Treatment: Initial treatment guidelines include gross reduction of the finger and the distal interphalangeal joint to an extended position and maintenance of this position via splinting. Commonly employed techniques include a dorsal finger splint via aluma foam or a tongue depressor secured to the digit extending from the proximal phalanx to the tip of the finger. Care must be taken to ensure perfusion of the digit tip is maintained following splinting by assessing capillary refill, color, warmth, and sensation. The patient should be referred to an orthopedic hand surgeon for close follow-up visits and to assess for need of surgical intervention. Healing of a nonoperative injury may take up to 12 weeks with the initial 6 weeks spent in a splint at all times.

Return-to-play guidelines: The patient is allowed to return to play if the athlete may safely participate with a splinted digit and comfortably performs activities required by the sport.[57]

Jersey Finger

Anatomy/pathology/epidemiology: Jersey finger is an eponym utilized to describe an injury at or to the volar distal phalanx of the hand creating a discontinuity of the flexor digitorum profundus tendon at its insertion site. Jersey injuries may be bony fractures or purely tendinous avulsions.

History/exam: The mechanism of injury is forced extension of the distal interphalangeal joint against a flexed digit tip.[58] The patient will be unable to flex the distal phalanx of the affected digit.

Treatment: Initial treatment guidelines are to place the digit into a flexed position at the distal interphalangeal joint and splint the phalange. Care must be taken after splinting the finger to ensure adequate digit tip perfusion is maintained by assessing the skin temperature, capillary refill, color, and sensation. The patient should be referred to an orthopedic hand surgeon in order to maintain close follow-up and assess need of surgical fixation—of note the necessity is of higher incidence than that of mallet injuries.[59]

Return-to-play guidelines: The athlete is not allowed to return to play until the tendon is well healed, functional, and painless range of motion regained. Operative intervention is probable; thus, the average return-to-play timeline is approximately 6 months.[57]

Gamekeeper Thumb

Anatomy/pathology/epidemiology: Gamekeeper thumb is an eponym utilized to describe an injury to the ulnar collateral ligament of the thumb at the metacarpal–phalangeal joint.[53,67] The mechanism of injury is forced abduction or a valgus force directed against the thumb. The force sprains the ulnar collateral ligament and may be graded in standard fashion as v1, 2 or 3. The injury may be purely ligamentous or may also result in an avulsion fracture from the base of the thumb proximal phalanx.

History/exam: The patient will complain of thumb pain, occasionally directly pointing to the insertion of the ulnar collateral ligament. The thumb is typically swollen and may be ecchymotic. Physical exam maneuver may include stress testing with the metacarpal phalangeal joint in 90° of flexion and extension applying ulnar stress. Should a firm endpoint not be felt, the patient should be considered as having sustained an ulnar collateral ligament rupture until further assessment.

Treatment: The treatment should involve immobilization of the thumb in a thumb spica splint. Most injuries have successful nonoperative outcomes.[60] However, following nonoperative management should the metacarpal–phalangeal joint remain unstable on stress testing, surgical intervention may be warranted.

Return-to-play guidelines: The athlete may return to play in a thumb spica cast if conducive to the sport. If a cast cannot be worn safely, return to play is delayed until the ligamentous sprain or disruption is healed and full painless motion and strength are restored to the hand. Most UCL sprains graded 2 or 3 are treated in a thumb spica cast for approximately 6 weeks.[57,60]

DISTAL RADIUS FRACTURES

Anatomy/pathology/epidemiology: Distal radius fractures are among the most common fractures of the upper extremity in the United States with greater than 450,000 occurring annually[61] and approximately 8% secondary to sports.[62] The injury is characterized as involving the intra-articular surface or the extra-articular surface.

History/exam: The mechanism of injury most commonly encountered in sports is a fall onto an outstretched hand aka FOOSH injury. Diagnosis of a distal radius fracture is confirmed radiographically but should be suspected with pain, swelling, or gross deformity at the wrist.

Treatment: The limb should be assessed for neurovascular status and placed into a padded volar splint.[61] The patient should be referred immediately to an orthopedic surgeon or an emergency room for initial treatment on the day of injury. Assessment of fracture type and further treatment plans including definitive management will be based upon fracture characteristics as delineated on anterior–posterior wrist radiograph, oblique views, and the lateral view.

Return-to-play guidelines: Depending upon the type and severity of the fracture, the return to play will be allowed once the fracture is healed (average 8–12 weeks) and painless full range of motion restored to the wrist.[57,63]

ELBOW DISLOCATION

Anatomy/pathology/epidemiology: Elbow dislocation involves incongruency of the joint surfaces of the ulnotrochlear articulation, radiocapitellar articulation, or the radio-ulnar joint proximally. Elbow dislocations are estimated to constitute 10%–25% of elbow injuries in adults.[64]

History/exam: The mechanism of injury is typically a fall onto an outstretched arm. The diagnosis is often obvious with notable gross deformation of the elbow. The most common pattern of dislocation is posterior or posterolateral accounting for approximately 90% of simple elbow dislocations.[65] Careful assessment of the neurovascular status of the arm is paramount.

Treatment: Gentle reduction of the dislocated elbow should be attempted utilizing traction and flexion of the forearm. Following closed reduction, the neurovascular status should again be assessed and gentle range of motion of the joint performed.[66] If the elbow is stable the arm should be placed into a sling, referral to an orthopedic surgeon made, and range of motion exercises initiated at 48 h following reduction. Unstable elbow injuries may require operative intervention.[61]

Return-to-play guidelines: Simple stable elbow dislocations may return to play once painless range of motion and strength are restored.[57]

INTRODUCTION

A concussion is a neurological injury sustained by forces from a blow to the head or transmitted to the head (e.g., from the body). The definition of concussion is not wholly agreed upon, but the basic premise is that force causes the brain to undergo a complex pathophysiological process, resulting in chemical changes in the brain that affect its function [1]. The cell membrane may become more permeable after injury, with resulting electrolyte imbalances, hyperglycolysis, and impaired oxidative metabolism, resulting in a functionally impaired cell [2]. The cellular impairments account for the functional, not structural, neurological problems we see in concussed athletes. Symptoms such as headache, dizziness, confusion, and others represent the injury.

Until the last few years, many medical and lay people considered concussion to be a fairly inconsequential injury. Whether referred to as "getting dinged" or "getting your bell rung," concussion was thought to be a normal part of many sports that did not interfere much with ability to play or have any long-term effects. New concerns about the long-term impact of sport-related concussion has come about, largely driven by media focus on professional athletes who have struggled to recover from brain injuries or on athletes who have died with a recent history of concussion [3]. In addition, there are emerging reports of potential long-term brain injury from concussion, in the form of chronic traumatic encephalopathy (CTE), in professional football and college football players [4–6]. The publicity generated from high-profile cases has resulted in a trend toward attitude change regarding concussion identification and management, with rule changes designed to mitigate concussion risk being implemented in many sports. In addition, federal and state legislation directed at improving concussion education, recognition, and care has been implemented in many parts of the United States.

With the new focus on concussion in sport, many questions remain unanswered.

What is the risk for concussion in sport? How should a concussion be managed? What is "normal" concussion recovery? What is the long-term risk of having a concussion? While we currently know some about concussion risk, there is probably more we *don't* know about the injury itself, how to assess recovery, and what to advice about long-term risk for injury.

We know more concussions are being sustained than previously recognized. Estimates in the 1990s put concussion incidence at 300,000 sport-related injuries per year [7], but more

recent estimates indicate incidence is likely to be between 1.6 and 3.6 *million* injuries yearly [8]. Several studies have shown the problem of concussion underreporting, which makes the real incidence difficult to pinpoint [9–11]. In any case, sports involvement at every age is increasing, with over 30 million children and adolescents participating in organized sports in the United States (US) [12]. Concussion rates are increasing in most high school sports, whether due to actual increased injuries or better detection/reporting [13]. As all types of injuries, including concussion, will logically increase as more people are involved, the knowledge of concussion risk, prevention, appropriate assessment and management if sustained, and outcome is more important than ever.

EPIDEMIOLOGY AND INJURY RISK

Effect of Age

Children up to age 18 account for the majority of sport-related concussions [14]. The pediatric population is of particular interest, since the brain is still rapidly forming and changing through adolescence, with potential for devastating effects if brain injury is sustained during development. In fact, the ongoing rapid brain development in children may actually increase their injury exposure [15]. Because children have anatomic and physiologic factors that make them more susceptible to injury and more difficult to assess, risk for injury is thought to be higher than that of adults. Increased forces are generally needed for clinical concussion symptoms to appear, due to head size and geometric differences (compared to adults) in the skull and brain [15,16]. Compared to adults, the brain undergoes a larger amount of force, with potentially more damage, to result in symptoms, which may help explain why children often take longer to recover than do adults. Lastly, cognitive function assessment in a developing brain is more difficult, and it is harder for children to accurately describe symptoms of concussion.

Given the increased risk for injury and problems with recovery, it is not surprising that a study of 100 U.S. high schools and 180 U.S. colleges showed that concussions were a greater proportion of all injuries sustained by the high school athletes (8.9%) compared to the college athletes (5.8%), even though the college athletes had a higher rate of concussion [17]. In other studies, high schoolers had both a higher concussion incidence and higher proportion of injury [18,19]. Reasons for increased injury risk are not clear, but potential causes, in addition to differences in brain structure and function, include skill of younger players compared to older, more highly selected players, protective equipment quality and condition, and increased injury exposure due to more playing time at younger ages [18].

Effect of Sex

When reviewing data on injury rates between sexes, it is important to acknowledge that there may be reporting bias that cannot be readily measured. Women have been shown to be more concerned about how their injury could affect future health [20], and they have also been shown to more honestly report injury. Sporting culture has long endorsed a mentality that men (and not women) should play certain sports (e.g., football), should play even while hurt, and should not report injuries that may keep them from playing. While these trends are slowly changing, this culture has also created a more protective environment for women, and it may be indeed easier for women to report injuries than men. As women continue to become more involved in sport and more involved in sports traditionally reserved for men, one of two things may happen: either men will become more comfortable with injury reporting, or women will become less comfortable. Hopefully our culture will continue to support what is becoming apparent with concussion; that getting an injury cared for is not only important for continuing sport play but is equally important for overall health.

Several studies have shown female athletes to be at higher risk for concussion than men in comparable sports (e.g., soccer, basketball). In a 2011 prospective study of high school sport injuries, women's high school basketball athletes had a 1.7 injury rate ratio compared to men; softball had a 1.9 rate ratio, and women's soccer had a 2.1 rate ratio.

This amounts to about twice the risk of men [13]. A 2009 critical review of sport concussion by gender [21] showed 9 of 10 studies reporting higher absolute injury rates for woman compared to men. Notably, even comparisons on absolute injury rates in ice hockey, where checking is illegal in the women's game, showed higher rates for women. In the review, mechanism of injury differed, with men having more concussions with player contact and women having more concussions with ball or surface contact. An NCAA-focused study over three seasons (1997–2000) [22] showed female soccer and basketball players to have higher concussion incidence than their male counterparts. There was no injury difference in lacrosse, softball, baseball, or gymnastics. The study did find, however, that women had a higher injury rate in games, while men had a higher injury rate in practices. Lastly, in 2007, a large study of high school and college athletes showed high school and college women to have higher concussion rates than men in the same sport [17]. The authors also note there were differences in how concussions were sustained; for example, in soccer, more girls were injured defending, while more boys were injured goalkeeping. This reminds us that how a sport is played potentially affects injury risk. In softball, pitching style is very different from that in baseball; accordingly, boys have been shown more likely to sustain a concussion being hit by a pitch than are girls.

There are theories on why women may have higher risk for concussion than men. In particular, differences in head size and shape and neck strength are thought to affect injury risk. While this is not definitive, it at least makes some sense. Women have been shown to have less head-neck mass, neck girth, and less neck muscle strength than men in several studies [23,24]. In soccer heading, increased head mass has been shown to decrease linear and angular head acceleration [25].

Given these parameters, it would follow that men are able to better control their heads and necks in sport, possibly resulting in less force transmitted to the brain, from any potential injurious situation. We understand that forces sustained by the brain are essential in the concussive injury, that those forces lead to the pathophysiological cascade of neuronal dysfunction and energy crisis that is at the center of the injury. If force can be mitigated by better head and neck control, then concussions may be reduced, especially in women [26]. Unfortunately, there is not much proof in this argument so far. Only one small prospective study has been done [27]; although 8 weeks of cervical strength training increased neck girth and some strength measures in 19 collegiate women, force application was not affected, and the study was too small to follow concussion incidence.

Effect of Sport

In the United States, football athletes have long had the highest number of concussions sustained. This is in large part due to the number of athletes playing the sport. A large study of high school injury rates confirmed that football had the highest number of concussions, but the percentage of total injuries sustained in the sport was less than women's soccer and basketball. Overall, football accounted for 40.5% of concussions. Women's soccer (21.5% of concussions), men's soccer (15.4% of concussions), and women's basketball (9.5% of concussions) followed football [17]. The most recent published study of high school concussion incidence showed football having the highest incidence and accounting for more than half of all concussions. Baseball and cheerleading had the lowest incidence of concussion [13]. Intuitively, one would think that higher contact sports would have higher exposure rates, and this has held true. Higher impact sports such as football, lacrosse, and soccer had the highest rates. However, there is concussion risk in all sports, and that should be conveyed to participants.

Knowledge of where children most often sustain concussions is helpful, since they account for so many injuries. Sport participation resulted in about a quarter of concussions sustained in a 3 year prospective study in Australia. Over half of all injuries were related to a fall. About a quarter of injuries occurred at home, and about a fifth of injuries occurred at school. Surprisingly, concussions classified as severe were sustained by children and adolescents participating in organized sports a rate *six times higher* than those participating in leisure physical activities [20]. In an emergency department study of visits for concussion, about half the concussions were sport related, and a quarter of those injuries were during organized sport [29].

Genetics

Limited research has been done on genetic influence of the ApoE protein and ApoE promoter gene on concussion risk, given association seen in some moderate-severe brain injury studies. A significant association was shown between the ApoE-TT promoter genotype and concussion in college female soccer and male football athletes in a recent retrospective study [30].

CONCUSSION EVALUATION

Despite the explosion of concussion research during the past decade, the diagnosis and management of concussion is still primarily made based on clinical assessment with the aid of supplementary tools such as symptom checklists, motor and neurocognitive evaluation, and imaging (when indicated) [1]. Current consensus guidelines recognize that concussion evaluation and management strategies are "works in progress" due to the rapid evolution of our understanding of concussion injuries themselves and expanding recognition of both their short and long-term sequelae [1,31–33]. Because of the inconsistency of presentation of concussive injuries between and within individuals and the variability of symptoms and deficits over time, many of these injuries are still unrecognized and underreported by athletes themselves, coaches, parents, and medical staff alike [10]. A high index of suspicion and consistent evaluation methods must be employed.

The evaluation process for concussion needs to begin during the preseason [34]. The pre-participation evaluation allows for an excellent opportunity to identify high-risk individuals and to provide educational opportunities regarding the signs and symptoms of a concussion to the athlete, coaches, medical staff, and parents. Athletes should be questioned on the number of previous concussions, length and type of previous symptoms, time missed from school and athletic participation, and any current problems or concerns. Knowing the athlete's concussion history is imperative to future management. Several "formal" tools have been widely utilized to aide in concussion management [1,31]. The Standardized Assessment of Concussion (SAC), Acute Concussion Evaluation (ACE), Standardized Concussion Assessment Tool (SCAT), or newly published updated version SCAT2, are a few of the many instruments that may be utilized to evaluate baseline athlete function as well as monitor post-injury progression [34]. Similarly, baseline cognitive testing during the preseason and prior to injury is being more widely implemented at all levels of athletic participation [35]. Post-injury assessments may then be compared to the individual's baseline levels to aid in return to play decisions. The implementation of computer-based neuropsychological testing has allowed for more formalized testing to a widespread audience in a cost-effective and efficient manner. Post-injury tests can then be compared to the individual's baseline performance. Attention should be given to examine preseason test results as up to 15% may be unreliable [36]. The regular use of postural or motor testing has also been gaining acceptance. Use of these and other concussion assessment tools are enhanced by obtaining baseline testing and should be considered as part of a larger concussion management policy or strategy. Many athletic governing bodies have recommended the use of one or more of these tools or

have developed/implemented policies or procedures requiring their availability as part of a structured concussion management policy. Medical providers should verify with their organization, league, state statues, or their athletic governing body as to what are their local obligations and requirements for managing concussed athletes. An emergency action plan should also be prepared and rehearsed to prepare for future injuries of this nature [37].

On-Field Assessment

The on-field evaluation of the injured athlete should focus on standard emergency response protocols including primary assessment of airway, breathing, and circulation [34,38]. Because concussions can occur concurrently with other injuries such as the cervical spine, these potential accompanying injuries need to be considered and evaluated before a decision is made on the injured athlete's immediate disposition (emergency transport versus transfer to the sideline for further evaluation). The athlete's mental status, neurologic status, and the potential for cervical spine involvement must be obtained in a judicious manner. Emergency protocols need to be enacted as necessary based on the providers' immediate assessment. Athletes with prolonged loss of consciousness should be transported emergently. Once concurrent catastrophic injuries have been excluded, the athlete can be removed from the field of play to continue the assessment process either on the sideline or ideally in a more private location such as the locker room. It is understood that practical limitations such as the number and training of the on-site medical providers and the location and proximity of the athletic contest will influence the feasibility of evaluation methods. Athletes who are acting inappropriately, or vary from their recognized baseline such as running the wrong plays, missing assignments, performing poorly, or identified by teammates should also be evaluated for a possible concussion.

Sideline, Locker-Room Evaluation

The sideline evaluation should be a continuation of the on-field assessment [38]. Less time restrictions would allow for a more in-depth assessment of athlete's function, symptoms, and mechanism of injury. Did the athlete lose consciousness? If yes, for how long? Is there associated antegrade or retrograde amnesia? What was the mechanism of injury? Loss of consciousness, historically considered a hallmark of concussion, actually is a rare finding occurring in approximately 10% of concussive injuries. Amnesia and dizziness have been associated with more severe injury and longer resolution of symptoms.

A complete neurologic assessment should be conducted. Evaluation for confusion, orientation, cranial nerve function, abnormal eye movements and pupillary response, strength of all major muscle groups, sensation of all limbs and trunk, and reflexes should be performed. Any abnormal or asymmetric finding should warrant further evaluation. A cognitive assessment should be performed to evaluate memory, the ability to perform calculations, speed, and concentration. Use of a standardized assessment tool and the availability of preseason baseline assessments allow for more appropriate interpretation of test results. An assessment of motor/postural function should also be performed when immediately possible. Single leg stance, stork test, and testing of tandem gait may be helpful in an immediate setting until a more formalized balance assessment may be performed. Comparison to the athletes' baseline data is ideal. Finally, a standardized symptom checklist should be performed post-injury and repeated serially as appropriate. Comparisons can be made with the preseason assessment to improve interpretability. Commonly reported symptoms are often reported in the somatic, cognitive, and emotional domains. Changes in athlete's behavior and personality post-injury are not uncommon and should be recognized by the medical team. Knowing the individual athlete can provide some insight into what may otherwise be subtle changes. Because concussions are dynamic injuries that evolve over time, serial assessments must be performed to monitor for deterioration or changes in status. The frequency of these evaluations will depend on the severity of injury, comfort level of the medical providers, athletes, and supervising adults. Any athletes with worsening symptoms, focal neurologic findings, or neurological deterioration may require more immediate assessment and intervention including emergent transport.

Emerging Evaluation Tools

Many new technologies are currently being evaluated for their contribution to the diagnosis and management of concussed athletes. The role of these tools is currently undefined. Software for handheld cognitive assessment, the use of biomarker from lumbar puncture and serum tests, various modalities to quantify reaction time, evaluation of the vestibular system, are some of the more common [35]. While currently considered investigational in nature, further research may emerge to justify their routine use to help guide our clinical assessment of the concussed athlete.

CONCUSSION MANAGEMENT AND RESOLUTION

Initial Management

Once an athlete is suspected of suffering a concussion, they should be immediately removed from competition [12]. Currently, many states have either enacted or are considering laws related to concussion identification and management. Many of these laws clarify who has the legal responsibility and authority to remove a suspected injured athlete from competition and who has the authority to return them to competition [39]. In addition, many athletic governing bodies have developed specific policies, protocols, or recommendations that outline an athlete's return to play. The purpose of these statements is to provide as much as possible, a uniform,

safe return to competition for the injured athlete without undue pressures from outside influences. Communication of the injury status of the athlete with the athlete themself, team medical staff, and coaches is crucial [40]. When possible, the athlete should be removed from the sideline for the remainder of the competition. An adult supervisor, ideally someone familiar with the particulars of the situation and concussion management, is recommended to monitor the injured athlete for the initial 24–48 h post-injury for any change in status or worsening of symptoms. Collection of an injured athlete's helmet or other medical equipment at the time of injury and diagnosis will help to ensure that they do not unintentionally return to competition [41]. Serial evaluations should be performed by the medical staff to monitor for changes in symptoms. When appropriate, a final disposition must be rendered as to the individual diagnosis (concussion or suspected concussion) and if the patient is considered safe to return home or travel with adult supervision, or will require more urgent evaluation. Signs and symptoms that would trigger a more immediate evaluation include worsening headache, seizure, focal neurologic signs, lethargy, repeated vomiting, slurred speech, unable to recognize person or places, increasing confusion, behavioral changes, or irritability, weakness or numbness in arms or legs, neck pain, or prolonged loss of consciousness [42].

Management of the acutely concussed athlete should include education of the signs and symptoms of concussion as well as communication with their adult supervisor. The injured athlete should *discontinue all physical activity* and limit extraneous or extracurricular daily activities as much as possible. The term cognitive rest has all been developed to describe similar limitations for activities that require higher brain function. Symptomatic athletes should limit all cellphone, Internet, and video game play. If they are attending school, considerations should be made regarding school attendance and limiting school work [43]. The purpose of these recommendations is to provide the athlete with a period of rest and recovery without provoking or worsening symptoms. Communication of these recommendations to the athlete's teachers, or counselor is important. The athlete should discontinue driving or operation of heavy machinery. They should be instructed to discontinue any use of alcohol and illegal substances. The use of any and all medications should be discussed with the medical provider to avoid masking of symptoms. An appropriate plan for follow-up should be developed and communicated [37,44].

A host of new treatment options are being explored in the management of acute concussion and post-concussion symptoms. Unfortunately, few well-conducted randomized controlled trials have been performed to support their use. Most of these current uses are considered off label. It is unclear as to what role these will play in the future, or which patients will be more optimally managed given their administration. Most of these drugs or supplements are theorized to treat particular symptoms, especially in athletes with more severe difficulties or prolonged symptoms. Some of the more widely used medications include amitriptyline, gabapentin, amantadine, methylphenidate, seizure medications, "triptans," muscle relaxants, anti-inflammatory agents, and SSRIs [45–50]. Various supplements such as fish oil, flax seed oil, DHA, omega-3, and antioxidants have been theorized to improve recovery of lessen the amount of injury. One important point to recognize is that, if medication is being used to manage an athlete's symptoms, it should be noted that they should not be considered asymptomatic. The risk of returning an athlete to play while taking medication to suppress symptoms is unknown. Other emerging treatment modalities have been implemented in an effort to facilitate recovery from a concussion. Heart rate–based rehabilitation programs are being implemented to stress an athlete at subthreshold levels. Vestibular rehabilitation programs can be utilized to help manage dizziness and postural difficulties. Manual techniques can help manage headache associated with cervical strain often occurring concurrently with a concussion. The exact role and timing for implementation of these therapies is still being investigated; however, they provide alternative measures to help treat more complicated injuries.

The decision on whether or not to image an acutely concussed athlete is dependent on several factors: the presentation of the athlete, symptoms, and changes in symptoms, presence or absence of any aforementioned "red flags," the comfort level and experience of the medical provider in managing concussions, and the comfort levels of the athlete themselves, their parent, or supervisor. In general, a CT scan is the imaging modality of choice to evaluate for underlying pathology that may mimic a concussion in an acutely injured athlete due its speed, cost, and availability [12]. While helpful to assess for a competing diagnosis, a negative CT scan does not "rule out" a concussion. Concussive injuries are not considered to cause visible structural defects on a standard CT image. MRI may also be considered to evaluate patients with more long-standing, severe, or worsening symptoms. Similar to CT, standard MRI sequences generally do not reveal abnormal structural changes induced by a concussive injury; however, newer sequencing techniques and enhanced resolution may provide additional insight than current standard imaging protocols [12]. Many other more advanced imaging techniques are being developed but are not widely available or considered the standard of care at this point in time (fMRI, MRI spect) [51–53].

New Management Technologies

Innovative tools are also being explored for the routine management of concussion. While these tools are currently considered investigational at this time due to their lack of standardization, cost, and availability, further research may justify their use in management of future concussed athletes. Some of the more promising technologies include ocular motor/vestibular testing, genetic studies such as Apo E4 and other genes, and biostatistical techniques to identify at-risk individuals [30,54,55]. Research continues in the area of protective equipment such as improved materials for helmets

and head gear, improved helmet fit, and design [56–58]. The use of helmet or mouthpiece-based accelerometers may help medical providers identify individuals at high risk of injury [59]. Additional assessment tools of reaction time and neurologic function such as EEG, MEG, ERP, and EP may help in both the diagnosis and management of injuries. Biochemical techniques such as use of CSF markers such as AB, APP, Tau, NF-L, GFAP, S100B, CK-BB, IL-1B, and IL-6 are being explored for their diagnostic and predictive value [60–64].

Similarly, serum markers such as AB, amyloid A, CRP, retinol-binding protein 4, neuron-specific enolase (NSE), myelin basic protein (MBP), Tau, CK-BB, GFAP, IL-1B, IL-6, and S-100B may contribute to future concussion management. While these technologies are promising, the use of these additional evaluation methods is still exploratory at this point and considered in the context of well-designed research trials only.

RETURN TO PLAY

One of the most difficult decisions in all of sports medicine is to decide when a concussed athlete is safe to return to play [65]. There have been more than 40 different return to play guidelines published over the last few decades, none of which were outcomes based. All of these former guidelines have since been abandoned. The current trend in concussion management has called for a more conservative return to play approach than outlined in historical reports. The current best medical consensus opinion was outlined by the Concussion in Sports (CIS) Group and updated in 2008. The CIS is an international panel of experts that has been meeting regularly to review the current medical evidence regarding the management of sports concussion. Their current recommendation acknowledges the need for an individualized assessment of the injured athlete followed by a gradual return to physical activity in a graded nature once symptoms have completely resolved. Before an athlete is returned to play, he/she is required to have a completely normal physical and neurocognitive exam. Athletes can be progressed from one step to the next if they remain symptom-free with a minimum of 24 h recommended between steps. If symptoms recur, the athlete should drop back to the previous step where they were asymptomatic. The progression is noted next [1]:

1. Rest (until asymptomatic)
2. Light exercise (walking, stationary bike)
3. Sport-specific activity (i.e., skating in hockey)
4. Noncontact drills
5. Full-contact drills
6. Game play

The use of supplementary assessments in addition to an athlete's reported symptoms has become more widely implemented. Specifically, the addition of a more formal cognitive assessment and postural testing has been found to complement assessments by symptoms alone. Broglio et al. [66] has reported on the value neurocognitive and postural assessment and that 89%–96% of athletes had abnormal finding on assessments at 24 h after injury. Unfortunately, it is still unclear if the tracking of reported symptoms, neurocognitive performance, postural testing, or a combination of these three domains truly mimic physiologic recovery. Each of these areas has its own limitations. Symptom assessment has been the mainstay of concussion management programs for decades; however, concerns of underreporting and denial of symptoms, or concomitant medical conditions necessitate that more objective measures be utilized in managing these athletes. Symptom recovery has been shown to take longer in children (greater than 1 month) compared with adolescent athletes [67]. Collegiate athletes reported a faster recovery compared to high school athletes with most recovering in 1–2 weeks [68,69]. Cognitive impairment has also been associated with concussive injury [69,70]. These often tend to resolve quickly in most individuals (5–7 days) [69], although resolution may precede or persist after symptom resolution [66]. Neurocognitive assessments have been shown to have their own limitation with "gaming," environmental factors, motivation, and fatigue affecting the results [71,72]. Finally, postural or balance testing is also gaining favor as an assessment tool given that it also may precede or show persistent deficits after symptom resolution [73]. Further investigation as to the ideal use and interpretation of these tools is necessary to optimize patient care [74].

Other Considerations

Several other factors should also be considered in guiding return to play decisions. While many of these are difficult to presently quantify, consideration should be given for a more conservative approach:

1. Age of the athlete—Children have been shown to have biochemical and structural differences that may influence recovery [75,76]. Symptom recovery has been shown to be slower in children versus adolescent athletes, as well as in high school versus collegiate athletes; thus a more conservative return to play may be reasonable [65,67,69,77]. The CIS group recognized these issues and applied their guidelines to children >10 but also noted that younger athletes may require a more conservative approach [15].
2. Concussion history—Athletes with a history of multiple concussions, prolonged symptoms, amnesia, or short interval between injuries may be at risk for repetitive head injury and require a more conservative approach [78].
3. Abnormal brain—Athletes with a previous history of neurologic disease (seizure disorder), learning disability, ADHD, etc., may be at increased risk for concussion [79].
4. Gender—Female athletes have reported more severe symptoms and a more prolonged recovery compared to male counterparts in the same sport [22].

5. Sport—The risk for concussion varies by the nature of sports, position, and possibly protective equipment. High-risk individuals returning to high-risk sports may require a more gradual return.

Same-Day Return to Play

Currently, the same-day return to play of a concussed athlete remains controversial. While common practice at some level of sports, the trend is clearly moving toward a more conservative nature. The National Football League reported that 51% of concussed players in 1990s to early 2000s returned to the same game [80,81]. Recent updates to league policy and new proposed updates regarding concussion no longer allow this practice. The CIS group guidelines from Prague initially did not allow for any same day return to play, but these were softened for adults in their Zurich update [1,31]. Currently, only the NATA guidelines allow for the same day return of an athlete in limited circumstances. Despite these differences, all guidelines agree that no symptomatic athlete at any level should be returned to play.

POTENTIAL CONCUSSION COMPLICATIONS

Post-Concussion Syndrome

Post-concussion syndrome (PCS) is a diagnosis that represents a delay from the expected healing from concussion. Simply put, patients who have concussion symptoms that last longer than we think should have PCS. The problem lies in the moving target that is concussion resolution. We do not know, with certainty, when symptoms should resolve. As noted earlier in the chapter, there are many issues that potentially affect concussions, such as age, gender, and genetics. There is controversy about when the diagnosis of PCS should be made, but there has been a trend toward earlier diagnosis, sometimes as early as 3–4 weeks after initial injury. *The Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, states three or more symptoms of concussion must persist for at least 3 months after injury to make a diagnosis of PCS.

PCS is important to identify, as the symptoms (cognitive, psychological, somatic, psychosocial) may start to dramatically affect the athlete's life. Every aspect of life can be altered, including social, sport, school, and work. The risk of PCS varies with comorbidities and treatment, and the exact incidence is not known, but it has been estimated to occur in 10% of concussion cases [82]. The diagnosis is often missed; a British study demonstrated that only 60% of general practitioners were able to recognize PCS on the basis of symptoms [83].

Radiographic imaging (e.g., CT, MRI, fMRI) is not currently used to make the diagnosis of PCS, as imaging techniques are not yet sensitive enough to demonstrate the injury. However, other cranial abnormalities can be identified or excluded by these techniques. The diagnosis of PCS should include evidence of neuropsychological test performance deficits, in addition to clinical symptoms. Neuropsychologists can assist with academic and work accommodations appropriate for present cognitive deficits and can help follow cognitive progress as the patient progresses.

Treatment of PCS is outside the scope of this chapter; however, realize that treatment can be very complex, with managing multiple symptoms over a long period of time. Managing headache, sleep, and neuropsychological symptoms may involve medication and psychotherapy, in addition to academic, work, physical, social, and other life accommodations.

Second Impact Syndrome

A much rarer, but more catastrophic, condition associated with concussion is second impact syndrome (SIS). SIS can occur when an athlete sustains a second concussive injury before symptoms from the first concussion have resolved. The brain is thought to lose ability to regulate its blood supply, and brain herniation occurs [84]. The second impact may be comparatively minor, but unfortunately, the vast majority of these cases are fatal. Reported cases in the literature almost exclusively involve high school aged athletes.

CONCUSSION PREVENTION

Protective Equipment

Although helmets were initially introduced into sport to prevent catastrophic head injuries, such as epidural hematomas and skull fractures, recent attempt has been made to decrease concussion incidence through helmet technology. It is difficult to separate concussion from all head injuries in many studies, but there are data showing skiers and snowboarders wearing helmets have risk reduction of head injury [85,86], as do bicyclers [57]. Almost all of the concussion-specific research has been done in American football. Some helmet designs have shown decreased force transmission, but definitive decrease in actual injury has not yet been demonstrated [56]. A methodologically flawed study in high school football athletes did show a 31% reduced relative concussion risk with a helmet designed to reduce head and face contact forces [77].

Rugby and soccer headgear have been introduced into their respective sports to decrease concussion risk. The intention is good; if headgear compatible with the game as currently played can reduce concussion, the sport is improved. No randomized controlled trials have been done in soccer. One large non-randomized study of youth soccer athletes [87] demonstrated those not wearing headgear had more concussions than those who did, but symptom self-report was used in this study that defined concussion as the presence of any concussion symptom (e.g., headache, fatigue), posing a real problem with methodology. In rugby, two randomized controlled trials have not found that protective headgear decreased concussion incidence [1,88].

The addition of protective equipment to sports not currently using it (e.g., helmets in women's lacrosse) may decrease concussion risk, but this is only theorized. Continued

injury epidemiology is important to understand where most injuries occur and to direct injury prevention toward those mechanisms.

Time away from sports participation for an injured athlete has physical, mental, and financial sequelae. Therapeutic modalities have the ability to impact these iatrogenic effects and improve the healing environment. Thermal and electrotherapeutic interventions do not directly accelerate biologic healing; however, when manipulated, they can maximize the effectiveness of rehabilitative care. This chapter provides the health care professional with an overview of the scientific basis for the use of therapeutic modalities. Superficial application of heat and cold, ultrasound, phonophoresis, iontophoresis, electrotherapy, and the emerging practice of laser application are discussed.

CRYOTHERAPY

Cryotherapy is one of the most commonly used modalities in sports medicine [1]. There is strong evidence for the efficacious use of cryotherapy in the treatment of acute inflammatory conditions and muscle soreness. Decreasing tissue temperature through the use of cryotherapeutic interventions can assist with decreasing pain [2,3], spasm [4], and swelling [4,5], caused by acute injury. Overall, cryotherapy decreases tissue temperature by removing heat "conduction" from the surrounding tissues. Conduction occurs at the interface between the cold modality and the skin as well as between superficial and deeper tissue layers. In the animal model, the therapeutic goal for reducing cellular metabolism without cellular damage is cooling tissue to 10°C–15°C; this may be considered in limb salvage, but the optimal temperature goal in cold use for rehabilitation in humans is unknown [6]. In general, human skin surface temperatures are between 30°C and 35°C before treatment, and the cold-induced analgesia begins as 13.6°C [3]. Temperatures during or after treatment should not be reduced below 10°C to preserve cell integrity [6]. Cryotherapy has been shown to decrease nerve conduction velocity and increase pain threshold and tolerance. In one study, nerve conduction velocity was shown to decrease 0.4 m/s for each 1°C decrease in temperature [7]. Diminished nerve conduction velocity is likely responsible for the decrease in pain associated with the use of cryotherapy.

A number of cold therapy application methods exist including ice bag, gel packs/chemical cold packs, cold or ice water immersion, ice massage, and commercial circulating and/or compressive cold devices. The goal in each of these devices is to reduce the tissue temperature, and each offers different advantages to the user. Ice gel and other chemical ice substitutes are reusable, do not melt or drip, and can mold to the target surface area especially at bending joints. These ice substitutes can reach temperatures in the freezer of –5°C to –15°C compared to ice at 0°C, creating a higher risk for tissue damage at the time of application [8]. Ice massage allows for local cooling combined with a therapeutic goal of

tissue friction while commercial circulating units combine the motion of ice chilled immersion with the convenience of a dry, contained apparatus easy to use in the home setting. Compression coupled with ice has the added benefit of increasing contact area and possibly limiting rewarming from surface air [9].

In 2000, Barber compared two cryotherapeutic interventions on 87 patients following anterior cruciate ligament (ACL) reconstruction. The study found continuous-flow cold therapy (commercial circulating unit) to be more beneficial than bagged crushed ice in terms of lowering pain, reducing the use of pain medication, increasing knee flexion, and improving functional ratings [10]. In this study, the patients were instructed to use the cold modality constantly for 3 days and as needed for days 4 through 7. The group using crushed ice was instructed to replace the ice when it melted. One must question the impact of compliance in the use of the crushed ice constantly for 3 days due to the challenges inherent with melting, dripping, and waking from sleep to add ice; a circulating unit avoids these challenges. Although compliance was not measured in this study, the convenience of commercial circulating units is likely to increase adherence to wearing schedules when long periods of cooling are suggested. In 2007, Kennet et al. compared 20 min application of four commonly used cold modalities (crushed ice, gel pack, frozen peas, and ice water immersion). Crushed ice and ice water immersion were found superior to gel pack and frozen peas at decreasing tissue temperature, 17°C–19.5°C drop compared to 13°C–14.5°C drop. The investigators also cautioned that the low pre-application temperature of both the gel pack and the frozen peas may place the tissue at risk and therefore the skin should be protected and routinely monitored with their use [11].

