect overtraining. Overtraining can be also interpreted as a physiological aggression to the body and this "aggression" leaves traces in a similar way that several pathophysiological conditions do. Through blood analysis, monitoring of the athlete and the evaluation of several biomarkers make it possible to detect those traces and use them to detect and/or prevent overtraining. There are many different parameters in the blood indicators that can be used to monitor overtraining. Different hematological, biochemical, hormonal, and serological biomarkers can be found in the blood. To describe all these parameters we would need an entire chapter so this is a short review of the most common parameters and biomarkers used.

Hemoglobin

Hemoglobin (Hgb) is a protein existing inside red blood cells (erythrocytes) that carries oxygen (O_2). Each Hgb molecule is made up of four heme groups containing iron to which O_2 ultimately binds. In a way, red blood cells are the taxi for O_2, and Hgb is the seat where O_2 sits. Each gram (g) of Hgb transports 1.34 mL of O_2. So for a normal male with 15 g/dL of Hgb in the blood, he can transport 20.1 g/dL of O_2 in the blood. This is also called the oxygen-carrying capacity. Hgb is a sensitive parameter affected by overtraining and decreasing exercise performance [98–101]. Any decrease in Hgb in the blood would lead to a decrease in the O_2-carrying capacity. As an example, if a normal person with 15 g/dL of Hgb (20.1 g/dL of O_2 capacity) decreases the Hgb content to 14 g/dL, the O_2 capacity would theoretically decrease to 18.76 g/dL of O_2, which would represent close to a 7% decrease in the O_2-carrying capacity, which can have an important impact on athletic performance. It is also not very rare to see athletes decreasing their Hgb content, i.e., from 15 to 13 g/dL, which will represent a theoretical decrease in O_2 capacity of about 13%, which could have profound consequences for performance.

Biomarkers for Muscle Damage

Although Hgb content and O_2-carrying capacity may be appropriate in an athlete, there may be muscle damage associated to overtraining as discussed earlier, and by analyzing several biomarkers, it is possible to assess muscle damage. Excessive eccentric exercises, excessive intensity training and competition, or training and competing under low muscle glycogen content or even depletion state may lead to excessive muscle damage. When this happens, muscle fibers break down and their cellular content escapes to the blood where it can be analyzed for muscle damage assessment. This cellular content is mainly made up of enzymes and if muscle damage is more severe it can also involve some contractile proteins. There are different muscle enzymes that can be used for the assessment of muscle damage. Creatine kinase (CK) and LDH are the enzymes most used as biomarkers for muscle damage [2,99,102–107]. Other enzymes that can be altered are alanine aminotransferase (ALT/GPT) and aspartate aminotransferase (AST/GOT). A contractile protein, Troponin I is also used to evaluate muscle damage [108]. Several inflammation mediators like the cytokines [109] free radicals or more appropriate, reactive oxidative species (ROS) [110], and hormonal responses [111] are also used for muscle damage assessment.

In summary, blood analysis is a very helpful and scientific methodology to monitor overtraining and fatigue in athletes of all levels.

63 Evaluation of Acute Sports Injuries in the Adult Athlete

Rebecca Sjostrom, MD, Eric McCarty, MD, Jennifer FitzPatrick, MD, Amy K. MacDougall, MD, and Lucas Rylander, MD

CONTENTS

Inspection, Palpation, ROM, Strength, and Special Tests 774
Acute Knee Injuries 774
- Meniscal Injuries 774
- Anterior Cruciate Ligament Tears 774
- Posterior Cruciate Ligament Tears 775
- Medial and Lateral Collateral Ligament Injuries 775
- Patellar Instability 776
- Quadriceps Tendon and Patellar Tendon Ruptures 777
- Acute Chondral Injuries 777

Acute Shoulder Injuries 778
- Acromioclavicular Joint Injury 778
- Anterior Shoulder Dislocation 778
- Posterior Instability 779
- Rotator Cuff Tear 779
- Clavicle Fractures 779
- Pectoralis Muscle Injuries 780

Acute Foot and Ankle Injuries 780
Common Injuries 780
- Ankle Sprains 780
  - High Ankle Sprain 781
  - Ankle Fractures 781
  - Peroneal Tendon Injuries 781
  - Osteochondral Lesions 782

Specific Injuries 782
- Achilles Tendon Rupture 782
- Calcaneus Fracture 782
- Jones Fractures 782
- LisFranc Injuries 782
- Turf Toe 783

Acute Hip Injuries 783
- Hamstring or Quadriceps Strains or Avulsions 783
- Hip Dislocation 783
- Proximal Femur Fracture 783

Acute Hand, Wrist, Elbow Injuries 784
Hands: Jersey, Mallet, Gamekeeper's Thumb 784
- Mallet Finger 784
- Jersey Finger 784
- Gamekeeper Thumb 784

Distal Radius Fractures 785
Elbow Dislocation 785
References 785

As health care providers we have the opportunity to observe acute athletic injuries in many contexts. On the field, management and evaluation can be critical in making the appropriate decisions for return to play. An athlete presenting a few days after an injury may have significant swelling or ecchymosis that obscures the diagnosis.

In this chapter, the goal is to outline some general principles in acute injury evaluation and identify, by body region, common differential diagnosis and pearls for assessment and management. This chapter has been divided into sections on knee, shoulder, foot/ankle, hip, and hand/elbow. It is important to start with comments on an overall approach and management to acute musculoskeletal injuries in the adult.

INSPECTION, PALPATION, ROM, STRENGTH, AND SPECIAL TESTS

A good initial evaluation begins with a systematic approach. The clinician should then progress in the order of inspection, palpation, range of motion, and then strength and special tests. The first emphasis is on inspection with direct visualization. This can be difficult in some environments and thus may necessitate moving the athlete to a different setting. For example, a skier with a shoulder injury may need to be moved indoors before disrobing and fully inspecting the injury.

Inspection is then followed by palpation. Specific attention is paid to crepitus and deformity, as these are keys in evaluating for fracture or perhaps tendon rupture. In the subacute setting, the amount of ecchymosis and the presence or absence of a defect is also helpful. The contralateral extremity is usually available for comparison and thus provides a good context to interpret the findings. This is then followed by an assessment of the neurovascular status of the extremity and then by functional testing. After functional tests are performed, including range of motion and strength, special tests or maneuvers may further delineate the injury based on the specific region. Some of these tests will be outlined further in the sections of this chapter.

ACUTE KNEE INJURIES

Meniscal Injuries

Anatomy/pathology/epidemiology: The medial and lateral menisci of the knee are C-shaped fibrocartilaginous disks between the femoral and tibial condyles. They provide shock absorption and contribute in part to joint stability. The vascular supply to meniscus cartilage is poor, particularly to the inner portion; thus, the healing ability of meniscal tears is very limited. Injury to a meniscus predisposes the knee to degenerative arthritis. Traumatic meniscal tears typically result from an injury involving the twisting of a slightly bent knee while the foot remains fixed in place. Medial meniscus injury is more common than lateral meniscus injury. The patient may develop gradual swelling over the days following injury, and complain of stiffness and pain located predominantly over the medial or lateral joint line.