Compliance in ice therapy is an important factor for effective use. Warren et al. [12] studied skin and intra-articular temperature changes in the knee during and following a 60 min treatment of ice compared to a chilled water cryotherapy device. The authors concurrently recorded pain levels on a visual analog scale (VAS) with the two devices. Ice was more effective at reducing both skin and intra-articular temperatures compared to the cryotherapy device at all time frames measured; skin/intra-articular decreases at 30 min ice (21.4°C/3.3°C) and cryo (14.8°C/2.2°C); 60 min ice (26.2°C/12.8°C) and cryo (16.7°C/7.1°C); 90 min ice (12.3°C/15.2°C) and cryo (8.2°C/9.7°C); and 120 min ice (5.8°C/11.2°C) and cryo (4.4°C/5.7°C). However, while measuring visual analog pain (scale of 0–10 cm), the authors found that the ice group had clinically significant higher pain (0.7 cm and 2.2 cm on VAS) at the 30 and 60 min time frame respectively when compared to the cryotherapy group (2/10 cm). As you can see by the average temperature reductions at different time periods, the intra-articular region benefited from cooling for 60 min compared to 30 min; however, higher associated pain may have implications on compliance. Research should continue to combine time, especially the multiple 10–30 min bout cycles, with pain reports to find the most tolerable yet clinically valuable cryotherapy parameters.

Compression has been proposed to assist with cooling and reducing tissue temperature. Tomchuk et al. compared 30 min of ice bag using an elastic wrap with a commercial wrap (Flex-i-Wrap, Cramer Products Inc, Gardner, KS) to no compression. They found that superficial temperature decreases were greater with compression (elastic and commercial) than without while intramuscular tissue temperature decreases were greater using the elastic compression versus the commercial wrap. Overall, [13] supported the use of elastic wraps for compression with acute injuries. Ice massage is an effective means of providing maximal tissue cooling more quickly than other cryotherapy methods and is most beneficial for a localized treatment area [14]. Ice massage performed for 5 min to a 4 in. × 6 in. area of the posterior thigh was found to decrease superficial tissue temperature by 13.5°C, tissue 1 cm deep by 8.8°C, and tissue 2 cm deep by 4.1°C [15]. A systematic review by MacAuley [18] on the literature available on tissue cooling concluded that many studies lack sufficient information to directly compare all cooling methods to determine the best method of cooling; however, they found that the literature routinely supports that standard ice packs applied directly to the target tissue through a wet towel are effective in achieving an optimal tissue temperature reduction of 10°–15°.

Depth of penetration of tissue cooling has also been studied. Merrick et al. looked at the thermodynamic properties of three methods: ice bag, ice in cloth lining "wet-ice," and frozen gel pack (Flexi-Cold), comparing the tissue temperature changes at three depths (skin surface, superficial adipose layer +1 cm, and superficial adipose layer +2 cm). They concluded that ice-based treatments (ice bag and wet-ice) were more effective at lowering superficial skin temperature and the superficial adipose layer +1 cm depth compared to frozen gel packs (Flexi-Cold). However, at a depth of the superficial adipose layer +2 cm, there was no significant difference between the treatments [16]. The authors conclude that tissue temperature decreases are not commonly seen at a depth of 2 cm below the subcutaneous adipose layer [16,17] and superficial skin temperature changes are not a predictor of deeper intramuscular tissue temperature changes (2 cm below subcutaneous adipose layer; [17]). Future studies must continue to measure temperature changes at multiple depths to provide meaningful information about tissue response to cryotherapy.

Longer time frames may be needed to cool deeper tissues. Since deeper tissue will conduct heat toward the more superficial layers as they cool, deeper layers can continue to become cooler over time [18]. Although evidence regarding the optimal duration of treatment is lacking, considering the average tissue depth, [8] performed a systematic review on time periods from 5 to 85 min of ice application and concluded that the first 10 min after cold application provided the greatest therapeutic effect, and much smaller and slower changes, if any, occurred after that time period. To maximize this effect, the author recommends repetitive application

bouts of 10 min to achieve lowered tissue temperature of both superficial and deeper structures [8]. Human studies looking at the influence of subcutaneous fat suggested that the time frame of cooling when an individual has less than 1 cm of adipose was optimally 10 min; however, if dealing with athletes with greater than 2 cm of adipose, their recommendation was to increase the cooling time to 20–30 min [19]. In combining data, the evidence recommends repetitive 10–30 min bouts for cryotherapy application; the optimal rest or off time between bouts is unknown.

Tissue damage can occur when cold modalities are incorrectly applied or not monitored. For that reason, one needs to consider the precautions and contraindications associated with the use of cold modalities. There are several precautions to using ice including diminished sensation, active infection, near or over eyes, and tissue that is at risk for damage [20]. Contraindications include impaired circulation (active deep vein thrombosis [DVT]), cold hypersensitivity (cold urticaria, Raynaud's disease), over-regenerating nerves, chronic wounds, and anterior neck and carotid sinus damage [20]. A layer of protection should be applied between the cold therapy and the skin with the exception of ice friction massage. Special attention should be paid for gel and chemical packs as their initial pre-application temperature is lower than ice, so skin should be monitored more closely with their use. Circulating cold units provide continued cold to the skin, and although they have a nylon cover holding the fluid, the skin should still be monitored as burns can occur (see Figure 65.1). When compression is added to these devices, it can also create pressure spots of increased cold density, and they should routinely be unwrapped and skin inspected.

Since cold has the ability to impact nerve conduction and cellular metabolism, an athlete should adequately warm up after receiving cryotherapy prior to participation in activity. The impact of cryotherapy on joint position sense is variable, but if altered, this loss of proprioception may place the cooled area or an adjacent area at risk for injury. Joint position sense was found to be altered at the knee following application of ice using a circulating device for 15 min [21] and at the ankle after a 15 min ice immersion treatment [22]. However, [23] found that an ice bag applied for 30 min did not impair shoulder joint position sense in healthy individuals. Muscle strength [24] and performance [25] have also been shown to be diminished after receiving cryotherapy. Clinicians need to take all of these physiological effects into account as precautions when using cryotherapy before an activity as the athlete may be more susceptible to injury during the first 30 min following ice treatment [8].

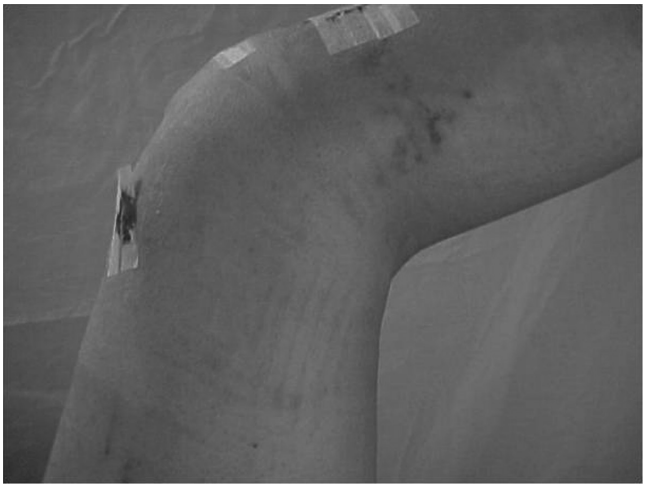

FIGURE 65.1 Example of burns following prolonged use of a commercial circulating cold device.

Ice may not always be readily available to an athlete or their therapist especially during travel activities. A prospective, randomized, double-blinded controlled study by [26] demonstrated the efficacy for use of a cold gel for minor, acute soft tissue injuries. The gel was made with 3.5% menthol and 8% ethanol as the primary cooling agents. The gel was applied four times a day for 14 days following sports-related soft tissue injury. Pain was monitored throughout the experiment and continued for an additional two weeks. Pain decreases were significant when compared to placebo group at 7, 14, and 28 days. Clearly, the most effective cooling agent is one of the cold modalities previously discussed; however, these findings may indicate that a cold gel is better than nothing when ice cannot be accessed.

Cryotherapy is a safe modality with few contraindications. The only danger occurs with long-duration applications at low temperatures. The evidence for effectiveness of cryotherapy in the treatment of acute musculoskeletal injuries is strong in theory and practice and therefore can be an inexpensive, effective modality.

SUPERFICIAL HEAT

Superficial heat, in the form of hot packs (moist or dry), hydrotherapy, infrared heat lamps, and over-the-counter commercial heat wraps, is most frequently used in sports medicine as an adjunct to rehabilitation training and/or conditioning. The therapeutic effects of increased circulation and muscle relaxation occur as a direct result of tissue warming while the corresponding pain relief is largely attributable to the muscle relaxation. In order to achieve a physiological response, tissue temperature must be elevated to 40°C–45°C [27–30]. Heating prior to activity or after activity or both are common in the sports medicine community.

The evidence is largely theoretical, but clinically, superficial heat is often used before stretching superficial muscles. Because heating increases blood flow, the increased tissue temperature rapidly dissipates after removal of the heat source. To maximize tissue extensibility, performing the stretch either concurrently with superficial heat or immediately following removal of the heat would minimize heat loss and theoretically increase the effectiveness of the stretch. However, recent studies suggest that the muscle flexibility changes seen with the combination of superficial heat and stretching did not outperform stretching alone [31,32].

Knight et al. [33] evaluated the combination of different types of heating coupled with a stretching program of ankle dorsiflexion (runner's stretch) performed three times weekly for 6 weeks on ankle dorsiflexion range of motion. The greatest gains in ankle dorsiflexion were seen in the group with 7 min of deep heat modality (ultrasound) prior to stretching compared to control with no stretching, static stretching only, active heel raises prior to static stretching, or superficial moist heat prior to static stretching. All groups outperformed controls at 2 and 4 weeks; however, the deep heat group outperformed the other experimental groups only at 2 weeks; neither deep nor superficial heat outperformed stretching alone after the 2 week time period. In general, superficial heating may feel better, but it does not appear to yield greater increases in tissue length, and the added benefit of deep heat may be short-lived.

The medium through which heat flows can also influence the tissue response. Petrofsky et al. studied the impact of 15 min of infrared heat lamp applied with either a wet towel (moist heat) or a dry towel (dry heat). He concluded that moist heat increased blood flow by 386% and skin moisture by 44% while dry heat increased blood flow by 282% with no corresponding increase in skin moisture [34]. Moisture present during the transfer of heat is a more effective medium than air. Dry heat must contend with air contact between the skin and the heating element slowing the rate of heat transfer [35]. Since the heat transfer is slowed, dry heat can be safely applied over a longer period of time.

The time needed to transfer heat can be influenced by body fat as it functions as an insulator preventing heat penetration. Petrofsky et al. measured the skin temperature and the temperature 25 mm below the skin surface under three conditions: warm whirlpool (40°C), moist hot packs with eight layers of towel (73°C), and dry heat with a chemical dry pack (42°C) [36]. He followed the treatment times most commonly used, 15 min for both the moist hot pack and whirlpool conditions and 6 h for the chemical heat pack (commercially available in drugstores to be worn throughout the day). Petrofsky et al. determined that body fat did not influence penetration depths of heat with the dry heat modality applied for 6 h. The thin and overweight subjects showed significant superficial heating increase (6°) by 30 min and the heating remained relatively stable for the 5–6 h; a lesser increase in deep muscle heating peaked at 2 h (2°) and continued until hour 6. The moist heat modalities applied for a shorter period of time (15 min) had rapid superficial changes of 6° within 5 min; however, the deep muscle was less responsive (1°) and all responses were diminished in the overweight group [34]. The authors concluded that a slower dry heating modality may be most effective in those overweight patients with higher adipose. The clinical goal of heating may also be beneficial over a longer period of time, for example, throughout a golf outing, and the use of these commercial self-stick heat packs can be considered when prolonged effectiveness and depth of penetration are important.

In a 3 year claims review, hot pack burns were identified as the second leading cause of malpractice claims in physical therapy behind traumatic fractures [37]. Fyfe [38] investigated the relationship among subject's first perception of warmth, skin temperature, and skin color following application of moist hot packs with eight layers of toweling (standard amount of toweling to protect the skin) to the lumbar spine. Warmth was first perceived by 99% of the individuals within 1 min of application and maximal heating occurred within 9 min of their first perception of warmth. The subject's skin temperature was recorded, the therapist was also asked to clarify the color of the skin (unchanged, slightly pink, pink, and very pink/red), and the subject was asked to report their sensation (slightly warm, definitely warm, very warm, hot). Interestingly, in those patients whose skin color was recorded as very pink/red, 7% rated the sensation as slightly warm, 28% as definitely warm, and only 30% felt the skin was hot. This lack of correlation between perception and the clinical indication of skin color means that asking a patient how they feel about the temperature is insufficient to ensure protection. The therapist should both visually inspect and verbally question a patient to ensure they are protected during the first 10 min of the treatment [38]. Reports of discomfort and visual color changes of an extreme nature warrant use of more toweling at a minimum or cessation of the modality.

Lying supine on hot packs is discouraged because the weight of the body on the hot pack can cause greater transfer of heat in prominent areas especially in areas where the pressure restricts blood flow and higher risk of burns exists. Additionally, special care should be taken when heat is applied over bony prominences even in non-weight-bearing positions. Less dense tissue can heat more quickly, and if pressure impedes blood flow, the heat dissipation can be retarded leading to higher burn risk. If sensation or circulation is impaired, gentle heating should be used and the skin should be monitored for signs of distress. Superficial heat should not be used over areas of acute inflammation, active infection or hemorrhage, or known malignancy. In the case of vascular insufficiency or absence of sensation, heat is not a viable treatment option. Use of heat should be avoided if the individual cannot communicate effectively to convey possible distress. Lastly, heat should not be used in conjunction with application of topical liniments or heat rubs as there could be an accumulation of heat that yields an adverse reaction. If liniments have been applied, the skin should be thoroughly washed prior to using any form of heat. Superficial heat can be used to increase temperature, increase circulation, and decrease muscle spasm.

HYDROTHERAPY

Hydrotherapy, including cold water immersion (CWI), hot water immersion (HWI), and contrast water therapy (CWT), is used to directly treat athletic injuries or as a form of recovery from athletic participation. Typically,

the water temperature for HWI is between 39°C and 41°C, and CWI is 13°C–16°C. The physiological effects of these applications are similar to those discussed in superficial heat and cold application with water serving as the medium. When agitation and movement in the water occur, the layer of insulation around the body continually erodes and the rate of temperature transfer is accelerated utilizing convection [39].

CWT, repetitive application of heat and cold in an alternating fashion, has been widely used in the treatment of athletic injuries and more recently attempting to contribute to recovery after rigorous exercise. Two systematic reviews of CWT by Stanton et al. [40] and Hing et al. [41] demonstrate that despite anecdotal evidence that CWT is beneficial, there is very little scientific evidence to support or refute its clinical value mainly due to the poor methodology of published articles on the topic. Additionally, it has been theorized that CWT produces a "pumping action" as the alternating between hot and cold creates vasodilation and vasoconstriction, respectively. Several have questioned the legitimacy of this theory, since intramuscular temperature changes were not significantly improved with the use of contrast therapy [41] and the lymphatic system is not capable of contracting to contribute to the removal of edema through this "pumping action."

Great variation in the literature exists regarding the parameters used in CWT only adding to the challenges in determining its efficacy. The 10–15 min treatments of 3:1 or 4:1 ratio (minutes in hot water compared to time in cold water) were the two most commonly utilized protocols in the literature, yet the ratio range was 1–10:1–5 and the total duration was 6–31 min [41]. Stanton et al. [99] found that the range of water temperature was 41°C–45°C for hot and 8°C–16°C for cold while [41] found the range to be more narrow for the hot water (38°C–40°C) and similar for the cold water (10°C–15°C). If the clinical goal is to cool or heat, contrast bath before the intended modality has no additive benefit and its role in assisting with swelling is unsupported.

Several recent studies have attempted to evaluate functional recovery to activity. Ingram et al. [42] found 2 min × 5 min of CWI (10°C) was superior to both CWT consisting of three alternating episodes of 2 min cold (10°C) and warm/hot (40°C) when assessing complaints of muscle soreness 24 h after exercise. Additionally, CWI demonstrated improved return to baseline strength when looking at leg extension and flexion. Vaile et al. [43] investigated four conditions (and control) for endurance cyclists randomly assigned following five consecutive days of high-intensity exercise. CWI (15°C for 14 min) and CWT (seven cycles of 1:1 cold at 15°C and warm at 38°C) were found to assist recovery as a result of seeing improvements with time trial performance and sprint performance when compared to decreases in performance noticed following HWI (38°C for 14 min) and passive (14 min sitting with minimal movement) interventions.

Anaerobic performance measured by maximal isometric voluntary contraction and maximal 30 s rowing test was found to have slightly improved recovery following both cold modalities of CWI and CWT [44]. CWI has been used by athletes with multiple competitive bouts in a day as a means to decrease delayed-onset muscle soreness (DOMS) or exercise-induced fatigue [45]. There is evidence to suggest that both cold modalities improve postexercise swelling, dynamic jump performance, and isometric force compared to no treatment at all. It is unclear if these outperform other forms of cold application; however, in general, cold treatment after exercise appears to have some potentially beneficial effects when available [42].

Full body water immersion techniques, "ice bath," have been used in an effort to accelerate the recovery period following successive bouts of strenuous exercise (e.g., tournaments when athletes have to compete multiple times in a short time frame) and are becoming a more popular trend. In a systematic review by Bleakley and Davison [46], cardiovascular, respiratory, temperature, metabolism, and biomechanical responses to short bouts of CWI (<15°C) were reviewed. Although physiological changes were seen in heart rate, blood pressure, respiratory volume, metabolism, and cerebral blood flow and biochemical changes in peripheral catecholamine, oxidative stress, and free radical formation, the studies were all performed on healthy individuals leaving the generalizability to recovery to athletic activity unanswered.

Hydrotherapy provides an environment for the entire limb to be immersed in water, increasing surface area coverage. Exercises can be performed simultaneously. The main disadvantage of whirlpools is that the limb is dependent. When swelling is a concern, whirlpool may not be an optimal therapeutic option. The decision to warming or cooling a limb is dependent on the intended therapeutic goal, and hydrotherapy can be considered as an application of these thermal agents. The new trend of whole-body ice immersion or "ice bath" has little scientific evidence to support or refute its usefulness while potential dangers exist. More high-quality efficacy and safety evidence on this intervention is needed.

ULTRASOUND

Ultrasound is the propagation of sound waves through soft tissue causing vibration of molecules and subsequent production of heat. The ultrasound sound head contains a piezoelectric crystal that creates the wave and is responsible for transmitting energy to the target tissue. The tissue density dictates the dissemination of ultrasound waves from the piezoelectric crystal to the targeted tissue. Dense tissue predominantly composed of protein absorbs ultrasound energy most effectively (i.e., tendon, cartilage, and bone) [47].

Ultrasound frequency, intensity, and mode can be altered to reach a variety of tissue depths for the desired

therapeutic effect. Ultrasound waves travel in a sinusoidal oscillatory pattern. The frequency is defined as the number of oscillations per second and dictates the depths of structures targeted within a treatment session [48]. Frequency is inversely proportional to the depth of penetration. Therefore, administration of 1.0 MHz ultrasound targets deeper tissues (up to 5 cm deep) such as the quadriceps or gastrocnemius muscle bellies, whereas 3.0 MHz ultrasound targets more superficial structures (1–2 cm deep) such as the patellar tendon [49]. If 1.0 MHz is used to heat superficial structures such as patellar, Achilles, or peroneal tendons, the underlying bone will absorb the ultrasound waves, creating discomfort due to overheating of the periosteum. At 3.0 MHz, the depth of ultrasound penetration is shallower, more energy is absorbed in the superficial soft tissue structures, and less energy is absorbed by bone, thus decreasing the risk of discomfort during ultrasound administration [50,51]. Clinically, if your targeted tissue is <2 cm deep, 3.0 MHz is the most appropriate frequency to utilize, while 1.0 MHz should be used if the targeted tissue is 2–5 cm deep.

Intensity refers to the strength (watts) of the ultrasound wave produced by the transducer with respect to the size (cm^2) of the transducer measured in watts per square centimeter (W/cm^2). As the ultrasound intensity increases, the rate of tissue temperature rises [49]. Tissue temperature increases between 1°C and 4°C have been shown to produce changes in soft tissue. Mild heating (1°C temperature increase) accelerates metabolic rate of tissue. Moderate heating (2°C–3°C temperature increase) reduces muscle spasm, pain, and chronic inflammation and increases blood flow. Vigorous heating (4°C temperature increase) alters the extensibility of collagen fibers allowing a clinician to stretch soft tissue [52]. Table 65.1 reflects the degree of tissue temperature increase expected at various intensities and treatment durations [47,53].

TABLE 65.1
Tissue Temperature Changes Related to Ultrasound Intensity and Time

Tissue Temperature Change at 1 MHz

	Time (min)			
Intensity (W/cm^2)	2.5	5.0	7.5	10
0.5	<0.5°	<0.5°	<0.5°	0.5°
1.0	<0.5°	1.0°	1.25°	1.75°
1.5	1.0°	1.75°	2.5°	3.5°
2.0	1.25°	2.25°	3.25°	4.0°

Tissue Temperature Change at 3 MHz

	Time (min)			
Intensity (W/cm^2)	2.5	5.0	7.5	10
0.5	0.75°	1.5°	2.0°	3.0°
1.0	2.5°	3.5°	5.0°	5.75°
1.5	2.75°	5.0°	***	***
2.0	4.0°	***	***	***

***Treatment was terminated due to subject discomfort.

Continuous-mode ultrasound is administered with an uninterrupted flow of energy whereas pulsed-mode ultrasound refers to the administration of ultrasound with periodic breaks in energy flow. Pulsed-mode ultrasound is defined by a duty cycle that describes the duration of energy flow during a single pulse period. For example, in a 20% duty cycle, the ultrasound is active 20% of the time and inactive 80% of the time. A 100% duty cycle is considered continuous mode. When pulsed-mode ultrasound is utilized, the amount of energy transmitted to the targeted tissue is described as the spatial average temporal intensity (I_{SATA}), which accounts for the peak intensity (I_{SATP}) chosen as well as the duty cycle. The following equation demonstrates how to calculate spatial average temporal intensity [47,53]:

$$I_{SATA} = I_{SATP} \times \text{Duty cycle}$$

Both pulsed and continuous modes have been shown to produce thermal effects in soft tissue. Gallo et al. [54] researched the thermal heating capabilities of pulsed versus continuous ultrasound when controlling for spatial temporal average intensities. The two conditions included continuous mode, 3 MHz, 0.5 W/cm^2 for 10 min, and pulsed mode, 3 MHz, 1.0 W/cm^2, 50% duty cycle for 10 min. The results of the study revealed no statistically significant difference in the rate or extent of tissue temperature increase. Under both conditions, Gallo discovered approximately 2.8°C temperature change in the gastrocnemius muscle. Therefore, in a clinical setting, either pulsed- or continuous-mode ultrasound can be utilized to effectively increase tissue temperature while accommodating to the comfort of the patient.

The ability for ultrasound to heat the underlying tissue is well established in the literature. Some clinicians believe that pairing ultrasound with other modalities such as superficial heat or cooling enhances the effectiveness of ultrasound. Draper et al. [55] investigated the deep heating ability of continuous ultrasound on skin at room temperature compared to precooled tissue. The use of a cold modality was thought to widen the temperature gradient before administering ultrasound, thus accelerating the rate of tissue temperature rise. Tissue temperature was taken at a depth of 5 cm, and ultrasound was administered for 10 min at 1 MHz frequency and 1.5 W/cm^2 intensity. The results demonstrated a 4°C temperature increase from baseline in the room temperature skin group and a 1.8°C temperature increase from baseline in the precooled tissue group. Draper concluded that the use of a cold modality prior to administering ultrasound did not enhance the thermal effects of ultrasound, and individuals receiving ultrasound alone demonstrated tissue temperature increase twice that of the experimental group. These findings suggest that application of ice prior to administering ultrasound decreases the efficacy of ultrasound when the clinician intends to heat subcutaneous structures. Conversely,

Draper et al. [56] also investigated the ability of moist heat to assist the thermal effects of ultrasound on target tissue. Participants were randomized to receive a 15 min moist hot pack treatment or a 15 min room temperature pack treatment prior to 10 min of 1.0 MHz continuous ultrasound at 1.5 W/cm^2 intensity. The moist hot pack had an additive thermal effect on soft tissue by targeting superficial structures (1 cm deep), while the 1 MHz ultrasound heated deeper soft tissue structures (3 cm deep). Based on the results of these studies, when ultrasound is paired with a second modality, moist heat is preferential over cold due to its additive thermal effect on soft tissue.

Ultrasound application requires the use of a coupling agent because ultrasound waves do not effectively travel through air. Coupling agents provide a medium for ultrasound waves to travel from the transducer through the skin. On primarily flat even surfaces such as the quadriceps, a water-based gel will provide adequate direct contact for the ultrasound waves to penetrate the skin [57,58]. Indirect contact coupling agents such as underwater or gel pads are warranted for use over uneven surfaces. For example, when treating the peroneal tendons, bony landmarks such as the lateral malleolus will prevent uniform contact between the ultrasound head and the skin. Draper et al. [59] found that use of water as an indirect coupling agent greatly reduced the ability to heat soft tissue, suggesting that indirect coupling methods required a greater treatment intensity to achieve the same thermal effects as direct method. However, Merrick et al. [60] explored the efficacy of gel pads and water-based ultrasound gel in heating underlying soft tissue and demonstrated similar heating capabilities of each method when ultrasound parameters were controlled. The research design focused only on the deep heating capacities of two different mediums used with continuous mode at a frequency of 1 MHz; therefore, the results of this study cannot be generalized to pulsed-mode or superficial heating at 3 MHz, and the clinician should always adjust treatment parameters in response to the patient's comfort level.

The effective radiating area (ERA) refers to the size of the ultrasound head used to administer the modality. The treatment area should be limited to 2× the ERA to allow for adequate thermal effects to occur [47]. Therefore, if the area of your ultrasound head measures 5 cm^2, the treatment area should not exceed 10 cm^2. When considering this concept, clinicians should be aware of the transducer size relative to the treatment area. A 5 cm^2 ultrasound head can treat a 10 cm^2 area of the low back or quadriceps; however, treating areas larger than this limit would be ineffective. The area needs to be limited to treatable sizes and smaller areas should be treated with small ultrasound heads.

When ultrasound is administered, it is important to recognize and understand the beam nonuniformity ratio (BNR) of the piezoelectric crystal, which produces areas of increased intensity from the ultrasound head. These areas produce "hot spots" and result in patient discomfort. The spatial peak intensity (I_{SP}) represents the greatest power of the ultrasound beam produced by the piezoelectric crystal. The spatial average intensity (I_{SA}) represents the average power of the ultrasound beam within the ERA. BNR can be calculated by dividing the spatial peak intensity by the spatial average intensity:

$$\text{BNR} = \frac{I_{SP}}{I_{SA}}$$

If an ultrasound head has a spatial peak intensity of 12 W/cm^2 and a spatial average intensity of 2 W/cm^2, the BNR is 6:1. A more uniform ultrasound beam is reflected in a smaller BNR. Ultrasound units with a BNR <6:1 are acceptable for therapeutic use. Despite the BNR, the variable energy produced by the piezoelectric crystal within the transducer creates a nonuniform delivery of energy; therefore, it is strongly recommended that the ultrasound head move constantly during application to avoid localized tissue damage and discomfort due to overheating [61].

In multiple research studies, the speed of ultrasound head movement has been controlled to within 2–4 cm/s to standardize the influence of speed on the thermal effects of ultrasound. However, Weaver et al. [62] assessed the difference in heating capacities when ultrasound was applied at 2–3, 4–5, and 7–8 cm/s and found no statistically significant difference in the tissue temperature increase among the three groups when intensity, frequency, and the treatment area were controlled. Weaver noted that therapists had a tendency to increase the treatment area when the ultrasound head is moved more quickly. This behavior disperses the thermal benefits of ultrasound across a larger surface area, thus reducing the degree of tissue temperature rise. This theory helps provide rationale supporting the previous literature stating suboptimal heating effects when the ultrasound head is moved at a faster speed. In a clinical setting, the speed of ultrasound head movement is not the most important treatment factor. The treatment area should be limited to 2× the ERA and the movement of the ultrasound head should be in overlapping circular or longitudinal movements [47].

The data supporting precautions and contraindications to ultrasound are not strong at this time. Therefore, it can be difficult to differentiate which conditions allow a clinician to proceed with caution or warrant discontinuation of the modality. Use of ultrasound over cardiac pacemaker is an absolute contraindication due to the ability of the acoustic power to alter the electrical activity of the cardiac device. Ultrasound also has the potential to disrupt cardiac activity and cause arrhythmias when used directly over the thoracic cavity. Ultrasound use for obstetric purposes has a significantly lower power; therefore, use of therapeutic ultrasound over the abdomen of a pregnant woman is not recommended due to potential risk. Avoid use of therapeutic ultrasound over reproductive organs due to the risk of excessive heating, which may lead to infertility. Although research has failed to provide strong evidence to support increased cell proliferation with therapeutic

ultrasound, use of ultrasound over malignant tumors, myositis ossificans, and heterotopic ossificans is generally not recommended. Due to the risk of increased bone formation, ultrasound may accelerate the growth of pathologic bony lesions. Proliferation of malignant cancer cells may allow for greater tumor growth or metastasis. Use of ultrasound over epiphyseal growth plates is not recommended; however, ultrasound is likely to create periosteal pain due to absorption of the ultrasound waves before stimulation of bone growth can occur. It is generally recommended to avoid therapeutic ultrasound over immature growth plates. Vibrations associated with ultrasound waves could dislodge blood clots; therefore, use of ultrasound over known regions of DVT is contraindicated. It is not recommended to use ultrasound over areas of active bleeding, infection, or acute injury because increased blood flow is the body's natural response to increased tissue temperature. Use of ultrasound will likely worsen these conditions [63].

Therapeutic ultrasound is primarily utilized as a deep heating modality in the sports medicine setting and is well supported in the literature for its thermal effects in soft tissue up to 5 cm deep. However, research fails to confirm nonthermal ultrasound effects such as pain reduction and facilitation of healing in musculoskeletal conditions. Shanks et al. [64] performed a literature review assessing the effectiveness of therapeutic ultrasound on lower extremity injuries such as heel pain, Achilles tendon pain, ankle sprains, and knee injuries. Six placebo-controlled studies showed no statistically significant benefit between sham and therapeutic ultrasound and failed to demonstrate strong evidence to support the use of ultrasound for musculoskeletal injuries. A recent Cochrane review analyzed the efficacy of ultrasound for the treatment of acute ankle sprains [65]. Five placebo-controlled trials met the inclusion criteria and were critiqued for their ability to improve pain, range of motion, swelling, and functional disability, and there was little evidence to support the use of ultrasound on acute ankle sprains. The limited information available on optimal treatment parameters warrants the need for more randomized placebo-controlled trials.

In general, ultrasound is effective as a superficial and deep heater. If the specifics of parameters are observed, both pulsed and continuous ultrasound can produce thermal effects. The ultrasound head should be moved in circular or longitudinal motions to avoid burns due to the BNR, and the nonthermal effects of pulsed ultrasound are not supported as a treatment guideline at this time.

PHONOPHORESIS

The properties of ultrasound can be manipulated to deliver medication transcutaneously, and this procedure is called phonophoresis. Ultrasound uses sound energy to theoretically alter the permeability of the skin to allow for medication placed on the skin surface to be absorbed into the underlying soft tissue. The goal of phonophoresis is to deliver medication through the skin directly to injured tissue to assist an athlete with recovery. Anti-inflammatory medication such as dexamethasone and hydrocortisone and analgesic medication such as lidocaine are commonly used in the form of a cream, gel, or ointment with phonophoresis. The use of phonophoresis to administer medication theoretically allows for a more direct route of transmission by placing the medication at the targeted site avoiding depletion of the medication due to digestion with oral ingestion. Oral medication enters the digestive tract and liver, which metabolize the medication and reduce the amount that enters the system and target tissue [66].

Cagnie et al. [67] compared the body's ability to absorb ketoprofen, a medication used to decrease pain and inflammation combined with a gel coupling agent, creating Fastum gel. The researchers observed patients with knee pain who were scheduled to undergo arthroscopic knee surgery under three treatment conditions. Group A was given ketoprofen gel with 1 MHz continuous ultrasound at an intensity of 1.5 W/cm^2, Group B was given ketoprofen gel with 100 Hz pulsed ultrasound (20% duty cycle), and Group C received ketoprofen gel with sham ultrasound. Adipose and synovial tissue samples were taken 47–77 min following phonophoresis to assess local penetration of ketoprofen, and blood samples were taken 2 h after application to assess systemic penetration of ketoprofen. Significantly greater amounts of medication were detected in synovial tissue in the groups using ultrasound, A and B, compared to sham ultrasound, group C. Minimal ketoprofen was detected in plasma or adipose tissue under all three conditions. The study demonstrated that phonophoresis was able to administer the medication locally without a systemic response; however, no therapeutic benefit of the treatment (change in pain or effusion) was observed in the groups. A list of commonly used medications complied by Ciccone is found in Table 65.2. More research is needed to further determine the usefulness of phonophoresis in a clinical setting.

IONTOPHORESIS

Iontophoresis is an electrotherapeutic modality that delivers medication transcutaneously with the purpose of decreasing pain or inflammation. Direct current produces an electrical field that repels ions and drives medication through the skin to reach the targeted tissue [68]. Ions are charged particles. Anions are negatively charged and cations are positively charged. When administering iontophoresis, the medication must be ionized to allow for electromigration of particles through the skin. The ionized medication is driven through the skin via repulsion of the like-charged particles with direct current [68]. A delivery electrode and a return electrode are used to administer iontophoresis. The medication is applied to the delivery electrode and the return electrode is placed on the skin to complete the circuit. The polarity of the medication dictates whether the delivery electrode is the cathode or anode. The cathode is utilized to deliver negatively charged medication and the anode is utilized to deliver positively charged medication.

TABLE 65.2
Common Medications Used for Iontophoresis and Phonophoresis

Drug	Principal Indication(s)	Treatment Rationale	Iontophoresis	Phonophoresis
Acetic acid	Calcific tendinitis	Acetate is believed to increase solubility of calcium deposits in tendons and other soft tissues	2%–5% aqueous solution from negative pole	—
Calcium chloride	Skeletal muscle spasms	Calcium stabilizes excitable membranes; appears to decrease the excitability of peripheral nerves and skeletal muscle	2% aqueous solution from positive pole	—
Dexamethasone	Inflammation	Synthetic steroidal anti-inflammatory agent (see Chapter 29)	4 mg/mL in aqueous solution from negative pole	0.4% ointment
Hydrocortisone	Inflammation	Anti-inflammatory steroid (see Chapter 29)	0.5% ointment from positive pole	0.5%–1.0% ointment
Iodine	Adhesive capsulitis and other soft tissue adhesions; microbial infections	Iodine is a broad-spectrum antibiotic, hence its use in infections, etc.; the sclerolytic actions of iodine are not fully understood	5%–10% solution or ointment from negative pole	10% ointment
Lidocaine	Soft tissue pain and inflammation (e.g., bursitis, tenosynovitis)	Local anesthetic effects (see Chapter 12)	4%–5% solution or ointment from positive pole	5% ointment
Magnesium sulfate	Skeletal muscle spasms; myositis	Muscle relaxant effect may be caused by decreased excitability of the skeletal muscle membrane and decreased transmission at the neuromuscular junction	2% aqueous solution or ointment from positive pole	2% ointment
Hyaluronidase	Local edema (subacute and chronic stages)	Hyaluronidase appears to increase permeability in connective tissue by hydrolyzing hyaluronic acid, thus decreasing encapsulation and allowing dispersion of local edema	Reconstitute with 0.9% sodium chloride to provide a 150 mg/mL solution from positive pole	—
Salicylates	Muscle and joint pain in acute and chronic conditions (e.g., overuse injuries, rheumatoid arthritis)	Aspirin-like drugs with analgesic and anti-inflammatory effects (see Chapter 15)	10% trolamine salicylate ointment or 2%–3% sodium salicylate solution from negative pole	10% trolamine salicylate ointment or 3% sodium salicylate ointment
Tolazoline hydrochloride	Indolent cutaneous ulcers	Tolazoline increases local blood flow and tissue healing by inhibiting	2% aqueous solution or ointment from negative pole	—
Zinc oxide	Skin ulcers, other dermatologic disorders	Zinc acts as a general antiseptic; may increase tissue healing	20% ointment from positive pole	20% ointment

The method in which the medication travels through the skin is not clearly understood; however, there are two main proposed theories. Some researchers believe that medication travels through the skin via sweat and sebaceous glands and hair follicles. It is also theorized that electrical current changes the permeability of the skin's surface, allowing for greater transmission of the medication through the skin. Mild skin irritation and small blister-like vesicles are common skin reactions in response to the local alteration of pH due to the chosen medication and these typically resolve within minutes to hours after conclusion of the treatment [53].

Dosage can vary based on amplitude (milliamperes) and duration (minutes) of the treatment and measured in mA · min. Research suggests that the optimal dosage response to iontophoresis ranges from 40 to 80 mA·min [68] and a greater delivery of medication is achieved with increasing treatment durations [69]. The dosage can be calculated by multiplying the intensity (milliamperes) by the treatment duration (minutes):

$$40\ \text{mA} = 1\ \text{mA} \times 40\ \text{min or } 2\ \text{mA} \times 20\ \text{min}$$

$$\text{or} \quad 4\ \text{mA} \times 10\ \text{min}$$

$$80\ \text{mA} = 2\ \text{mA} \times 40\ \text{min} \quad \text{or} \quad 4\ \text{mA} \times 20\ \text{min}$$

Anderson et al. [69] compared the absorptive capabilities of dexamethasone under three treatment conditions each totaling 40 mA·min dosage: 4.0 mA/min for 10 min, 4.0 mA/min for 10 min followed by 400 min of passive absorption of medication (leaving the iontophoresis delivery electrode in contact with the skin without electrical current), and 0.1 mA/min for 400 min. The results of the study revealed deeper penetration

of medication when a prolonged treatment time was utilized. Both 400 min of passive absorption of medication and 0.1 mA/min for 400 min demonstrated the ability to penetrate a small percentage of medication up to 12 mm whereas the medication administered at 4.0 mA/min for 10 min penetrated only 2 mm below the surface of the skin. The results of this study indicate the most important treatment parameter when using iontophoresis in a clinical setting is time. The longer treatment duration allows for deeper penetration of medication into underlying soft tissue. New technology has created iontophoresis patches that do not require wires or an external unit to provide the direct current. The newer patches allow a therapist to apply iontophoresis and allow it to run throughout the day without the patient present in the clinic. This new technology will allow for longer treatment durations and maximize the pharmacological benefit of iontophoresis.