History/exam: Symptoms may wax and wane to some extent but often recur with twisting or squatting motions such as getting out of a car. The patient may also describe the sensation of mechanical symptoms of a meniscal tear, such as catching, popping, or locking. Common physical exam findings can include joint effusion (often less dramatic than those associated with an acute ACL tear or patellar dislocation, given the relative avascularity of the inner portions of the menisci) and pain with maximal flexion. Tenderness along the medial or lateral joint line is one of the most sensitive findings in meniscal injuries.[1] Meniscal rotation tests, such as McMurray's and Apley Grind, attempt to reproduce pain and clicking of the injured meniscus, and are considered more specific signs of a meniscal tear.[1]

Imaging: Standard knee radiographs are important in the evaluation of suspected meniscal injury to rule out bony pathology that could explain joint line pain or mechanical symptoms. However, an isolated acute meniscal tear will not be visualized on x-ray. MRI is very useful in confirming the diagnosis and characterizing the type of meniscal injury, being both sensitive and specific for meniscal pathology.

Treatment: While some small peripheral meniscal tears may heal nonoperatively, typically, arthroscopic partial meniscectomy or repair is indicated in the young, active population, particularly those with mechanical symptoms. In contrast, degenerative meniscal tears, more common in the older population, are typically best managed conservatively (rest, ice, NSAIDs) rather than surgically.

Anterior Cruciate Ligament Tears

Anatomy/pathology/epidemiology: The anterior cruciate ligament (ACL) originates from the posteromedial aspect of the lateral femoral condyle in the intracondylar notch, and inserts onto the anterior tibia between the tibial condyles. This thick ligament, approximately 10 mm in width, is composed of two principal parts, the anteromedial and posterolateral bundles. The ACL is the primary stabilizer of the knee, and acts to resist anterior translation of the tibia. Contrary to popular belief, ACL injuries most frequently occur with a noncontact mechanism in more than 70% of cases,[2] though contact injuries certainly do occur as well. Common noncontact mechanisms of injury include a sudden deceleration prior to a change in direction, a pivot on a planted foot, or hyperextension of the knee during a landing motion, whereas contact-related injuries classically occur as a result of a forced valgus collapse of the knee. Approximately 70% of ACL injuries occur during sports participation,[3] particularly in activities such as football, basketball, soccer, and skiing.

History/exam: With traumatic ACL rupture, the patient often describes feeling or hearing a "pop" at the moment of injury. Rapid and dramatic swelling of the knee typically follows within the first few minutes to hours after injury. The patient is almost always unable to continue in the activity due to pain and a sensation of knee instability. On examination,

a significant effusion is typically present. The Lachman test, in which an anterior force applied to the tibia results in laxity evidenced by excess anterior translation and lack of a firm endpoint compared to the nonaffected knee, is one of the most reliable physical exam findings of an acutely ruptured ACL.[2] The positive pivot-shift test, in which an anterior subluxation/reduction of the tibia is felt as the knee is passively brought from extension into flexion while applying an internal rotation, gentle valgus force, and axial load to the tibia, is another highly sensitive and specific test for ACL injury.[2] Clinically, however, the pivot-shift test can be more challenging to reliably evaluate in a nonanesthetized patient, particularly one demonstrating protective guarding.

Imaging: Standard knee radiographs should be closely examined for associated injuries such as a tibial spine avulsion or tibial plateau fracture. Additional supporting evidence of an ACL tear may be seen on plain radiograph of the knee. For example, a Segond fracture is an uncommon lateral capsule avulsion fracture from the proximal tibia, which is highly specific for ACL tear. On lateral knee images, visualization of a lateral femoral notch, which is deeper than the normal <2 mm notch size, is associated with impaction injury at the time of the original pivot shift. MRI of the knee is useful in confirming the diagnosis of an ACL injury, as well as evaluating for associated injuries that may influence surgical planning, such as osteochondral damage or concomitant meniscal tears.

Treatment: The goal of treatment in ACL injury is to prevent any further pivot-shift events, as every episode of instability has the potential to result in further chondral damage and predispose to degenerative arthritis. Most young, active patients engaged in activities requiring lower extremity agility will require surgical reconstruction of the ACL with various options of allo- or autograft tendon tissues. ACL reconstruction is typically performed at least 3 weeks after injury, to allow decrease in swelling and increase in range of motion prior to surgery.

Return to play: Postoperative rehabilitation is extensive, and patients should understand that safe return to full activities is expected to take at least 6–12 months. However, a subset of patients, considered "copers," have been shown to have satisfactory outcomes with rehabilitation alone without ACL reconstruction surgery, despite the inability of the torn ACL to heal itself, through optimizing muscular stability.

Posterior Cruciate Ligament Tears

Anatomy/pathology/epidemiology: The posterior cruciate ligament (PCL) is broader than and almost twice as strong as the ACL, and is less commonly injured. The PCL originates from the anterolateral aspect of the medial femoral condyle, anterior to the ACL, and inserts over the back of the tibial plateau, approximately 1 cm distal to the joint line. Like the ACL, the PCL also consists of an anterolateral bundle and a posteromedial bundle. This ligament prevents posterior translation of the tibia relative to the femur, as well contributing to resistance of varus, valgus, and external rotation stresses. The most common mechanism of injury to the PCL is the so-called dashboard injury, in which a force strikes the shin backward while the knee is in a flexed position, or in athletes, when an athlete falls onto a hyperflexed knee with a plantarflexed foot. Hyperextension or rotation injuries associated with varus or valgus force can also result in PCL tears. Due to the significant forces required to cause damage to the PCL, it is relatively rare to see isolated PCL tears. Most PCL tears are seen in combination injuries that also involve damage to the ACL, medial collateral ligament, medial meniscus, or posterolateral corner structures.[4]

History/exam: Patients with an acute PCL tear typically report diffuse knee pain, with tenderness both posteriorly as well as over the anterior tibia or area that received the impact force. Swelling is usually present, but often less than the typical hemarthrosis effusion observed with ACL tear. A Posterior Drawer test demonstrating posterior tibial subluxation is considered one of the most accurate signs of PCL injury.[2] The similar posterior sag test can demonstrate posterior subluxation of the tibia relative to the femur due to gravity in the absence of an intact PCL, with the auadriceps active test being used to reveal the ability of active quadriceps contraction to move the sagging tibia anteriorly, back into position.

Imaging: Standard plain radiographs are useful to rule out other boney injuries of the knee, such as avulsion of the PCL's tibial attachment, while cross-table lateral views may show a radiographic sag sign compared to the unaffected side. MRI is helpful to confirm the diagnosis and evaluate for other, frequently associated injuries.