Dexamethasone is one of the most commonly used corticosteroids utilized to decrease inflammation. Neeter et al. [70] researched the effects of dexamethasone on acute Achilles tendon pain. Participants were randomized to receive either four 20 min treatments with 3 mL of dexamethasone or saline. Both groups improved at 1 year follow-up; however, the dexamethasone group demonstrated larger improvements in pain level during and after walking, stair climbing, and physical activity. Nirschl et al. [71] also demonstrated short-term benefits of dexamethasone on acute epicondylitis. Patients received six dexamethasone or sodium chloride treatments 1–3 days apart over the course of 15 days. At 1 month follow-up, each patient completed a questionnaire regarding any change in symptom severity and received a phone call to discuss any adverse events concerning their epicondylitis. Post hoc analysis found that subjects receiving the six designated treatments within a shorter period of time (<10 days) demonstrated greater pain relief. For acute conditions, early and frequent application of anti-inflammatory medication appears to effectively reduce a patient's pain and disability.

Although some researchers have found iontophoresis an efficacious treatment intervention, several other researchers failed to identify strong evidence to support the use of this modality. Gurcay et al. [72] compared the use of iontophoresis with betamethasone, phonophoresis with betamethasone, and night splints in a patient with carpal tunnel syndrome. No treatment proved to be more effective in reducing severity of symptoms or improving function. However, the iontophoresis dosage did not fall within the recommended 40–80 mA min treatment, which may account for the inability to distinguish a superior treatment method in this study. In treatment of plantar fasciitis, Cleland et al. [73] found that soft tissue mobilizations and joint mobilizations were superior to iontophoresis and ultrasound interventions.

Japour et al. [74] researched the effectiveness of acetic acid iontophoresis on the conservative management of heel pain. Patients reporting chronic heel pain were recruited for the study and received iontophoresis with 5% acetic acid solution, at 2–3 mA for 15–20 min, 2–3 times/week for 3 weeks. Prior to initiation of treatment, the patients' average numeric pain rating score (0–10) was 7.5 out of 10. After the course of iontophoresis, the average numeric pain rating score was 1.8, demonstrating a clinically and statistically significant difference in heel pain. First-step pain is a common impairment affecting patients with heel pain. Participants in this study experienced a resolution of first-step pain with 2.8 weeks of acetic acid iontophoresis treatment whereas the other 11 cited studies averaged 7.8 weeks of conservative treatment for similar symptom response. The research design failed to utilize a control group, and success of the intervention was compared to other studies that utilized various methods of conservative treatment (i.e., orthotics, shoe modification, oral medication, injections, rest, physical therapy, etc.), which limits the clinical usefulness of this study.

Iontophoresis appears to be an effective treatment intervention when a therapeutic dosage is administered, and the appropriate medication is chosen for a given musculoskeletal pathology. Dexamethasone is an anti-inflammatory agent. Some clinicians utilize dexamethasone on tendinosis pathologies that no longer possess an inflammatory process. In these instances, if improvements in pain or function are achieved, it is unclear if this was due to medication or potential benefits of electrical stimulation. On the other hand, failure to improve is expected when the medication administered is not appropriate for the given pathology. In general, anti-inflammatory medications should be administered in acute conditions immediately following the acute inflammatory phase in order to allow for initiation of the healing response to occur.

Table 65.2 summarizes commonly used medication for iontophoresis and phonophoresis [75].

There are very few contraindications to iontophoresis. Allergy to the administered drug is a relative contraindication for use of iontophoresis. Discussing the drug allergy with the prescribing physician and pharmacist may allow the patient to receive an alternate medication and still gain benefit from this modality. The electrical current used to deliver the ionized medication can alter the electrical output of pacemakers, bladder stimulators, and phrenic nerve stimulators; therefore, iontophoresis is an absolute contraindication in these circumstances. Electrotherapeutic agents have the potential to cause skin burns; therefore, it is recommended that the patient have intact sensation. However, in the absence of sensation, frequent skin checks can prevent adverse reactions to iontophoresis [66].

ELECTROTHERAPY

Electrical stimulation is frequently used in the rehabilitation of athletic injuries to reduce pain, muscle spasm, and disuse atrophy and promote strengthening and tissue healing. Electrical stimulation appears to have impacts on biological tissue in a myriad of ways depending on the target condition and parameters utilized. This modality is versatile and effective when used in rehabilitation for recovery and return to sport.

PAIN CONTROL

Pain is the most frequent complaint of those seeking medical care. Pain is a complicated phenomenon that includes both a sensory (pain location and intensity) and an affective-motivational component (unpleasantness). Pain assessment will generally take both of these components into consideration, and information collected during the athlete interview may help direct the therapist to the source of the patient's pain complaint. Acute pain is typically seen in the athletic population and is in response to current or impending tissue damage. This information can be protective in nature; for example, if an athlete has suffered a fracture of the fifth metatarsal, running and even walking can be painful. If the pain is removed too early, the athlete may consider returning to activity and risk further injury or delay healing. It is important to be sure that if pain is treated when it is providing a protective function, another protective mechanism must take its place, such as a walking boot, to ensure that the healing structures receive sufficient protection. Chronic pain does not provide the same protective information as acute pain and routinely outlasts tissue healing time frames. This pain is less informative and can inhibit recovery and return to sports participation.

Pain rating scales such as a VAS are generally 10 cm lines numbered 1–10 or 1–100 with anchors such as No Pain to Worst Imaginable Pain or anchors related more to unpleasantness such as Pleasant to Extremely Unpleasant. These scales are very reliable when the athlete places a mark along the line representing their current pain level [76]. Less reliable but commonly used is the verbal rating scale when the athlete reports their level of pain (0–10) on a scale of 11 [77]. These scales can provide data on current levels of pain but may be more useful when changes in pain levels from pre- to post-intervention are measured and calculated. Measuring the change in pain level before and after or during the use of electrical stimulation can give the therapist evidence needed to decide if the treatment should be continued or be modified.

Electrical stimulation for pain control is generally characterized by four levels: subsensory level, sensory level, motor level, and noxious level. All of these types of stimulation are classified as transcutaneous electrical nerve stimulation (TENS) since they utilize surface electrodes applied to the skin. The parameters for each of these types of stimulation are seen in Table 65.3. Microcurrent electrical nerve stimulators have very short pulse durations and current amplitudes. There has been some emerging evidence in the use of this modality in wound healing [78,79]; however, in most studies, microcurrent does not demonstrate a better effect than sham [80,81]. Currently, there is insufficient evidence to support the use of electrical stimulation below sensory threshold for pain management.

Sensory-level stimulation above the sensory level but below the motor threshold is commonly used and studied as a pain control modality. Although sensory stimulation can still occur when muscular contractions are present, they are often unneeded or can interfere with the intended action of the stimulation treatment. Muscular contractions can move a painful joint or create a protective response from the athlete in the presence of acute or significant pain and are often undesirable. Patients are educated to tolerate increases in the amplitude of sensory stimulation until they perceive comfortable paresthesia. This is often described as tingling, buzzing, or even an intense crawling feeling. The pain relief that develops during the use of sensory stimulation is likely due to a block of pain signal transmission in the periphery or central inhibition of pain transmission by large-diameter nerve fibers [82]. The stimulation is most effective when the unit is on and has little lasting effect once the stimulator is turned off [83]. Sensory-level stimulation has been found to be as effective as acetaminophen with codeine in controlling the pain associated with acute traumatic conditions such as sprains, contusions, fractures, and lacerations [84]. Denegar and Perrin [85] found that electrical stimulation significantly reduced the pain associated with induced DOMS compared with sham stimulation and no treatment.

TABLE 65.3
Commonly Used Stimulation Parameters Associated with the Four Clinical Levels of Stimulation for Pain Control

Mode of Stimulation	Amplitude Adjusted to Produce	Phase/Pulse Duration	Frequency (pps, bps)	Duration of Treatment	Duration of Analgesia[a]
Subsensory level	No perception of stimulation	Not specified	<3	Not specified	Not known
Sensory level	Perceptible tingling ("pins and needs")	2–50 μs	50–100	20–60 min	Short none to few minutes
Motor level	Strong visible muscle contraction	>150 μs	2–4	30–45 min	Long hours
Noxious level	Painful sensation	≤1 ms	1–5 or <100	Seconds to few minutes	Long hours

pps, pulse per second; bps: bursts per second.

[a] Both the time to onset of analgesia and the duration of analgesia have not been clearly established in the literature for the majority of commonly encountered pain syndromes that may be managed with TENS interventions.

Electrode placement in sensory stimulation is generally over the painful site or surrounding the painful site. There is no specific pad location most effective for a body region such as the low back or ankle; instead, the clinician should systematically rule in or out locations based on the location of the pain, the size of the area, and most importantly, the response of the patient to the treatment. There is some evidence that placement of pads in areas remote from the pain but related such as trigger points or acupuncture points may also provide relief [86]. Hidderley and Weinel [87] found that pain relief with sensory stimulation applied to acupuncture points outperformed stimulation over unrelated sham acupuncture points.

Electroanalgesia can be produced through sensory-level stimulation. Typically higher frequencies (>100 pulses/s) and pulse durations (>50 μs) are used with close pad placement to create interelectrode analgesia [80,82]. Small electrodes in close proximity will increase the corresponding current density in the area coupled with high-intensity current to create a local analgesic response. This stimulation can be used to calm a superficially irritated structure or reduce discomfort to allow for another procedure to be performed (i.e., joint or scar manipulation). Manal [88] advocate the use of high-intensity electrical stimulation to control pain in noncontractile tissue [89]. The area to be treated must be localized and palpable. Parameters for the stimulation are classic Russian current; 2500 Hz AC current (400 μs pulse duration), 50 bursts/s, 12 s on, 8 s off. See Figure 65.2 for setup. The current is increased to the maximal tolerable level (beyond comfort level). Interelectrode analgesia occurs quickly generally within the first 5 min. The treatment can be stopped at 5 min or be increased to 10–15 min depending on tolerance. The improvement from pretreatment pain levels is generally immediate and long lasting. If no response is seen to an initial treatment, intensity and time can be increased in the next session; if still unsuccessful, the patient may not be responsive to this intervention.

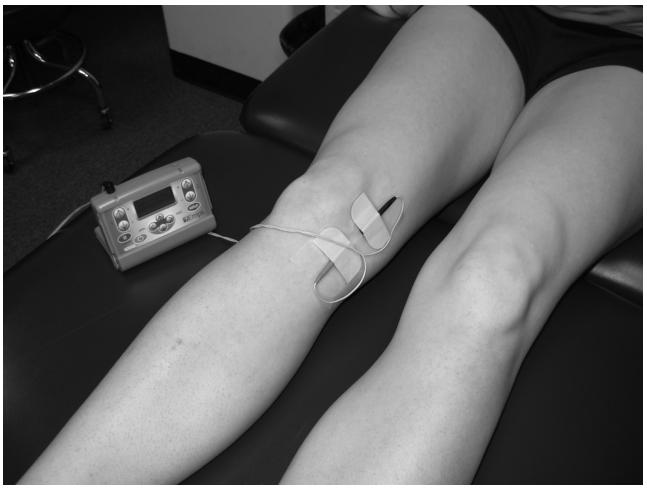

FIGURE 65.2 Electrode setup for administering high-intensity electrical stimulation.

Motor-level stimulation is used most often in chronic pain. The goal in motor stimulation is a visible muscle response. Pulse durations are longer (>150 μs) in order to generate a strong contraction while frequency is shorter (2–4 pps) to create rhythmic contractions. This has also been called strong, low-rate frequency motor TENS or acupuncture-like TENS [90]. Since muscle contraction and "jumping" of the muscle is expected, patients should be prepared for this response and their target tissue or limb should be supported so movement will not aggravate or worsen their condition. Electrodes can be placed over areas of muscular hypersensitivity or often a local point stimulator with a remote dispersive pad can be used. In ultrasound/electrical stimulation combination units, the ultrasound head (with the sound modality turned off) serves as the stimulation applicator. Interelectrode analgesia is slower under these conditions so treatment times are longer and performed more frequently.

Noxious-level stimulation is intended to create a painful stimulus at or remote from the site of pain, causing a rapid hyperstimulation analgesia followed by an endorphin-mediated response [91]. The choice for noxious-level stimulation is generally made after failure of other types of stimulation due to the inherent nature of discomfort; however, in the athletic population it may be utilized more often.

Research on the benefits of TENS for pain is challenging. The Cochrane Report on the value of TENS for chronic pain states that "The published trials do not provide information on the stimulation parameters which are most likely to provide optimum relief, nor do they answer questions about long-term effectiveness" ([92]: p. 2). The variety of parameters and lack of clarity in written papers make reproduction in a clinical setting challenging and provide conflicting results. Studies are emerging to address dose–response for frequency; however, other characteristics lack study [93].

STRENGTHENING

The desire to enhance athletic performance beyond the level attainable through an intensive volitional training program has led to the investigation of electrical stimulation as a strength supplement. Studies of clinical stimulation have examined the most effective electrode size [94], pad placement [95], stimulators [96], and wave form [97] and frequency [98] in hopes of generating the most efficacious electrical stimulation parameters to give athletes a training advantage and competitive edge.

Neuromuscular electrical stimulation (NMES) has been used with success to strengthen the abdominal muscles [108], trunk extensors [100,101], latissimus dorsi [102], and the quadriceps [103–106]. The exact mechanism by which electrical stimulation improves strength of the target muscle is unknown. It has been theorized that electrical stimulation can preferentially recruit large-diameter type 2 fibers (fast-twitch) compared to smaller-diameter type 1 (fatigue-resistant) fibers. Early in the postoperative or injury phase, it may be difficult if not impossible for an athlete to recruit

these fibers due to reduced activity and effort level. It has been theorized that activation of these fibers when they may otherwise be underutilized may help delay the consequences of disuse. Delitto et al. [107] utilized high-intensity electrical stimulation for quadriceps training on an elite weight lifter; biopsies before and after the stimulation protocol demonstrated a reduction in type 1 fibers and an increase in type 2 fibers, suggesting a conversion of fiber type in response to stimulation. High-force contractions can also increase the available actin and myosin in muscle allowing for increased number of cross bridges and correspondingly increased force-generating capability. This may also contribute to increases in force production capabilities seen with electrical stimulation strengthening regimens.

Alon et al. [108] compared NMES alone with NMES plus volitional exercise on the strength of abdominal muscle training three times weekly for 4 weeks. The contractions utilized a symmetrical biphasic waveform with maximal intensity for 5 s on and 5 s off. The on time was lengthened each week from 5–7.5 to 10–12.5 coupled with an increase in repetitions by 20% weekly to increase the stimulation dosage. Electrical stimulation plus volitional exercise produced greater strength gains than electrical stimulation alone.

In the lumbar spine, training programs utilizing low-frequency stimulation and high-frequency stimulation have both demonstrated increases in muscular endurance while [101] demonstrated that subjects receiving electrical stimulation to the lumbar paraspinals developed increased isometric back extensor strength compared to a group performing exercise alone. Electrical stimulation to the lumbar spine has been performed in a quasi-isometric fashion by stabilizing the pelvis to the table in the prone position over pillows. Once the hips are stabilized, the patient attempts an anterior pelvic tilt and the pelvis is considered stable if little to no movement occurs. Small 2 cm × 2 cm electrodes are configured in two channels, each on the right and left sides of the spine at the target spinal levels. Parameters vary among studies—pulse duration: 250–400 μs, on time 15 s, off time 30–50 s, ramp time 0–5 s, total treatment duration 15–30 min. Intensity of the stimulation is increased to maximal tolerable by the patient; however, a visible muscle contraction should be apparent and in some cases a strong contraction creating pelvic movement on the stabilizing belt is expected [109].

Electrical stimulation of the latissimus dorsi muscle of swimmers resulted in isometric, concentric, and eccentric improvements in peak torque coupled with improved pool performance swimming times [102]. Similar parameters as described in lumbar spine have also been utilized to supplement recovery and strengthening of the posterior rotator cuff of the shoulder [110]. Isometric stabilization can be achieved by strapping the arm across the patient's stomach in an elbow flexed position. A more rotational neutral position can be achieved using pillows between the trunk and the arm and anteriorly to support the arm at the side. Electrodes are placed over the muscle belly of the target muscle, most often the infraspinatus or supraspinatus or both, which can be palpated during a resisted isometric contraction.

A recent systematic review of the role of NMES of the quadriceps after anterior cruciate ligament reconstruction reviewed eight randomized controlled clinical trials and concluded that although there was variability in the parameters (see Table 65.4), electrical stimulation coupled with volitional exercise exceeded strength recovery when compared to volitional exercise alone [104]. This conclusion agrees with two prior literature reviews also concluding that electrical stimulation plus exercise outperforms exercise alone in quadriceps recovery after anterior cruciate ligament reconstruction [117,118]. Although variations exist, the majority of the study stabilized the leg in a mechanical device with straps at a flexed knee angle of 60°–90° or in full knee

TABLE 65.4
Summary of Neuromuscular Electrical Stimulation Treatment Parameters

Author	Frequency (Hz)	Pulse Width (μs)	Duty Cycle	Intensity	Treatment Course[a] (Duration)	Treatment Sessions[b]	Follow-Up Time[c]
Sisk [111]	40	300	10 s on, 30 s off	MTL	1st–6th week (6 week)	38	7th week
Delitto [112]	50	400	15 s on, 50 s off	MTL	2nd or 3rd–6th week (3 week)	15	6th week
Wigerstad-Lossing [113]	30	300	6 s on, 10 s off	65–100 mA	1st–6th week (6 week)	18	6th week
Draper [114]	35	N/A	10 s on, 20 s off	MTL <50 mA	1st–6th week (6 week)	105	6th week
Snyder-Mackler [105]	75	400	15 s on, 50 s off	MTL	3rd–6th week (4 week)	12	6th week
Paternostro [115]	30	200	5 s on, 15 s off	MTL	1st–6th week (6 week)	38	6th week
Ross [116]	50	200	15 s on, 35 s off	MTL	1st–6th week (6 week)	26	6th week
Fitzgerald [103]	75	400	10 s on, 50 s off	MTL	3rd–14th week (11 week)	21	12th–16th week

MTL, maximally tolerated level; N/A, not available.

[a] Start and end of treatment in the postoperative weeks.

[b] Estimated number of treatment sessions (treatment a week multiplied by the number of weeks).

[c] Time point after anterior cruciate ligament reconstruction when outcome measures were taken.

extension supported on a table. Electrodes are placed on the quadriceps, one proximally and one distally, and the electrical stimulation parameters found in Table 65.4 provide a summary of acceptable options. Electrical stimulation has been shown to improve strength in healthy muscle as well as muscle impaired by injury or disuse. Whether strength gains result from retraining the nervous system, recruiting more motor units, or changing recruitment pattern or fiber type, the outcome is improved function.

TISSUE HEALING

Electrical stimulation can assist in wound healing through a variety of mechanisms. Fibroblast proliferation and collagen synthesis both contribute to wound healing and respond favorably to electrical stimulation. Bourguignon et al. [119] utilized high-voltage pulsed current (HVPC), a form of interrupted direct current also called "hi-volt," on fibroblast cells at 150 pps at 50–150 V. Under the anode, fibroblasts proliferated and increased DNA production and collagen synthesis. These positive changes have implications in wound healing as well as soft tissue, such as tendon and ligament healing. Scientists are looking at the value of electrical stimulation on healing rates of animal tendon and ligaments to provide preliminary guidelines and efficacy data to be applied later in future human population studies. Daily treatment for 2 weeks with anodal current via implanted electrode in rat Achilles tendon increased tensile strength after surgical tenotomy [120]; similar results were seen in the Achilles tendon and patellar ligament in rabbits [121,122]. The transfer of this success to human tendon and ligament is currently not available.

A 44% increase in vascular perfusion (angiogenesis) is also seen in venous ulcers in response to monophasic pulsed current (pulse duration 140 μs, 64–128 pps, 30 min daily for 38 days) accompanied by an 82% increase in oxygen delivery to the wound site [123]. The use of low-intensity direct current and HVPC both appears to have the ability to inhibit the growth of bacteria such as *Escherichia coli*, *Pseudomonas aeruginosa*, and *Staphylococcus aureus* but do not kill formed bacteria colonies [124]. Most studies suggest that the bacteriostatic effect occurs under the cathode, but recent evidence demonstrates a positive effect under both the cathode and the anode with HVPC at 250 V, 100 pps, 1 h daily for 3 days [125].

Electrostimulation is also used to promote bone healing in fractures with delayed bony healing, including those most likely to present with a nonunion after fracture such as the distal tibia and scaphoid. Three methods of stimulation have been applied to fracture sites: a percutaneous direct current bone stimulator [126] is partially invasive, allows for patient mobility, and can be used with a magnetic fixation device but does require an operation for implantation and is contraindicated in the presence of infection. An implanted direct current stimulator is fully invasive and has similar challenges as the percutaneous stimulator. An external pulsed electromagnetic field stimulator is noninvasive and can be utilized in the presence of infection [126,127]. No bone stimulators are effective in the presence of a synovial pseudoarthrosis where scar tissue and fluid prevent the approximation of the healing ends or a sizable gap of another cause exists. It may be of value to note that bone stimulators are not routinely covered by insurance carriers unless certain requirements are met such as failure of healing for at least 3 months' duration, a fracture gap of 1 cm or less and patient compliance with non-weight bearing, one or more previous failed fusion, or fresh fractures in distal tibia or scaphoid due to the high incidence of nonunion.

The most common adverse reactions from electrical stimulation are skin irritation, rash, and burning sensation [128]. Contraindications include patients with a demand-type pacemaker, placement of electrodes over medical stimulators, monitors or leads; over damaged skin, malignancies, arterial or venous thrombus, or carotid sinus; over phrenic or vagus nerve, eyes or transcranially. Precautions include skin irritation after prolonged use; consultation is suggested for use with pregnant women, and monitoring of vital signs during use is suggested in patients with cardiac disorders. Careful monitoring is recommended when electrical stimulation is used in an area with decreased sensation.

EMG BIOFEEDBACK

Electromyographic (EMG) biofeedback involves the use of a voltmeter to make electromyographic measurements. EMG biofeedback is used to improve motor recruitment to generate stronger voluntary muscular contractions and to inhibit muscular contractions to promote relaxation of overactive muscles. Biofeedback is not as useful for eliciting muscle contraction in patients with spastic neuromuscular disease as it is with those with an intact central nervous system.

EMG biofeedback can be used over any superficial muscle. The purpose is to provide the patient or athlete with immediate feedback regarding performance regardless of whether the desired outcome is to increase or decrease muscle activity. Studies have demonstrated strength gains [129,130], improved motor learning, and neuromuscular reeducation [131,132].

Draper et al. [129] compared exercise with biofeedback and exercise with electrical stimulation to exercise alone for quadriceps strengthening after ACL reconstruction. EMG biofeedback outperformed both groups, electrical stimulation plus exercise and exercise alone. Interestingly, when comparison is made between the contraction intensities used in the electrical stimulation arm of this study, the intensity was below what would be expected to generate large strength gains [133]; therefore, the lack of gains with electrical stimulation appears suspect due to insufficient treatment application. However, regardless of the performance of the electrical stimulation wing of the study, it is still evident that EMG plus exercise was better at improving quadriceps strength than exercise alone. So although electrical stimulation is still the preferred method, when not possible, EMG biofeedback with exercise should be considered an alternative to exercise alone. The added benefit of electrical stimulation and exercise plus biofeedback has not been studied.

Levitt et al. [130] concluded that biofeedback with exercise improved extensor torque and quadriceps muscle recruitment after knee arthroscopy while Krebs [134] found a similar response in patients following meniscectomy. EMG biofeedback can assist the postoperative patient with muscle recovery especially in the quadriceps. A similar improvement in neuromuscular control of muscles has been demonstrated following EMG biofeedback training in the shoulder in patients with recurrent dislocations. Young [135] demonstrated that patients had improved function and reduced occurrence of instability after training.

In some cases, the desired action of the athlete is not a stronger contraction but rather decreased muscular activity to promote relaxation. Rokicki and associates [136] found that biofeedback-assisted relaxation training led to decreased incidence of headaches in patients with tension headaches, and similar results have been demonstrated in the management of temporomandibular joint dysfunction [137]. EMG biofeedback has been used successfully to promote relaxation of the quadriceps during anterior tibial translation testing of the cruciate ligaments [138] and can assist with hamstring relaxation during stretching at end range of knee extension in a stiff knee. Reducing compensations such as decreasing substitution of the upper trapezius muscle during shoulder elevation can provide clinical value. Since voluntary muscle contraction is a necessity during sports and other daily activities, it seems obvious that providing feedback during the performance of the desired movement pattern would lead to improved motor learning by reinforcing the correct movement. The use of EMG biofeedback provides information about the strength of contraction and can help improve control and eliminate over- and underuse as well as muscular substitution.

LASER THERAPY

Laser therapy has been commonplace in the medical office for many years. It is utilized for hair removal, vision correction, and dermatological care. The term "low-level laser" or "cold laser" has been used to describe lasers of the red beam or near-infrared of wavelength of 600 and 1000 nm power from 5 to 500 mW. Surgical lasers are much stronger in the 300 W range. To date, there are no uniform dosages, number of treatments, or treatment length specification for laser. Low-level lasers produce no sensation and do not burn the skin. The mechanism of action is proposed to be a photochemical response of cells to the laser light although the exact action is not known. One leading theory is that cytochrome c in intercellular membrane mitochondria is a photoreceptor causing excitation and bonding with oxygen resulting in cytochrome c oxidase, an ATP building block [139]. There are many possible biochemical factors stimulated by the use of laser that may influence pain and edema in tissue; however, to date their contribution remains theoretical.

Many currently published studies are on laser with lower dosages than are currently recommended and lack sufficient sample size and scientific rigor to make definitive clinical efficacy determinations. The American Pain Society of the American College of Physicians [140] reviewed low-level laser for the treatment of low back pain, and four trials found laser superior to sham up to 1 year after treatment while another high-quality study disagreed [140]. The authors noted that treatment parameters, wavelength, dosage, and dose intensity were variable and the preferred parameters are elusive.

A Cochrane systematic review by Brosseau et al. [141] reexamined the role of laser as a treatment for rheumatoid arthritis (RA). Six studies of 220 aggregate patients were included, but the variability of the application of the modality made comparisons difficult, and the authors lamented that negative trials may have been suppressed and never published, skewing the data pool. Nonetheless, authors concluded that some positive effect may be present; however, sufficient conflict in results suggests that a determination on the added value of low-level laser in the RA population cannot be made. Currently, laser is not reimbursed by commercial insurance and is considered by them to be investigational for musculoskeletal pain. The future will determine if this is an emerging practice or fad.

SUMMARY

We have reviewed the scientific basis and evidence for the use of thermal agents and electrotherapy in rehabilitation of sport injuries. The evidence ranges from theoretical to strong with the best evidence in cryotherapy, continuous ultrasound, iontophoresis, neuromuscular stimulation for strengthening muscle, and EMG biofeedback for muscle activity. Other agents that are commonly used in sports settings such as pulsed ultrasound, phonophoresis, superficial heating for flexibility, ice bath, and laser are supported by only weak evidence at best. An understanding of support in the literature for the use of these therapeutic agent and the parameters most likely to maximize the physiological response should allow for more effective treatments of athletes with musculoskeletal injuries.

INTRODUCTION

Preconception care is a fundamental component of preventative medicine. Preconception care aims to promote the health of women before conception in an attempt to improve health outcomes for both the mother and her offspring and to reduce societal costs.[1]

While it is commonly recognized that access to prenatal care is associated with improved outcomes, there are now increasing data that preconception care is equally important. Today, we have more data and testing options in the field of genetics and have more knowledge on the effects of the environmental exposures and medical illness on fertility, as well as the effects of these on fetal growth and development. Unfortunately, very few women visit a health care provider for the express purpose of optimizing their health prior to pregnancy. In fact, in one study it was noted that only one in six obstetrician gynecologists or family physicians had provided preconception care to a majority of patients for whom they provided prenatal care.[1]

Since the rates of unplanned pregnancy in the United States approach 50%, coupled with the fact that it is increasingly common for women to receive primary health care and routine gynecologic care with a primary care physician, nurse practitioner, physician's assistant, or midwife, it is imperative that all providers who provide preventive care for women of reproductive age assess risk and provide appropriate counseling and management for those women for whom future pregnancy is planned. The 2006 Report of the CDC/Agency for Toxic Substances and Disease Registry (ATSD) Preconception Care Work Group and the Select Panel on Preconception care recommends that preconception care be an essential part of primary and preventive care. Components of preconception care include lifestyle counseling, identification of risks related to pregnancy, patient education regarding these risks, management options and alternatives, as well as the initiation of interventions that may lead to optimal pregnancy outcomes.[1]

AGE

Both extremes of reproductive age are associated with complications in pregnancy. Risk of chromosomal abnormalities increases with advanced maternal age, as does risk of gestational diabetes, preeclampsia, intrauterine growth restriction, and stillbirth. Some of this risk is attributable to increases in the prevalence of chronic medical conditions such as diabetes and chronic hypertension in older women. Older women should be counseled about these risks and, in the case of chromosomal abnormalities, options for screening tests or diagnostic testing such as chorionic villous sampling and amniocentesis should be offered when indicated during the pregnancy.

For adolescent patients, there is also an increase risk of preeclampsia and intrauterine growth restriction and stillbirth. However, in adolescents, the increased risks are likely associated with social factors including lack of prenatal care as well as a contribution from nutritional factors due to both poor diet and knowledge, as well as potential for competition for nutrients between the growing adolescent and her fetus.[2] Some of these can be mitigated with patient education, making resources available to patients, and lifestyle counseling.

While there may be different reasons and underlying causes for women at both ends of the reproductive age spectrum to be at higher risk during pregnancy, both groups can successfully carry healthy pregnancies to term. Clinicians should provide age-appropriate counseling and education and offer contraceptive education or preconception counseling.

GYNECOLOGIC HISTORY

A complete gynecologic history is of utmost importance in helping to identify potential factors that might affect future fertility and pregnancies. A menstrual history allows the assessment of ovulatory status and the potential for difficulty in conception. Patients who are attempting conception can be counseled about this issue, and some may seek fertility counseling and treatment earlier in the process. A history of a uterine anomaly may put patients at risk of spontaneous abortion or preterm birth. A history of tubal surgery puts women at risk for an ectopic pregnancy, and a prior uterine surgery such as a myomectomy may necessitate a c-section in a future pregnancy. Patients should be questioned about a history of abnormal pap smears. A history of high-grade cervical dysplasia, CIN II–III, requiring a cervical loop electrosurgical excision procedure or cone biopsy, puts some women at risk for cervical incompetence and preterm birth.[3]

Lastly, patients should be questioned about diethylstilbestrol (DES) exposure in utero. DES, a synthetic estrogen, was prescribed to pregnant women from the late 1940s to early 1970s to prevent pregnancy loss. This hormone was not effective and has been found to cause malformations of the female genital tract in utero. This has been linked to infertility, pregnancy loss, and premature delivery in women.[4] Women who have been DES exposed need an additional evaluation by an obstetrician with experience.

Eliciting a sexual history and history of risk factors for sexually transmitted infections (STIs) allows for screening and treatment for infection at a preconception visit. STIs have been associated with miscarriage, preterm labor, preterm birth, preterm rupture of membranes, and congenital infections. Untreated infections such as gonorrhea and chlamydia prior to pregnancy can lead to pelvic inflammatory disease, tubal scarring, infertility, and risk of ectopic pregnancy. A history of herpes with an outbreak or prodromal symptoms at the time of labor would necessitate a c-section due to the risk of transmission to the fetus. Women with partners who have a history of herpes are also at risk to contract herpes in pregnancy, and the risk of transmission to the neonate is greatest at the time of an initial outbreak. Women should be offered testing for gonorrhea, chlamydia, syphilis, HIV, and hepatitis B and C. HIV and hepatitis are chronic infections that can be transmitted to the fetus. If identified and managed by experienced providers prior to and during pregnancy, the risk of transmission to the fetus and overall health of the mother can be significantly improved.

REPRODUCTIVE HISTORY

Prior reproductive history is extremely important in identifying the risk for future complications in pregnancy. A thorough reproductive history includes inquiry about prior miscarriages, terminations, ectopic pregnancies, and the details of any deliveries.

Approximately 20%–30% of all pregnancies result in pregnancy loss from spontaneous abortion. While 10% of these will be clinically recognized as a spontaneous abortion, another 20% will be only transient increases in human chorionic gonadotropin around the time of menses.[5] The majority of pregnancy losses occur in the first trimester. The rate of miscarriage increases with a maternal age of less than 18 years or an age of 35 years or more. One in five women will have a miscarriage. Two consecutive losses can occur in up to 5% of all reproductively active couples, and this percentage is higher in women 35 years of age or older. Recurrent pregnancy loss, defined as three or more losses, occurs in about 1% of patients trying to conceive.[6] While some providers will start a workup in patients with a history of two consecutive losses, many patients do not undergo evaluation until three losses.

Initial testing in the evaluation of recurrent pregnancy loss that may be considered part of a preventative health visit includes screening for underlying medical issues such as diabetes, thyroid disorders, and autoimmune disorders, all of which can lead to recurrent pregnancy losses. For women who have had three miscarriages and initial evaluation for underlying medical diseases is negative, referral to an obstetrician gynecologist for further evaluation is indicated.

While early losses before 10 weeks of gestation are common, losses occurring in the second trimester, especially after 15–16 weeks, are not. Women with late losses should be evaluated after one loss, and this should occur prior to another pregnancy. While the same etiology of recurrent

first-trimester losses may also cause a late pregnancy loss, other causes such as cervical insufficiency should be considered. Cervical insufficiency is characterized by painless dilation of the cervix due to a structural or functional defect. Patients at risk may have a history of cervical trauma or cervical surgery, but some women have no risk factors. Women who have a history consistent with cervical insufficiency should be advised to seek care with an obstetric provider early in their next pregnancy.[7]

Information about prior deliveries should include gestational age at delivery, mode of delivery, birth weight, health of the infant, and any complications that occurred in the pregnancy. Previous complications such as diabetes in pregnancy and preeclampsia indicate an increased risk of those complications in subsequent pregnancies and indicate an increase risk of medical complications even when not pregnant. Women with a history of gestational diabetes have an increase risk of developing diabetes later in life and preeclampsia increases a woman's risk of sudden cardiac death. Patients who have had a prior pregnancy complicated by neural tube defects (NTDs) have a 2% risk of recurrence, and folate supplementation at the level of 4 mg/day will reduce this risk.[8]

MEDICAL HISTORY

Identifying medical conditions, including mental health issues, prior to pregnancy allows the primary care provider the opportunity to modify medical care and medications as needed to optimize a woman's health and disease status prior to pregnancy. If needed, appropriate specialists can be consulted so women and their partners can be educated on the potential effects of medical conditions on a future pregnancy, as well as the effect of pregnancy on their medical conditions.

Hypertension

Chronic hypertension occurs in up to 5% of pregnant women. Chronic high blood pressure puts women at risk for preterm birth, fetal growth restriction, placental abruption, and cesarean delivery in pregnancy. There is also an increased risk in the development of superimposed preeclampsia. The incidence of these potential adverse effects is related to the degree and duration of hypertension and other organ system involvement or damage.[9,10]

During a preconception visit, the age of onset, results of previous testing, severity and duration of high blood pressure, medications used, and physical examination determine what testing should be done prior to pregnancy. Ideally, women with chronic hypertension are evaluated for potentially reversible secondary causes of hypertension and end-organ damage including serum creatinine, blood urea nitrogen, and 24 h urine evaluation for total protein and creatinine clearance. Depending on the duration and severity of disease, additional testing may include EKG, echocardiography, ophthalmologic examination, and renal ultrasonography. While most women with mild chronic hypertension are successfully managed in pregnancy, women with significant left ventricular hypertrophy on echocardiogram prior to pregnancy may have worsening of cardiac function in pregnancy and develop heart failure. Women with severe renal disease and a serum creatinine greater than 1.4 mg/dL may have a significant deterioration of renal function during pregnancy.[9]

Ideally, blood pressure is well controlled prior to pregnancy with diet and exercise as first-line agents. If medication is needed, beta-blockers and calcium channel blockers are considered safe in pregnancy. Angiotensin-converting enzyme inhibitors are contraindicated, as they are associated with significant fetal renal dysgenesis leading to fetal renal failure and death.

Diabetes

Preconception evaluation and planning are essential for optimizing both maternal and fetal outcome in women with pregestational diabetes mellitus. Glycemic control at the time of conception plays a key role in reducing fetal and neonatal complications. Offspring of women with pregestational diabetes are at increased risk for congenital malformations due to poor periconception glycemic control. Women with pregestational diabetes should be informed of the importance of glycemic control. Glycosylated hemoglobin (A1C) values above 8% have been linked to an increase in the risk of congenital anomalies as well as spontaneous abortion. One meta-analysis evaluating the relationship of periconceptional maternal A1C to congenital anomalies in the offspring found that for each one standard deviation unit increase in A1C above normal, there was an associated increase in congenital malformations by an odds ratio of 1.2.[11]

Preconception care for women with pregestational diabetes mellitus should aim to educate the patient and her partner regarding issues for the patient and her unborn child and how she can best achieve a healthy pregnancy. Interventions directed at improving diabetes care prior to pregnancy should strive for euglycemia with AIC levels less than 7% prior to conception. Studies evaluating the effect of preconception care on the risk of congenital anomalies have linked preconception care to a reduction in the risk of congenital anomalies.[12]

In addition to the risk of spontaneous abortion and congenital anomalies associated with glycemic control prior to pregnancy, poor glycemic control increases the risk of macrosomia and birth trauma. Pregestational diabetes mellitus has also been associated with increased risk of preeclampsia, intrauterine fetal demise, and worsening of maternal end-organ disease. Preconception counseling should educate women with preexisting diabetes in pregnancy about the importance of glycemic control and close follow-up for the entirety of their pregnancies.