Treatment: Optimal treatment of a PCL tear will depend on the injury characteristics. Surgical reconstruction of the PCL is somewhat controversial, and is typically reserved for high-grade PCL tears associated with other knee injuries. Many PCL tears have a good prognosis with nonoperative, rehabilitation treatment. Unlike ACL tears, PCL injuries are considered to have the potential for intrinsic healing, which has been attributed to superior blood supply of the PCL compared to the ACL. However, individuals who have suffered injury to the PCL do appear to be at increased risk of developing degenerative arthritis of the knee, particularly of the patellofemoral compartment, related to changes in knee kinematics.[5]

Medial and Lateral Collateral Ligament Injuries

Anatomy/pathology/epidemiology: The medial collateral ligament (MCL) and lateral collateral ligament (LCL) are integral in restraining valgus and varus angulation of the knee, respectively. The MCL is made up of both superficial and deep portions, and is augmented by the medial capsular ligament at the deepest layer. The fibers of the superficial MCL originate proximally from the posterior aspect of the medial femoral

condyle, and insert distally onto the medial tibia deep into the pes anserinus, approximately 5 cm distal to the joint line, while the deep fibers originate from the medial joint capsule, and insert directly onto body of the medial meniscus via the meniscofemoral and meniscotibial ligaments. The LCL originates from the posterior lateral femoral epicondyle and inserts onto the fibular head, and, unlike the MCL, does not fuse to the capsular ligament nor attach onto the lateral meniscus.

History/exam: The MCL is the most commonly injured ligament in the knee, with damage most often caused by a direct blow to the lateral aspect of the knee, resulting in an overwhelming valgus stress and external tibial rotation, though, noncontact twisting injuries can result in MCL sprains as well. Isolated LCL injuries are rare, and typically result from a varus or twisting injury, with associated damage to the posterolateral structures frequently stemming from a hyperextension mechanism due to a blow to the anteromedial tibia. With either MCL or LCL sprains, patients typically complain of pain directly over the injured ligament complex, and the sensation of the knee giving way into valgus or varus with walking or pivoting. On examination, localizing the point of maximal tenderness may assist in determining whether a tear has occurred proximally, mid-substance, or distally, which may have treatment implications. The varus and valgus stress tests, performed at 30° knee flexion to relax the stabilization component from the cruciate ligaments, suggest LCL or MCL injury, respectively, when the patient has pain (in low-grade sprains), or pain with ligamentous laxity in the form of excessive opening of the joint line compared to that of the opposite knee (in higher grade sprains). Joint opening with varus or valgus stress in a knee at full extension is highly concerning for concomitant cruciate ligament or posterolateral corner injuries.

Imaging: Knee radiographs in the evaluation of suspected MCL or LCL injuries are frequently normal, but useful in ruling out other bony injury. Some may occasionally demonstrate a small bony fragment if the injured collateral ligament is avulsed from the epicondyle acutely, though those with mid-substance tears will not. Radiographs of chronic MCL injuries may reveal calcification at the MCL origin, known as Pellegrini-Stieda syndrome. MRI is not necessary to confirm the diagnosis but can be helpful in delineating the degree of disruption of the collateral complex, determining whether the injury is proximal, mid-substance, or distal, as well as in evaluation for frequently associated meniscal or cruciate tears.

Treatment: Conservative management of almost all MCL sprains with hinged knee bracing and progression to early motion and rehabilitation is usually highly successful, though surgical repair may be considered in some complete tears, particularly if there are other associated injuries.

Patellar Instability

Anatomy/pathology/epidemiology: Patellar instability includes patellar subluxation and dislocation. Patellar subluxation describes abnormal tracking of the patella while it remains within the trochlear groove of the femur, while patella dislocation refers to events in which the patella is displaced completely from the sulcus. Patellar dislocation should not be confused with a potentially limb-threatening "knee dislocation." Acute patellar dislocations almost always occur with the patella displacing laterally from the trochlea. The typical inciting mechanism involves a valgus or twisting movement with internal rotation of the femur associated with a strong quadriceps contraction, often occurring in soccer, gymnastics, and hockey, or from a direct blow to the patella knocking it out of position. Patella dislocation occurs most often in adolescents and young adults, with a number of anatomic risk factors, including patella alta, genu valgum, trochlear dysplasia, and increased Q-angle, predisposing some individuals to instability.

History/exam: Patients who suffer a patellar dislocation typically describe sudden severe pain followed by falling to the ground, and often note an obvious, visibly deformed knee. This deformity may be described medially, in which case it likely represents the appearance of the uncovered medial femoral condyle, or be described as laterally, due to the patella sitting lateral to the trochlea, where it remains until it is reduced. Reduction is usually achieved easily by passively extending the knee with gentle pressure applied along the lateral patellar edge, and rarely requires anesthesia. First-time dislocations of the patella are associated with rapid, dramatic swelling from an acute hemarthrosis. On examination, maximal tenderness typically overlies the injured medial restraint that has failed, most commonly, the medial patellofemoral ligament avulsing off its femoral attachment,[6] or according to more recent research, off its patellar attachment.[7] Tenderness over the lateral femoral condyle and medial facet of the patella may represent osteochondral fractures sustained during the dislocation event. A classic finding of patellar instability is patellar apprehension, in which the patient reports pain and anxiety as the examiner gently attempts to manually sublux the patella laterally while holding the relaxed knee in approximately 30° of flexion. Aspiration of the knee effusion following a patellar dislocation typically demonstrates hemarthrosis and may reveal floating fat globules, particularly in the setting of associated osteochondral fractures.

Imaging: Radiographs rarely demonstrate patellar dislocation, as positioning the knee extended on the x-ray table usually results in its reduction back into the trochlear groove. However, radiographs may reveal large osteochondral fractures of the lateral femoral condyle or patella, or anatomic features predisposing an individual to patellar instability, such as patella alta or trochlear dysplasia with a hypoplastic lateral condyle. Including an axial patellar image, such as the merchant view, is recommended to evaluate patellofemoral congruity. MRI is useful to demonstrate damage of the medial supporting structures associated with acute dislocation, as well as bony edema or osteochondral injuries to the lateral femoral condyle and/or medial patellar facet.

Treatment: Acute patellar dislocations and subluxation events are typically treated nonoperatively with brief immobilization

only as needed for symptoms, followed by early, extensive rehabilitation and functional patellar bracing with lateral support. Patellar dislocations associated with a loose fracture fragment in the joint, however, may require surgical intervention. Unfortunately, up to 44% of patients will experience recurrent episodes of patellofemoral instability.[8] Surgical correction of an underlying extensor mechanism mal-alignment is rarely required but may be considered as a last option in cases of recurrent instability despite appropriate rehabilitation.

Quadriceps Tendon and Patellar Tendon Ruptures

Anatomy/pathology/epidemiology: The extensor mechanism of the knee can generate substantial forces that can result in rupture of the quadriceps tendon or the patellar tendon (occasionally known as the patellar ligament). These injuries typically occur due to direct blunt trauma or excessive tension being applied through the extensor mechanism, such as with a fall onto a partially flexed knee as the quadriceps is forcibly contracting. The quadriceps tendon is the largest tendon in the body, and connects the quadriceps femoris to the superior aspect of the patella, technically a sesamoid bone within the extensor mechanism of the knee. The fibers of the quadriceps tendon traverse the patella and condense inferiorly to form the patellar tendon (or ligament), which inserts onto the tibial tubercle. Quadriceps tendon ruptures are more common in patients over age 40,[9] and are more likely to occur in patients with a history of multiple corticosteroid injections, diabetes, gout, and certain other underlying conditions. The use of anabolic steroids has also been associated with quadriceps rupture. Patellar tendon ruptures are comparatively less common, typically occurring in patients under age 40,[9] and are frequently associated with sports activities involving jumping, such as basketball and volleyball. Patellar tendon ruptures are frequently found in the setting of underlying patellar tendinosis. In the skeletally immature, young athlete, similar mechanisms of forceful quadriceps contraction against a partially flexed knee can result in a patellar sleeve fracture, an avulsion injury in which the distal patellar pole and articular surface pull free with the tendon.

History/exam: Patients often report feeling a pop at the time of injury and are unable to walk due to the loss of active knee extension, though knee flexion is preserved. Patients with partial tears may retain the ability to partially extend the knee but may lack full extension. On examination, ecchymosis and a large effusion are common, and a tender, palpable defect may be demonstrated in the injured tendon. With complete rupture, patients are almost always unable to perform a straight-leg raise or extend the knee against gravity.

Imaging: Radiographs may reveal a small avulsion from either the superior patella or inferior patellar pole, depending on the site of injury. Radiographs, particularly the lateral knee image, may demonstrate either a high-riding patella, known as patella alta, after patellar tendon rupture, or a low-riding patella, or patella baja, after complete quadriceps rupture. MRI is often not necessary but may be used to confirm the diagnosis, particularly in partial tears, and assist with surgical planning.

Treatment: Prompt surgical repair is indicated for complete tears of either tendon. Delayed surgical treatment beyond 1–2 weeks can prevent attainability of end-to-end suturing in otherwise appropriate cases, and is associated with poorer outcomes.[9] Partial tears of the quadriceps or patellar tendons with normal patellar height and preserved active extension may be treated nonoperatively with immobilization in extension for 3–6 weeks, followed by gradual range of motion and quadriceps-strengthening exercises.

Acute Chondral Injuries

Anatomy/pathology/epidemiology: Articular cartilage, the glistening, white hyaline cartilage that caps the end surfaces of bones making up synovial joints, is made up of chondrocytes and an extracellular matrix consisting of water, proteoglycans, and Type II collagen. This layer functions to provide a low-friction, highly lubricated contact area between articulating surfaces, while distributing contact pressure to the underlying subchondral bone. These features can allow joints to tolerate repetitive compressive loading and shear forces for many decades. However, direct trauma to the knee, including ACL tears, meniscal injuries, and patellar dislocations, can frequently result in focal damage to the articular cartilage, known as acute chondral injury. Classification systems of chondral injuries are based on the depth of injury, from mild, superficial fissuring to more severe lesions extending through the articular cartilage into the underlying subchondral plate. Once damaged, articular cartilage cannot repair itself, and over time, elevated joint contact pressures at the site of damage will predispose the knee to developing symptomatic osteoarthrosis.

History/exam: Symptoms of an acute focal chondral injury may be subtle, and may overlap with or be overshadowed by symptoms stemming from other associated injuries; thus, a high index of suspicion is required for diagnosis. Crepitus, giving way, intermittent locking, persistent localized pain, and recurrent effusions may all be associated with a chondral injury.

Imaging: Knee radiographs may reveal large osteochondral defects extending into the subchondral bone; however, typically MRI is necessary to evaluate more subtle subchondral bone and cartilaginous injuries, particularly in surgical planning and selection of the procedure of choice.

Treatment: Treatment of focal chondral injuries of the knee can include conservative management in patients preferring to avoid surgery, or those with advanced degenerative arthritis deemed inappropriate for articular cartilage restoration procedures. Nonoperative interventions in the treatment of chondral defects typically include NSAIDs, judicious use of corticosteroid injections, and use of oral or injectable

chondroprotective agents, such as viscosupplementation injection. Surgical intervention options are principally based on the size of the defect, are typically considered as palliative (typically arthroscopic debridement and lavage), reparative (such as microfracture techniques to stimulate fibrocartilage repair), or restorative (including autologous chondrocyte implantation and osteochondral allografting).

ACUTE SHOULDER INJURIES

Evaluation of an acute injury in the shoulder begins with the patient's history, as this will almost always narrow the differential diagnosis. In addition, it is often possible to stratify injuries by age and sport to assist in the evaluation.

Acromioclavicular Joint Injury

Anatomy/pathology/epidemiology: Injuries to the acromioclavicular (AC) joint represent between 40% and 50% of athletic shoulder injuries.[10] It can result from a direct or an indirect blow to the shoulder. AC joint injuries are commonly seen in sports such as football and hockey but can also be seen in many contact sports including mountain biking and mixed martial arts.

The severity of injury can be quantified by the Rockwood classification system.[11] This system divides AC joint injuries into six different types. Types I, II, and III involve progressive degrees of injury to the AC joint capsule and coracoclavicular ligaments. Type I involves isolated injury to the AC joint capsule. Type II involves a greater degree of injury, with disruption of the AC joint capsule in addition to some degree of incomplete tearing of the coracoclavicular ligaments. In a Type III separation, both the AC joint capsule and coracoclavicular ligaments are completely disrupted often with significant superior displacement of the clavicle relative to the acromion. Types IV and VI, in which the clavicle is displaced posteriorly and inferiorly, respectively, are extremely uncommon. Type V is an exaggerated Type II injury, in which there is considerable additional injury to the envelope of surrounding soft tissue, the deltotrapezial fascia. The increased severity of this injury leads to a greater degree of displacement that can be appreciated both clinically and radiographically with vertical joint displacement between 100% and 300%.

History/exam: Depending on the time-out from injury, there can be evidence of bruising and swelling in the anterior shoulder and deformity at the AC joint. Patients will often be able to localize the pain to the AC joint. In addition, the pain and muscle spasm will often radiate up into the trapezius and down into the deltoid fascia.

Imaging: Optimal radiographs for evaluating these injuries include an anteroposterior (AP) view of both AC joints on a single film; if possible, an axillary view to assess AP displacement and evaluate for intra-articular fracture; and the 15° cephalic tilt view (Zanca) with under-penetration to visualize the AC joint specifically.

Although some in the past have advocated a weighted view to differentiate between Type II and Type III injuries, it typically does not change the treatment and therefore is not necessary.[10]

Treatment: Over 85% of acromioclavicular joint injuries represent Type I–III injuries.[10] These, for the most part, may be treated nonoperatively by conservative measures and then gradual return to play when symptoms allow. Conservative measures include rest, sling, and gradual mobilization with a strengthening program and possible injection into the acromioclavicular joint if necessary. There remains some controversy as to how to treat Type III injuries in the overhead throwing athlete and perhaps some overhead laborers but the best evidence at this time still supports the role of nonoperative management.[12] Types IV–VI are generally treated with surgical intervention.