Seizure Disorder

Women with seizure disorders are at increased risk for giving birth to infants with congenital anomalies, with 6%–8%

risk for women with seizure disorder at risk versus 2%–3% for women without a seizure disorder. Congenital anomalies seen more frequently in offspring of women with seizure disorders include cleft lip or palate, cardiac defects, NTDs, urogenital defects, and intrauterine growth restriction. Low folate levels are independently associated with congenital abnormalities in women with a seizure disorder. It remains unclear if these increased risks are associated with the use of antiepileptic drugs alone or the seizure disorder itself. In either case, there is compelling evidence that the use of folic acid supplementation prior to pregnancy reduces these risks.[13,14] Women with seizure disorders should be followed closely but reassured that with folic acid supplementation and preconception care, 90% of women will have a healthy pregnancy.[13]

In each woman planning a pregnancy, the need for antiepileptic drugs should be assessed, as some women may be successfully withdrawn from medication prior to pregnancy. The need for medication and the best medication to use should be tailored to each patient. Monotherapy with a single agent is preferred, as the risk for congenital anomalies is directly related to the number of antiepileptic drugs to which the fetus is exposed in the first trimester.[15] In general, as there is no consensus on which medication is best in pregnancy, the one that is most effective at stopping seizure activity in a given patient should be used. The exceptions to this are valproate and carbamazepine, which should be avoided if possible. Of the antiseizure medications, valproate has been shown to have the highest risk of teratogenicity and has increased levels in cord blood. Carbamazepine has been independently associated with major congenital malformations.[14]

Mental Health

For women with a history of psychiatric illness that predates pregnancy, a review of current psychoactive medications during a preconception visit is imperative. Advising a woman planning a pregnancy to discontinue psychiatric medications exchanges fetal or neonatal risks of medication exposure for the risks of untreated maternal illness. Untreated maternal psychiatric illness can result in significant complications including increases in alcohol and drug abuse, disruption of family environment, poor compliance in prenatal care, and poor maternal–infant bonding. Pregnancy and the postpartum period may also serve to exacerbate psychiatric illness. Ideally, shared decision making among obstetric and mental health clinicians and the patient should occur before pregnancy. A discussion of the risks and benefits of medication use, alternatives to medication, and therapy should involve the patient and her family support and occur within a multidisciplinary framework.[16,17]

The management of women with mental illness who are on medication should be individualized. For example, for those with mild depression or no symptoms for 6 months or longer, consideration can be given to tapering and discontinuing medication before becoming pregnant. However, for women who have psychosis, bipolar disorder, a history of suicide attempts, severe depression, or other major psychiatric illness, it may not be appropriate to taper or discontinue medications, and management should be done in partnership with a psychiatrist experienced in treating these disorders in pregnancy.[18]

Phenylketonuria

Phenylketonuria (PKU) is an autosomal recessive disorder of phenylalanine (Phe) metabolism characterized by a deficiency of the hepatic enzyme, phenylalanine hydroxylase (PAH). A deficiency of the PAH enzyme results in increased blood phenylalanine levels, which are toxic to the developing embryo. If untreated, PKU can result in fetal growth failure, microcephaly, seizures, and mental retardation. Children born to women with PKU on unrestricted diets have a 92% risk for mental retardation, a 73% risk for microcephaly, and a 12% risk for congenital heart defects. If phenylalanine levels are normalized before conception or by 8 weeks of gestation, there is evidence to suggest a significant reduction in the fetal sequelae of hyperphenylalaninemia. Although evidence suggests that women with PKU will benefit from remaining on a phenylalanine-free diet throughout their lives, many are not adherent to such a diet because of the unpalatable nature of many phenylalanine-free products. The failure of young women with PKU to adhere to dietary modification represents a significant public health challenge because of the significant fetal consequences of maternal hyperphenylalaninemia.[19] Women with PKU who are at risk of an unplanned pregnancy or are considering planning a pregnancy should be instructed to resume a phenylalanine-restricted diet.

Thyroid Disease

Thyroid disease is the second most common endocrine disorder in women of reproductive age. Both maternal hypothyroidism and hyperthyroidism can lead to complications in pregnancy. Inadequately treated maternal hyperthyroidism has been associated with a greater risk of fetal loss, preterm delivery, low-birth-weight infants, severe preeclampsia, and heart failure than in those with treated, controlled maternal hyperthyroidism. Poorly controlled maternal hypothyroidism has been associated with a slight increase in risk of preeclampsia, low-birth-weight infants, and fetal demise. Women with iodine-deficient hypothyroidism are at significant risk of having babies with congenital cretinism (growth failure, mental retardation, and other neuropsychological deficits).[20]

A euthyroid state should be achieved prior to conception with medications or surgery as appropriate. Maternal thyroid function should be followed in pregnancy due to the changes in maternal requirements throughout gestation. Currently, there is no evidence that identification and treatment of women with subclinical hypothyroidism improve maternal or infant outcomes, and therefore routine screening for subclinical hypothyroidism is not recommended during the preconception or prenatal period.[21]

Warfarin

MEDICATIONS

An important aspect of preconception counseling is the review of a woman's medication list, including over-the-counter medications, prescription drugs, vitamins, and herbal supplements, in order to evaluate for potential risk to the developing fetus. Women with underlying health issues should continue medications needed to optimize their health, but providers should evaluate whether there is known teratogenic risk to these medications and whether alternate medications known to be safer in pregnancy are suitable. Women that are required to remain on teratogenic medications for their own health should be counseled about the risks of unplanned pregnancy and the use of a reliable method of birth control. While there are some medications known to be teratogenic (see Table 66.1 for partial listing), many medications have not been well studied in pregnancy. Providers should discuss with women the available data on the use of the particular medication in pregnancy, the risks of being off of the medication, and the alternative medications that may be available.

FAMILY HISTORY

Review of family history for the patient and her partner during a well-woman visit often reveals potential risks in pregnancy. A positive history in the patient or her partner for genetic diseases should prompt referral to a genetics counselor (Table 66.2).

In addition, in certain ethnic groups, even with a negative family history, patients are at an increased risk for having a child with a genetic disease. For example, in individuals of Eastern European Jewish (Ashkenazi) descent, carrier screening for cystic fibrosis, Tay–Sachs disease, Canavan disease, and familial dysautonomia should be offered. In addition, in this population, screening for mucolipidosis IV, Niemann–Pick disease type A, Fanconi anemia group C, Bloom syndrome, and Gaucher disease may be considered. Tay–Sachs disease carrier screening should also be offered to individuals of French Canadian and Cajun descent.[22] In addition, individuals of African, Southeast Asian, and Mediterranean descent are at increased risk for being carriers of hemoglobinopathies and should be offered carrier screening (Table 66.3).[23]

TABLE 66.2
Genetic Diseases

Hemoglobinopathies
Sickle cell disease or known carrier status
Beta-thalassemia
Alpha-thalassemia
Hemophilia
Muscular dystrophy
Mental retardation
Unexplained
Fragile X
Cystic fibrosis or known carrier status

TABLE 66.3
Genetics Diseases by Ethnic Group

Disease	Ethnic Group at Highest Risk	Screening Test
Sickle cell anemia	African, Southeast Asian, Mediterranean, Caribbean	Hemoglobin electrophoresis
Beta-thalassemia	African, Indian, Mediterranean, Southeast and East Asian	CBC with indices
Alpha-thalassemia	African, Chinese, Filipino, Southeast Asian	CBC with indices
Tay–Sachs disease	Ashkenazi Jews Eastern European, French Canadian, Cajun	Assay for enzyme hexosaminidase A
Cystic fibrosis	Non-Hispanic Caucasian, Ashkenazi Jews	DNA analysis

TABLE 66.4
Rates of Cystic Fibrosis Carrier Status by Ethnicity

Ashkenazi Jewish	1/25
Non-Hispanic Caucasian	1/25
Hispanic American	1/46
African American	1/65
Asian American	1/94

While the carrier rates for cystic fibrosis are highest in the Ashkenazi Jewish population and non-Hispanic Caucasian population at rates of 1/25, it is becoming harder for patients to identify with a single ethnic group. Therefore, in 2005, the American College of Obstetrics and Gynecology Committee on Genetics recommended offering screening to all pregnant patients and to all patients considering conception regardless of ethnicity (Table 66.4).[24]

Providing these evaluations before pregnancy allows women and their partners greater control over their reproductive future. All screening for genetic disorders should involve informed consent. Patients may benefit from genetic counseling, especially in the Ashkenazi Jewish population.

SOCIAL HISTORY

The preconception period is an excellent time to educate patients on the risks posed by their lifestyle, behaviors, and environmental exposures. This counseling prior to pregnancy

gives the patient an opportunity to modify parameters under their control before exposing her fetus. In addition, many patients are more motivated to make positive changes if they are planning a pregnancy.

Smoking

Cigarette smoking is universally recognized to be harmful to both mother and fetus. Despite this, a 2004 survey found that in the United States an estimated 18% of pregnant women aged 15–44 years smoke cigarettes compared to an estimated 30% of nonpregnant women of the same age.[25]

In addition to the well-known health effects for the mother, smoking is associated with an increased risk of infertility, spontaneous abortions, preterm labor, low-birth-weight infants, stillbirth, placental abruption, and sudden infant death syndrome.[26,27]

While many women report they will stop smoking when pregnant, it is of greater benefit to the patient and the pregnancy to stop prior to pregnancy. Smoking cessation at any point in pregnancy leads to health benefits. Providers should specifically address the reproductive health risks of smoking to patients as part of any preventative health visit for women who are smokers and are of reproductive age. For nonpregnant women, the U.S. Preventive Services Task Force concluded that the combination of counseling and medications is more effective at increasing smoking cessation rates than from either alone. For nonpregnant women, however, they found inadequate evidence to evaluate the safety or efficacy of pharmacotherapy that is continued during pregnancy and so recommend only pregnancy-tailored counseling.[28] For patients who are pregnant, the use of nicotine replacement products or alternative smoking cessation agents should be undertaken with close supervision and with clear counseling of the patient in regard to the risks and benefits of smoking cessation and the risks and benefits of the agents being used.

Alcohol

Alcohol consumption in pregnancy may lead to fetal alcohol syndrome (FAS). FAS is characterized by growth deficiencies, abnormal facial features, and central nervous system abnormalities. FAS falls under the spectrum of adverse outcomes caused by prenatal alcohol exposure called fetal alcohol spectrum disorders (FASDs). In the United States, it is estimated that the rate of FAS is approximately 0.5–2 per 1000 births with FASDs occurring approximately three times as often.[29]

In the United States, alcohol is the most common potentially teratogenic substance to which pregnant women are exposed. In a 1991–2005 study of alcohol consumption among women in the United States, the average annual percentage of any alcohol among nonpregnant women was 53.7% and among pregnant women was 12.2%.[29] There is no threshold amount of alcohol consumption in pregnancy that has been proven safe. Women considering conception or who are not using adequate birth control should be counseled to avoid alcohol consumption.

Substance Abuse

Data from the National Center for Health Statistics estimates that in 2008 approximately 8% of individuals over the age of 12 had used illicit drugs in the last month. Substance abuse in pregnancy has increased over the past three decades in the United States, resulting in approximately 225,000 infants yearly with prenatal exposure to illicit substances.[30] Cocaine causes vasoconstriction that can lead to decreases in uterine blood flow. Use of cocaine in pregnancy can lead to premature rupture of membranes, preterm labor, placental abruption, small-for-gestational-age infants, and low-birth-weight newborns. In addition, neonatal issues include poor feeding, lethargy, and seizures.[30,31] The use of heroin and other opiates has been associated with an increase in the rate of poor obstetric outcomes by six times and neonates can undergo a severe withdrawal syndrome. Lastly, marijuana use has not been definitely linked to congenital anomalies, but has been linked to fetal growth restriction.[30] In addition to these risks, use of illicit drugs in pregnancy does not occur in a vacuum. It is associated with other comorbid conditions known to contribute to adverse maternal and fetal outcomes including other psychiatric disorders, and environmental factors such as poor nutrition, inadequate medical care, and domestic violence.[31] Routine screening for drug use in women of reproductive age, education, and referral for treatment are the most important ways that substance use in pregnancy can be decreased.

Domestic Violence

Maternal exposure to domestic violence is associated with a significantly increased risk of low birth weight and preterm birth.[32] Routine screening for domestic violence is important for women of all ages, but women who are of reproductive age are at particular risk. Women who are being abused before pregnancy are even more likely to be abused when they become pregnant. Screening for domestic violence in women should be part of every preventive health care visit. Every clinician should have a system set up for referrals to local resources and social services for patients.

Environmental Exposures

The Occupational Safety and Health Administration sets and enforces standards that require employers to maintain a workplace free of known hazards likely to cause physical harm. Patients who are at apparent risk should be encouraged to investigate this information in their workplace. High levels of exposure to organic solvents, such as those levels of exposure typically found in industrial workers, are thought to be harmful to the embryo and have been linked to an increase in spontaneous abortions.[33] Lead exposure, even moderate to low levels found in the U.S. population in the 1970s, has also been shown to increase the risk of spontaneous abortion, preterm birth, low birth weight, and developmental delays in the infant.[34] Lastly, exposure to waste anesthetic gases in the fields of human and veterinary

medicine has also been linked to an increased risk of spontaneous abortion. Studies indicating this relationship were primarily prior to the implementation of systems that scavenge waste anesthetic gases, so the actual risk at this time is not known.[35] Patients should be screened for environmental and occupational exposures.

Women contemplating pregnancy may be concerned about the safety of insect repellants. There is currently no reliable evidence that exposure to pest-control products at levels commonly used at home poses a risk either in the preconception period or during pregnancy. There is also no evidence that household cleaning products pose any additional risk in the preconception period or during pregnancy. Like all individuals, women of reproductive age should take precautions such as opening windows and doors and wearing rubber gloves when using cleaning products that contain ammonia or chlorine.

PHYSICAL EXAMINATION

The physical exam in the setting of a preconception evaluation is the same as for a routine periodic health evaluation. Aspects that should be concentrated on include the examination of the thyroid, breasts, heart, skin, and pelvis. Blood pressure and weight should also be checked. In addition, patients should be encouraged to see a dentist, as periodontal disease has been associated with pregnancy complications. If any underlying medical conditions are uncovered, they are best managed prior to pregnancy.

Laboratory testing is dependent on the woman's past medical, obstetric, and gynecologic history and in general should be individualized, and patients should be fully counseled on the implications of the testing. Laboratory testing may include those tests found in Table 66.5.

TABLE 66.5
Preconception Laboratory Testing

Test	Indication
Rubella titer	All women planning pregnancy
Hepatitis B surface antigen	All women planning pregnancy
Complete blood count with indices	Screening for hemoglobinopathy and anemia
HIV counseling and testing	All women planning pregnancy
Plasma glucose	Women at increased risk for diabetes
Mantoux test	Populations at high risk for TB
Hepatitis C antibody	Populations at high risk
Toxoplasmosis titer	Women with occupational exposure, pet cats, or high-risk food intake
Cytomegalovirus titer	Hospital workers, workers in childcare facilities
Gonorrhea and chlamydia testing	Women at high risk or under age 25
RPR	Women at high risk or under age 25
Cystic fibrosis mutation analysis	Offered to all women
Genetic carrier testing	Based on family history or ethnic origin

COUNSELING

Diet and Nutrition

A woman's nutritional status should be assessed at preconception with the goal of optimizing fetal, maternal, and infant health. The preconception period is an ideal time to reinforce that all women should eat a healthy, well-balanced diet and achieve a healthy weight. Fish and shellfish are a part of a healthy diet and are high in protein and omega-3 fatty acids. Mercury is known to be harmful in high doses to the developing fetal nervous system. Fish absorb methylmercury from the water they swim in and the food they eat. Nearly all fish contain some methylmercury. Large predatory fish accumulate the highest levels of methylmercury. Women should be advised to follow the FDA guidelines for consumption of fish and shellfish (Table 66.6) prior to pregnancy as mercury can remain in the body for several weeks after ingestion and levels can build up over time.[36]

Folic acid supplementation prior to pregnancy can significantly reduce the risk of NTDs both in women with a prior history of pregnancy complicated by NTDs and in women with no prior history. The U.S. Preventive Services Task Force currently recommends that all women planning or capable of pregnancy take a daily supplement containing 0.4–0.8 mg of folic acid.[8] For women with a prior history of a pregnancy with an NTD, those with a positive family history, or who are taking antiepileptic drugs, a dose of 4 mg/day is recommended. Folic acid is a water-soluble vitamin, easily metabolized and excreted, and no toxicity has ever been reported.

Because the neural tube closes at approximately 26 days after conception, 6 weeks after a missed period, and typically 2 weeks prior to a first prenatal visit, all women of reproductive age who are capable of becoming pregnant should be counseled to take folic acid supplements to reduce the risk of NTD. In 1998, the U.S. Food and Drug Administration mandated folic acid fortification of enriched grain products.

TABLE 66.6
2004 EPA and FDA Guidelines for Fish Consumption in Pregnancy

1. Do not eat shark, swordfish, or tilefish, tuna steak, mackerel, marlin, or grouper
2. Eat up to 12 oz of a week of a variety of fish and shellfish that are lower in mercury. Albacore "white" tuna has more mercury than canned "light" tuna so limit consumption of albacore tuna to 6 oz per week
3. Check local advisories about the safety of fish caught locally. If no advisories are available limit consumption to 6 oz per week

Source: EPA/FDA, What you need to know about mercury in fish and shellfish, EPA-823-R-04-005, March, 2004, http://www.fda.gov/food/foodsafety/product-specificinformation/seafood/foodbornepathogenscontaminants/methylmercury/ucm115662.htm

Despite this, many women consume less than 400 μg daily from their diet, and thus supplementation with folic acid in the preconception period is still recommended.

Exercise and Body Weight

Obese women are at increased risk for several pregnancy complications, and therefore preconception assessment and counseling are strongly encouraged. Providers should educate obese patients about potential complications in pregnancy and should encourage them to undertake a weight reduction program, including diet, exercise, and behavior modification before attempting pregnancy. Specific medical clearance may be indicated for some patients. Obese women are more likely to develop preeclampsia, gestational diabetes, gestational hypertension, and fetal macrosomia.[37]

In addition to pregnancy complications, obese women are more likely to have difficulty with conception. An increased body mass index is associated with ovulatory subfertility and anovulatory infertility. Overweight and obese women have poorer outcomes following fertility treatment.[38]

Regular exercise provides benefits for pregnant and nonpregnant women alike. Preconception counseling should encourage a regular exercise program prior to pregnancy. Many exercises are safe in pregnancy and prepregnancy exercise regimens may be continued. Activities to be avoided in pregnancy, but not in the preconception period, include exercises that put women at risk for abdominal trauma.

Vaccinations

The preconception or interconception period is the optimal time to make sure that women are up to date on their immunizations (Table 66.7). There is no evidence of risk from vaccinating pregnant women with an inactivated virus or bacterial vaccines or toxoids, and these should be administered if indicated during pregnancy. However, live vaccines do pose a theoretic risk to the fetus and generally should be avoided during pregnancy. The preconception period is the ideal time for vaccination with live virus vaccines, and women should be advised to wait to conceive for 1 month after vaccination with such live virus vaccines as rubella and varicella.

In 2008, looking to prevent infantile pertussis, the CDC's Advisory Committee on Immunization Practices came out with a new recommendation to vaccinate adults for pertussis who will have contact with children less than 12 years and for women during the immediate postpartum period. They specifically recommend that pregnant women who were not vaccinated previously with Tdap may (1) receive Tdap in the immediate postpartum period before discharge from hospital or birthing center, (2) receive Tdap at an interval as short as 2 years since the most recent Td vaccine, (3) receive Td during pregnancy for tetanus and diphtheria protection when indicated, or (4) defer the Td vaccine indicated during pregnancy to substitute Tdap vaccine in the immediate postpartum period if the woman is likely to have sufficient protection against tetanus and diphtheria. Although pregnancy is not a contraindication for receiving Tdap vaccine, there is currently not sufficient evidence to address its safety in pregnancy.[39]

TABLE 66.7
Immunizations

Immunization	Frequency	Patients	Safe in Pregnancy?
Diphtheria/ tetanus	Every 10 years	All	Yes
Pertussis (in TDaP)	Once	Postpartum and adults who will have contact with children <12	Unknown
Influenza	Annually	All	Yes
H1N1	Annually	All	Yes
Pneumococcal	Once	Susceptible individuals	Yes
Hepatitis B	Once (three-shot series)	All	Yes
MMR	Once	All	No
Varicella	Once	Susceptible individuals	No

CONCLUSION

Preconception care is an important part of preventive health care in women of reproductive age. As the field of preventive care has developed, the importance and demand for preconception care, counseling, and education have grown too. Primary care providers plan a key role in determining the health of the mother and the child even before pregnancy occurs. Preconception evaluation and counseling should be a standard element of the primary care of any woman of childbearing age.

Diet and lifestyle practices during pregnancy can provide maternal and fetal benefits as well as an investment in future health for both the mother and her baby. Pregnancy is a normal physiological state, not a disease, and healthy women can engage in work, leisure, and exercise armed with knowledge to utilize pregnancy as a launching point for a healthy diet and lifestyle that lays a solid foundation for both themselves and their children, now and in the future. Health care providers play an important role in giving evidence-based diet and lifestyle counseling that can help women make good choices in pregnancy, since myths, media, and culture can confuse even the most motivated woman.

A CHANGING POPULATION

In recent years, the characteristics of women in the United States having babies have changed dramatically. Today, women entering pregnancy are older and many are overweight or obese. Studies estimate that over 60% of adults in the United States are overweight (body mass index [BMI] of 25 or higher) and up to 32% are obese (BMI of 30 or higher). For the prime childbearing ages 20–39, 57% are either overweight or obese.[1] Since 1970, the prevalence of multiple births has been increasing. A combination of factors are associated with this change, including the widespread use of assisted reproductive techniques and advancing maternal age at conception.[2] These changing demographics and characteristics are linked with an increased risk of maternal issues that can put both the mother's and her baby's health at risk. Recommendations for diet in pregnancy must be tailored to meet these changing needs.

The diet that a fetus is exposed to in utero may set the stage for future health. Both fetal under- and overnutrition in utero have been linked with health risks later in life. The joint WHO/FAO Expert Consultation on Diet, Nutrition and the Prevention of Chronic Diseases identified the period of fetal development as a critical life stage to initiate prevention of chronic diseases, including obesity, diabetes, and cardiovascular disease.[3] A growing body of knowledge about fetal origins of adult diseases suggests that through the diet and environment that a fetus is exposed to in utero, there may be an opportunity to prevent or mitigate many chronic diseases that arise in adulthood.[4,5]

Helping mothers to have babies within a healthy birth weight range is an area of focus, since babies that are born either too big or too small appear to have increased health risks. On one end of the spectrum, babies who are born with low birth weight have health risks. Intrauterine growth restriction has been recognized as a long-term health risk. Later in life, babies who were born small for gestational age at birth, especially those born to undernourished mothers, have increased risks of coronary heart disease, type 2 diabetes, and hyperlipidemia.[3–5] At the other extreme, concerns

over the consequences of fetal overnutrition resulting in high birth weight have grown, especially in light of the epidemic of overweight, obesity, and diabetes among women of childbearing age. In babies exposed to overnutrition and high glucose in utero, resulting problems can include congenital birth defects, macrosomia, birth trauma, and childhood obesity.[4–6] Pregnancy is a balancing act, in which women need to take in enough, but not too many, calories and nutrients in order to optimize health for themselves and their babies.

MATERNAL WEIGHT TARGETS

Many women are gaining more weight in pregnancy than is currently recommended. The goals of nutrition during pregnancy are to provide adequate maternal and fetal nutrition and energy intake that result in the appropriate maternal weight gain. Gaining excessive weight during pregnancy is a strong predictor of high postpartum maternal weight retention and the development of overweight and obesity later in life.[7] Excessive weight gain during pregnancy, along with preexisting maternal overweight and obesity, increases the risk of maternal complications during pregnancy and delivery in mothers. Maternal weight gain influences infant birth weight, which in turn influences future health for children. Neonatal birth weights that are too high or too low have both been associated with increased risks of future diseases.

The Institute of Medicine (IOM) recommended weight gain guidelines for pregnancy were published in 1990 and revised in 2009.[8] A woman's weight at the start of pregnancy is one of the most important modifiers of pregnancy weight gain and its impact on a mother's and her baby's health. The revised weight gain guidelines take into account both the welfare of the infant and the health of the mother based upon the weight that the mother begins her pregnancy, so that nutritional needs can be balanced in order for both mother and baby to thrive. They help to clarify weight gain for expectant mothers based upon pre-pregnancy BMI, with a new category for obese women added, and more specific recommendations for women having multiple pregnancies. The guidelines help ensure that the baby will gain the appropriate amount of weight, while balancing the maternal needs so that women will not be left with a large amount of weight to lose postpartum. The guidelines and recommendations are intended to be used in concert with good clinical judgment and should include a discussion between the woman and her care provider about both diet and exercise.

The recommended weight gain during pregnancy for normal-weight women is 25–35 lb, which translates into approximately a 200–300-cal increase daily in a pregnant woman's dietary needs. Daily energy needs during pregnancy vary due to such factors as physical activity and age and range from 2500 to 2700 kcal.[8] Overweight women can limit weight gain to 15 lb, and obese women can limit it to 11 lb. Underweight women should gain a minimum of 28 lb. After the first trimester, this translates into approximately 1 lb of weight gain per week for underweight and normal-weight women, and 0.5–0.6 lb of weight gain for overweight and obese women. For many women, this means gaining less weight than in the past, which may be particularly challenging for those starting pregnancy overweight or obese. Ideally, women should be within a normal BMI range when they conceive and then should gain within the ranges recommended in the new guidelines once pregnant (Table 67.1).

TABLE 67.1
Institute of Medicine Recommended Weight Gain in Pregnancy

Weight Status	BMI	Total Weight Gain	Rates of Weight Gain
Underweight	<20	28–40	1 lb/week
Normal	20–25	25–35	1 lb/week
Overweight	25–29	15–25	6 lb/week
Obese	>30	11–20	5 lb/week

Source: Institute of Medicine, *Weight Gain During Pregnancy: Reexamining the Guidelines*, National Academy Press, Washington, DC, May 2009.

Calculations assume a 1.1–4.4 lb weight gain in the first trimester.

HISTORICAL VIEW OF WEIGHT GAIN IN PREGNANCY

The weight recommendations for pregnancy have evolved over the last 50 years. In the past, obstetricians in the United States recommended that women restrict weight gain to as little as 25 lb (12.5 kg) in hopes that it would reduce the risk of preeclampsia. When scientific evidence did not support this risk reduction through caloric limitation, the restriction on weight gain was lifted.[9] In 1990, the IOM recommended increased weight gain ranges with the primary goal of improving infant birth weight, with weight gain recommendations individualized based upon pre-pregnancy BMI.[10] These recommendations were endorsed by the American College of Obstetricians and Gynecologists in 1993.[11] However, concerns grew that the 1990 IOM guidelines resulted in overgrown newborns with increased health risks later in life.[12] Critics argued that many of the prior recommendations for weight gain in pregnancy rested on observational studies that may have had confounding factors that accounted for the adverse birth outcomes associated with low birth weight. For example, hypertension, smoking, low family income, and poor antenatal care are linked with low birth weight. Another observational study linked too much weight gain in pregnancy with future risk of obesity in the mother.[13] Women weigh more today than they did in 1990, and many experts thought the 1990 guidelines emphasized fetal health over maternal health, resulting in women gaining too much weight in pregnancy and retaining weight from one pregnancy to the next, adding to the growing problem of overweight and obesity.

COUNSELING ABOUT WEIGHT GAIN

Studies suggest that women are not getting adequate counseling about proper weight gain targets for pregnancy.[14] Women who start pregnancy at the extremes of BMI, either underweight or overweight, are prone to targeting weight gains that are outside the IOM guidelines. Women who are overweight strive to gain too much weight, and underweight women strive to gain too little. Women with low BMI have the highest risk for inadequate target weight gains, while women with high BMI have the highest risk for excessive weight gain. Patients with poor health literacy and lower education status tend to target incorrect weight gain goals. In addition, African American and Latina patients are more likely than white women to report target weight gains below the guidelines, even when controlling for education status, pointing toward cultural factors that may influence target weight gain.[14,15] It is not known if these target behaviors are due to providers giving incorrect advice, cultural factors, or lack of patient knowledge about appropriate target weights. It may be a combination of all of these factors.

Studies of the U.S. women show that 30%–40% of women gain either above or below the guidelines. Overweight women are much more likely to gain above the guidelines, and underweight women are more likely to gain below the guidelines.[16] This points toward the need for health care providers to reinforce and encourage underweight women to gain relatively more weight, and overweight women to aim to gain relatively less, as recommended by the IOM guidelines. There is currently little information about evidence-based recommendations for clinicians to follow in order to help stem excessive maternal weight gain. One trial actually demonstrated that including weight gain counseling in prenatal care resulted in increased maternal weight gain (although nonsignificant) in overweight women, suggesting that the dietary advice may not have been effective.[17]

WEIGHT RETENTION AFTER PREGNANCY

Weight retention after pregnancy is one factor contributing to the problem of overweight and obesity in adult women. The average weight retention after pregnancy ranges from 0.4 kg (0.88 lb) to 3.8 kg (8.38 lb) at 6 weeks to 1 year after pregnancy.[18,19] Studies indicate that pregnancy is associated with future weight gain beyond that expected with age alone. The weight retention appears to be largely associated with a first pregnancy. Primiparas gain 2–3 kg more weight during a 5-year period after pregnancy than do women who do not carry a pregnancy. Primiparas also have greater increases in waist-to-hip ratio that are independent of weight gain, suggesting changes in adiposity patterns that result from pregnancy. Multiparas do not show further adiposity changes, so it appears that these changes are not made worse in subsequent pregnancies. Black women demonstrate greater adverse changes in adiposity than white women. Interestingly, most studies suggest that the effect of breast-feeding on maternal postpartum weight loss is negligible.[18,19]

Studies show that women are much more likely to be able to return to their pre-pregnancy weight if they gain within the IOM weight guidelines. If the upper limit of the weight gain guidelines is exceeded, the amount of weight retained goes up exponentially. In a study of postpartum weight retention, women starting pregnancy with high BMIs who gained more than 25 lb (11.4 kg) had a high risk of significant postpartum weight retention, with 34% retaining more than 14 lb (6.4 kg) several months after delivery.[20]

FETAL ORIGINS OF ADULT DISEASE

There is a growing body of scientific evidence that suggests the environment in utero may affect future adult health and risk of disease for the fetus. There are several epidemiologic studies that support this idea. Low birth weight has been linked to an increased risk of cardiovascular disease and type 2 diabetes. It is theorized that this risk is due to an adaptation by the fetus in the in utero environment in which the fetus becomes "thrifty" by being small and insulin resistant.[21] This "thrifty phenotype" hypothesis suggests that the metabolic adjustments, which are adaptive in the face of an in utero environment in which nutrient supplies are limited, are maladaptive and unhealthy in an adult in a nutritionally rich environment.

Both under- and overnutrition, as well as the timing of the in utero exposure, appear to make a difference for disease risk as an adult. For example, survivors of the Dutch famine of 1945 had an increased risk of impaired glucose tolerance as adults if their intrauterine environment was calorie restricted in late pregnancy.[22] However, if the calorie restriction occurred early in gestation, adults had an increased risk of coronary heart disease and dyslipidemia.[23] Less information is available with regard to the specifics of macro- and micronutrient imbalances, but again, data from the Dutch famine suggest that fetal exposure in the third trimester to a low protein-to-carbohydrate ratio in the maternal diet is associated with hypertension as an adult.[24] A study of adults whose mothers had been advised to eat a high-protein diet during pregnancy showed higher blood pressure and elevated basal cortisol levels in those whose mothers had higher meat (protein) and lower vegetable intake during pregnancy.[25]

LOW-GLYCEMIC-INDEX DIET

Pregnancy is a state of maternal insulin resistance, with glucose serving as the main fuel for the fetus. As our knowledge of the potential health benefits of a low-glycemic-index diet in the nonpregnant state has increased,[26,27] interest has grown in examining the health effects of a low-glycemic-index diet in pregnancy. Poor glucose control in pregnancies complicated by gestational diabetes has known adverse effects, including fetal macrosomia, neonatal hypoglycemia, birth trauma, and other pregnancy complications.[28] There are currently some data on the potential beneficial effects of a low-glycemic-index diet in pregnancy. One study comparing a low-glycemic-index diet compared to a usual diet in pregnancy

found that women who consumed a low-glycemic-index diet had infants that were in the normal size range for gestational age, but were smaller and had less body fat than those from women who consumed a high-glycemic-index diet.[29] The infants of mothers in the low-glycemic-index group were normal size for gestational age, but the infants of mothers who consumed a high-glycemic-index diet group were more likely to be large for gestational age, with 33.3% of the infants in the >90%. Another study using a low-glycemic-index diet for women with gestational diabetes found that the number of women needing to use insulin was halved, with no compromise of obstetric or fetal outcomes.[30] One small pilot study that randomized 46 overweight or obese pregnant women to either a low-fat or low-glycemic-load diet found no differences in birth weight or infant adiposity, but in the low-glycemic-load group, gestational duration was longer (mean 39.3 compared with 37.9 weeks; P = 0.05) and fewer deliveries occurred at <38.0 weeks of gestation. Maternal benefits in women in the low-glycemic-load group showed smaller increases in triglycerides and total cholesterol and a greater decrease in C-reactive protein.[31] Studies on glycemic index in pregnancy are ongoing.

VITAMINS AND SUPPLEMENTS

Many women inquire about vitamin and supplement use during pregnancy. The evidence regarding their use is reviewed here.

Several trials of maternal calcium supplementation during pregnancy have suggested a potential role of in utero exposure to calcium and later blood pressure in offspring. A prospective cohort study found a protective effect of maternal calcium intake from supplements and infant blood pressure at 6 months of age.[32] There is evidence in the literature to support an association between maternal calcium intake during pregnancy and offspring blood pressure.[33] However, more research is needed, especially in populations with calcium deficits, to confirm these findings, given the small sample sizes and the methodological problems in many of the studies conducted to date. If confirmed, these findings could have important public health implications since calcium supplementation during pregnancy is simple and inexpensive and may be a way to reduce the risk of hypertension and its sequelae in the next generation.

The American Dietetic Association states that pregnant women should eat a diet that enables appropriate weight gain, and adequate nutrition may be obtained through consumption of a variety of foods, with vitamin and mineral supplementation appropriate for some nutrients.[9] The need for vitamin supplements in order to obtain adequate micronutrients in pregnancy has been examined in a recent Cochrane review.[34] The review identified nine trials undertaken in low- or middle-income countries. There was a reduction in low birth weight and small-for-gestational-age babies and anemia in mothers who received supplementation. Further research is ongoing to look at the maternal and fetal benefits of micronutrient supplementation, while also examining the risks of excess supplementation and adverse interactions among micronutrients.

Probably the best-known example of nutrient supplementation in pregnancy is folic acid supplementation and the subsequent reduced risk of neural tube defects (NTDs). NTDs, the most common of which are spina bifida and anencephaly, are related to homocysteine metabolism, and the risk of having a fetus with an NTD is significantly reduced with dietary folic acid supplementation.[35] Much evidence indicates that 0.4 mg (400 µg) per day of folic acid, one of the B vitamins, will reduce the number of cases of NTDs. The U.S. Public Health Service recommends that "all women of childbearing age in the United States who are capable of becoming pregnant should consume 0.4 mg of folic acid per day for the purpose of reducing their risk of having a pregnancy affected with spina bifida or other NTDs."[36] In 1998, the U.S. Food and Drug Administration mandated folic acid fortification of enriched grain products.[37] Since that time, studies suggest that fewer than 1000 NTD-affected pregnancies occur in the United States each year.[38]

MATERNAL SUPPLEMENTATION WITH OMEGA-3 FATTY ACIDS

Interest in maternal supplementation with omega-3 fatty acids during pregnancy and lactation has grown since several epidemiologic studies have shown benefits in infant neurocognitive scores as well as improved maternal depressive symptoms and maternal lipid benefits. There is a growth spurt in the human brain during the last trimester of pregnancy and the early neonatal months and a large increase in the content of docosahexaenoic acid (DHA) in the brain during this time. DHA (omega-3) is important for the development of the central nervous system, and the fetus and the breast-feeding newborn depend upon maternal consumption to supply these fatty acids. The concentrations of these fatty acids in breast milk are variable and depend on maternal consumption.[39]

One study examining the long-term effects of maternal supplementation with omega-3 fatty acid supplements during pregnancy and lactation found that 4-year-old children have higher mental processing scores when the mothers are supplemented with omega-3 fatty acids from cod-liver oil compared to omega-6 fatty acids from corn oil.[40] Another study showed that there were potential maternal lipid benefits to supplementation with cod-liver oil in pregnancy.[41] The maternal plasma triacylglycerol increase during pregnancy was less pronounced in women supplemented with cod-liver oil as compared to corn oil. The concentration of high-density lipoprotein (HDL)-cholesterol was unchanged during pregnancy in the cod-liver oil group, whereas it decreased in the corn oil group, promoting a greater increase in the ratio of total cholesterol/HDL-cholesterol in the corn oil group. Finally, one study of cod-liver supplementation in pregnancy revealed that higher levels of omega-3 fatty acids in the bloodstream of neonates correlated with longer gestational length and better cerebral maturation of the newborn, and improved neurodevelopmental outcomes in children.[42,43] Higher intakes of these *n*-3 long-chain polyunsaturated fatty

acids from fish and seafood during pregnancy are also associated with a reduced risk of maternal depressive symptoms in the postnatal period.[44] However, one randomized controlled trial, the DHA to Optimize Mother Infant Outcome (DOMInO trial), did not find improved cognitive and language development in early childhood of the offspring of mothers who used DHA-rich fish oil capsules during pregnancy compared with vegetable oil capsules, and there were not lower levels of postpartum depression in mothers who took DHA.[45] The supplement used in the DOMInO trial contained 800 mg/day of DHA and 100 mg/day of eicosapentaenoic acid (EPA). The authors did demonstrate that supplementation with predominantly DHA in pregnancy caused a small to modest increase in the duration of gestation. The effect of DHA treatment on gestational length was most notable at the extremes. In the DHA group, significantly fewer infants were born less than 34 weeks' gestation but significantly more women were induced or had cesarean sections because they were postterm. The clinical significance of these findings is difficult to balance, although the reduction in preterm birth at less than 34 weeks' gestation was also associated with fewer low-birth-weight infants and fewer admissions to neonatal intensive care in the DHA group. Other studies on omega-3 supplements and pregnancy are ongoing.