Anterior Shoulder Dislocation

Anatomy/pathology/epidemiology: The shoulder is the most commonly dislocated joint in the body. Risks factors for shoulder dislocations include overall ligamentous laxity and history of previous dislocation. Anterior shoulder dislocations far exceed posterior shoulder dislocations and represent over 90% of instability events.[13] More common in contact and collision sports such as football, rugby, and hockey, the instability event usually results from application of a strong external rotation or extension force to the vulnerably positioned arm. The arm is most vulnerable in abduction and external rotation.

History/exam: On visual inspection of the acutely dislocated shoulder, the patient will usually hold the arm at the side in slight abduction and external rotation. The deltoid loses its rounded contour and often a sulcus can be appreciated beneath the acromion. It can be difficult to examine the patient if they have a large body habitus.

It is important to perform a neurovascular exam at the time of injury. It is estimated that there is an incidence of axillary nerve contusion or injury in 9%–20% of anterior shoulder dislocations.[13] The neuropraxia usually resolves with time but may take several weeks.

Imaging: Minimum radiographic views should include a true AP view, perpendicular to the plane of the scapula rather than the thorax, and an axillary lateral view. Additional views may be helpful in determining additional bony pathology.

Treatment: It is best to attempt to reduce the dislocation as soon as possible. The longer that it is out of position allows the body to produce greater muscular spasm. This makes it increasing difficult to reduce without anesthesia. If there are any concerns that on-the-field reduction cannot be done without causing further injury, then reduction should be delayed until radiographs are obtained.

There are a number of maneuvers that have been described for reducing the shoulder. Some reduction techniques include those described by Stimson, Hippocrates, and Milch. After

reduction or in cases of difficult reduction, it is important to evaluate the shoulder neurovascularly and radiographically. It is important to again note the status of the axillary nerve.

The recurrence rate for anterior shoulder dislocation varies between 17% and 96% and is directly related to age.[14] Patients younger than 20 years have the highest incidence for recurrent dislocation. CT scans are usually reserved for dislocations that are irreducible, chronic, or associated with fracture. MRI has little value in the acutely dislocated shoulder but can demonstrate soft tissue, muscular, and labral pathology in the subacute or chronic setting.

Immobilization with a sling for comfort and then gradual return to a functional strengthening program is usually recommended for first-time dislocations. However, as a result of the high recurrence rates up to 90% among young adults and adolescents, some advocate primary surgical stabilization in this group of athletes.[14]

Posterior Instability

Anatomy/pathology/epidemiology: Posterior dislocations account for just 4% of all glenohumeral joint dislocations and may present as acute or chronic.[15] Approximately 50%–80% of posterior dislocations are unrecognized at the time of initial presentation.[15] In athletes, a direct blow to the anterior shoulder or a posteriorly directed force to a flexed, internally rotated, and adducted shoulder is the typical mechanism of injury. Posterior subluxation can be related to a specific traumatic event or repetitive minor traumatic episodes. Athletes participating in swimming or overhead activities may be subject to tensile failure of the posterior capsule from repetitive microtrauma, thereby precipitating symptoms of posterior instability.

History/exam: Unlike anterior dislocations, most acute posterior dislocations reduce spontaneously. Patients with an acute posterior dislocation usually present with the arm in an adducted, internally rotated position. The coracoid is typically prominent, and the dislocated humeral head creates a posterior fullness. Although the presentation may be subtle, a lack of external rotation and inability to supinate the forearm are the hallmarks of diagnosis.

Imaging: Radiographic evaluation should consist of a three-view trauma series. The axillary view will reveal an empty glenoid with the humeral head displaced posteriorly. CT may be helpful for identifying impaction fractures or bone loss. The more common presentation of posterior instability includes pain, instability, or both when the arm is placed in the provocative position of flexion, adduction, and internal rotation. Patients may describe crepitus or clicking in certain positions.

Reproduction of the instability should be attempted during physical examination. Stability tests include the posterior drawer test, load and shift test, and jerk test.[15] Instability testing more frequently elicits symptoms rather than produces a discernable translation that can be appreciated by the examiner.

Rotator Cuff Tear

Anatomy/pathology/epidemiology: While the majority of rotator cuff tears are degenerative, the rotator cuff can be torn from a single traumatic injury. These types of tears tend to happen more in people under age 50 following an acute trauma or repetitive overhead work or sports activity. The rotator cuff includes the tendons of supraspinatous, infraspinatous, teres minor, and subscapularis. The majority of rotator cuff tears occur in supraspinatous tendon.

History/exam: An acute tear often involves the history of a fall onto an elbow or hand with forces transmitted through the arm to the shoulder. In a significant sized tear there can be ecchymosis present, although not usually. Testing for rotator cuff injuries involves the empty can test (supraspinatus), strength with internal and external rotation with the arm at the side at 90° of forearm flexion (testing supraspinatus/infraspinatus and subscapularis, respectively). Other tests for rotator cuff function involve the Napoleon's "Bear Hug" or lift-off test for subscapularis and the "horn blower" sign for infraspinatous.[16] Inspection and palpation of the biceps tendon and the bicipital groove are also important as a rotator cuff injury may also involve the bicipital sling.

Imaging: Radiographs are helpful in evaluating for other associated findings including fracture, dislocation, slope of the acromion, presence of osteoarthritis, and other factors that may have predisposed the patient to this injury. However, MRI is the imaging modality of choice for a rotator cuff tear. Contrast is not necessary in the setting of an acute injury.[16]

Treatment: Most full thickness rotator cuff tears require surgical intervention. Older patients who present with a small tear on MRI imaging may be treated initially or definitively with physical therapy. Should these patients fail a course of formal physical therapy focusing on the rotator cuff, scapular stabilizers surgical intervention may be warranted. Younger patients with acute large rotator cuff tears or those athletes who present with rotator cuff tear and instability may be considered for surgical intervention earlier. Younger patients with small tears and no evidence of instability may also trial physical therapy.

Clavicle Fractures

Anatomy/pathology/epidemiology/exam: Clavicle fractures are caused by direct trauma. Localized pain along the clavicle, deformity, crepitus, and swelling are consistent findings. Mid-shaft clavicle fractures are the most common and represent over 80% of all clavicle fractures.[17] Clavicle fractures of the distal third represent 10%–15% of clavicle fractures.[17] They can be further characterized into Types I through III. These types represent minimal displacement, fracture medial to the coracoclavicular ligaments, and fracture that extends into the AC joint, respectively. Distal clavicle fractures have a high incidence of non-union but most of these are asymptomatic, and only a small number of these will be severe enough to require surgery.

Clavicle fractures of the medial third are relatively rare and represent less than 5% of clavicle fractures. These can be successfully managed with nonsurgical intervention, with the exception of a posteriorly displaced fracture that may threaten underlying neurovascular structures.

Uncommon associated injuries with clavicle fractures include ipsilateral scapula and rib fractures, pneumothorax and neurovascular injury.