VEGETARIANS

Approximately 2.5% of adults in the United States describe themselves as vegetarian. The American Dietetic Association and Dieticians of Canada have stated that well-planned lacto-ovo vegetarian and vegan diets are appropriate for all stages of the life cycle, including during pregnancy and lactation.[46] Studies of birth weight show that neonates born to vegetarians are similar to nonvegetarians and well within birth weight norms for gestational age.[47] Pregnant vegans need to be vigilant about obtaining adequate protein, as well as reliable sources of B_{12} and zinc from their diet. Vegans can meet vitamin B_{12} needs with the use of foods fortified with vitamin B_{12}, such as yeast extracts, vegetable stock, veggie burgers, textured vegetable protein, soymilk, vegetable and sunflower margarines, and breakfast cereals. Unreliable and therefore inappropriate sources of vitamin B_{12} are tempeh, sea vegetables, and algae, since these foods may contain vitamin B_{12} analogues, substances that mimic vitamin B_{12} but actually block vitamin B_{12} absorption. Thus, there are no natural B_{12} sources available for a vegan diet, but fortified foods can be utilized.

Some studies have found that cord blood levels of the omega-3 fatty acid DHA are lower in infants of vegetarian mothers.[48] This fatty acid is most often found in fish oil and thus would be limited in the diets of vegetarians. Although DHA plays a role in the development of the brain and nervous system, the clinical significance of this observation is not known.

FOOD SAFETY

Several food-borne illnesses are of particular concern in pregnancy. *Listeria monocytogenes* is a gram-positive rod-shaped bacterium found in soil, water, and manure used as fertilizer. Uncooked meats and processed foods can become contaminated with listeria after preparation, such as soft cheeses, cold cuts from the deli counter, and ready-to-eat foods such as hot dogs, since contamination may occur after cooking but before packaging. Foods or dairy products that contain unpasteurized (raw) milk may contain the bacterium. Listeria is killed by pasteurization and cooking.

Listeria infection is a food-borne disease that, in immunocompetent individuals, is often a self-limited and mild febrile gastrointestinal process. Pregnant women are approximately 20 times more likely than other healthy adults to get listeriosis, and about one-third of all listeriosis cases happen during pregnancy. Infected pregnant women may experience only a mild, flu-like illness. However, listeria has a predilection for the placenta and can infect the fetus and neonate. In some cases, infections during pregnancy can lead to miscarriage, stillbirth, premature delivery, or neonatal infection.

Simple precautions during pregnancy can prevent listeria infection. The Center for Disease Control recommends that pregnant women avoid eating lunchmeats, hot dogs, or prepared foods from the deli counter unless they are reheated until they are hot and steamy throughout. Pregnant women should also avoid soft cheeses such as feta, Brie, and Camembert, blue-veined cheeses, or Mexican-style cheeses such as queso blanco, queso fresco, and Panela, unless they have labels that clearly state they are made from pasteurized milk.[49] Most pregnant women have limited knowledge of listeriosis prevention. A recent study suggests that most women were aware of avoiding eating unpasteurized dairy products, but were unaware of the risk associated with ready-to-eat foods.[50]

Toxoplasma gondii infection is caused by a parasite and, in immunocompetent individuals, is usually either an asymptomatic or self-limited flu-like syndrome consisting of fever, malaise, and lymphadenopathy. Toxoplasmosis can cause a mild flu-like illness in the mother during pregnancy, but can be then transmitted to the fetus and cause severe issues, especially if transmitted in the first trimester. In utero infection can result in mental retardation, blindness, and seizures.

Toxoplasma is transmitted to humans in three major ways: ingestion of raw or inadequately cooked infected meat; ingestion of oocysts, an environmentally resistant form of the organism that cats pass in their feces; and a newly infected pregnant woman passing the infection to her unborn fetus. Approximately half of toxoplasmosis infections are caused by eating contaminated meat. Immunity to toxoplasmosis is long lasting, but most U.S. adults have not been exposed to the pathogen. It is estimated that 23% of U.S. adults and approximately 14% of women of childbearing age are immune.[51] Thus, prevention is a key issue for women of childbearing age.

Pregnant women should be instructed on lifestyle and dietary precautions to prevent toxoplasma infection. These include cooking meat well, and peeling or washing fruits

and vegetables before eating. Cross contamination in the kitchen can be avoided by cleaning cooking surfaces and utensils after they have come in contact with uncooked food. Pregnant women should be counseled to avoid changing cat litter.

Fetal exposure to mercury is a health concern, because mercury is a neurotoxin. Humans are primarily exposed to mercury by consuming fish. Mercury exists in three forms: metallic, inorganic, and organic. Metallic mercury (elemental or pure form of mercury) is a metal that is liquid at room temperature and is the form used in thermometers and dental amalgam. Inorganic mercury occurs when mercury combines with chlorine, sulfur, or oxygen. Mercury enters the environment as a pollutant, most commonly from coal-fired power plants. Inorganic mercury is released into the environment in the form of air pollution, pesticides, and medical waste and accumulates in streams and oceans. Humans do not readily absorb inorganic mercury, but microorganisms in the environment can convert inorganic mercury to organic mercury. When mercury combines with carbon, the compounds are called organic mercury, the most common of which is methylmercury.[52] This form is absorbable by animals and humans, and when consumed by animals low on the food chain, it later becomes more concentrated in larger longer-lived predatory fish at the top of the food chain. Nearly all fish contain trace amounts of mercury, but these trace amounts are not harmful. However, the large predator fish accumulate the highest levels of mercury. Mercury is accumulated in humans primarily by eating fish.

Fish and shellfish are an important part of a healthy diet. However, because nearly all contain trace amounts of mercury, pregnant women, breast-feeding women, and young children should avoid seafood known to be high in mercury and limit total seafood consumption. The Environment Protection Agency recommends that the following fish be avoided in pregnancy: swordfish, shark, king mackerel, and tilefish. In addition, it is recommended that local fish advisories be followed regarding the safety of fish caught in lakes, rivers, and coastal areas. Since all fish contain some mercury, pregnant women should limit total intake of seafood to an average of 12 oz, or about two average servings, per week. Albacore ("white") tuna should be limited to 6 oz (one average meal) per week. Most women rarely exceed these amounts. The more variety in the types of fish eaten, the less likely any one will have excessive levels of mercury.[52–55]

Consumption of seafood has many benefits for both mother and fetus, and it is important that pregnant women not be overly restrictive in their seafood intake. Seafood is the major natural food source of the omega-3 fatty acids DHA and EPA, which are necessary for optimum fetal neural development. Indeed, a recent study found that consumption of fish during pregnancy outweighs any risks associated with trace contamination, since risks from the loss of nutrients were greater than the risks of harm from exposure to trace contaminants.[43] In this study, low maternal seafood intake was associated with an increased risk of children being in the lowest quartile for verbal intelligence quotient (IQ). Thus, worries about contamination need to be balanced with the need to ensure adequate maternal intake of these essential fatty acids, especially through fish consumption that are low in mercury.

CAFFEINE

Data are conflicting with regard to the effect of caffeine on pregnancy. Most authors agree that the primary concern with caffeine exposure in pregnancy is an increased risk of miscarriage; however, the magnitude of that risk varies in different studies. Caffeine passes through the placenta to the fetus. Epidemiologic evidence suggests that caffeine may be associated with an increased risk of spontaneous abortion in the first trimester. One of the most widely quoted studies on caffeine consumption and miscarriage found that there are more spontaneous abortions in women who ingest at least 100 mg of caffeine per day, and the risk increases with larger amounts of caffeine (100–299 mg per day: odds ratio, 1.3; 95% confidence interval, 0.9–1.8; 300–499 mg per day: odds ratio, 1.4; 95% confidence interval, 0.9–2.0; and 500 mg or more per day: odds ratio, 2.2; 95% confidence interval, 1.3–3.8).[56] There is wide individual variability in caffeine metabolism and clearance, and other studies have found differences in susceptibility to the effects of caffeine based upon enzyme activity differences from one individual to another.[57] It is generally recommended that pregnant women keep consumption of caffeine at or below 150 mg of caffeine per day. There have been some associations between caffeine intake and difficulties conceiving for women. This has not, however, been a consistent finding in all studies. There are approximately 100 mg of caffeine in a cup of coffee, 50 mg in tea, though this varies widely with brews and brands.

ALCOHOL

Alcohol consumption during pregnancy can lead to adverse physical and neurodevelopmental outcomes in offspring. Alcohol consumption can result in teratogenesis, including fetal facial dysmorphology and damage to the central nervous system.[58] There is no known safe level of alcohol consumption in pregnancy, and several studies have suggested that even low levels of alcohol intake, such as less than one drink per week, might be associated with. Several studies have found that even low levels of alcohol intake, <1 drink per week during pregnancy, may be associated with mental health problems and adverse child behaviors at 6–7 years of age.[59,60] However, there is controversy about the issue of low-level exposure, as a study from Australia suggested that mild gestational drinking is not associated with adverse fetal effects and may even be associated with favorable outcomes as compared to "no drinking."[61] Methodological limitations in this and other studies of alcohol use in pregnancy make drawing clear conclusions difficult, but there does appear to be a dose–response curve with respect to alcohol exposure *in utero* and adverse pediatric outcomes.

SMOKING

Smoking is known to increase a host of pregnancy-related complications, including miscarriage, premature delivery, intrauterine growth restriction, placental abruption, and sudden infant death syndrome. Smoking is the one of the most important modifiable causes of poor pregnancy outcomes in the United States, and health care providers should be certain to identify pregnant women who smoke and offer support and treatment to increase quit rates. Pregnancy appears to motivate women to stop smoking, as 46% of women quit smoking just before or during pregnancy.[62] Smoking cessation or a reduction in the number of cigarettes per day during pregnancy reduces these risks.[63] The risks of smoking during pregnancy also extend beyond pregnancy, since children born to mothers who smoke during pregnancy are at an increased risk of asthma, infantile colic, and childhood obesity.[64–66] Although quitting smoking before 15 weeks of pregnancy results in the greatest benefits for the pregnant woman and fetus, quitting at any point is beneficial. For example, smoking cessation before the third trimester can eliminate much of the reduction in birth weight caused by maternal smoking.[67]

The five As is an office-based intervention that can help health care providers work with pregnant women to quit smoking.

FIVE AS OF SMOKING CESSATION

1. *ASK* the patient about smoking status at the first prenatal visit and follow-up with her at subsequent visits. The patient should choose the statement that best describes her smoking status:
   a. I have NEVER smoked or have smoked LESS THAN 100 cigarettes in my lifetime.
   b. I stopped smoking BEFORE I found out I was pregnant, and I am not smoking now.
   c. I stopped smoking AFTER I found out I was pregnant, and I am not smoking now.
   d. I smoke some now, but I have cut down on the number of cigarettes I smoke SINCE I found out I was pregnant.
   e. I smoke regularly now, about the same as BEFORE I found out I was pregnant.

   If the patient stopped smoking before or after she found out she was pregnant (b or c), reinforce her decision to quit, congratulate her on success in quitting, and encourage her to stay smoke-free throughout pregnancy and postpartum. If the patient is still smoking (d or e), document smoking status in her medical record, and proceed to Advise, Assess, Assist, and Arrange.
2. *ADVISE* the patient who smokes to stop by providing advice to quit with information about the risks of continued smoking to the woman, fetus, and newborn.
3. *ASSESS* the patient's willingness to attempt to quit smoking at the time. Quitting advice, assessment, and motivational assistance should be offered at subsequent prenatal care visits.
4. *ASSIST* the patient who is interested in quitting by providing pregnancy-specific, self-help smoking cessation materials. Support the importance of having smoke-free space at home and seeking out a "quitting buddy," such as a former smoker or nonsmoker. Encourage the patient to talk about the process of quitting. Offer a direct referral to the smoker's quit line (1-800-QUIT NOW) to provide ongoing counseling and support.
5. *ARRANGE* follow-up visits to track the progress of the patient's attempt to quit smoking. For current and former smokers, smoking status should be monitored and recorded throughout pregnancy, providing opportunities to congratulate and support success, reinforce steps taken toward quitting, and advise those still considering a cessation attempt.

Rockville (MD): US Department of Health and Human Services, Public Health Service, Agency for Health care Research and Quality, 2008.

The use of nicotine replacement therapy to aid in quitting smoking in pregnancy should be undertaken with close supervision and after careful consideration and discussion with the patient of the known risks of continued smoking and the possible risks of nicotine replacement therapy. If nicotine replacement is used, it should be done with the clear resolve of the patient to quit smoking. Many small studies using nicotine replacement do not show increased risks to the pregnancy, but it is not yet clear if this therapy results in improved pregnancy outcomes.[63]

CONCLUSION

Our knowledge about nutrition and lifestyle issues in pregnancy has grown tremendously in the last decade. Pregnancy is a time when many women are motivated to make lifestyle changes such as diet and exercise that can make a difference in the future health of their babies, as well as to their own health. While some foods may cause harm to the fetus, it is also clear that certain nutrients that are consumed during pregnancy may be one way to prevent or mitigate disease in her future child. Thus, eating for two is doubly important. Pregnancy is not a state of confinement; it is a state of health, and evidence-based guidance and counseling about diet and lifestyle can promote healthy mothers and babies.

The recommendations regarding exercise in pregnancy have been in flux over the years. In 1985, the American College of Obstetricians and Gynecologists provided the first guidelines for exercise during pregnancy based on the limited evidence available [1]. Prior to this time, women were often told to avoid strenuous physical activity, stretching, or bending for fear of pregnancy complications that might result. Since that time, a great deal of research has been done focusing on the safety, risks, and benefits of physical activity in pregnancy. Currently, both the Centers for Disease Control and Prevention and the American College of Obstetricians and Gynecologists encourage regular physical activity during pregnancy as the benefits are thought to far outweigh the risks [2]. This chapter will review the benefits and potential risks of exercise in pregnancy, the contraindications to exercise in pregnancy, and the current recommendations for type, intensity, frequency, and duration of activity in pregnancy.

BENEFITS OF EXERCISE IN PREGNANCY

Weight Management

The population as a whole is heavier today than in previous times. A greater percentage of women are entering pregnancy overweight or obese, and many are gaining significantly more weight during pregnancy than is recommended [3]. Excessive weight gain is emerging as an important predictor of adverse pregnancy outcomes. Independent of prepregnancy weight, women who gain excessively during the course of the pregnancy are more likely to deliver by cesarean section, have an unsuccessful trial of labor after cesarean section, develop hypertension or preeclampsia, deliver preterm, have a macrosomic or small-for-gestational-age infant, retain excessive weight after delivery, and become overweight or obese later in life [4–7]. The Institute of Medicine recently reexamined the guidelines for weight gain during pregnancy and

TABLE 68.1
Recommendations for Weight Gain during Singleton Pregnancy Based on the Current IOM Guidelines

Prepregnancy BMI (kg/m^2)	Recommended Weight Gain (lb)	Rate of Weight Gain Suggested in Second and Third Trimesters (lb/week)
<18 (underweight)	28–40	1
18.5–24.9 (normal weight)	25–35	1
25.0–29.9 (overweight)	15–25	0.6
>30 (obese)	11–20	0.5

Source: Institute of Medicine, Brief report: Weight gain during pregnancy: Reexamining the guidelines, May 2009.

provided new recommendations for weight gain based on prepregnancy body mass index (BMI; Table 68.1) [3].

Exercising during pregnancy has been shown to reduce excess weight gain and decrease weight retention postpartum. In one study of women who continued their preconception exercise regimen compared to women who stopped or significantly reduced their level of physical activity during pregnancy, women who continued to exercise had a reduced rate of weight gain (though within the normal range) and decreased subcutaneous fat deposition later in pregnancy [8]. Stuebe et al. assessed the association of physical activity with excessive weight gain among women enrolled in the Project Viva cohort study [4]. The cohort included women receiving prenatal care in one of eight urban and suburban obstetrical offices in a multispecialty group practice in eastern Massachusetts. This study of 1388 women included information about prepregnancy weight, gestational weight gain, and dietary and exercise habits. Within this cohort of women, 379 (27%) were overweight entering the pregnancy and 703 (51%) experienced excessive weight gain based on the 1998 Institute of Medicine guidelines for weight gain in pregnancy. The study concluded that walking (30 min daily), vigorous physical activity in the second trimester, and increased total activity were inversely associated with excessive weight gain, while a sedentary lifestyle was associated with a nonsignificant increase in the risk of excessive weight gain [4]. These are just two studies among many that demonstrate the positive role of exercise in weight management during pregnancy.

Postpartum weight retention is strongly related to weight gain during the pregnancy [9,10]. Average estimates of weight retention postpartum range from −0.27 kg (0.6 lb) to 3.0 kg (6.6 lb) though this varies significantly between different studies [9]. Scholl et al. categorized the rate of gestational weight gain per trimester as more, less, or appropriate compared to the recommended amount of weight gain as per the Institute of Medicine guidelines at the time of the study. They found that at 6 months postpartum, women with an excessive rate of weight gain during the pregnancy weighed 12% (7.9 kg or 17.4 lb) more than they did prepregnancy and retained about 40% of the gestational weight gain. This was in contrast to women who gained weight at or below the recommended guidelines, who were only 5%–7% (3.2 kg or 7.1 lb) heavier at 6 months postpartum [11]. Rooney and Schauberger found that women who gained excessive weight during pregnancy and failed to lose the weight by 6 months postpartum were as much as 15 lb heavier at 10-year follow-up [12]. Women who exercise during pregnancy may be less likely to gain more than the recommended amount of weight and be at less risk of postpartum weight retention and lasting weight retention or obesity.

Glycemic Control

Gestational diabetes mellitus (GDM) is one of the most common pregnancy complications affecting approximately 7% of pregnancies in the United States. It is highest among obese and overweight women [13]. GDM is associated with adverse perinatal outcomes including an increased risk for macrosomia, maternal and neonatal birth injury, neonatal hypoglycemia and hyperbilirubinemia, as well as an increased risk of impaired glucose intolerance and type 2 diabetes mellitus in the years following pregnancy (Table 68.2) [14].

Insulin resistance in normal pregnancy is estimated to increase by 40%–70% and is related to the increase in cortisol, growth hormone, human placental lactogen, estrogen, progesterone, and prolactin associated with the growth of the fetal–placental unit [14]. An increase in insulin resistance decreases maternal blood glucose uptake by the muscles, ensuring an adequate glucose supply for fetal growth and development. This balance can tip, however, leading to abnormally high maternal blood glucose and insulin concentrations yielding the diagnosis of GDM [15]. Physical activity has long been known to improve glucose homeostasis by increasing insulin sensitivity in maternal skeletal muscle and increasing lean body mass [16]. A sedentary lifestyle is one of the modifiable risk factors associated with GDM [15]. Physical activity decreases the risk of developing GDM and can serve as an adjunctive therapy in the treatment of GDM. This is of particular importance since a significant number of women with GDM go on to develop type 2 diabetes later in life.

TABLE 68.2
Risks Associated with Gestational Diabetes

Mother	Birth trauma, cesarean delivery, preeclampsia, gestational hypertension, Type 2 diabetes
Fetus	Hyperinsulinemia, cardiomyopathy, stillbirth, macrosomia, birth injury
Newborn	Respiratory distress syndrome, hypoglycemia, hyperbilirubinemia, cardiomyopathy
Child/adult	Obesity, type 2 diabetes, metabolic syndrome

Source: Adapted from Pridjian, G. and Benjamin, T.D., *Obstet. Gynecol. Clin. North Am.*, 37, 255, 2010.

Many studies have examined the impact of exercise before and during pregnancy on the development of gestational diabetes. Though there are no randomized controlled studies demonstrating exercise as a means for prevention of GDM, current evidence suggests a benefit. The influence of recreational activity on GDM risk was evaluated in a case–control study of 155 women with GDM and 386 normotensive nondiabetic pregnant controls. After adjustment for age, race, parity, prepregnancy BMI, and smoking, physical activity both prepregnancy and during pregnancy were associated with a significant reduction in GDM by 51% and 48%, respectively [17]. Similar results were confirmed in a prospective cohort study of more than 900 normotensive nondiabetic women [18]. These data are supported by a recent meta-analysis published by Tobias et al. [19]. Prepregnancy physical activity was assessed in 34,929 total participants, yielding a pooled odds ratio of 0.45 (95% CI 0.28–0.75) for developing GDM when comparing women in the highest category of prepregnancy physical activity with those in the lowest. Exercise during early pregnancy was also found to be protective, yielding an odds ratio of 0.76 (95% CI 0.7–0.83).

Exercise serves not only to prevent gestational diabetes but also as an adjunctive treatment in women who have been previously diagnosed. The American Diabetes Association suggests that women without medical or obstetrical contraindications to exercise should be encouraged to start or continue a program of moderate exercise as part of treatment for GDM [13]. Jovanovic-Peterson et al. randomized a small group of women diagnosed with GDM (N = 19) to diet alone versus diet plus exercise with an arm ergometer [20]. They found lower glycosylated hemoglobin, fasting, and 1 h postprandial plasma glucose concentrations in the diet-plus-exercise group as compared to diet alone [20]. Garcia-Patterson et al. found that women with GDM who performed light postprandial walking also showed improvement in postprandial glucose concentrations [21]. Bung et al. randomized women diagnosed with GDM who failed to attain adequate glucose control with diet alone to insulin plus diet versus exercise plus diet. There were no significant differences between the two groups in terms of glycemic control, maternal outcomes, or fetal outcomes and thus concluded exercise to be a valuable tool in the treatment of GDM [22].

Reduction of Risk of Hypertensive Disorders in Pregnancy

Hypertensive disorders occur in approximately 12%–22% of pregnancies and are among the leading causes of maternal mortality in the United States, accounting for 15%–20% of maternal deaths [23]. There is a spectrum of hypertensive disorders that affect pregnancy including chronic hypertension, gestational hypertension, preeclampsia, and HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome. Maternal complications resulting from hypertensive disorders in pregnancy can be catastrophic and include abruptio placentae, disseminated intravascular coagulation, cerebral hemorrhage, seizure, hepatic failure, and acute renal failure [24]. There are also significant risks to the fetus including intrauterine growth restriction, oligohydramnios, preterm delivery, and intrauterine fetal demise [24].

Metabolic disturbances associated with preeclampsia include but are not limited to hypertriglyceridemia, excessive lipid peroxidation, antioxidant deficiency, insulin resistance, plasma elevations of proinflammatory cytokines and C-reactive protein, and a thromboxane–prostacyclin imbalance favoring vasoconstriction [15]. There is considerable overlap between the epidemiology of preeclampsia with that of essential hypertension and atherosclerotic vascular disease [15]. Nonpregnant women with hypertension or vascular disease are encouraged to exercise in order to improve their blood pressures and/or halt disease progression [25]. It is likely then that increased physical activity would be associated with a decreased risk of hypertensive disorders in pregnancy.

To date, there are few studies looking at the relationship between the hypertensive disorders of pregnancy and maternal exercise. Yeo et al. suggest that exercise lowers blood pressure during pregnancy (as it does in nonpregnant women) based on the results from a randomized controlled trial conducted on a small group of pregnant women recruited before 14 weeks of gestation [26]. All women had a history significant for mild hypertension, gestational hypertensive disorders, or a family history of hypertensive disorders and were therefore thought to be at significant risk for developing hypertension in their current pregnancy. Among women randomized to the exercise arm, there was a strong trend toward lowered diastolic blood pressures though their results were not statistically significant. Other mechanisms by which exercise may reduce the risk of hypertensive disorders in pregnancy, and specifically the risk of preeclampsia, include improving pregnancy-induced dyslipidemia, decreasing concentrations of proinflammatory cytokines, and decreasing insulin resistance [15].

Sorensen et al. conducted a case–control study between 1998 and 2001 in order to characterize the relation between recreational physical activity and the risk of preeclampsia [27]. They identified 201 women with preeclampsia and 383 normotensive controls. All patients were given a structured questionnaire during their postpartum stay. Women who participated in recreational physical activity (e.g., brisk walking, stair climbing) during the first 20 weeks of pregnancy experienced a 35% reduction in the risk of preeclampsia after controlling for maternal age, race, parity, tobacco use, and prepregnancy BMI. Increased energy expenditure was inversely associated with the risk of preeclampsia. These results were similar to those published by Marcoux et al. in 1989 [28]. In this case–control study, women participating in recreational physical activity in the first 20 weeks of pregnancy were significantly less likely to develop gestational hypertension or preeclampsia.

More prospective research is needed to further characterize the relationship between exercise and maternal hypertensive disorders, but current data suggest that exercise before pregnancy and during the first 20 weeks plays a protective role.

Psychological Benefits

Maternal mental health has been reported to have a significant impact on physical health and pregnancy outcome. Mood fluctuations are common during and after pregnancy with the prevalence of prenatal depression nearly 11% [29] and postpartum depression up to 16% [30]. Several factors may increase the risk for mood disturbances during pregnancy including reproductive hormones, psychosocial stressors, isolation, personal or family history of depression, and chronic medical conditions [15]. Consequences of untreated perinatal mood disorders can be significant and are associated substance use, lack of compliance with medical care, disruption of relationships, preterm delivery, low birth weight, impaired mother–child bonding, and childhood behavioral issues [15,31,32].

Physical activity is linked with improvement of mental health in nonpregnant woman and likely confers the same benefits during pregnancy. The advantageous effects of physical activity on mental health likely result from a combination of psychological and physiological components. Proposed hypotheses regarding the psychological impact of exercise on mood include distraction, self-efficacy, social interaction [33], and improved body image [34]. Physiological mechanisms by which exercise may improve mood include the release of monoamines and endorphins [33]. Improvements noted in women who engage in physical activity include increased vigor, decreased fatigue, less stress and anxiety, decreased symptoms of negative mood and depression, and improved self-image [35].

Wallace et al. [36] found that pregnant women participating in an aerobic exercise program during pregnancy had higher self-esteem and lower fatigue than sedentary women. Goodwin et al. [37] found that women who exercised during pregnancy reported better feelings of overall well-being and had fewer symptoms of somatic discomfort, anxiety, and insomnia. These results were echoed by Marquez-Sterling et al. who demonstrated improvement in energy levels and body satisfaction in a small group of previously sedentary pregnant women randomized to an exercise program as compared to controls that remained sedentary [38]. Similarly, pregnant adolescents participating in a 6 week aerobic exercise program reported significantly less depressive symptoms and an increase in self-esteem compared to controls [39]. Given the prevalence of symptoms associated with depression and anxiety in pregnancy and the negative impact that these symptoms may have on pregnancy outcome, an exercise regimen may be a helpful tool in the maintenance of emotional well-being. Exercise during pregnancy has also been associated with improved mood postpartum and therefore may plan an important role in preventing postpartum depression [15,40].

Improvement in Musculoskeletal Pain

Studies indicate that 50%–90% of women experience some degree of musculoskeletal discomfort during pregnancy, most commonly low back and pelvic girdle pain [15,41]. Proposed mechanisms for pregnancy-associated musculoskeletal pain include a change in weight distribution and posture as well as hormonal influence on joint laxity [42]. Musculoskeletal discomfort tends to worsen over the course of the pregnancy and has been linked to disability, functional impairment, and missed work [31].

A regular exercise program before pregnancy and during early pregnancy likely reduces the risk of back pain during pregnancy [43,44]. Sternfeld et al. found that women who exercised more during early pregnancy had statistically fewer discomforts later in pregnancy and those symptoms were inversely proportional with the level of exercise women performed [44]. In women who already have low back pain associated with pregnancy, exercises to strengthen core abdominal and back muscles are likely of benefit. Sitting pelvic tilt exercises and aquatic exercises have both been shown to decrease the incidence and severity of low back pain experienced in pregnancy [45,46]. Yoga is also thought to play a role in improving back pain as well [47], possibly secondary to improvement in core strength. Beddoe et al. [31] analyzed the effect of a 7 week mindfulness-based yoga intervention on several variables, one of which was pain. They found women in the second trimester experienced fewer hours of pain and less pain interference with activity from baseline to post-intervention.

Lowered Rates of Intervention during the Time of Labor and Delivery

Though the evidence is of limited quality, some studies suggest that less medical intervention is required during labor in women who exercised routinely during pregnancy. These interventions may include analgesia, labor augmentation, operative vaginal delivery, and cesarean delivery. A case–control study by Hall and Kaufman demonstrated a lower incidence of cesarean delivery and a shorter peripartum hospitalization course in women who participated in a conditioning program over the course of their pregnancy [48]. Clapp compared the onset, course, and outcome of labor among women who continued their prepregnancy exercise regimen throughout gestation with those who discontinued their exercise routine before the end of the first trimester. Results indicated a lower incidence of operative vaginal delivery and cesarean delivery as well as a shorter active phase of labor among the women who delivered vaginally [49]. A randomized controlled trial looking at the effect of water aerobic in pregnancy did not find a difference in the duration of labor or type of delivery; however, they found that women who participated in the exercise group were significantly less likely to request analgesia [50]. This was true after controlling for parity and level of education as well.

Other Benefits

Women who are active during pregnancy may report less nausea, heartburn, leg cramps, varicose veins, constipation, and insomnia [43,50].

RISKS OF EXERCISE IN PREGNANCY

With regard to the risks of exercise in pregnancy, there are many conflicting studies and most are limited in design and quality. Concerns regarding exercise in pregnancy are generally related to the risk of spontaneous abortion (SAB), fetal distress, low birth weight, preterm delivery, and maternal injury. Physiological mechanisms hypothesized to mediate a potentially detrimental effect of maternal exercise on embryonic and fetal health include the following:

1. Reduction of placental blood flow secondary to redirection toward working skeletal muscles [51,52]
2. Rise in core body temperature/hyperthermia [53,54]
3. Release of hormones (adrenaline, noradrenaline) stimulating uterine contractility [55,56]
4. Hypoglycemia [57]

Spontaneous Abortion

The current literature yields mixed results when evaluating the risk of SAB in relation to a woman's physical activity level. Hjollund et al. [58] followed a cohort of women planning their first pregnancy in order to assess the relationship between physical strain and SAB. Women were recruited between 1992 and 1994 and followed from the time of termination of contraception until pregnancy was achieved for a maximum of six menstrual cycles. Women recorded their level of daily physical strain in a structured diary, and pregnancy outcomes were analyzed with an SAB being defined as pregnancy loss prior to 28 weeks of gestation in this study. They found an increased risk of SAB among women who reported high physical strain during the time of implantation of the embryo as calculated based on menstrual cycle length. No clear effect was seen at any other time point. Madsen et al. [59] found similar results from a study within the Danish National Birth Cohort in that women who exercised, high-impact exercisers in particular, had an increased risk of SAB prior to 18 weeks of gestation as compared to sedentary controls. Caution must be made when interpreting these results, given the potential bias that results from largely retrospective data collection and confounders such as chronic medical conditions that were not accounted for in the results.

Other studies have found substantially different results. For example, Clapp [60] followed exercise performance before and during pregnancy in 47 recreational runners, 40 aerobic dancers, and 28 controls. In this group of women, SAB occurred in 19% of pregnancies and was not statistically different among the groups and he therefore concluded that exercise in the preconceptional period and early pregnancy does not appreciably alter early pregnancy outcomes. In one large prospective study with 158 active women and 83 matched sedentary controls, there was no association between exercise and the risk of infertility, SAB, or other adverse pregnancy outcome [61]. Also, Latka et al. [62] reported a lower risk of chromosomally normal SAB among women who participated in leisure-time exercise.

In summary, the data are quite limited in both the number and the quality of studies examining the relationship between physical activity and risk of SAB. At this point, the benefits of exercise in pregnancy as mentioned earlier likely far outweigh the risk of early pregnancy loss, if there is any risk at all.

Fetal Distress

Studies of animal models have demonstrated that maternal exercise may reduce uterine blood flow secondary to redistribution toward maternal skeletal muscle and thus may result in relative fetal hypoxia [52]. Fetal heart rate (FHR) monitoring is a noninvasive method for determining fetal well-being with specific patterns recognized to be associated with fetal hypoxia [63]. For this reason, it is frequently used in studies attempting to evaluate the risk of fetal distress associated with maternal exercise. The most common response to maternal exercise is a rise in FHR, which returns to baseline after cessation of exercise [53,64] and is likely a response to a slight drop in oxygenation secondary to increased maternal consumption [63], release of maternal catecholamines, and an increase in maternal core body temperature [64]. Less common and more concerning are the few reports of transient bradycardia occurring with or following exercise [65]. Another technique used to assess fetal status is ultrasonography with attention to fetal movements and breathing as these are thought to be markers of fetal well-being [66].

Webb et al. [67] sought to evaluate the effects of acute and chronic maternal exercise on FHR. In this study, a group of women took part in a conditioning program during the second and third trimesters and were matched with sedentary controls. At three different time points, both the study group and the controls were asked to perform on a cycle ergometer. Maternal heart rate, blood pressure, and temperature were monitored as was the FHR. While the most common response was a rise in FHR baseline by approximately 10–20 bpm during exercise, there were three incidences of fetal bradycardia (one after 10 min of exercise and two following cessation of exercise). All FHRs normalized and none were associated with adverse pregnancy outcomes. Of note, there were no differences in the FHR response between conditioned and sedentary women [67]. Manders et al. described similar FHR findings and added that fetal body movements were decreased immediately following cessation of exercise whereas fetal breathing movements were increased during this time frame [68]. Winn et al., on the other hand, found a decrease in the total duration and frequency of fetal breathing and fetal body movement following acute maternal exercise [69]. Neither Manders nor Winn reported adverse pregnancy outcomes associated with these findings.

With regard to pregnancy outcomes, Clapp found that women who continued to exercise regularly throughout pregnancy were actually less likely to have clinical evidence of fetal distress as indicated by the presence of meconium,

abnormal FHR tracing, or low APGAR score at the time of labor and delivery [49]. Rose et al. showed no difference in the rate of fetal or neonatal death among women who reported moderate or vigorous activity levels during the second trimesters compared to women who reported light activity [70]. It is important to recognize that neither FHR monitoring nor ultrasound is a perfect measure of fetal oxygenation or acid base status. While transient abnormalities in fetal testing have been associated with maternal exercise, there are no differences in fetal morbidity or mortality [49,67,71,72] in pregnancy outcomes.

Low Birth Weight

Exercise leads to a redistribution of blood flow toward skeletal muscle, and splanchnic blood flow (which includes uterine blood flow) may decrease substantially. With high-intensity exercise, oxygen and glucose are shunted to skeletal muscles and away from the placenta and developing fetus [65]. There has been concern that this redistribution may lead to a decrease in birth weight or intrauterine growth restriction, but studies are inconsistent. Recent literature suggests that the timing, volume, and intensity of exercise likely impact placental and fetal growth [73,74].

Though the majority of the data regarding the effects of exercise on birth weight stem from retrospective cohort studies, two recent prospective randomized studies have been conducted to evaluate the relationship between exercise and fetoplacental growth. In the first, women who did not exercise regularly were randomly assigned at 8 weeks of gestation either to no exercise or to weight-bearing exercise—three to five times per week for the remainder of the pregnancy [73]. The midtrimester placental growth rate was faster and the birth weights were increased significantly (3.75 vs. 3.49 kg) in the exercise group.

A follow-up study aimed to further determine the effect of the timing and the volume of exercise on placental and fetal growth during pregnancy. Clapp et al. randomly assigned women at 8 weeks of gestation who exercised regularly to one of three exercise regimens for the remainder of the pregnancy [74]. The first group increased their volume of exercise in the third trimester, the second maintained a moderate exercise regimen throughout the pregnancy, and the third decreased their exercise volume in the third trimester. Women who maintained a moderate exercise regimen or increased their exercise volume in the third trimester had significantly slower fetoplacental growth than women who decreased their exercise volume in the third trimester. While these infants were significantly lighter (3.39 vs. 3.81 kg), there was no increased risk of intrauterine growth restriction or birth weight classified as small for gestational age [74].

In summary, exercise in early pregnancy seems to promote placental growth and development [73,74], which may account for the finding that many women who start or maintain exercise regimens during pregnancy actually have increased mean birth weights when compared to less active or sedentary controls [75–77]. Vigorous and high-volume activity later in pregnancy does appear to be associated with a small decrease in mean birth weight [8,49,74,78], which some believe to be the result of a loss of fat mass in the fetuses of endurance exercisers, while others feel this may be related to gestational age at delivery (addressed in the following text) or maternal weight gain [78]. In either case, there does not appear to be an increase in intrauterine growth restriction or small-for-gestational-age infants among women who exercise during pregnancy [79,80].

Preterm Delivery

Preterm birth is defined as delivery prior to 37 weeks of gestation and is associated with significant neonatal morbidity and mortality, especially for infants born prior to 32 weeks of gestation [81]. Approximately 12.5% of deliveries in the United States are preterm, and this number has been rising over the last two decades [81]. Lifestyle-related risk factors for preterm birth include maternal stress, smoking, and intensity and duration of work [81]. An association between physically demanding occupations and the risk of preterm birth has been described in the literature. The relationship between exercise and the risk of preterm delivery is questionable [82].

During exercise, catecholamine output increases substantially, which could in turn stimulate uterine activity [83]. However, studies are conflicting whether physical exercise actually increases uterine contractility [56]. The most recent literature suggests that exercise or leisure-time physical activity does not increase the risk for preterm delivery and may instead actually be protective. In a study published in 1990, Clapp compared birth weights and labor courses among women who maintained exercise at greater than or equal to 50% of preconception levels with those who stopped exercising in the first trimester [49]. The incidence of preterm labor was equivalent in the two groups at 9%. Labor did begin an average of 5 days earlier in the exercise group, which was statistically significant [49], but may be clinically irrelevant, as this did not result in preterm delivery or adverse outcomes.

Juhl et al. [56], in contrast, reported a reduced risk of preterm birth among women who engaged in some form of exercise during pregnancy as compared to sedentary women. The association was not affected by the type of exercise, and no dose–response relationship was found [56]. Important things to consider in the interpretation of these results include the reliance on patient self-report and the possibility that the women who were exercising may have been at a lower baseline risk of preterm birth, resulting in a healthy exerciser effect [56]. Randomization helps to eliminate these biases, and recently two randomized controlled trials designed to evaluate the association between exercise and gestational age at the time of delivery were published.

Barakat et al. [82] randomized previously sedentary women with singleton pregnancies to a control group or an exercise group. The exercise program consisted of light

resistance and toning exercises 3 days a week for 35 min between 12 and 39 weeks. The mean gestational age at delivery did not differ between the two groups, and there was no significant difference in the percentage of women with preterm delivery [82]. Cavalcante et al. [79] similarly randomized low-risk sedentary pregnant women to a water aerobics group or a sedentary control group, and they reported no difference in the rate of preterm delivery between the two groups.

Based on the limited available data, there is not an increased risk of preterm delivery associated with exercise during pregnancy. These studies do not address the effects of exercise on preterm birth in women who have an increased underlying risk for preterm labor. Thus, caution should be used when counseling these women with regard to exercise during the course of their gestation.

Maternal Injury

Profound physical changes occur over the course of a pregnancy. Postural changes include a significant increase in lumbar lordosis and a forward tilt of the pelvis. Combined with pregnancy-associated weight gain and a shift in the center of gravity forward, balance coordination and exercise tolerance can be greatly altered [65]. Joint laxity and mobilization are also increased secondary to the hormonal changes of pregnancy [84]. Thus, pregnant women engaging in exercise should take caution when performing high-velocity or jerking movements as they may be more prone to joint injury.

TABLE 68.3
Absolute and Relative Contraindications to Exercise in Pregnancy

Absolute Contraindications	Relative Contraindications
Preterm labor in current pregnancy	Unevaluated maternal arrhythmia
Ruptured membranes	Uncontrolled preexisting maternal medical conditions (seizure disorder, hyperthyroidism, hypertension)
Persistent second/third trimester bleeding	Orthopedic limitations
Known placenta previa	History of preterm delivery or preterm premature rupture of membranes in prior pregnancy
Incompetent cervix (± cerclage)	Eating disorders, extreme underweight/malnutrition
Multiple gestations identified at increased risk of preterm labor	
Intrauterine growth restriction or suspected placental insufficiency	
Preeclampsia	
Hemodynamically significant heart disease (valvular or ischemic)	
Restrictive lung disease

CONTRAINDICATIONS TO EXERCISE IN PREGNANCY

Understanding the absolute and relative contraindications to exercise in pregnancy is essential when counseling a patient (see Table 68.3). Any factor that may compromise maternal physiological reserve could put her health and the health of her fetus at risk. In these situations, the risks will far outweigh the exercise-related benefits. Of note, a history of sedentary lifestyle was previously described as a relative or even absolute contraindication to exercise in pregnancy as there was thought to be the potential for harm. There are now studies to show that this is unlikely and when done appropriately, beginning an exercise regimen in pregnancy is safe even for previously inactive women [79].

RECOMMENDATIONS FOR EXERCISE IN PREGNANCY

The most recent ACOG committee opinion on exercise during pregnancy and the postpartum period was published in 2002. At that time, it was recommended that in the absence of contraindications, pregnant women should engage in regular, moderate-intensity physical activity for 30 min on most, if not all, days of the week [2]. More recently, the 2008 physical activity guidelines for Americans were published by the Centers for Disease Control and Prevention, which recommends the following [85]:

1. Healthy women should get at least 150 min/week of moderate-intensity aerobic activity during and after their pregnancy. This may be broken down to 30 min/day, 5 days/week and furthermore can be done in 10 min segments of exercise.
2. For previously inactive women without medical contraindication to exercise, it is reasonable to begin a moderate-intensity exercise regimen.
3. For healthy women who regularly perform vigorous intensity aerobic activity, they may continue to do so during pregnancy so long as they stay healthy and are followed closely by a health care provider.
4. While pregnant, women should not partake in activities that involve lying directly on ones back or increase the risk of falling or abdominal trauma.

In the United States, only 16% of pregnant women comply with the physical activity recommendations compared with 26% of nonpregnant women [86]. Even healthy, otherwise active women tend to decrease physical activity in pregnancy [87]. Given the proven benefits of exercise in pregnancy, it is important to educate and encourage women to participate in moderate physical activity during the course of their gestation.

Exercise Prescription

When counseling a patient regarding an appropriate exercise regimen, there are several factors to consider: the women's age, weight, prepregnancy or current fitness level, medical history, and obstetric history. Contraindications should be ruled out or at least weighed against the potential benefits in pregnancy that exercise may confer (i.e., weight management, glucose control, reduction in the risk of hypertensive disorders, psychological benefits, and improvement in musculoskeletal pain). An exercise prescription should include recommendations for intensity, duration, frequency, and type of exercise and should be tailored to patients on an individual basis.

Intensity of Training

No safe upper limit of exercise in pregnancy has been established though many studies demonstrate that physically fit women may participate in vigorous activity without compromising the pregnancy [64]. Methods to monitor exercise intensity, including heart rate monitoring, Borg's rate of perceived exertion, and the "talk" test [88], may all be helpful in achieving a safe level of exercise. The goal is for healthy women to achieve regular moderate-intensity exercise.

Cardiovascular adaptations in pregnancy include an increased resting heart rate and a decreased maximal heart rate, which results in reduced heart rate reserve and a lowered slope of heart rate response to increasing work [89]. Thus, heart rate alone may be an inaccurate reflection of the intensity of aerobic exercise. It has been proposed that during pregnancy, the target heart rate range represents about 60%–80% of aerobic capacity [89]. Davies et al. propose that the target heart rate range for pregnant women under 20 years old is 140–155 bpm, 20–29 years old is 135–150 bpm, 30–39 years old is 130–145, and over 40 years old is 125–140 bpm [90]. Literature suggests that the target heart rate should also be adjusted according to BMI because overweight and obese pregnant women may be exercising at a higher intensity (%VO_2) than intended for a given heart rate [91]. Borg's rate of perceived exertion is a 15-point scale from 6 to 20 (see Table 68.4). A target range of 12–14, which corresponds with moderate to somewhat hard intensity, is suggested to be appropriate during pregnancy [88]. The "talk test" simply refers to exercising mothers being able to carry on a conversation while exercising [53,88]. One should be able to hold a conversation during moderate-intensity exercise. It is likely a combination of the earlier methods that allows for determination of the appropriate intensity of exercise.

Duration/Frequency

The current recommendation for exercise in pregnancy is for 150 min of exercise per week [85], and it is generally suggested that this be spread over the course of the week on most, if not all, days (rather than performed in long but infrequent sessions). During exercise, glucose levels decrease and temperature increases with time [57]. Blood glucose decreases at a faster rate and to a significantly lower level postexercise in pregnant women as compared to nonpregnant women. After 45 min of continuous exercise at 50%–60% of maximal oxygen consumption, the blood glucose in pregnant women may fall substantially, which could adversely impact the fetus [57]. It is therefore important to balance caloric intake with output, and perhaps limiting exercise sessions to 45 min or less may be advisable [89]. Core body temperature also rises but when exercise is self-paced, body temperature tends to stay within safe limits [57]. In order to avoid complications such as hyperthermia, women should exercise in a thermo-neutral environment or in controlled environmental conditions and pay careful attention to hydration and subjective feelings of heat stress [89].

TABLE 68.4
Borg's Rate of Perceived Exertion Scale

	Effort (%)	Correlates with
6	20	
7	30	Very, very light (near rest)
8	40	
9	50	Very light (gentle walking)
10	55	
11	60	Fairly light
12	65	
13	70	Somewhat hard (moderate)
14	75	
15	80	Hard
16	85	
17	90	Very hard
18	95	
19	100	Extremely hard
20	Exhaustion

Types of Exercise

Most forms of exercise are safe during pregnancy, though there are some that involve risks and should be avoided. Women should avoid exercises that require them to lie flat on their backs (especially after 16 weeks of gestation) or stand still for prolonged periods of time, as well as those activities that place women at risk for injury or abdominal trauma [89,92]. Reasonable activities to suggest for pregnant women include walking, jogging, cycling, aerobics, swimming, and yoga [2,89,92]. Contact sports such as soccer, basketball, hockey, or football put one at risk for abdominal trauma, and it generally thought best to avoid such activities [2]. Participation in skiing, snowboarding, gymnastics, and horseback riding comes with a significant risk for falls and thus should be discouraged [2]. Scuba diving is considered to

be particularly dangerous during pregnancy secondary to the risk of fetal decompression sickness because the fetal pulmonary circulation is unable to filter bubble formation and therefore should be avoided during pregnancy [93].

Know When to Stop

There are a few basic principles that pregnant women should adhere to: stay cool, stay hydrated, stay nourished, and know when to stop. It is important for women exercising during pregnancy to have a clear understanding of the signs and symptoms that should prompt them to stop exercising and contact a physician. Any symptoms of excessive fatigue, chest pain, shortness of breath, palpitations, dizziness, lightheadedness, difficulty walking, vaginal bleeding, uterine contractions, or decreased fetal movement should prompt immediate cessation of exercise and medical assessment as soon as possible [2,88].

For most women, the benefits of exercise far outweigh any potential risks, and clinicians should educate themselves so that they can provide evidence-based advice to pregnant women.

INTRODUCTION

Breast-feeding is a lifestyle that promotes health for both mother and baby. Physicians and other health care providers play a major role in encouraging, teaching, and helping to manage breast-feeding. From practices as simple as ensuring educational messages through posters and brochures in the offices to communication styles that encourage breast-feeding, today's health care provider is a vital part of the team that encourages this behavior in our society.

Human breast milk is the physiological form of nutrition for infants and young children. Although formula feeding is widespread worldwide, a significant body of literature and research strongly supports infant as well as maternal benefits of breast-feeding. It is the responsibility of providers to counsel and encourage patients to breast-feed. Education on and evaluation of the mother regarding breast-feeding should begin at the initial prenatal appointment and extend through the postpartum period. The impact that providers may have on breast-feeding initiation and maintenance should not be underestimated.[1,2] There are few circumstances where breast-feeding should be discouraged.

The American Academy of Pediatrics (AAP) states that breast-feeding ensures the best possible health outcome for the child and recommends exclusive breast-feeding for at least the first 6 months of life.[3] The World Health Organization endorses breast-feeding for the first 2 years of life.[4] Based upon these recommendations, the goals of Healthy People 2010 were established: an initiation rate of 75% and a continuation rate of 50% at 6 months and 25% at 12 months after delivery.[5] However, the current U.S. rates for breast-feeding miss this target. Of infants born in 2007 to U.S. mothers, 75% were initially breast-fed, but only 43% breast-fed at 6 months, and 23% at 12 months.[6] The Healthy People 2020 guidelines are more ambitious, with a goal of 82% of babies to have ever been breast-fed, and continuation rates of 61% at 6 months, and 34% at 1 year.[7]

To help improve breast-feeding rates, the WHO proposed guidelines for "Baby Friendly Hospitals" in 1991. These include 10 steps that hospitals should follow in the immediate peripartum period to increase breast-feeding initiation rates. Throughout the world, many hospitals have adopted these recommendations and are certified as "Baby Friendly." In these hospitals, breast-feeding rates have gone up.[8] However, in the United States, the designation applies to only 105 hospitals.[9] In addition, not only do current U.S. surveys estimate breast-feed rates well below public health guidelines among African American babies; the rates are significantly lower than the general rates: 58% start out breast-feeding, and 28% breast-feed at 6 months, with 8% exclusively breast-fed at 6 months.[7]

National breast-feeding rates have been further scrutinized to evaluate potential regional, ethnic, and socioeconomic differences. One study identified significant variation among geographic regions, with the highest rates of breast-feeding noted in the Pacific, Northwest, and New England region. The lowest rates of breast-feeding were identified in the East South Central region, which includes Alabama, Kentucky, Mississippi, and Tennessee. There also appeared to be an association between breast-feeding rates and socioeconomic status and ethnicity. Mothers of non-Hispanic black children were less likely to initiate and continue breast-feeding as compared to mothers of non-Hispanic white children (51.5% vs. 72.1%). Finally, mothers of a higher socioeconomic status consistently had higher breast-feeding rates compared to their counterparts. These data demonstrate several instances of significant disparity and identify potential populations where it is possible to conduct outreach and initiate change to improve infant and maternal health.

Breast-feeding is most often viewed and presented as a "choice" by providers. Given the ample availability of formula as a substitute, many people do treat breast-feeding as a lifestyle choice. Formula is viewed by many as equivalent, rather than inferior to, breast milk. Women should be educated that breast-feeding and formula feeding are not equal and that breast-feeding is indeed the best "choice" they can make for themselves and their infants. It has long-lasting influence on the health of both. One breast-feeding expert has carried this a step further and has written about the risks of not breast-feeding and the harms of formula feeding.[10] We propose that this concept be considered by medical professionals in their approach to counseling patients regarding breast-feeding.

ANATOMY AND PHYSIOLOGY OF THE BREAST

Anatomy

The breast undergoes a series of developmental changes throughout a woman's lifetime, most notably during puberty, pregnancy, and lactation and then at menopause. The breast tissue is composed of two main components, the stroma, which contains fat and connective tissue, as well as a network of tubules and glands that are responsible for the formation and excretion of breast milk.

Each breast is composed of approximately 15–25 lobes and each lobe is composed of a series of lobules with a single lactiferous duct draining each lobe at the nipple. Each lobule is composed of a number of alveoli and ductules.[11] The alveoli are surrounded by myoepithelial cells. Secretory cells of the alveoli are responsible for milk production; milk is secreted into the lumen of the ductule and excreted by contraction of the myoepithelial cells. Natural hormonal cycles influence further development of these structures as well as milk production and excretion.

At puberty, estrogen production stimulates duct formation and lobule development within the breast.[12] The ductal tree extends and forms new branches and lateral buds alongside ducts. Alveolar buds begin within the first 2 years following the onset of menses. In the follicular phase of the menstrual cycle, the stroma becomes less dense and lumina expansion occurs in the ducts.[13] In the luteal phase, the stroma becomes more dense, and the ducts now have a lumen and may begin secretion. Without establishment of a pregnancy, apoptosis of epithelial cells occurs. The majority of breast development occurs by age 20, although the most significant changes take place in pregnancy and lactation.

The first 3–4 weeks of pregnancy are marked by estrogen-stimulated sprouting of ducts. External changes to the breast are evident by 8 weeks, with increased breast heaviness and increased nipple and areolar pigmentation. As pregnancy progresses, ductal tissue infiltrates and replaces the adipose and connective tissues of the breast. The cells of the alveoli proliferate and develop secretory abilities, most rapidly in the third trimester of pregnancy. Involution of the milk production apparatus occurs as breast-feeding ceases, and in between pregnancies the breast returns to the quiescent state.[12]

Hormonal Influences

There are two major stages of lactation initiation: secretory differentiation and secretory activation.[14] As described, secretory differentiation begins when epithelial cells in the breast become secretory cells with the capacity to produce milk constituents and can happen only with the occurrence of pregnancy. This is called stage I of lactogenesis. As the breast gains the capacity for milk production, high levels of progesterone—released by the placenta—inhibit the production of milk itself (secretory activation). The rapid decline of progesterone following delivery of the placenta releases this negative feedback, resulting in milk production and excretion—this constitutes stage II of lactogenesis. Other hormones required for this process include estrogen, prolactin, placental lactogen, human chorionic gonadotropin, insulin, and growth hormones.

The alveolar cells initially produce colostrum, which can be manually expressed in small amounts by most women in the late stage of pregnancy. Colostrum is the only product of the breast for the first 30–40 h after birth. Colostrum is a yellowish-clear, thick, fluid containing high amounts of secretory IgA and lactoferrin. Mature milk contains lactose, lipids, and proteins and is a more dilute substance than colostrum.

Approximately 30 mL are produced in the first 24 h after birth.[15] The volume and concentration of colostrum is thought to allow for the most effective coating of the infant's gastrointestinal (GI) tract with these protective substances.

While milk synthesis occurs continuously, milk ejection is the result of a neurohumoral reflex. The areola is the most sensitive part of the breast and plays the largest role in stimulating the milk ejection reflex. With adequate infant latching and subsequent suckling, oxytocin from the posterior pituitary is released and enters the blood stream where it causes the myoepithelial cells to contract and eject milk from the alveoli into the ducts. Prolactin is also released and stimulates milk synthesis and secretion.

Once the milk supply has been established, it is imperative that the mother continue to empty the breasts on a regular basis. Failure to empty the breasts regularly leads to alveolar distension and increased intramammary pressure. It has been shown that increased intramammary pressure leads to feedback inhibition that downregulates receptors for prolactin.[16] It is important to emphasize, especially with the growing number of women who are pumping, that frequent breast emptying is required to establish and maintain milk supply.

The physiology explained earlier clarifies the reason for some important aspects of initiating breast-feeding addressed later, such as the importance of frequent and regular feedings as well as breast emptying.

Milk Content

Milk is a complex fluid composed of a variety of components, including proteins, fats, and carbohydrates. It is species specific. The major nutrient in human breast milk is lactose, a disaccharide that is a primary determinant of milk volume due to its osmotic effects.[17]

Protein content of human milk is highest in the immediate postpartum period and decreases over the next 2 weeks.[18] Protein accounts for 8% of caloric requirement of full-term infants.[19] Milk proteins are divided into two fractions based on their solubility in acid: the whey fraction (soluble) and the casein fraction (insoluble). Human milk whey:casein ratios change during lactation, with a higher proportion in early milk, 90:10, compared to late milk, 50:50.[20] In comparison, bovine milk is 18% whey and 82% casein.[21] Whey is more easily digested and contains lactalbumin, lactoferrin, secretory IgA, and lysozyme, which promote host defense.[22] The amino acid content of human milk is also very specialized, containing a relatively large amount of cysteine, methionine, and taurine compared to bovine milk.[12] Nucleotides and carnitine are also present.

Fat represents 50% of the caloric content of human milk, and the fat content increases throughout lactation.[23] Human milk fat is organized into globules that are easily digested. Human milk contains a high proportion of long-chain polyunsaturated fatty acids, such as arachidonic acid and docosahexaenoic acid (DHA); these are both important for brain development. The final drops of milk, called "hindmilk" have the highest fat and calorie content.[24] Breast massage at the end of feeding can increase the expression of hindmilk, as well as assisting in complete emptying of the breasts, reducing the potential for blocked ducts and mastitis.

Carbohydrate content in human milk is primarily due to lactose, a disaccharide composed of galactose and glucose. A multitude of oligosaccharides have been identified in human milk as well and are the third largest component of milk after lactose and fats. More than 130 oligosaccharides have been identified.[25] The composition of oligosaccharides may be genetically determined.[26]

Vitamin content in human milk reflects maternal nutritional status. For instance, there is a direct relationship between maternal and infant levels of 25-hydroxy vitamin D and maternal diet.[27] It is the recommendation of the AAP that all infants receive 200 IU of oral vitamin D drops daily for the first 2 months of life[3] because of the high incidence of vitamin D deficiency in women. Minerals may be bound to proteins or available in complex or ionized states. Although iron content of human milk is less than the recommended dose for infants, exclusively breast-fed infants do not need iron supplementation for the first 6 months of life[28] as iron content in human milk is easily absorbed and sufficient to support optimal growth and development.

Milk also has cellular components such as macrophages and lymphocytes, and these are present at approximately the same concentration as found in maternal peripheral blood.[29] The total number of cells appears to decrease during the first 3 months of lactation.[30] These cells in human milk are thought to play a protective role in the infant GI tract.

BENEFITS OF BREAST-FEEDING

The literature on breast-feeding has exploded in the last 20 years. The benefits of breast milk for infants and the benefits of breast-feeding for mothers are both much better understood, although many questions are unanswered and new research in this field continues.

Maternal Benefits

A lactating mother may spend nearly 500 kcal/day more to produce breast milk.[31] Likely related to this increased energy expenditure, a breast-feeding mother may lose more weight postpartum.[32] and also keep this weight off longer than women who do not breast-feed although not all women who breast-feed lose weight.

Metabolic changes induced by lactation may persist into later life.[33] Data from the Nurses' Health Study showed that parous women who had breast-fed had a reduced risk of developing type II diabetes.[34] Data from the Women's Health Initiative (WHI) demonstrated that women who had breast-fed for 1–6 months had an odds ratio of developing type II diabetes of 0.91, and women who had breast-fed for 13–23 months had an odds ratio of 0.75.[35] The risk of developing the metabolic syndrome also appears to be decreased in women who had ever breast-fed, with an increased benefit seen for longer duration of lactation.[36]

Data from both the WHI and the Nurses' Health Study have been used to examine the relationship between future risk of cardiovascular disease and breast-feeding. The WHI data demonstrated that for postmenopausal women, an increased duration of lactation (>12 months total) was associated with a lower prevalence of hypertension, diabetes, and cardiovascular disease.[35] These authors estimated that for every 29 women who breast-fed for more than 1 year, 1 case of postmenopausal hypertension could be prevented. They also estimated that for every 40 women who breast-fed for over 1 year, one case of hyperlipidemia could be prevented. Parous women who had never breast-fed were 28% more likely to develop cardiovascular disease than women who had breast-fed for 7–12 months. In the Nurses' Health Study, women who had breast-fed for 2 years had a 37% decreased risk of coronary heart disease compared to parous women who had never breast-fed.[37]

Some studies demonstrate that breast-feeding can impact a woman's future chance of breast cancer. In 2002, a meta-analysis in the Lancet[38] analyzed data from 47 studies comprising 50,302 women with breast cancer and 96,973 women without. They showed a decrease in relative risk of breast cancer of 4.3% for every 12 months of breast-feeding, with an additional relative risk reduction of 7% for each birth. Other evidence has been mixed, however, and many studies may be limited by recall bias.

The Nurses' Health Study looked at the risk of epithelial ovarian cancer in women who breast-fed for over 18 months compared with parous women who had never breast-fed[39] and found a significant difference. It has been postulated that this may be related to the presence of antibodies to epithelial mucin (MUC1 antibodies); these antibodies have been associated with a more favorable prognosis in women with ovarian cancer.[40] Formation of these antibodies may be precipitated by episodes of mastitis in women who have ever breast-fed.[41]

Breast-feeding promotes child spacing. The lactational amenorrhea method is up to 98% effective when used properly; women attempting to use this method should be exclusively breast-feeding infants who are under 6 months of age.[42] Women who frequently supplement with formula should be advised to use other contraceptive methods.

Hormonal changes induced by breast-feeding may be beneficial to the mother. Oxytocin secretion during the milk ejection reflex assists in uterine involution. Oxytocin secretion is also felt to play a role in maternal–infant bonding.[43] Breast-feeding appears to reduce the maternal response to stress,[44] perhaps due to modulation of the sympathetic nervous system.

The long-term effect of lactation on osteoporosis is unclear. A study on women aged 20–25 who had breast-fed their infants during pregnancies as adolescents demonstrated increased DEXA scores compared to women who had infants during their adolescent years but who had not breast-fed.[45] Whether this difference persists and has any measurable effect on the development of osteoporosis or decrease in hip fracture rates is still uncertain, with some studies proving an effect,[46] and others not.[47]

Infant Benefits

Human breast milk is specifically made for human infants. Similar to other mammals, the composition of milk has the appropriate nutrients to supply a growing infant's needs. Many of the beneficial effects of breast-feeding are presumed to be due to the unique factors inherent to human breast milk; formula is an expensive albeit improving imitation.

Significant short- and long-term infant benefits to breast-feeding have been identified through extensive epidemiological research. These infant benefits include decreasing rates of chronic diseases and infectious diseases, improving neurodevelopment, and decreasing the rate of childhood autoimmune diseases. The breadth and depth of the literature in this topic continue to expand; while areas of controversy certainly remain, the benefits of breast-feeding are numerous.

The particular effects of breast-feeding in developing countries should not be overlooked. Morbidity and mortality are lower in breast-fed compared with formula-fed infants. They have a lower incidence of gastroenteritis and respiratory infections.[48,49] In developed countries, breast-fed infants are hospitalized less and require fewer outpatient visits for acute illness than formula-fed infants.[50]

While data extolling the benefits of breast-feeding are vast, breast-feeding research is still incomplete. Some studies are limited by recall bias, as mothers may over- or underreport the time they actually breast-fed their infants. Older studies may be limited by presenting breast-feeding as "ever-breast-fed" versus "never-breast-fed" without taking into account the length of time or role of supplementation. Few are prospective and even fewer are randomized—indeed, it would be unethical to randomize to breast-feeding versus not-breast-feeding. In the review that follows, we have attempted to discuss only points that have stood up to multiple investigations. As in most contentious areas of research, further investigation into the benefits of breast-feeding is crucial, in particular regarding the long-term effects of breast-feeding.

Gastrointestinal Effects

The fetus has a sterile GI tract; upon delivery and exposure to the outside world, a newborn's gut is colonized. The colonization of the infant gut begins with delivery. This can take up to 1 week to become stable.[51] Differences in infant gut flora are seen at 1 month of age based on mode of delivery as well as based on breast or formula feeding.[52] Breast-fed infants have a preponderance of *Lactobacillus bifidus* and *Bifidobacterium*, up to 95% of organisms in culture. Infants fed formula have a predominantly gram-negative-based flora, including *Enterobacter*, *Bacteroides*, *Clostridium*, and *Escherichia coli*.[53] Infants born through cesarean section may also have a lower number of bifidobacteria and lactobacillus. Breast milk and colostrum appear to facilitate the preponderance of bifidobacteria; oligosaccharides found in human milk appear to specifically facilitate their growth.[54] The actions of lactoferrin and lysozyme in human milk also seem to control growth of pathogenic bacteria.[55] Free amino

acids such as taurine and glutamine may assist in intestinal growth.[56] Compared to formula, human milk increases the rate of gastric emptying,[57] increases the lactase activity in premature infants,[58] and decreases the intestinal permeability in early life in premature infants.[59]

There is a great deal of literature from premature infants demonstrating a reduced risk of necrotizing enterocolitis in infants fed breast milk.[60] This may be related to a number of anti-inflammatory agents (interleukin 10) and mediators (polyunsaturated fatty acids, PUFAs) present in breast milk.[61,62] This may also be due to the large differences in flora seen in these infants compared with infants who are fed only formula.

Infectious Processes

The immunological factors present in breast milk protect breast-fed babies and infants against infections in the first year of life. The concept of the enteromammary and bronchomammary immune systems may play a role.[29,63] Plasma cells from both of these locations migrate to the mammary epithelium, where they then produce IgA antibodies and provide specific protection against local pathogens. Formula-fed infants are more likely to develop a GI infection within the first year of life than breast-fed babies.[64,65]

Oligosaccharides also prevent attachment of respiratory pathogens such as *Haemophilus influenzae* and *Streptococcus pneumoniae to* respiratory epithelium.[66] Breast milk may also transfer an innate immunity against respiratory syncytial virus (RSV). Compared to infants breast-fed for over 4 months, non-breast-fed infants were shown to be 3.6 times more likely to be hospitalized in their first year of life with lower respiratory tract infections.[67] Most hospitalizations for respiratory issues are related to RSV infections. RSV-specific IgA has been shown to be expressed in breast milk,[63] and milk lipids have antiviral activity as well.

Episodes of acute and recurrent otitis media are also decreased in breast-fed infants. Infants breast-fed for at least 4 months had half the number of episodes of acute OM compared to infants who were not breast-fed.[68] In this same study, infants breast-fed for over 6 months had a 10% rate of recurrent OM compared to infants breast-fed for less than 4 months.

Atopic Disease and Asthma

In families with a history of allergic disease, breast-feeding may confer a protective effect on high-risk infants. Infants are at high risk for developing allergic disease when they have one or more affected first-degree relatives. In a meta-analysis of 18 studies, a protective effect against atopic disease (i.e., eczema) was shown with breast-feeding for over 3 months in infants with an affected first-degree relative.[69] The prospective PROBIT trial (Promotion of Breast-feeding Intervention Trial), where breast-feeding was promoted at specific "intervention" hospitals, demonstrated a decreased risk in the first year of developing eczema among infants born at these intervention hospitals.[70]

Development of asthma also appears to be decreased in infants who have been breast-fed. A meta-analysis of 12 studies demonstrated that less than 3 months of exclusive breast-feeding increased the risk of developing asthma 1.9 times that of infants who were breast-fed for over 3 months.[71] However, further research is needed, as not all studies support this conclusion. In particular, a large population-based cohort from Tasmania found no protective effect of breast-feeding on the development of asthma after age 7; in fact, breast-feeding was instead a risk factor for current asthma at age 14 and older.[72]

Development of food allergies in relationship to breast-feeding is also another issue under scrutiny. Breast-feeding for 4 months or longer may be protective in the development of cow's milk allergy.[73] Once a food allergy has developed, intact allergens may be passed directly into breast milk.[74] Regarding peanut allergy, an association between increased consumption by the mother during pregnancy and lactation has been shown to be associated with increased risk of peanut allergy in infants.[75,76]

Other Diseases

Available studies point to an increased risk of developing type I diabetes mellitus later in life in infants exposed early to cow's milk protein or breast-fed for shorter intervals. A meta-analysis from 1994 of available case–control studies showed that patients who had type I DM were less likely to have been breast-fed for >3 months and were more likely to have been exposed to cow's milk protein under 4 months old.[77] This is theorized to be due to a higher prevalence of islet cell autoantibodies in infants exposed to cow's milk.[78]

The risk of developing type 2 DM in breast-fed infants has been studied in several observational trials, but the data are mixed and do not clearly indicate a protective effect. In theory, adipokines, such as ghrelin and leptin, that are present in breast milk[79,80] may influence energy intake as well as the risk of future obesity and the metabolic syndrome.

The data on childhood obesity and breast-feeding are also mixed. An American study of over 15,000 children showed a decreased risk of obesity from ages 9 to 14 in children who were breast-fed for 7 months or longer after adjusting for a number of variables such as energy intake, physical activity, or maternal BMI.[81] However, at the 6.5 year follow-up point for the PROBIT trial, children who had been part of the intervention group (increased breast-feeding promotion in the postpartum period, with a 3-month continuation rate of 43.3% at 3 months) did not have any differences in adiposity or blood pressure than children who were part of the control group.[82] Clearly, further investigation of this subject is necessary.

Breast-feeding may be protective against future development of childhood leukemia, perhaps related to increased immunity to viral infections that may predispose children to the development of leukemia. Breast-feeding over 6 months is protective against acute lymphoblastic leukemia as well as acute myeloblastic leukemia.[83]

Neurodevelopment

Establishing a clear benefit of breast-feeding on infant cognitive development is challenging. There are numerous variables that may confound studies, including maternal social class, maternal cognitive ability, or intrauterine events. Additionally, breast-feeding may have effects that are limited to the time of active breast-feeding or it may induce a "programming" effect on infants, with effects that carry over onto later periods of development.

We do know that the human brain nearly triples in size in the first year of life.[12] Fifty to sixty percent of this growth is lipid. Fatty acid composition appears to be dependent on dietary intake, and breast-fed infants have been shown to have a higher cortical DHA content than formula-fed infants when necropsy specimens were examined after sudden death.[84] Brain growth is also associated with increased uptake of PUFAs into cerebral cortex phospholipids.

The PROBIT study was able to demonstrate a long-term effect of their breast-feeding intervention on verbal IQ scores—children in the intervention group had scores that were 7.5 points higher at 6.5 years compared to the control group. A study in Honduras randomized children to early introduction of complementary foods at 4 months versus exclusive breast-feeding for 6 months. Infants who were in the complementary food group crawled later and were less likely to be walking at 12 months.[85]

It is postulated that these effects may be related to intake of PUFAs found normally in breast milk. Increased dietary intake of these compounds has been linked to protection against heart disease and inflammatory diseases.[86] Visual acuity has been studied in very-low-birth-weight infants who had diets supplemented with omega-3 fatty acids versus linoleic acid ± linolenic acid and demonstrated improved parameters in the omega-3 supplemented infants.[87] Arachidonic and docosahexaenoic acids have been associated with improved cognition, growth, and vision.[88] There is evidence that these two PUFAs regulate a gene called FADS2, which encodes an enzyme involved in their metabolism; in a study investigating this gene, breast-feeding, and IQ, a certain variant was found in over 90% of the study cohort.[89] Infants with this variant who were also breast-fed were found to have significantly higher IQs (6.4–7.0 points higher) than infants without this variant; breast-fed infants with other variants did not have the same IQ advantage.

PRACTICAL MANAGEMENT OF BREAST-FEEDING

To establish an optimal cycle of milk production and release, mothers who plan to breast-feed their infants should begin to do so immediately after birth. The WHO and UNICEF published the guideline "Ten Steps to Successful Breastfeeding" in their Baby-Friendly Hospital Initiative.[90] These provisions are listed in Table 69.1. The 10 steps include initiation of breast-feeding within the first hour after delivery. Direct skin-to-skin contact between mother and infant immediately after delivery may assist with latching and future breast-feeding success. Most infants can latch on to the breast within an hour after birth. All infant care may be provided with the infant on the mother during the immediate postpartum recovery period. But most importantly, the memory of her baby successfully nursing immediately postpartum can sometimes help sustain a mother's confidence that her baby can and will latch through the next ≥24 h when many newborns are reluctant and uncoordinated feeders.

TABLE 69.1
Ten Steps to Successful Breast-Feeding

1. Have a written breast-feeding policy that is routinely communicated to all health care staff.
2. Train all health care staff in skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breast-feeding.
4. Help mothers initiate breast-feeding within 1 h of birth.
5. Show mothers how to breast-feed and how to maintain lactation, even if they are separated from their infants.
6. Give newborn infants no food or drink other than breast milk, unless medically indicated. (A hospital must pay fair market price for all formula and infant feeding supplies that it uses and cannot accept free or heavily discounted formula and supplies.)
7. Practice rooming-in—allow mothers and infants to remain together—24 h a day.
8. Encourage breast-feeding on demand.
9. Give no artificial teats or pacifiers to breast-feeding infants.
10. Foster the establishment of breast-feeding support groups and refer mothers to them on discharge from the hospital or clinic.

Source: Adapted from the World Health Organization, Division of Child Health and Development, *Evidence for the Ten Steps to Successful Breastfeeding (Revised)*, World Health Organization, Geneva, Switzerland, 1998.

The breast-feeding mother should be supported and educated during her postpartum care in the hospital. Rooming-in allows parents to learn the infant's feeding cues in order to feed on demand. Nurses caring for multiple babies in a nursery are not likely to be in tune with these sometimes-subtle activities.

Direct assistance with and feedback regarding positioning and latching should be provided by nursing and medical staff. Proper positioning is crucial to establishing a proper latch-on. The three common positions are the cradle, football (also referred to as the "clutch"), and side-by-side positions. The infant's head should be opposite the nipple, with the neck slightly extended. The infant's head, shoulders, and hips should then be in alignment. Latching involves forming a tight seal between the infant's lips around the nipple, drawing the nipple into the back of the mouth. The breast may be supported by the mother or her support person's hand in the shape of a "C," with four fingers below the breast and the thumb above the areola, pointing toward the midline. The infant's head and neck are supported with the mother's other hand, and the infant's lips can then be rubbed with the nipple to elicit a rooting reflex. As the infant opens his or her mouth wide (which sometimes requires waiting 30–60 s), the infant's head is quickly brought to the breast with the mouth over the nipple. A proper latch

includes the whole nipple and as much of the areola as possible. The pressure of the infant's hard palate during suckling compresses lactiferous sinuses beyond the base of the nipple to increase the amount of milk transferred.

Specific features of an adequate latch can be assessed. Audible sucking can be heard. The infant's cheeks should be full. Both the chin and nose are close to the breast, and the lower lip should be turned out toward the breast. The tongue may extend over the lower dental ridge and should be in contact with the breast when the lower lip is moved away. An audible swallow provides some assurance the baby is accomplishing nutritive sucking.

Length of feeding on each breast varies with infant age. In the immediate postpartum period, this ranges from 10 to 15 min, while after 1 month, the range is 8–10 min. In a typical feeding session, the infant should first be offered one breast. Feeding from this breast should continue until the infant demonstrates a loss of interest. The infant should then be offered the second breast and may need to be awakened by undressing, changing the diaper, or repeatedly changing the infant's position in order to encourage latching.

The infant signals satiety by voluntary release of the nipple and relaxation of the facial muscles and hands, and young infants may fall asleep. Breast-feeding for some infants may be soporific, leading to sleep almost immediately after latching on to the breast. In these cases, stimulation of the infant to maintain an awake state in order for milk transfer to occur requires careful attention by the parents. Normal satiety signals may not apply to these infants, and their nutritional adequacy may have to be monitored by weight gain and assessment of hydration.

The initial frequency of breast-feeding in the first 1–2 weeks postpartum may be as often as every hour, with an average of 8–12 times/day. Breast-feeding mothers should be encouraged to wake their infants at least every 4 h for feeding during the first 2 weeks postpartum. This will promote the infant receiving adequate nutrition. The overall frequency of breast-feeding diminishes by 4 weeks, with an average of seven to nine feedings per day. This is a result of improved nursing skills and increased milk volume. Cluster feeding, or periods where the infant feeds with greater frequency during growth spurts, is also common intermittently.