Treatment: Treatment involves use of supportive measures such as a sling and analgesics rather than attempts at reduction. The sling may be utilized for up to 4 weeks; however, range of motion exercises must be instituted starting approximately 48 h post injury to prevent joint contractures. Fortunately, most mid-shaft clavicle fractures will heal, although there are some characteristics that place some patients at risk for nonunion and decrease in function. These include "Z" pattern fractures and those with greater than 2.0 cm of shortening. These fractures may be considered for surgical management.[17]

Imaging: The clavicle is best visualized with an AP view and a view with the beam aimed 30° cephalad. The serendipity view may be used to visualize the sternoclavicular joint and medial clavicle fractures. This is a 40° cephalic tilt view focusing on the sternoclavicular joint.

Pectoralis Muscle Injuries

Anatomy/pathology/epidemiology: Ruptures of the pectoralis major muscle were thought to be uncommon but are being reported with increasing frequency. Interestingly, almost all documented cases of rupture are in male athletes.[18] Most ruptures are complete and involve the sternal head at or near the humeral insertion site.

History/exam: The most common mechanism of injury is during the eccentric loading of the pectoralis major tendon while weight lifting. This typically involves the arm in a position of abduction, extension, and external rotation, as seen in flat or decline bench press. However, rupture has also been reported in wrestling, water skiing, rugby, and other sports. Swelling and ecchymosis often complicate the initial diagnosis of this injury and, while not optimal, it is not uncommon for a patient to have a delay in diagnosis. The presentation of a male athlete with a history of an acute eccentric event and a large amount of ecchymosis, especially in the anterior chest wall and biceps region, should lead one to be highly suspicious for a pectoralis major muscle rupture. Inspection of the anterior axillary fold will likely have an abnormal contour as compared to the contralateral side. The absence of the pectoralis major contour in the axilla can be accentuated when asking the patient to forward flex the arm to 90°, with the elbow also bent at 90°, and asking the patient to resist shoulder adduction. Many of these patients will be able to relate to this maneuver, as it is similar to the "pec deck" in weight lifting. Medial retraction of the pectoralis major muscle may create abnormal bulging of the anterior chest wall.

Imaging: While the physical examination is the mainstay in diagnosis, radiographs may be helpful to evaluate for an avulsed bony fragment. MRI also can aid in earlier detection of the injury when physical examination findings are inconclusive and it may also aid in the identification of partial tears. It is important to specify the diagnosis in question for the MRI so that the anterior chest wall and insertion site of the pectoralis major on the humerus can be imaged. Most standard shoulder MRI protocols do not extend distally enough to visualize the pectoralis major tendon insertion.

Treatment: Nonsurgical treatment is appropriate for incomplete tears or the rare muscle belly injury. Surgical treatment is advocated for both athletes and in most patients. The ideal time for intervention is less than a month from injury to minimize the effects of tendon retraction and scar tissue. However, repair has been reported at 2 years out from injury with good results.[18] The benefits of surgical intervention include improved cosmesis and restoration of strength. Peak torque strength has been shown to return to 99% after repair versus 56% with nonsurgical treatment.[18]

ACUTE FOOT AND ANKLE INJURIES

Anatomy/pathology/epidemiology: Injuries to the foot and ankle are among the most common ailments experienced by the athlete. Adherence to the RICE mantra, as well as early protected weight bearing, remains the mainstay of treatment for most injuries. While most of these injuries are mild and self-limiting, several injuries to this anatomical region require special attention, due to either their relative frequency of occurrence or to make sure rarer, more severe injuries requiring specialized treatment are not misdiagnosed and undertreated. While a complete listing of these injuries is beyond the scope of this chapter, several such injuries are outlined in the following.

History/exam: Perhaps more importantly than any other anatomical region, careful attention to specific location of pain or dysfunction on history and exam can be diagnostic for the foot and ankle injury. Commonly, patients are quite general in regards to their pain and its location; the clinician may find it helpful to ask the athlete to point to his or her area of worst pain with a single finger. This can sometimes be difficult, however, as multiple concomitant injuries can occur. Further, it is not uncommon for one to experience an acute-on-chronic injury, making it hard to sort a mild injury from one more severe. Careful attention to areas of edema and questions about prior history of trauma also aid the clinician in accurate diagnosis. Mechanism of injury can often be helpful as well, such as in the common inversion mechanism seen with most ankle sprains.[19]

COMMON INJURIES

Ankle Sprains

Anatomy/pathology/epidemiology: In combination with benign muscular strains, ligamentous ankle sprains make up the majority of injuries to the foot and ankle—14.9% of

all injuries in the NCAA population.[20] Most sprains involve the lateral ligamentous complex of the ankle.[21] The anterior talofibular ligament (ATFL) connecting the anterior distal fibula to the talus is the most commonly sprained ligament, followed closely by the calcaneofibular ligament (CFL). This ligament connects the inferior fibular tip to the lateral calcaneus.[21]

History/exam: Swelling over this area is common with ankle sprains. Patients commonly report an inversion mechanism of injury.[19] When asked about the area of maximal pain, the athlete will point to a region just anterior to the fibula or just distal to its tip. Recurrent ankle sprains can become a common problem after a severe ankle sprain, with recurrent sprains occurring 10% of the time.[21]

Ligamentous laxity, either generalized or posttraumatic, may predispose the patient to recurrent sprain. Side-to-side exam of the affected ankle compared to the contralateral normal ankle may demonstrate increased anterior translation of the calcaneus compared to the tibia when an anterior pressure is applied to the posterior heel. This anterior drawer test signifies laxity of the ATFL. Similarly, a positive talar tilt test where the calcaneus is firmly tilted via varus stress while stabilizing the tibia signifies CFL laxity.

Treatment: Regardless of whether the sprain represents a grade I, II, or III injury, initial treatment consists of RICE and protected weight bearing, with gradual return to full weight bearing and play. Common treatments for recurrent sprains involve either ankle bracing or taping, muscular strengthening about the ankle, and most importantly, proprioception exercises. Proprioception is the body's ability to sense its position in space; retraining ankle proprioception via balancing exercises such as a trampoline or wobble board has been shown to be helpful in preventing recurrent ankle sprains.[22] Rarely, in severe recurrent sprains surgery may be indicated.

High Ankle Sprain

Anatomy/pathology/epidemiology: One specific type of ankle sprain deserving special mention is the high ankle sprain, which makes up 1% of all ankle sprains.[23] Unlike the common ankle sprain, which involves the lateral ligamentous complex, the high ankle sprain involves injury to a confluence of tissue connecting the tibia to the fibula termed the syndesmosis. By definition, this injury occurs above the ankle joint.

History/exam: Pain is typically more vague and hard to locate than with common sprains and swelling is minimal or nonexistent. Pain is worsened by activities where the tibia is stabilized and the foot/ankle is externally rotated. On physical exam, recreation of this mechanism or pain with the squeeze test, i.e., compression of the tibia and fibula by squeezing of the calf, will exacerbate pain.[23]

Imaging: Essential radiographs include three views of the ankle and a full length tibia/fibula radiograph in the AP and lateral planes.

Treatment: A non-displaced high fibular fracture with no evidence of ankle mortise incongruency may be treated nonoperatively with non-weight bearing in a short leg cast. Recovery time for this injury depends on severity and can average from 2 to 3 weeks to 6 weeks or longer.[23] Rarely, for severe unstable injuries surgery is indicated.