Sore nipples are a frequent challenge for the new nursing mother. The sensation of suckling should be perceived by the mother as a painless undulation. Nipples are increasingly sensitive in the immediate postpartum period, peaking around 4 days postpartum. Nipple soreness or pain should be differentiated from sensitivity when assessing a woman with this complaint. Normal sensitivity typically goes away after the first minute of suckling and should overall disappear after 1 week. Nipple pain is typically persistent throughout the cycle of breast-feeding and may be a result of trauma to the nipple. This is frequently the result of poor latch or positioning. Skin breakdown is manifest by blistered, cracking skin with bruising of the nipples and areola.

Infant thrush and candidiasis of the breast are a common cause of nipple pain, and both the mother and infant should be treated if this is suspected. In women with sore nipples, the infant should also be assessed for ankyloglossia, or "tongue tie," which is caused by a tight frenulum limiting tongue extension and possibly impairing latch. Sometimes this requires that the frenulum be clipped—a simple procedure for those familiar with the technique. Additionally, the mother's choice of breast cleansing agents may play a role in skin breakdown, and the use of harsh agents or abrasive cleansing should be discouraged.

Relief of soreness can be provided in several ways. Nipples should be air-dried after nursing to promote healing; in addition, breast milk or colostrum can be expressed and spread on the affected surface and to assist with healing. The use of soap to clean the breast should be avoided as it removes the natural lubrication produced by the glands of Montgomery. Lanolin cream application can also provide moisture to promote healing. "All Purpose Nipple Ointment," a combination of mupirocin, steroid cream such as betamethasone, and an antifungal powder, can be prescribed for women with refractory breakdown and pain. Although no formal evaluations of its efficacy have been performed, it is widely used as an apparent helpful adjunct for women in this situation. The formulation is mupirocin 2% ointment (15 g), betamethasone 0.1% ointment (15 g), and miconazole powder mixed to a final concentration of 2%; the ointment is available only through compounding pharmacies. This may be applied sparingly after each feeding and does not need to be washed off in between feedings. Most importantly, the mother should be supported and encouraged to continue breast-feeding during the time of nipple soreness.

Flat or inverted nipples can be another challenge encountered by the breast-feeding mother. It has been estimated that 10% of women have inverted or non-protractile nipples, which may contribute to breast-feeding problems.[91] To diagnose a truly inverted nipple, one may press the areola between the thumb and index finger; an inverted nipple will retract while a normal or flat nipple will protrude. Multiple treatments have been suggested for inverted nipples, such as Hoffman exercises, which involve stretching or pulling on the nipple, or wearing breast shells, which are plastic disks with holes in the center. However, evidence suggests that these do not improve breast-feeding rates in these women.[91] When flat or inverted nipples are identified prenatally, mothers should be instructed to seek consultation from a lactation consultant in the postpartum period to address any problems with latching. The use of a pulsatile electric pump may facilitate latch-on in these patients. Sometimes a nipple shield will be required (a nipple-shaped flexible device placed over the areola to help the baby latch), but these should be used only with instruction.

Assessment of Intake Adequacy

Infants typically lose 5%–7% of body weight in the first 5 days of life. This weight is usually regained by 1–2 weeks. Infants receiving appropriate nutrition should gain between 15 and 40 g/day. The AAP recommends a post-discharge hospital visit within 3–5 days of age for all breast-feeding infants.[92] At this time, the infant should be weighed,

TABLE 69.2
Breastfeeding Checklist for New Mothers

Day	Feedings/Day	Wet Diapers/Day	Bowel Movements/Day
1 (in the hospital)	6	2	1 (black, tarry soiled diaper)
2	8–12	3	2 (brown, tarry soiled diapers)
3	8–12	3 or 4	2 or 3 (green soiled diapers)
4	8–12	4	3 or more (yellow soiled diapers)
5	8–12	4 or 5	3 or more (yellow soiled diapers)
6	8–12	6–8	3 or more (yellow soiled diapers)
7	8–12	8 or more	3 or more (yellow soiled diapers)

After day 7, your baby should continue to have at least eight wet diapers a day. The number of bowel movements varies. If you are still concerned about how much milk your baby is getting, talk to your pediatric clinician. She or he may want to weigh the baby.

breast-feeding practices can be assessed, and the mother can be instructed and encouraged.

In our hospital, we give new mothers a checklist to help them track the number of feeds, voids, and bowel movements their infant has on a daily basis (Table 69.2). A well-hydrated infant should have three-to-five voids and three-to-four stools daily by days 3–5, then four-to-eight voids and three or more stools daily by days 5–7 of age.[3] Weight loss greater than 7% from birth weight indicates possible feeding problems and should initiate investigation into practices and improvement of milk transfer.

Clinicians caring for the nursing dyad are often faced with the dilemma of when to supplement.

Health care workers sometimes offer formula to support tired mothers while not taking into account the adverse effect this may have on the initiation and maintenance of milk supply.

The American Academy of Breastfeeding Medicine recommends hospitals have a policy that supplementation of a breast-fed baby requires a physician's order. Their thorough protocol is available at http://www.bfmed.org/Resources/Protocols.aspx.[93]

Contraindications to Breast-Feeding

In the United States, there are a few contraindications to exclusive breast-feeding. These are as follows[3]:

- Infant with classic galactosemia
- Maternal active untreated tuberculosis
- Maternal positivity for human T-cell lymphotropic virus type I or II
- Mothers receiving diagnostic or therapeutic radioactive isotopes or with exposure to radioactive materials (at least until the materials are no longer present in the milk)
- Maternal antimetabolite or chemotherapeutic agent use
- Maternal drug abuse
- Active herpes simplex outbreak on the breast

Maternal HIV infection is also considered a contraindication to breast-feeding in the United States,[94] while in developing countries many experts think that the risks to infants of infectious diseases and nutritional deficiencies outweigh the risks of HIV transmission in breast milk.

Maternal infection with hepatitis B or C is not a contraindication to breast-feeding, as the risk of transmission of either of these viruses via breast milk is low.[12] Infants born to hepatitis B-positive mothers should receive the hepatitis B immunoglobulin at birth and the full vaccine series; if a breast-feeding mother has acute peripartum hepatitis, it is reasonable to abstain from breast-feeding until its etiology can be determined.

Maternal cytomegalovirus (CMV) seropositivity does not seem to be related to significant clinical illness in healthy full-term infants; however, premature infants should not be given milk that is known to be CMV-positive.[95] Freeze–thaw cycles may reduce CMV transmission, but further prospective studies are needed.

Recent alcohol use is a relative contraindication to breast-feeding, and mothers should be encouraged to abstain from feeding for 2 h after a single alcoholic beverage in general.[96,97]

PROBLEMS RELATED TO BREAST-FEEDING

Engorgement

Engorgement is a problem best managed with prevention. It involves three elements[12]: (1) congestion and increased vascularity of the breast, a physiological response following delivery of the placenta, (2) milk accumulation, and (3) edema from swelling and obstruction of lymphatic system drainage by alveolar fullness. When skin edema is noted on the breast, intervention is needed.

Areolar engorgement may be solved by manual expression or warm soaks of the nipple prior to feeding. Peripheral engorgement may be a physiological response as milk production increases in the immediate postpartum period; for these women, pumping early does not help relieve this engorgement. Women may feel throbbing or aching pain. Proper support of the breasts is crucial with a well-fitting brassiere. Standing in a warm shower and massaging the breasts to express milk may provide some relief and facilitate the baby's latch to further empty the breast. Cold packs may reduce edema and pain. Medications for pain relief may also be used safely. The application of cooled cabbage leaves to the breast has been used for generations, but in a small study comparing cold gel packs and cabbage leaves, no differences

in relief were found.[98] If an infant is less interested in breast-feeding in the early postpartum period, women may need to manually express breast milk. However, the most important step is to ensure continued drainage of the breasts however possible to prevent increased intraductal pressure, which may ultimately decrease milk supply.[16]

Mastitis

Mastitis is a bacterial infection within breast tissue that may be seen at any time during lactation. The incidence is up to 20%, and it is most common within the first 6 weeks postpartum. The symptoms include redness, tenderness, and warmth of the overlying skin, with systemic symptoms of fever of 101°F or higher, myalgias, and malaise. The most common organisms are staphylococcus species and *E. coli*; streptococci are less commonly implicated. Risk factors include incomplete emptying of the breasts or missed feedings, plugged ducts, broken skin on the nipples, or breast constriction.

Treatment includes oral antibiotic therapy for 10–14 days. Dicloxacillin is first-line in women who are not allergic to penicillins. Sulfa drugs should be avoided for women with infants less than 1 month. In addition to antibiotics, it is equally important that women with mastitis use local measures to promote recovery. They can continue feeding on both sides and should use heat and massage prior to feedings to increase emptying of the breasts.

Many centers are noticing an increase in mastitis caused by methicillin-resistant *Staphylococcus aureus* (MRSA).[99] Trimethoprim-sulfamethoxazole, clindamycin, and linezolid are all appropriate outpatient therapies for women suspected of having MRSA mastitis. If a patient is unresponsive to first-line treatment, milk cultures and sensitivities should be obtained.

Breast abscess formation is an infrequent complication of mastitis, with a reported incidence of 0.1%, and may be related to delayed or inadequate treatment. It may be more common when MRSA is the offending organism. The primary treatment is drainage, and fluid collected should be sent for culture and sensitivities. Drainage may be accomplished with needle aspiration, with or without ultrasound guidance, for women without overlying skin changes and should be repeated every 2–3 days until the fluid collection resolves.[100,101] For women with more advanced cases, incision and drainage should be considered. Both of these approaches require adjunct use of antibiotics with anti-staphylococcal coverage or coverage based on culture results. Breast-feeding should be continued if the site of drainage does not interfere with latching. If that is the case, pumping or hand expression should continue until feeding can be resumed.

Prior Breast Surgery

Breast augmentation surgery has become a more accepted and common procedure. According to the American Society of Plastic Surgeons, 289,328 women underwent augmentation mammoplasty in 2009.[102] Many young women who undergo this surgery do so prior to childbearing and lactation. Most implants used are inserted between the chest wall and breast and do not interfere with breast tissue. The incision used to place the implant may be on the axilla or near the areola; for women who desire future breast-feeding, an axillary incision is preferable. Saline implants have replaced silicone implants, and women with intact silicone implants do not have any contraindications for breast-feeding. Women who undergo augmentation for underdeveloped breasts may not have adequate functional breast tissue, which may lead to underproduction during lactation, but this is rare.

Because of its destructive nature, breast reduction surgery may pose a different picture for the woman who desires to breast-feed. In 2009, 78,427 women had breast reduction surgery.[102] This surgery often interferes with ductal anatomy and the innervation of remaining tissue. Breast-feeding may be successful in up to 65% of women after reduction,[103,104] depending somewhat on the location of tissue removed. Importantly, breast-feeding should not be discouraged in these patients. Rather they should be offered anticipatory guidance and support, and the baby's weight should be carefully monitored. Women who have undergone breast surgery may find the website www.BFAR.org[105] a helpful resource—this site compiles information and supports resources for women who have undergone breast or nipple surgery.

Medications and Lactation

The risks and benefits of medications in lactating women must be considered by all prescribers. Many factors influence the passage of a medication into the milk supply as well as its effect on infants. These include consideration of each drug's route of administration, absorption, size, solubility, and protein binding. Passive diffusion is the main way most drugs enter into milk. The effects of drugs on the infant itself is often less well-studied but is important to consider as nearly any drug a breast-feeding mother consumes will be found in her milk. Length of time of administration may also be a factor. In certain cases, a woman may need to pump and discard milk until she has completed her course of therapy.

As women breast-feed for longer periods of time, physicians from all medical specialties will care for them and will need to be familiar with principles of medication use. Many resources exist both online and in print form. LactMed[106] is a searchable online reference developed by an expert panel through the National Library of Medicine. The web address is http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?LACT

BREAST-FEEDING SUPPORT

Support for breast-feeding is best begun with the provider in routine medical encounters, but does not end there. Physicians and other providers should educate themselves about the resources in their own community to better serve their breast-feeding mothers.

International Board Certified Lactation Consultants (IBCLCs) are specialists in the clinical management of breast-feeding. They may work in a variety of settings, including in hospitals, pediatric practices, private clinics, and public health settings. They provide support and management of many common breast-feeding concerns. In the United States, the International Lactation Consultant Association is the professional association for IBCLCs, and their website, www.ilca.org, provides information about practitioners throughout the country. As of December, 2010, the United States had over 11,000 IBCLCs, with practitioners in every state and territory.[107]

Many community resources also exist. La Leche League, International (LLLI), is an international organization initially formed in the 1950s to combat low breast-feeding rates. Today, they have a global mission to help women breast-feed. Their Internet resources are available to practitioners and patients at www.llli.org, and there are LLL chapters in every U.S. state.[108]

Many states also offer breast-feeding resources and support. The U.S. Breastfeeding Committee is an independent nonprofit coalition with organizations in all 50 states. Their website, http://www.usbreastfeeding.org/, provides links to the coalition sites for each state, which in turn provides resources for patients and practitioners in their areas.[109] Often hospitals or sometimes organizations that do childbirth education have breast-feeding support programs. Identifying such local options is important for those who work in clinical settings that frequently deal with the breast-feeding dyad.

Pumping Breast Milk (Working and Nursing)

With so many women in the workforce, it is impossible to meet national breast-feeding goals without the expression of breast milk, often referred to as "pumping." Data from the Infant Feeding Practices Study II revealed that from 2005 to 2007, 85% of mothers with infants under 4.5 months had expressed milk at some time since delivery.[110] The commercial market for breast pumps has expanded greatly from the initial manual pumping devices. These devices are all FDA-regulated and are available to mothers for purchase or rent.

Many insurance companies cover these for various indications, in particular for mothers who must be separated from their infant. In most states, women, infants, and children (WIC) also provides breast pumps at no cost. Pumping supplies are now considered a deductible medical expense by the IRS.[111] For women who plan to pump only occasionally, manual pumps or battery-operated pumps may be adequate. For women who intend to return to work, need to pump large volumes of milk for their infant for any reason, or need to stimulate their milk supply, an electric pump is ideal. These pumps both allow a greater volume of milk to be obtained including milk with a higher cream content and employ a certain number of pressure cycles per minute, which more naturally simulate the sucking reflex of an infant.

The federal Fair Labor Standards Act states that employers are required to provide "reasonable break time for an employee to express breast milk for her nursing child for 1 year after the child's birth each time such employee has need to express the milk."[112] Employers are also required to provide "a place, other than a bathroom, that is shielded from view and free from intrusion from coworkers and the public, which may be used by an employee to express breast milk." While there are exceptions to these rules, an increasing number of workplaces are making breast-feeding facilities available to their workers. Legislation protecting a woman's right to breast-feed in public and at work is an important component to reaching national breast-feeding goals.

Ideally, women should empty their breasts at the same frequency they would as if they were doing in-person feeding. This helps maintain the supply necessary for adequate nutrition. Mothers who pump should also be encouraged to breast-feed while at home, not only for the purpose of feeding but also to promote bonding and maintain supply. Massage of the breast while pumping increases delivery of hindmilk as well.

The Human Milk Banking Association of North America recommends storage of breast milk at room temperature (<79°F) within 4 h.[113] Breast milk can also be immediately refrigerated, where it may be used for 48 h after collection. Bactericidal capacity of breast milk declines after 48 h of refrigeration. If breast milk is to be frozen, this should be performed immediately. Guidelines for limits on the use frozen milk vary from 3 to 6 months in storage. Milk stored in a conventional refrigerator-freezer should be stored near the back and should be used within 1 month, as the freeze–thaw cycles decrease the energy content of the milk and increase the likelihood of separation of the fat layer.[12] Fat in frozen milk may be broken down by lipase, leading to altered smell and taste. While this breakdown is not harmful, some infants may refuse to drink it. Many of the beneficial compounds present in milk such as immunoglobulins, lactoferrin, lysozyme, and other enzymes and proteins are generally preserved in frozen milk.[114]

Weaning

Timing of weaning can be a complex process related to the interplay of multiple factors. Women may stop because they think their infant is "old enough to wean," a phrase that is interpreted differently based on perspective.[115] In practice, mothers are the primary determinants to weaning time. The return to work, demands of breast-feeding, or multiple other social factors may play a part in their decisions. Additionally, lack of knowledge regarding the benefits of prolonging breast-feeding and psychological difficulties in the postpartum period may also decrease the length of breast-feeding.[116]

While there is still considerable controversy regarding the timing of introduction of solid foods, the AAP recommends exclusive breast-feeding for 6 months, with gradual introduction of complementary iron-rich foods at 6 months. They say "Breastfeeding should be continued for at least the first year of life and beyond as long as desired by the mother-infant dyad."[117] As discussed, increased breast-feeding duration does confer health benefits on both the infant and the mother, and there is no upper limit to breast-feeding.

For infants who are fully breast-fed, solids can be given during the day and breast-feeding should continue on demand. With a diet increasing in solid content, women may expect fewer or shorter feedings. Weaning can also be accomplished by eliminating one breast-feeding session every several days and replacing it with a solid meal. Gradually, only the morning and night feedings remain in this schedule, and they can be maintained for months to years. Abrupt weaning is sometimes demanded due to maternal medical problems or necessary separation of the mother and the infant. Interestingly, studies of women who had to abruptly stop breast-feeding demonstrated that involuting mammary tissue remained partially functional for up to 42 days,[118] although the milk content changed over time to become saltier and more protein rich.

It is normal for mothers to experience sadness at the thought of the last feeding.[119] This may be both an emotional process and a physiological one. In particular, the decrease in prolactin, which has been associated with a general feeling of well-being, may lead to a relative depression. Medical professionals can help normalize these feelings and provide professional support to women during this period.

CONCLUSION

A single chapter is inadequate to address the many issues and challenges that breast-feeding can to present both the nursing dyad and those who care for them. That said, there are many resources available to support both women and their providers in this immensely valuable effort. A list of places to seek more information is provided in the following, and thankfully many of these organizations are involved in furthering our understanding of this awe-inspiring physiological phenomenon whereby a mother nourishes her newborn with a highly evolved, species-specific, perfectly balanced food.

INTRODUCTION

The ability to plan and control reproduction is an essential part of a healthy lifestyle. Contraceptive success requires an understanding of the efficacy of each method, the risks and benefits associated with each method, and matching the method to the individual needs of each woman. Despite an apparent myriad of choices, unintended pregnancy remains a public health challenge in the United States. The goal of this chapter is to assist clinicians in informing women about their contraceptive options, reviewing the risks, benefits, and efficacy of these methods while helping women choose a method that will be highly efficacious for them and their unique lifestyle thus.

Approximately one-half of the 6.3 million pregnancies in the United States annually are unintended and one-half of these unintended pregnancies end in elective abortion.[1] What is most striking about the unintended pregnancies in the United States is that almost one-half of these pregnancies occur among women who report using some form of reversible contraception at the time of conception and the other half are among women who did not use any contraception even though they did not desire a pregnancy.[2] Analysis of reasons for contraceptive failure include failure to adhere to a method, inappropriate use, lack of continuation of the method, inability to access the method regularly, as well as failure of the method itself.

American women have fewer contraceptive options than women in most other industrialized nations because of lack of awareness and misconceptions about methods and because contraception is more expensive for most women in the United States. More than half of women, including those who are highly educated, are not accurately aware of the efficacy or the benefits and side effects associated with many methods of contraception.[3–5]

For clinicians, the approach to contraceptive counseling should include discussion of the efficacy of a method, which should be discussed in terms of both the theoretical (perfect use) efficacy and the actual (typical use) efficacy of a method. Theoretical (perfect use) is based on pregnancy rates among women who use the chosen method correctly on every occasion, while actual (typical use) efficacy of a method is the pregnancy rate that occurs among women who use the method inconsistently or incorrectly. The actual use efficacy rates are important to emphasize during comprehensive contraceptive counseling because they reflect real-life experiences of women. Though no method of contraception is without failure, there are methods in which the actual efficacy is the same as the perfect use or lowest expected failure rate.

Reversible methods of contraception include intrauterine contraception, contraceptive implants, injectables, oral, transdermal, and vaginal ring contraceptives. These methods can be categorized by actual efficacy rates or the usual expected failure rate. Intrauterine contraception and implants are considered long-acting reversible contraception (LARC) and are associated with the lowest pregnancy rates (less than 1 pregnancy per 100 women in 1 year) and are considered most effective because they are minimally influenced by adherence to the method and can be left in place for extended periods of time. With LARC, the actual efficacy approaches perfect use.

Injectable contraceptives are considered effective methods with very low pregnancy rates and high actual efficacy, but do require adherence with periodic follow-up for reinjection. Other methods in this category include user-controlled methods that rely on more frequent adherence with a method, including oral contraceptives, the transdermal contraceptive system, and the vaginal ring. These methods are also associated with a very low pregnancy rate if utilized consistently in an optimal fashion, but actual pregnancy rates are significantly higher because of frequent misuse by women in the general population.

Other methods of contraception such as condoms, diaphragms, cervical caps, spermicides, and natural family planning methods, including withdrawal and abstinence, are considered least effective and are associated with actual pregnancy rates that are significantly higher than perfect use rates. The overall actual efficacy rates of these methods have varied among studies but generally have a rate of about 30 pregnancies per 100 women in 1 year.

Along with a discussion of method effectiveness, clinicians should individualize care for each woman with a discussion of method safety in relation to each woman's medical history. In general, contraceptives pose few serious health risks to most women and the risks of pregnancy, delivery, and abortion outweigh the risks of using contraception for most women. However, particular attention needs to be given to women with certain characteristics and medical conditions, as use of a method that is unsafe within a certain context could result in harmful medical consequences.

The use of evidence-based guidelines in counseling women about their options will ensure that women are not exposed to inappropriate risks, while also assuring that women are not denied access to methods that are medically appropriate. The World Health Organization (WHO) has created a set of consensus guidelines—*The Medical Eligibility Criteria for Contraception*—which addresses contraceptive guidelines for women based on personal characteristics and medical conditions based on the best available evidence. This information is easily accessible in comprehensive online tables of medical conditions and personal characteristics that may affect contraceptive choice. In 2010, these guidelines were adapted for the U.S. clinical context by the Centers for Disease Control and Prevention and can be found at U.S. Medical Eligibility Criteria for Contraceptive Use, 2010: http://www.cdc.gov/mmwr/pdf.

The use of these guidelines in counseling women has ensured that unnecessary restrictions are not placed on women's choices for contraception, resulting in improved access to family planning services.

ORAL CONTRACEPTION

In 2002, the most frequently used method of contraception was the oral contraceptive pill.[6] Oral contraceptive methods continue to be the most commonly used method among American women and are a reliable method of contraception if used correctly and consistently. Studies have shown that oral contraceptives result in 3 pregnancies in 1000 women or 0.3% failure within the first year of use when used perfectly. However, an 8% failure rate has been reported with typical use. The average woman misses at least one pill per cycle,[7] and greater than 50% of users miss more than two pills by their third cycle of use.[8] It is for these reasons that oral contraception is considered a second-tier method in terms of efficacy as compared with more effective methods such as intrauterine contraception, injectables, and implants. Non-contraceptive benefits of combined oral contraceptives (COCs) include a decreased risk of endometrial cancer, pelvic inflammatory disease, endometriosis, and uterine fibroids.[9]

Mechanism of Action

COCs all contain an estrogen and a progestin component. Most current COCs in the United States contain ethinyl estradiol (EE) as the estrogen component in a 20–35 mcg dosage, which is decreased from the earlier high-dose 50 µcg EE pills, while the progestin component is one of eight different progestins. Depending on the dosage of the EE and the type of progestin, COCs are categorized as first- through fourth-generation COCs. The oldest or first-generation COCs were those with 50 µcg of EE and first-generation progestins (norethindrone, norethindrone acetate, and ethynodiol diacetate). While the first-generation progestins are tolerated well and have excellent potency, unscheduled bleeding occurs more commonly with these progestins as the dosage is lowered. Second-generation progestins (norgestrel and levonorgestrel) were developed with higher potency and longer half-lives as compared with the first-generation progestins, thus resulting in lower rates of unscheduled bleeding. Second- through fourth-generation COCs are those with a lower dosage of EE (20, 30, or 35 µcg). The second-generation progestins, however, are more androgenic than

the first-generation progestins. As a result, the third-generation progestins (desogestrel, norgestimate, and gestodene) were developed, which have increased progestational activity similar to the second-generation progestins, but with lower androgenic activity allowing for greater impact of estrogen on sex hormone-binding globulin. With higher levels of sex hormone-binding globulin, the overall levels of testosterone are reduced with the third-generation COCs, thus having a greater impact on acne and hirsutism. The newest group of progestins, the fourth generation, is drospirenone, which is a derivative of spironolactone and also has significant anti-androgenic activity and is beneficial for androgenic states such as acne, hirsutism, and polycystic ovary syndrome.[10]

Pregnancy prevention on COCs occurs by prevention of fertilization. The primary mechanism of action is due to the progestin component, which results in ovulation suppression through negative feedback on the hypothalamic–pituitary system. The levels of progestin in the chosen pill suppress GnRH pulsatility resulting in suppression of LH and FSH production and inhibition of the mid-cycle LH surge. It is critical that therapeutic serum levels of the progestin component be maintained for at least 24 h and the potency of the progestin in the pill is dependent on its potency and dosage.[9] Additionally, the progestin component results in thickening of cervical mucus, which prevents sperm from entering the cervical canal.

Initiation and Administration

Hormonal contraception can be safely initiated after careful medical history has been taken and the only required examination is a blood pressure measurement. All other routine screening tests including pap smears, breast exams, and sexually transmitted disease screening, while important, are not required at the time of initiation of contraception.[11] Traditionally, COCs are started on the Sunday after the next menses or the first day of the next menses. However, COCs can be started at any time during the cycle as long as pregnancy has been excluded. The Quick Start or Same-Day Start method allows women to begin taking their COC on the day they receive the prescription and is the preferred approach recommended by the WHO.[12] This is because Quick Start avoids a delay between method prescription and method initiation associated with the other traditional start methods. Up to 25% of women given prescriptions to start a method with their next menses or the Sunday after their menses fail to initiate their pill as instructed due to multiple factors including failure to fill the prescription, fear of side effects, or becoming pregnant in the interim.[13,14] In addition, Quick Start not only has resulted in greater initiation of a method but has also been found to have great continuation of the method by the third month as compared with the conventional methods for starting contraception.[15]

Clinical Considerations

Myocardial Infarction

Previous studies established that higher-dose estrogen pills were associated with an increased risk of arterial thrombosis and thus increased risk of MI. This increased risk of MI on COCs is attributed to the estrogen component of the pill in a dose-related response.[16] The advent of pills with less than 50 mcg of EE has decreased this risk. A comparison of women on low-dose COCs with women who have never used the pill found current users to have a relative risk of 1.3 for MI compared with nonusers. However, the increased risk was seen among women with known risk factors for MI, indicating that low-dose COCs do not significantly increase the risk of MI or stroke in healthy, nonsmoking women.[17] The overall risk for MI increases with age and is further amplified by other risk factors such as smoking and hypertension.[18,19] In addition, it has been established that the duration of use of COCs or previous use of the method does not increase the risk of MI.[20]

Stroke

Cerebrovascular disease or stroke is rare among younger women, but more common among women in their age of 40 and beyond. Women with risk factors such as smoking, hypertension, diabetes, obesity, and lower socioeconomic status have a higher risk of ischemic stroke at baseline, and healthy women who used low-dose COCs in one study did not have an increased risk of stroke.[21] Women with hypertension on COCs have 3 times the risk of ischemic stroke as compared with those women without hypertension on COCs and 15–20 times the risk of ischemic stroke in smokers on COCs as compared with nonsmokers.[22,23] Past use of COCs or duration of use does not increase the risk of either type of stroke.[24] Similarly, hemorrhagic stroke is associated with risk factors including age, hypertension, smoking, and obesity. The risk of hemorrhagic stroke is 10 times higher in COC users with hypertension as compared with COC users without hypertension and triple the risk in COC users who smoke compared with nonsmokers.[25]

Venous Thromboembolism

Venous thromboembolism (VTE) includes deep vein thromboses and pulmonary embolism and can be life-threatening. Risk factors for VTE include increasing age, obesity, previous venous compromise, immobilization, and estrogen-rich states such as pregnancy and COC use. Estrogen promotes a hypercoagulable state by increasing the clotting factors VII, VIII, and X while also increasing resistance to anticoagulant effects of activated protein C.[26] The reduction in estrogen dosage in the newer formulation of COCs has greatly decreased the risk of VTE risk associated with the COCs. Among healthy young women, the incidence of VTE is—4–5 per 100,000 women years. Pregnancy confers a significant risk of VTE because of its associated hypercoagulable state with an RR = 12 when compared with the general population (incidence of VTE = 48–60 events per 100,000). Previously prescribed higher-dose COCs containing 50 µcg or higher of EE have an RR = 6–10 when compared with the general population and an incidence of 24–60 events per 100,000. Studies have shown that with lower doses of estrogen (35 µcg or less of EE), the risk of VTE is reduced to an RR = 3–4 and an incidence of 12–20 events per 100,000 as compared with

the general population while the contraceptive efficacy is not reduced when compared with the higher-dose pills.[27–29] The absolute risk of VTE in the setting of COCs is low despite the increased relative risk when compared with nonusers because VTE is rare. The greatest risk of thrombosis in the setting of COCs is within the first year of use, a slight increase in risk persists subsequent to the first year, and the risk diminishes 30 days after discontinuation of COCs.[30] The impact of obesity and increasing age on VTE risk in the setting of COC use is significant. A large study looking at the incidence of thrombosis among women undergoing venography reported an incidence of 0.5 per 10,000 for women under 20, 1.1 for women aged 20–29, 2.6 for women aged 30–39, and 9.7 for women aged 40–49.[31] Another study compared the risk of VTE in women with body mass index (BMI) less than 25 on COCs to those with BMI greater than 25 and found that the relative risk was 1.78 for COC users with BMIs between 25 and 30, and the relative risk is 3.47 for COC users with BMI greater than 30.[32] It is for these reasons that the American College of Obstetrics and Gynecology (ACOG) cautions the use of methods with estrogen in obese women (BMI > 30) who are over 35.

The progestin component of hormonal contraception does not have any impact on the clotting system alone but, in combination with estrogen, can modify the risk of VTE. Older studies in the 1990s reported that COCs with desogestrel and gestodene (third-generation progestins) are possibly associated with an increase in venous thrombosis risk compared with formulations containing levonorgestrel and norgestrel (second-generation progestins).[33–35] These studies have been critiqued for confounding factors that may have influenced these findings. A recent large Danish prospective cohort study assessed the risk of VTE by the type of progestin and the dosage of estrogen and found that compared with oral contraceptives with the same dose of estrogen-containing levonorgestrel (second generation) and with the same dose of estrogen and length of use, the rate ratio for oral contraceptives with norethisterone was 0.98 (0.71–1.37), with norgestimate 1.19 (0.96–1.47), with desogestrel 1.82 (1.49–2.22), with gestodene 1.86 (1.59–2.18), with drospirenone 1.64 (1.27–2.10), and with cyproterone 1.88 (1.47–2.42).[36]

Genetic thrombogenic mutations such as factor V Leiden mutation, the most common inherited coagulation disorder, as well as other inherited disorders including deficiencies in prothrombin, protein C, and protein S are associated with increased risk of VTE in the setting of COC use. A WHO literature review reported an increased risk of VTE by 6.4–99.0 times the risk in COC users with factor V Leiden mutations as compared with nonusers without a mutation.[37] The use of COCs by a prothrombin gene mutation carrier increases VTE risk by 100-fold than nonusers without the mutation.[38] Despite this increased risk of VTE in the setting of inherited thrombophilias, routine screening in healthy women prior to initiation of hormonal contraception is not warranted because of the low incidence of VTE in the general population (4–5 per 100,000 women year).[39,40] The prevalence of all mutations is also rare occurring in only 0.5% of the asymptomatic population. Thus, it would require screening of a large number of women to detect and prevent one death from VTE. Screening prior to initiation of COCs is recommended only in women with a history of previous VTE or a positive family history of VTE in a first-degree relative (parent or sibling).[41]

TRANSDERMAL CONTRACEPTIVE PATCH

A transdermal contraceptive patch (Ortho Evra™) is a newer method of combined estrogen-and-progestin-based contraception. It was approved for use in the United States in 2002. The patch is a 20 cm^2 three-layer system with an outer protective water-resistant layer, a middle medicated adhesive layer, and a clear release liner inner layer, which is removed at the time of patch application. Each patch contains a total of 0.75 mg of EE and 6 mg of norelgestromin, the primary metabolite of norgestimate (third-generation progestin), and provides 20 mcg of EE and 150 mcg of norelgestromin daily.[42] This results in a sustained release of hormonal contraception over several days, thereby avoiding peak and trough hormone levels and need for daily administration. The patch is applied once a week for 3 weeks in a different discrete location each week followed by a patch-free week during which menses occurs. Application of the patch should be rotated between the lower abdomen, upper outer arm, the buttock, or the upper torso excluding the breasts.

Transdermal contraception is highly effective with efficacy rates equal to oral contraceptives with pregnancy rates equal to less than 1 pregnancy per 100 women years with perfect use.[43–45] Although typical use efficacy has not been established for the patch, studies suggest higher compliance with the patch as compared with oral contraception with patch users achieving perfect compliance more often than oral contraceptive users (88% vs. 78% of cycles).[46]

Mechanism of Action

The patch, like other combined hormonal contraception, works primarily through ovulation inhibition by hormonal suppression of gonadotropins.[47] Because transdermal contraception has the same mechanism of action and hormonal levels as the combined pill, it should be given the same considerations for contraindications and non-contraceptive benefits.

Clinical Considerations

Overweight and obese women require additional counseling regarding patch failure, as increasing weight is associated with lower serum levels of EE and norelgestromin in patch users.[48] Women weighing more than 90 kg (198 lb) may be at higher risk for failure based on findings from 3 clinical trials in which 5 of the 15 pregnancies across the 3 studies occurred in women weighing more than 90 kg.[47] Though there is a potential decrease in efficacy among heavier women, it is unclear how much lower efficacy is for these women. It is likely that a small decline in efficacy, and with appropriate counseling, may still be a reasonable choice for contraception for these women.

As is the case with combined oral contraception, transdermal contraception is also associated with an increased risk of VTE due to the estrogen component of the method. The average overall EE concentration and exposure to estrogen is 60% higher among patch users than in women using a 35 mcg EE combined pill, although the peak concentration is 25% lower.[49,50] Because of the higher overall exposure to estrogen with the patch, there is concern for increased risk of VTE as compared with COCs. Studies comparing the risk of VTE in the norgestimate-containing 35 mcg EE oral contraceptive pill with the patch have mixed results. The Boston Collaborative Drug Surveillance Program (BCDSP) has an ongoing nested case–control study that uses managed care claims data to evaluate the risk of nonfatal VTE. The primary outcome of this study is to measure the risk of nonfatal VTE in new users of either transdermal contraceptive patch or a 35 mcg EE and norgestimate COC. Their initial findings analyzing data from 2002 to 2006 reported similar risks of VTE in both the patch and the pill users with an OR of 1.0 (95% CI 0.7–1.5).[51] However, in subsequent analysis reported to the Food and Drug Administration (FDA) in 2008, BCDSP found an increased risk of VTE compared with COC users of a 30 mcg EE and levonorgestrel pill (OR = 2.0, 95% CI 0.9–4.1).[52] The same group then evaluated the risk of nonfatal risk among patch and OC users by age and found that patch-using women under 40 did not have an increased risk compared with COC users, but for women between 40 and 44 years of age, a significantly increased risk could not be excluded.[53] Another study also using insurance claims data also compared patch users with 35 mcg EE and norgestimate pill users and found a significantly higher risk of VTE among patch users compared with the pill group with an OR = 2.2 (95% CI 1.2–4.0). This study, however, compared new users of patch with continuing COC users. This introduces "new user" bias to the results, since it is well known that the highest risk of VTE in the setting of hormonal contraception occurs within the initial months of use.[54]

CONTRACEPTIVE VAGINAL RING

Many methods of vaginal contraceptive rings are available worldwide. In the United States, a combined hormonal contraceptive ring, the Nuvaring™, is the only available method currently. The ring is a flexible, soft, plastic ring made of ethylene vinyl acetate copolymer with crystals of hormone within the ring. The ring delivers 15 mcg of EE and 120 mcg of etonogestrel daily. The plastic ring is placed vaginally for 3 weeks and does not need to be fitted or placed in a specific location in the vagina, since it needs only to be in contact with the vaginal mucosa. Menses occur during the fourth ring-free week.[55]

The ring has similar risks, benefits, mechanisms of action, and clinical considerations as COCs and the patch. The ring has some specific advantages over the other methods. Monthly placement of the ring allows for ease of use and higher compliance with the method. The vaginal route of administration of hormones increases the bioavailability, as it bypasses the first-pass metabolism, resulting in lower doses of hormones required to achieve equal efficacy. A systematic review of studies comparing COCs with the ring found that overall exposure to EE was significantly lower with the ring with half of the systemic exposure to EE as compared with 30 mcg COC, less fluctuation in serum levels, but equally effective.[56] This results in lower rates of side effects related to estrogen such as breast tenderness and nausea and lower rates of breakthrough bleeding and spotting compared with these side effects on COCs.[54,57,58]

Despite the lower levels of EE in the ring, there is equivalent inhibition of gonadotropins and suppression of ovulation as a compared with a COC with 30 mcg of EE and 150 mcg of desogestrel with pregnancy rates of less than 1% in clinical trials of perfect use.[54,56,59] Like the patch, typical use efficacy has not yet been established for the ring, but perfect compliance with the ring is reported to be as high as 86%–91%, suggesting potentially higher typical use efficacy when compared with the pill.[54,60] Though the ring is conventionally placed for 3 weeks at a time, there are sufficient hormones within the ring to prevent ovulation for up to 5 weeks; therefore, the ring can be used in a continuous fashion.[58] If removed from the vagina for greater than 3 h, it is recommended that backup contraception be used until the ring has been replaced for 7 days.