Ankle Fractures

Anatomy/pathology/epidemiology: While not as common as ligamentous sprains, ankle fractures are also quite common and differentiation from sprains is necessary as fractures require radiological imaging and medical consultation. Many sprains, on the other hand, are self-limiting and easily self-treated.

History/exam: Mechanism of injury is typically more severe than with sprains, and maximal pain is typically located directly over bony prominences rather than the soft tissue surrounding them. With obvious fracture and deformity, the ankle should be splinted in position and the patient should be made non-weight bearing with crutches until medical evaluation with radiograph is available. More subtle injuries can be difficult to distinguish from ankle sprains. If any doubt exists as to the diagnosis, radiologic imaging should be performed.

Imaging: The Ottawa ankle rules were designed to help decide when imaging may or may not be indicated.[24] These rules state that radiographs are only needed when there is pain over the posterior aspect of the bony prominence of the distal fibula, the same area over the distal tibial malleolus, or when the patient cannot bear weight both initially and at the time of physical exam. These rules are nearly 100% sensitive for fracture, although only modestly specific. Therefore, very few fractures are missed using these rules, while they can reduce the number of unnecessary radiographs taken by 30%–40%.[25]

Treatment: Unstable ankle fractures are treated surgically involving non-weight bearing for 6–12 weeks depending upon the severity of the injury. For non-displaced or isolated fibular fractures, weight bearing may be started immediately; however, pain may limit full weight bearing and crutch assist may be warranted until pain resolves—approximately 2–3 weeks post injury. A supportive walking boot may aid in allowing early weight bearing.

Peroneal Tendon Injuries

Anatomy/pathology/epidemiology/exam: While pain over the soft tissue about the anterior or distal fibula is consistent with ankle sprain, and pain directly over the bone is suggestive of fracture, pain over the soft tissue just posterior to the fibula suggests injury to the peroneal tendons or musculature. While it is quite common to experience peroneal muscular strains, either in an isolated manner or secondary to another injury process, occasionally injuries to this area are more severe. The superior retinacular tissue holding the tendons in place can become injured, allowing subluxation or frank

dislocation of the tendons out of the bony groove behind the fibula.[26] The soft tissue surrounding the area can become quite boggy, and pain or instability can be maximized by performing resisted ankle eversion with the ankle in plantarflexion.[27] Further, peroneal tendon tears can occur as the tendons reverse directions about the distal end of the fibula, especially tears of the peroneus brevis.

Treatment: Treatment with RICE and protected weight bearing are first-line treatment, but if the injury fails to resolve, advanced imaging in the form of MRI or ultrasound is indicated, followed by the occasional need for surgery.

Osteochondral Lesions

Anatomy/pathology/epidemiology: Osteochondral lesions of the ankle most commonly involve the talar dome. These lesions are essentially a chip of bone attached to cartilage of varying size that comes off of the host bone.

History/exam: Varying symptoms according to size and location of the lesion may occur, sometimes involving locking and catching of the ankle due to the loose body formed. More often, the lesions are small and without mechanical symptoms. Pain location is usually ill defined and deep; as a result, delayed diagnosis is more the rule than the exception. Ankle swelling commonly occurs, especially after impact activities such as running or jogging.

Imaging: Although these injuries can sometimes be seen on x-ray, more often MRI or CT scan is required for diagnosis.

Treatment: Treatment may involve ankle injections and physical therapy or surgical intervention, and is best managed by orthopedic referral.

SPECIFIC INJURIES

Achilles Tendon Rupture

Anatomy/pathology/epidemiology: Injury to the Achilles tendon most commonly occurs with an eccentric muscular load, which involves aggressive contraction of the gastrocnemius-soleus complex while simultaneously lengthening the muscle and tendon.[28]

History/exam: Patients commonly report a feeling of being kicked or shot in the back of the leg. An inability to bear weight on the affected extremity is common initially. A palpable gap may be apparent in the tendon just superior to its insertion on the posterior calcaneus. With full tears, an inability to actively plantarflex the foot can occur, although the exam may be complicated by compensation with the remaining foot flexors and the peroneus longus. The Thompson test involves laying the patient prone and squeezing the posterior calf muscles. With this motion, the ankle should passively plantarflex. A lack of plantarflexion is consistent with a full Achilles tear.

Imaging: Although x-rays are often ordered to rule out bony involvement, the diagnosis of Achilles rupture remains a clinical rather than a radiographic diagnosis, and MRI is rarely needed.

Treatment: Achilles ruptures can be treated either surgically or nonsurgically.[29] Orthopedic consultation to discuss treatment is indicated as the optimal management of this injury must be tailored to the individual patient.

Calcaneus Fracture

Anatomy/pathology/epidemiology/exam: Calcaneus fractures usually involve a severe injury or fall from a height. A large amount of severe heel pain, bruising, and inability to bear weight are found.

Imaging: X-rays and potentially CT scans are indicated to rule out this diagnosis when one is suspicious of this injury.

Treatment: Non-weight-bearing status should be maintained with crutches until this diagnosis is ruled out if one suspects a calcaneus fracture. Calcaneus fractures are indicated for surgical intervention if a displaced intra-articular fracture involves the posterior facet, the anterior process of the calcaneal cuboid articulation is involved >25%, the calcaneal tuberosity is displaced, and selected open fractures.

Jones Fractures

Anatomy/pathology/epidemiology: Injury to the lateral midfoot and pain isolated to the base of the fifth metatarsal bone should suggest the potential for a Jones fracture or one of its variants. A Jones fracture is a fracture at the base of the fifth metatarsal near its metaphyseal–diaphyseal junction.[30] Unlike its variants, including an avulsion of the tip of the bone or a proximal fracture found within only the diaphyseal shaft, a true Jones fracture is notable due to its tendency for prolonged difficulty in healing.[30] The reason for this problem is due to the poor vascularity of this bone, with its predominate blood supply coming in a retrograde manner from distal to proximal.

Treatment: Because of its difficulty in healing, either prolonged casting with non-weight-bearing status or primary surgical fixation with a screw is indicated. Therefore, after radiographic diagnosis, orthopedic consultation is indicated.

LisFranc Injuries

Anatomy/pathology/epidemiology/exam: Injuries to the midfoot are often termed mid-foot sprains, or LisFranc injuries. Most mid-foot sprains are benign and self-limiting injuries that respond to RICE.[31] However, with severe injury, large amounts of mid-foot edema, or inability to bear weight, a full LisFranc injury should be ruled out. This involves tearing of the ligaments attaching the tarsal to the metatarsal bones, and most specifically the LisFranc ligament attaching the base of the second metatarsal to the medial cuneiform.[31] If fully torn, the normal arch of the foot is lost and instability of the midfoot joints occurs. Prolonged delays in diagnosis may result in early posttraumatic mid-foot arthritis, a difficult problem to treat effectively in the active athletic population.

Imaging: Initial weight-bearing x-rays are taken to look for bony gaping. Further, stress views of the foot in abduction or MRI are also usually indicated.[32,33]

Treatment: Strict non-weight bearing and elevation should be initiated. Referral to a foot and ankle specialist is indicated if this diagnosis is made or suspected.

Turf Toe

Anatomy/pathology/epidemiology/exam: Pain after a vigorous hyperextension of the great toe with tenderness mainly at the metatarsophalangeal (MTP) joint is suggestive of turf toe.[34] The injury occurs most commonly on artificial playing surfaces, and involves an injury to the plantar capsular structures of the joint.[35]

Imaging: X-rays are often indicated to rule out associated fracture.

Treatment: RICE and protected weight bearing are the initial treatments, followed by return to full weight bearing over several days to weeks depending on injury severity. Extended carbon fiber turf toe plates may be used in shoes to help prevent joint hyperextension for severe or recurrent injury. Recovery often takes 3–4 weeks. If symptoms are recurrent and not cared for properly, the condition can progress to arthritis of the MTP joint over time. This condition is termed hallux rigidus.

ACUTE HIP INJURIES

Sports-related injuries have been reported to account for approximately 2.6 million visits to the emergency room by children and adolescents yearly.[36] However, hip injuries are less commonly encountered in sports, accounting for only 5% and 9% of injuries.[37] Injuries to the hip/large-weight-bearing joints have gained recent increased attention as these injuries may significantly impact short- and long-term sports performances resulting in increased morbidity.[38,39] The hip is estimated to transfer up to eight times body weight loads during jogging or vigorous sports activities.[40] Among the most commonly encountered injuries are hamstring/quadriceps strains/avulsions, hip dislocation, and rarely fractures of the proximal femur. This chapter will define these injuries including anatomy/pathology/epidemiology, history/exam, initial treatment, and return-to-play guidelines.

Hamstring or Quadriceps Strains or Avulsions

Anatomy/pathology/epidemiology: Muscle strains are some of the most common hip injuries in athletics and of hip muscle strains, the hamstring bone–tendon unit is among the most commonly injured.[41] The most common avulsion fractures of the pelvis include the ischial tuberosity in approximately half of all cases, anterior inferior iliac spine, and anterior superior iliac spine.[42]

History/exam: The diagnosis is made when the patient complains of pain at the muscle insertions, rarely in the muscle belly itself, and is usually found in muscles crossing two joints.[43] Most commonly encountered is groin or medial thigh pain following an eccentric muscle contraction, for example, soccer players experience strain of the iliopsoas muscle due to eccentric hip flexion.[44]

Treatment: Initial treatment should involve RICE principles, i.e., rest, ice, compression, and elevation of the limb along with nonsteroidal anti-inflammatory medications.[45] Absent motion of the affected joints or a palpable defect should prompt referral to an emergency room as these may indicated grade III strains or complete ruptures and or avulsions at the insertions of the affected muscles.

Return-to-play guidelines: Avulsions are more commonly encountered in the skeletally immature athletes and may be managed nonoperatively in certain cases; however, referral to an orthopedic surgeon is essential to confirm treatment.[41,46] Return to play is allowed when pain-free range of motion and strength returns.

Hip Dislocation

Anatomy/pathology/epidemiology: Hip dislocation is defined as displacement of the femoral head outside the acetabular confines. True dislocation is uncommon in athletes. The most commonly encountered traumatic closed hip dislocation pattern is posterior, usually the result of large forces directed across the flexed knee into the femoro-acetabular joint[47] such as in collisions in skiing or contact sports.

History/exam/imaging: The diagnosis is confirmed radiographically on a plain AP pelvis radiograph, however a posterior dislocation should be suspected when a collision results in an athlete complaining of hip or groin pain and the leg held in a flexed, adducted, and internally rotated for posterior dislocations.[48] The patient will be unable to bear weight and is typically in extreme pain.

Treatment: A closed hip dislocation is best treated with closed reduction as quickly as possible due to the fragile vascular supply to the femoral head, in which osteonecrosis may occur in up to 20% of patients.[49] The patient should be transferred to an emergency room quickly and reduction of the hip performed within 6 h to decrease incidence of osteonecrosis of the femoral head.[50] Prior to transfer, the patient should be examined carefully for neurovascular deficits such as sciatic nerve palsy or vascular injury. The patient is treated with touchdown weight bearing for approximately 6 weeks with hip precautions consistent with the dislocation pattern (posterior or anterior).

Return-to-play guidelines: Return to play is allowed after 6 weeks and when the hip has a full range of motion that is pain free and strength is regained to symmetrical with the contralateral hip.[37]

Proximal Femur Fracture

Anatomy/pathology/epidemiology: Fractures of the proximal femur are an extremely rare entity in athletics. Case reports

have been described for intra-capsular proximal femur fractures in sports such as skiing.[51] These fractures are considered surgical emergencies due to the resultant risk of osteonecrosis of the femoral head, which has been cited upward of 38%–100% in Delbet Type I transphyseal fractures.[52] The mechanism of injury is similar to hip dislocation but typically involves a high velocity or force.

History/exam/imaging: The hip is typically held in a flexed shortened, abducted, and externally rotated position. The diagnosis should be suspected in high energy trauma with the patient unable to bear weight and complaining of groin or hip pain.[48] The diagnosis of hip fracture—physeal, nonphyseal, and intra- or extracapsular is confirmed radiographically and subsequent treatment guided based on type of fracture, displacement, and skeletal maturity of the patient.

Treatment: Immediate referral to an emergency room via ambulance transport is prudent as long bone fractures are serious injuries and can be life threatening. Immobilization of the athlete in a position of comfort is essential.

Return to play: Return to play is not allowed until the fracture is healed and range of motion with strength returns.[50]

ACUTE HAND, WRIST, ELBOW INJURIES

Hand, wrist, and elbow injuries occur acutely in many sports and athletic activities with an incidence between 9% and 29% reported for upper extremity injuries. Commonly encountered injuries include distal radius fractures and tendinous/ligamentous injuries in the hand/digits such as jersey, mallet, and gamekeeper's thumb. Elbow dislocations are also commonly encountered both simple and in combination with various fractures.[53,54] This chapter will serve to define these injuries including anatomy/pathology/epidemiology, history/exam, initial treatment, and return-to-play guidelines.

HANDS: JERSEY, MALLET, GAMEKEEPER'S THUMB

Mallet Finger

Anatomy/pathology/epidemiology: Mallet finger is an eponym utilized to describe a finger that following injury is unable to be actively fully extended at the distal interphalangeal joint.[55] The mallet injury is secondary to a discontinuity and disruption of the extensor tendon at the insertion site of the dorsal distal phalanx. Mallet injuries may be bony with an avulsion fracture at the extensor digitorum communus insertion on the dorsum of the phalanx. Mallet fingers may also be completely tendinous ruptures at the insertion site in the absence of bony injury.

History/exam: The injury mechanism of closed mallet fingers is forced flexion of the distal interphalangeal joint against an extended finger.[56] The athlete will be unable to extend the distal phalanx of the affected digit.