PROGESTIN-ONLY METHODS

Progestins primarily act by inhibition of gonadotropin secretion inhibiting follicular development and suppressing ovulation. This results in a hypoestrogenic state less suitable for implantation. In addition, progestin causes cervical mucous thickening and decrease tubal motility resulting in difficulty for sperm to enter the cervix or travel through the tubes. As a result, fertilization is prevented even if ovulation does indeed occur. In addition, unlike estrogen-based methods, large studies have not shown an increased risk of stroke, myocardial infarction, or VTE among users of progestin-based methods.[35,61–64] Thus, progestin-only contraceptive methods are a reasonable choice for women with a history of VTE or at high risk for VTE.

Depot-Medroxyprogesterone Acetate

Injectable contraceptive methods are safe, highly efficacious, and commonly used worldwide.

Depo-Provera (depot-medroxyprogesterone acetate) is the only injectable contraceptive used in the United States. It is a convenient, discrete, and low-maintenance method and is ideal for women with contraindications to estrogen use and certain medical conditions. In addition, there are many noncontraceptive benefits to use.

According to the 2002 National Survey of Family Growth (NSFG), 5.3% of all U.S. women between the ages of 15 and 44 currently use depot-medroxyprogesterone acetate (DMPA or Depo-Provera) as their chosen method of contraception.[65] A higher proportion of women in younger age groups use DMPA with 13.9% of women aged 15–19 using DMPA compared with 10.1% between the age of 20 and 24, and 1.6%

between the ages of 40 and 44. DMPA is one of the most widely used and thoroughly studied contraceptive methods. It was approved for use as contraception in the United States in 1992. It is composed of microcrystals suspended in an aqueous solution. Studies comparing 100 mg intramuscular (IM) doses compared with 150 mg IM doses found that 150 mg IM dose (gluteal or deltoid) is required to effectively prevent pregnancy with a theoretical effectiveness of 99.7% and a lowest expected first-year pregnancy rate of 0.3%.[66] A new formulation of DMPA, 104 mg, has recently been approved for subcutaneous administration in the United States and has been dose adjusted for to be given every 12 weeks with similar efficacy rates as the IM formulation. Typical use efficacy for both options is 97% based on follow-up reinjection at 11–13 weeks.[67] Following either IM or SC DMPA injection, ovulation does not occur for at least 14 weeks (98 days).[68] However, follow-up injections are routinely scheduled at 12 weeks. Serum concentrations of DMPA are high, so efficacy of the method is not compromised by increasing body weight or medication-induced increased hepatic enzyme activity in patients with contraindications to estrogen use. DMPA, a progestin-only method, is a safe and effective alternative.

Mechanism of Action

Depo-Provera, like other progestin-only methods, alters the endometrial lining, thickens the cervical mucus, and blocks the luteinizing hormone surge to prevent ovulation. After method discontinuation, ovulation resumes at 14 weeks, but can take up to 18 months. In comparison with combined hormonal methods, DMPA does not impact follicle-stimulating hormone as consistently or as intensely. Thus, for one-third of DMPA users, estradiol levels remain unchanged from early- to mid-follicular phase levels at approximately 40–50 pg/mL. For most DMPA users, estradiol levels vary throughout the injection period and may reach postmenopausal levels of <20 pg/mL, but vasomotor symptoms such as hot flashes and vaginal atrophy are uncommon in DMPA users. Absence of these symptoms is likely due to the fact that progestins, like estrogens, also suppress these symptoms and can be used for menopausal women who need to avoid estrogen therapy.[69]

Onset of contraceptive efficacy of DMPA is within 24 h after injection and is maintained for at least 14 weeks, providing a margin of protection if reinjection typically scheduled at 12 weeks is delayed. If reinjection is delayed beyond 14 weeks, women should be questioned regarding unprotected intercourse since they were due for their injection and should be evaluated for emergency contraception.[70] Subsequent studies have suggested that a grace period as long as 4 weeks is reasonable, and the WHO has adopted the longer grace period in its updated guideline.[71]

DMPA takes 6–8 months after the last injection to disappear, and clearance is slower in heavier women. Approximately half of women who discontinue DMPA can expect normal menses to return in 6 months after the last injection, but 25% will take a year before resumption of a normal menstrual pattern. This delay should be taken into consideration when counseling patients about method choice.[72]

Clinical Considerations

DMPA as a progestin-only method can be used in patients with contraindications to estrogen, such as women over age 35 at risk because of smoking, hypertension, or diabetes. DMPA can also be used safely in women with seizure disorder, sickle-cell anemia, congenital heart disease, migraines with aura, and a previous history of VTE. Observational data from epidemiologic studies and a WHO case–control study have not shown increased risks of stroke, myocardial infarction, or VTE.[60] DMPA is a good contraceptive option for women with a history of seizure disorder and sickle-cell anemia. In patients with seizure disorder taking antiepileptic drugs, hepatic enzyme activity increases the metabolism of contraceptive steroids, and thus oral contraceptives are not recommended in these patients as per WHO guidelines. However, DMPA hormone levels are high enough that contraceptive efficacy is not compromised by increased metabolic activity of hepatic enzymes. Furthermore, DMPA can have a beneficial effect on seizure control, as it is thought that progestins increase the seizure threshold in patients with seizure disorders. In patients with sickle-cell anemia, there is evidence that DMPA results in decreased sickling of red blood cells and a reduction in the frequency and intensity of sickle-cell crisis. Non-contraceptive benefits of DMPA also include a decreased risk of endometrial cancer,[73] which is similar to that observed with oral contraceptive pills. In addition, like oral contraceptive pills, DMPA decreases the risk of pelvic inflammatory disease, endometriosis, and uterine fibroids.

Lactation

The physiologic changes required for breast-feeding are dependent on the drop in serum concentrations of progesterone after the delivery of the placenta. This mechanism causes some concern regarding the use of DMPA during breast-feeding. A prospective cohort study evaluated the effect of early administration of DMPA on initiation of breast-feeding. This study found no adverse effects on breast-feeding. However, the mean time of initiation of DMPA was 50 h postpartum.[74] This delay should be kept in mind when initiating DMPA postpartum as there is a theoretical risk of decreasing breast-feeding if progesterone is introduced too soon after delivery, not allowing for the natural physiologic drop in progesterone to occur for initiation of milk production. Studies have shown no adverse effect on breast-feeding in women who receive DMPA at postpartum follow-up visits. In particular, there was no effect on the quantity and quality of milk production while on Depo-Provera. Thus, DMPA can safely be administered at the 2 or 6 week postpartum visit. This schedule will provide full contraceptive protection for lactating mothers in whom ovulation does not occur until at least 12 weeks after delivery.

Use of DMPA does not affect the duration of breast-feeding. The concentration of DMPA in the breast milk is negligible, and no effects of the drug on infant growth and development have been observed. One group of women, obese Latina women with prior gestational diabetes, requires extra

caution when prescribing DMPA postpartum. In this group of breast-feeding women who were taking the progestin-only oral contraceptive pill, a threefold increased risk of non-insulin-dependent diabetes was observed.[75] It is unknown whether other progestin-only methods might pose a risk in obese Latinas who have a history of gestational diabetes.

Unlike most other methods of hormonal contraception, there are a few major side effects associated with Depo-Provera use. Proactive counseling about the expected side effects should be provided as women who are well informed about their method tend to have higher continuation rates. Major side effects on DMPA include irregular menstrual bleeding, breast tenderness, weight gain, depression, acne, and headache. These side effects combined resulted in over 70% discontinuation at 1 year with irregular bleeding being the most common side effect. One-quarter of women initiating DMPA use discontinue it due to irregular bleeding in the first year.[76] If bleeding occurs shortly after beginning DMPA, patients should be counseled and advised that irregular bleeding decreases with the use of DMPA for a few more cycles. Overall incidence of irregular bleeding is 70% in the first year with a decrease in irregular bleeding with each reinjection, and rates as low as 10% after the first year. Fifty percent of the patients report amenorrhea by 1 year with 10% becoming amenorrheic by the first injection interval, 40% reporting amenorrhea by the fourth injection cycle, and 80% reporting amenorrhea at 5 years.[71] Irregular bleeding that begins several months after initiation is due to decidualization of the endometrium and can be treated with exogenous estrogen such as 1.25 mg conjugated estrogens, or 2 mg estradiol, given daily for 7–14 days. In addition, nonsteroidal anti-inflammatory drugs given for a week or oral contraception pill supplementation during the first 1–3 months of DMPA injection, which is when irregular bleeding tends to be worst, can be used for treating it. These interventions will decrease bleeding in the short term, but irregular bleeding will resume after discontinuation.[77,78] Overall continuation of DMPA at year 1 is about 33%, 50% at year 2, and as low as 20% at the end of 3 years.[76]

Weight gain is a common complaint among DMPA users with approximately 2.1% of users discontinuing the method due to weight increase. As is the case with other hormonal contraceptive methods, weight gain while using DMPA may be a result of dietary changes and aging and not hormonally induced. Studies of weight gain and DMPA use have shown mixed results. Prospective randomized controlled studies evaluating weight gain in normal-weight women showed no relationship between DMPA use and food intake, energy expenditure, or body weight.[79]

However, in certain subgroups, DMPA use has been correlated with weight gain. A systematic review found that obese adolescent DMPA users gained more weight compared with normal-weight users, but this was not the case with adults.[80] Similarly, it has been show that Navajo women using DMPA have significant weight gain.[81] Potential weight change should be taken into consideration when counseling patients about using DMPA.

Cancer

Though earlier small studies were suggestive of an association between DMPA use and breast cancer,[82] recent studies have shown that there is no such increase in risk. A large international case–control study found the overall relative risk of breast cancer associated with the use of DMPA was 1.1 (95% CI = 0.97–1.4) with no increase in risk with the duration of use. However, those DMPA users who had initiated use within the past 5 years were found to have increased risk (RR = 2.0; 95% CI = 1.5–2.8).[83] As is the case with oral contraceptive pills and hormone replacement therapy, it is possible that DMPA accelerates the growth of an already present tumor or detection of the tumor occurred earlier because of study-related surveillance. More recent data have also shown no association with DMPA and breast cancer and also did not show an increase in risk in recent or current users of the method.[84,85]

Multiple studies including data from the WHO Collaborative Study of 2009 women with invasive cervical cancer and greater than 9000 controls failed to demonstrate a significantly increased risk of cervical cancer among DMPA users (RR = 1.1; 95% CI = 1.0–1.3).[86]

Strong evidence supports a reduction in the risk of endometrial cancer in DMPA users at least as great as that seen with oral contraceptive users; relative risk was 0.21 (95% CI = 0.06, 0.79) in women who had never used DMPA.[73] There is no evidence for increased risk of ovarian cancer with DMPA use, and potentially a modest decrease in overall risk.

Depression

Although DMPA labeling suggests that depression may worsen with use of the method, studies regarding the impact of DMPA use on mood are inconclusive. One study showed a slight increase in DMPA users while other studies have not shown an association.[87–89] A prospective study set in an urban clinic compared adolescents on DMPA with controls and used two standardized questionnaires, the Beck Depression Inventory and the Multiple Affect Adjective Checklist-Revised, and found no statistically significant differences in depressive symptoms when using DMPA as a contraceptive agent over a period of 12 months and no significant changes in negative or positive affect.[90] There is little evidence for increasing depression with short- or long-term DMPA use, and it is not a contraindication to DMPA use as per WHO and CDC guidelines. Thus, depression should not be a reason to withhold DMPA administration in patients for whom DMPA is an ideal contraceptive method.

Cardiovascular Disease

Studies have not shown an increase in adverse cardiovascular effects including venous thrombosis, stroke, and acute myocardial infarction in the past or current DMPA users.[60,91–93] The ACOG states that progestin-only methods of contraception including DMPA are an appropriate contraceptive option for women with a previous history of VTE or in women with other contraindications to estrogen therapy.[94]

The overall impact of Depo-Provera on lipoproteins remains uncertain. There seems to be no clinically significant

alterations in lipoprotein profiles while on Depo-Provera. It is thought that there may be no impact on lipoproteins due to the avoidance of a first-pass metabolism through the liver. However, there does seem to be a theoretical risk of increased total cholesterol and low-density lipoprotein cholesterol and a decrease in high-density lipoprotein cholesterol during the initial period after initiation of DMPA. A multicenter clinical trial by the WHO found a transient adverse impact in the first few weeks after injection when hormonal levels in the blood were high.[86] In addition, use of DMPA has been shown to reduce plasma high-density lipoprotein levels and peripheral arterial hyperemia-induced flow-mediated dilatation. However, there is no increase in coagulation factors and there is no impact on blood pressure.[95–97] The clinical significance of these findings is unclear. Depo-Provera does not affect carbohydrate metabolism or coagulation factors, and lipid changes have not been linked to adverse cardiovascular effects.[98]

Effect on Bone Density

A major concern about the safety of long-term DMPA use is its effect on bone mineral density (BMD). Due to the decrease in endogenous serum estradiol levels secondary to DMPA's suppression of gonadotropins, a relative hypoestrogenic state exists among users, which is associated with increased bone resorption.[99] Given this physiologic change in DMPA users, there has been increasing concern about the impact of DMPA on bone health. In 2004, the U.S. FDA added a black box warning to DMPA labeling, which stated that women who use DMPA might lose significant BMD. The warning also cautioned providers that bone loss increases with greater duration of DMPA use and may not be completely reversible. Furthermore, the warning states that it is unknown whether use of DMPA during adolescence or early adulthood will reduce peak bone mass or increase risk for osteoporotic fracture later in life. The FDA then concluded that DMPA should be used as birth control for longer than 2 years only if other contraceptive methods are not advisable.

The BMD effects of DMPA are equivalent to those during hypoestrogenic states of pregnancy and lactation. A hypoestrogenic state occurs in which bone resorption exceeds bone formation, resulting in a decline in bone density.[100]

Comparing DMPA users with nonusers, it appears that BMD at the hip and spine of DMPA users decreases by 0.5%–3.5% after 1 year of use and by 5.7%–7.5% after 2 years of use.[101] However, the greatest loss in BMD occurs within the first year to second year of use with little incremental BMD loss during additional years of use.[102–107]

Available data do not suggest that DMPA will reduce peak bone mass and increase the risk of osteoporotic fracture rate. A systematic review of DMPA studies revealed that longitudinal data from adult DMPA users had results that differed about the rates of BMD reduction and seemed to change over time. Most studies showed reduction in BMD of less than 1% per year of use.[108]

There are no data on postmenopausal fracture rates in women who used DMPA as adolescents or adults; thus, the clinical significance of DMPA-associated decline in BMD is unknown. Furthermore, most of the evidence currently available indicates that women regain BMD after discontinuation of DMPA use. A 7 year prospective study found that at 96 weeks (1.8 years) after DMPA was discontinued, total hip BMD had returned almost to baseline levels, only −0.20% lower than baseline, and BMD measurements at the lumbar spine showed partial recovery (−1.19%).[109] After discontinuation of DMPA in adult women users, BMD recovery differed by anatomic site and length of DMPA use. All women had returned to levels comparable with nonuser controls by 76 months and returned to baseline levels by 92 months. Two years after discontinuation of long-term (median 10 years; range: 3–17 years) DMPA use, BMD in the lumbar spine increased significantly ($P < 0.002$), with mean increases overall of 3% (0.4%–5.6%) at 1 year and 6.4% (3.4%–9.4%) at 2 years.[110] Because adolescence is a period of critical bone formation, there has been even more concern about the use of DMPA in adolescent users. Evidence regarding DMPA use in adolescents and BMD recovery is similar to that in adults and is overall reassuring. A population-based prospective cohort study of 170 adolescent girls of age 14–18 including 80 DMPA users at baseline followed BMD at various anatomic sites every 6 months for up to 24–36 months and compared measurements among girls who used DMPA, those who discontinued use during the study, and nonusers. DMPA use was associated with BMD loss during use; however, the mean BMD at all anatomic sites reached or exceeded the levels of never-users by 12 months after DMPA discontinuation, a faster rate of recovery than that seen in the adult studies.[111]

In response to the FDA black box warning and changes in Depo-Provera labeling, many professional organizations including the ACOG, the Society for Adolescent Medicine (SAM), and the WHO reviewed the existing evidence and endorsed guidelines differing from DMPA product labeling. All three of these organizations stated that though there is an association between DMPA use and decreased BMD, there is a lack of quality evidence demonstrating a significant increase in risk of fractures in DMPA users, and the advantages of DMPA use for contraception generally outweigh the theoretical concerns about skeletal health.[112] There should be no restriction on initiation or duration of Depo-Provera use in adult women who are eligible to use this method as the risk of osteoporotic fractures is only theoretical and does not warrant alteration in current practice patterns. Furthermore, adolescents should not be denied DMPA as the risk of unintended pregnancy far outweighs the theoretical concerns about fracture risk. Overall risks and benefits for continuing DMPA use and counseling for all methods of contraception should be reviewed and reconsidered at 2 years and then periodically over time with individual users.

Bone densitometry testing or antiresorptive agents should not be used in otherwise healthy adolescents or adults before, during, or after DMPA use.[113,114] All users of contraception, including DMPA users, should be encouraged to perform weight-bearing exercise, not to smoke, and have a sufficient amount of dietary calcium (1300 mg) and vitamin D (400 IU) daily in order for adolescents to attain peak bone mass and adults to decrease osteoporotic risk. Concerns about skeletal

health in adults and adolescents should not restrict initiation, continuation, or duration of DMPA use.

Effect on Future Fertility

Despite concern about the delay in becoming pregnant after cessation of DMPA use, it does not permanently suppress ovarian function, and the pregnancy rate in women with a desire to become pregnant after discontinuing DMPA is normal. By 18 months after discontinuation of the method, 90% of Depo-Provera users have become pregnant, which is the same proportion as other methods.[115] There is, however, a delay in conception after DMPA. This delay is approximately 9 months after discontinuation of the method, and there is no increase in the delay with duration of use. Need for pregnancy planning should be taken into consideration when counseling patients as those patients wanting to conceive immediately after stopping the method should not use DMPA. If menstrual function remains suppressed beyond 18 months after discontinuation, further evaluation of other etiologies unrelated to DMPA administration should be pursued.

CONTRACEPTIVE IMPLANT

A number of different contraceptive implants have been developed, with Implanon™, a single-rod progestin implant, the only one available in the United States. Implanon is a 40 mm × 2 mm semirigid plastic rod made of ethinyl acetate with 68 mg of etonogestrel crystals suspended within. It is placed within the subdermal region in the inner upper arm and is effective for up to 3 years. There is an initial release of 60–70 mcg/day with a decline to 35–45 mcg/day at the end of the second year followed by additional decline to 25–30 mcg at the end of the third year.[116]

Efficacy

Implanon is a highly effective method with less than 1 pregnancy per 100 women in 1 year. It is considered among the most effective methods of contraception with actual efficacy equivalent to sterilization and intrauterine contraception because it does not rely on patient compliance with the method.[117] An analysis of 942 women enrolled in 11 clinical trials over 2–4 years found no pregnancies to occur during this time period.[63] The efficacy of Implanon has not been evaluated in women with a BMI greater than 30 kg/m^2. Efficacy may be decreased in women taking medications that are hepatic enzyme inducers that affect the metabolism of etonogestrel, as is the case with other hormonal methods of contraception including the pill, patch, and ring.

Mechanism of Action

Implanon's primary mechanism of action is suppression of gonadotropin secretion thereby inhibition of ovulation.[118] In addition, the progestin inhibits gonadotropin secretion resulting in a hypoestrogenic state. This leads to inhibition of endometrial proliferation resulting in a less hospitable environment for implantation. The progestin effect also leads to thickening of the cervical mucous and decrease in tubal motility, impeding sperm penetration and migration.[119]

Clinical Considerations

As is the case with other progestin-only methods, Implanon causes significant bleeding changes among most users, and this is the most common reason for discontinuation. The changes with Implanon are unpredictable and can fall into a wide range of bleeding patterns including prolonged bleeding, frequent bleeding, irregular bleeding, infrequent bleeding, or amenorrhea.[120–125] After Implanon removal, etonogestrel levels become undetectable within 1 week, and most women ovulate within 6 weeks, with menses returning to normal for the majority of women by 3 months.[117,126]

Implanon is approved for contraception only, but has also been shown to treat dysmenorrhea and endometriosis. One study of 315 women reported a 48% decrease in dysmenorrhea after insertion likely due to decrease in ovulatory bleeding induced by Implanon. It has also has been shown to decrease endometriosis-related pelvic pain.[119,127] Unlike DMPA, the progestin levels in Implanon are significantly lower, and thus it does not appear to have an effect on bone density despite the hypoestrogenic state. There is also no evidence to suggest changes in lipid metabolism or liver function.[128]

Insertion and removal of Implanon requires a simple office-based procedure under local anesthesia by a trained provider who has undergone an FDA-required training session through Merck, the marketer of the device. Complications related to insertion or removal are rare. The device can be removed at any time, but must be removed by the end of 3 years. If the patient desires reinsertion at 3 years, Implanon can be removed and replaced with a new rod simultaneously through the same incision or in the other arm.

INTRAUTERINE CONTRACEPTION

Intrauterine contraceptives (IUCs) are one of the oldest methods of contraception used worldwide, with numerous types of devices available globally. Most modern IUCs contain either copper or progestin to accentuate the mechanism of action of the device itself and increase contraceptive efficacy. Progestin-containing IUCs are known as an intrauterine system (IUS). The modern IUC is a long-acting highly effective, reversible method of contraception with minimal side effect.[129]

Despite these benefits, IUCs remain underutilized in the United States with only 2% of contraceptive users choosing the method in 2002 as compared with 27% of contracepting women in Europe and 50% of contracepting women in Asia.[130–132] The limited use of modern IUCs currently in the United States stems from much of the fear that surrounded the Dalkon Shield, an IUC used in the 1970s, which was linked to increased risk of pelvic inflammatory disease, which resulted in discontinuation of the method. The risk of infection with the Dalkon Shield was due to the braided multifilament string. Modern IUCs have monofilament strings

and do not have the same infectious complications as the Dalkon Shield.[133,134] In addition, other factors such as misperceptions about the risks of ectopic pregnancy, infection, and infertility as well as lack of clinical training and fears of litigation have also led to limited use within the United States.[135]

Recent data from the NSFG show a changing trend with an increase to 5.5% of women using the method between 2006 and 2008 as compared with 2.0% in 2002 likely due to the increasing data on safety and non-contraceptive benefits as well as women's positive experiences.[136]

In the United States, women can currently use the Copper T380A (CuT380A or Paragard™) IUD or the levonorgestrel-releasing intrauterine system (LNgIUS or Mirena™). CuT380A was approved by the FDA in 1984 and first marketed in 1988 for 10 years with evidence indicating efficacy through 20 years.[137,138] The CuT380A is composed of a T-shaped polyethylene frame with 380 mm^2 of exposed surface consisting of fine copper wire and an attached polyethylene monofilament string. The device is radiopaque and latex free, and clinically significant allergy to copper is very rare.[139]

Perfect use efficacy and typical use are extremely high for all IUCs as they are long-acting reversible methods of contraception with little need for patient compliance. If women use the CuT380A perfectly, which means that they are checking strings routinely to detect expulsion, the first-year pregnancy rate is 0.6% while with typical use (no routine string checks), the first-year pregnancy rate is 0.5%–0.8%.[140,141]

The LNgIUS was approved in December 2000 and was first marketed in 2001 for 5 years of use though evidence supports efficacy through 7 years.[142] It consists of a T-shaped polyethylene frame with 52 mg of levonorgestrel, which initially releases 20 mcg of levonorgestrel daily declining to about 14 mcg/day after 5 years, which is within the therapeutic range. Limited systemic absorption of levonorgestrel does occur, and some women can experience some systemic side effects related to this. However, compared with an oral contraceptive containing 150 mcg levonorgestrel, the mean plasma concentration with the LNgIUS is only 5% of that with the pill. It is the hormonal method with the lowest possible systemic levels of hormone.[143] LNgIUS is also latex free and radiopaque and, thus, visible by x-ray. Similar to the CuT380A, the LNgIUS is highly effective with the first-year pregnancy rate equal to 0.1% with perfect use and 0.1%–0.2% with typical use.[141]

Mechanism of Action

The exact mechanism by which IUCs prevent pregnancy is not completely understood. However, it is likely that several factors are involved, including a foreign body effect secondary to the plastic frame, in addition to actions specific to the copper or levonorgestrel. The primary mechanism of action is prevention of fertilization. They do not act as an abortifacient as they do not interrupt an implanted pregnancy.[139] The foreign body effect results in a sterile inflammatory reaction within the uterine cavity that is toxic to sperm and inhibits sperm motility and survival. It is also toxic to ova and impairs implantation.[139,144–149] The CuT380A undergoes an in utero oxidation, which releases free copper and copper salts, enhancing the cytotoxic inflammatory reaction within the endometrium, which is toxic to sperm and ova.[145,146] Levonorgestrel secreted by the LNgIUS causes cervical mucous thickening, which creates a barrier for sperm, preventing penetration into the upper genital tract.[132] Additionally, like other progestin-based methods, the LNgIUS causes endometrial decidualization and glandular atrophy resulting in a suboptimal environment for fertilization.[150] Because the serum levels of levonorgestrel are very low, there is a limited effect on ovarian follicular development and ovulation, with at least 75% of women who use the LNgIUS ovulating regularly.[151]

Clinical Considerations

For most women, an IUC is an excellent option for contraception as it is a highly effective, long-acting, rapidly reversible, and cost-effective method with very few side effects. It offers a minimally invasive, but equally effective alternative to tubal sterilization. Ideal candidates for IUCs include women of reproductive age who desire highly effective reversible contraception, are not planning a pregnancy for at least a year, are at low risk of acquiring sexually transmitted infection, and want or need to avoid estrogen-based methods. In addition, nulliparous women, adolescents, and women with a history of pelvic inflammatory disease or ectopic pregnancy can all safely use the IUC.[141,152–155] IUCs can be placed safely immediately postpartum and post-abortion and in women who are breastfeeding.[156] There is a rapid return to fertility immediately after the removal of either IUC, and no increased risk of infertility. A large case–control study of nulligravid women with tubal infertility found no association with history of CuT380A use, but there was an increased risk of tubal infertility among women who had a history of prior Chlamydia infection.[157]

There are very few evidence-based absolute contraindications to intrauterine contraception. Major conditions in which an IUC is contraindicated include severe uterine distortion including bicornuate uteri, fibroids severely distorting the cavity, and other distorted uterine cavities that can result in increased risk of expulsion.[158,159] Fibroids that minimally distort the cavity are not contraindicated, and IUCs have been placed bilaterally in bicornuate uteri to ensure efficacy from placement in both horns. Active pelvic infection including pelvic inflammatory disease, endometritis, mucopurulent cervicitis, and pelvic tuberculosis are contraindications for IUC, as presence of a foreign body may worsen infection or delay resolution. Women with previous infections can have an IUC placed 3 months after treatment.

Most women can safely use either the CuT380A or LNgIUS. Counseling is focused on a discussion of a woman's menstrual history, medical history, preferred bleeding pattern, desire for lighter bleeding or spotting, and less painful menses. Women who may prefer the copper IUC include women with breast cancer within 5 years, women who want to avoid exogenous hormones, and those who want to continue to have monthly

menses. Women choosing the CuT380A should be counseled about that their menses may be heavier, longer, and more uncomfortable especially during the first 3–6 months after insertion. Several non-contraceptive health benefits with the LNgIUS may result in women choosing the method instead of the CuT380A. Women using the LNgIUS have a reduction in dysmenorrhea and menorrhagia including decreased bleeding among women with bleeding diatheses and on anticoagulation.[160,161] The LNgIUS also decreases pain from endometriosis, has a protective effect on the endometrium, can be used for treatment of nonatypical endometrial hyperplasia, and protects against pelvic inflammatory disease due to the barrier effect of progestin-induced cervical mucous thickening.[158,162–165] The LNgIUS is a good choice for women who prefer amenorrhea, which occurs over time, and are comfortable with unscheduled light bleeding. Of LNgIUS users, 50% have amenorrhea at 24 months, 25% have oligomenorrhea, and 11% have spotting while the rest have normal or heavy bleeding.[166]

EMERGENCY CONTRACEPTION

Women who have had recent unprotected intercourse or possible failure of another method of contraception are candidates for emergency contraception. In the United States, emergency contraception is available over the counter for men and women who are of age 17 and older while a prescription is required for patients who are 16 and under. There are no medical contraindications to emergency contraception.

Mechanism of Action

The mechanism of action of emergency contraception is not completely understood, but strong evidence indicates that the primary mechanism is inhibition of ovulation and prevention of fertilization. In addition, there is some impact on the endometrium preventing implantation and decrease in tubal transport of sperm and ova in the setting of emergency contraception.[167–172]

Efficacy

Although women can conceive only during specific periods of time during their cycle, emergency contraception is offered when indicated at any point in the menstrual cycle due to the uncertainty in the timing of ovulation. Use of oral emergency contraception is reported to result in pregnancy rates of 0.2%–3% and 0.0%–0.2% with use of copper intrauterine contraception.[173–176]

Options

Several methods of emergency contraception are available in the United States including combined EE (Yuzpe regimen) plus levonorgestrel, levonorgestrel alone (Plan B™), CuT380A and IUC, and the newest available method is the antiprogestin ulipristal acetate (Ella™).

Levonorgestrel alone (Plan B™) is the preferred method over the Yuzpe regimen as it has been proven to be more effective and associated with lower side effects. It can also be self-administered, thus not requiring a clinic visit as compared with the CuT380A IUC. Levonorgestrel is now available in a single 1.5 mg single dose as Plan B One-Step™. Both the Yuzpe and levonorgestrel regimens are most effective if given as soon as possible after unprotected intercourse, and efficacy is the highest within the first 72 h after unprotected intercourse.[177–180] Both regimens can be given up to 120 h from unprotected intercourse, but women should be counseled that efficacy is likely reduced as compared with administration at less than 72 h.

The advantage of placing the CuT380A for emergency contraception is that it is slightly more effective over a longer period of time (through 120 h) than the oral regimens and provides ongoing contraception after the initial event.

Ulipristal acetate is a 30 mg antiprogestin and was found to be as effective as levonorgestrel within the first 72 h after unprotected intercourse. Studies have shown that ulipristal has greater efficacy as compared with levonorgestrel between 72 and 120 h after unprotected intercourse and has been FDA approved since August 2010 for use up to 120 h from unprotected intercourse.[181]

No routine follow-up is required after administration of emergency contraception, but women should be advised that they should take a pregnancy test if they do not have menses within 3–4 weeks of taking emergency contraception. Women should be counseled to seek medical care if they have persistent vaginal bleeding or abdominal pain. Lastly, women should be counseled to start another method of contraception immediately after using emergency contraception because of the ongoing risk of unintended pregnancy with unprotected intercourse.

An essential part of providing holistic care to women includes evidence-based reproductive health care. Health care providers should arm themselves with the latest knowledge in order to help care for women as equal partners in their health care, allowing them to make informed choices in contraception.

Physicians and other health care providers play a major role in prevention, screening, and treatment of sexually transmitted infections (STIs). From practices as simple as ensuring educational messages through posters and brochures in the offices to communication styles that encourage open dialogue, to offering up-to-date prevention, screening, and treatment practices, today's health care provider is a vital part of ensuring the sexual and reproductive health of the population.

PREVENTION

Epidemiology

Every year nearly 900,000 women are diagnosed and treated for chlamydia while nearly 200,000 are diagnosed and treated for gonorrhea. These infections represent the two most common STIs; however, a myriad of other infections also result in significant morbidity. Several of the most common STIs are reported to the Centers for Disease

TABLE 71.1
Incidence of STIs in Women as Reported to the CDC in 2008

Disease	Incidence	Rate per 100,000 Women
Chlamydia	899,860	579.98
Gonorrhea	182,849	117.85
HIV (2006)	14,472	9.33
Total syphilis	13,210	8.51
Chancroid	14	0.01

Note: Most recent data available for HIV is from 2006.

Control (CDC) as seen in Table 71.1; however, these numbers probably reflect a significant underrepresentation.[1] Many STIs are undiagnosed while others are not required to be reported to the local public health department.

Of particular concern is the prevalence of STIs among America's youth. Of the approximately 19 million cases of STIs that occurred in 2000, 48% were among persons aged 15–24. Of these infections, 88% consisted of human papillomavirus (HPV), chlamydia, and trichomoniasis.[2]

Education

Education is of critical importance in the prevention of STIs. There are many opportunities for education, including in schools, in community groups, and at the health care provider's office. Sexual education in public schools has a potentially broad reach but has been subject to great controversy in recent years, particularly surrounding abstinence-only education. Under Title V, Section 510 of the Social Security Act in 1996, Community Based Abstinence Education projects, and the Adolescent Family Life Act Program, the federal government supplies approximately $175 million annually for abstinence-only education.[3] Notably, multiple organizations including the American College of Obstetricians and Gynecologists (ACOG) and Planned Parenthood, as well as the American Academy of Pediatrics, strongly recommend against abstinence-only education.[4,5] In 2007, the U.S. Congress sponsored a study of abstinence-only education's efficacy. The resulting document by Mathematica Policy Research showed no differences in the rates of abstinence or condom use among adolescents exposed to the abstinence-only education programs as measured in 2500 adolescents 4 years after the educational exposure. Additionally, these youth were less likely to acknowledge that condoms prevent STIs and human immunodeficiency virus (HIV) in particular.[6] Concerns have been raised that abstinence-only education may be inaccurate, reinforcing the role of the health care provider in giving evidence-based counseling.[5]

Contraceptive Counseling

Arguably the best contraceptive method for prevention of STIs is the male condom.[7] It is sometimes lauded as the singular method of contraception also effective at preventing transmission of infection, including HIV; however, it is not without disadvantages.[8] First, condoms do not fully protect against diseases spread by skin-to-skin contact, namely, genital herpes simplex, syphilis, chancroid, and HPV.[9] Second, the failure rate is approximately 14% with typical use, as it is dependent on consistent use and proper placement. Still, the male condom is responsible for reducing the number of infections in communities. With regard to HIV, consistent use of the male condom appears to reduce the risk of infection by 80% in heterosexual couples as compared with couples without any condom use.[10] An extensive meta-analysis showed that condoms also reduce the genital herpes simplex virus (HSV)-2, syphilis, and chlamydial infection rates in both men and women as well as reduce gonorrhea and trichomoniasis infections in women.[11]

Other barrier methods are also worth noting, including the female condom and cervical barriers such as the cervical cap and diaphragm. The female condom first became available in the United States in 1993 with an updated model (the nitrile FC2 condom) receiving FDA approval in 2009. The updated FC2 has pregnancy failure rates of 5% and 21% at 12 months for perfect and typical use respectively.[12] Limited data suggest that the female condom is impenetrable to HIV, cytomegalovirus (CMV), and presumably other sexually transmitted diseases.[13] One study investigated the rate of STIs in a group of sex workers using only the male condom or using their preference of the male or female condom. This study group had a nonsignificant reduction in STI after 24 weeks in those with access to the female condom, again suggesting that the female condom is an efficacious barrier to STIs.[14] There are limited data on cervical barriers as a means of preventing infection. A review in 2005 concluded that there was a "suggestion" that these methods did indeed provide some protection although this review cites only observational data.[15]

An exciting area of research and development is vaginal microbicides, which are topical agents that potentially would prevent HIV transmission and may function well as an adjunct to another method such as the male condom. Several classes of microbicides have been developed including surfactants, membrane disruptors, vaginal milieu protectors (altering pH), viral entry inhibitors, and reverse transcriptase inhibitors.[16] Unfortunately, to date no effective microbicide is available.[16]

Of note, intrauterine contraceptive devices are not contraindicated in patients with a prior history of sexually transmitted disease or pelvic inflammatory disease (PID). As per the World Health Organization Medical Eligibility Criteria, only current PID, current purulent cervicitis, active chlamydial, and gonorrheal infection are relatively or absolutely contraindicated (WHO category 3 or 4) in an otherwise low-risk patient.[17] Placement of an intrauterine device elevates a patient's risk of PID approximately sixfold for 20 days.[18] Beyond this window, there is no elevated risk of PID. If a patient has an active chlamydial or gonorrheal infection at the time of insertion, there is an approximately 11% risk of

developing PID.[19] There is currently no recommendation for routine screening at the time of insertion or any role for prophylactic antibiotics in a patient with a benign pelvic examination. The manufacturers of both the Tcu380A and LNg 20 devices recommend testing "as indicated" by the patient's risk factors.[20,21] This recommendation is concordant with those issued by the ACOG.[22]

Vaccines

Vaccines are now available for two STIs: hepatitis B virus (HBV) and select stains of HPV. The hepatitis B vaccine is administered in a series of three immunizations at 0, 1, and 6 months. Approximately 3%–6% of recipients do not seroconvert.[23] The CDC recommends universal immunization starting at the time of birth.[24]

Initially marketed in 2006, there are now two different vaccinations for HPV. The first vaccine, Gardasil produced by Merck, protects against HPV strains 6, 11, 16, and 18, which are responsible for both genital warts (6 and 11) and cervical dysplasia (16 and 18). A more recent vaccine, Cervarix produced by GlaxoSmithKline, protects against strains 16 and 18 only. There is some evidence that Cervarix offers protection from additional oncogenic strands of HPV in addition to 16 and 18.[25] Both of these vaccines are given in a series of three immunizations. The Advisory Counsel on Immunization Practices recommends immunization of all girls ages 11 and 12 with a catch-up schedule up to age 26.[26] Notably, protection from cervical intra-epithelial neoplasia 2 or more is greatly affected by timing of the vaccine. Efficacy among women who were HPV naive was approximately 97% while for the general population this number fell to 44%.[27] Thus, universal administration of the vaccine series prior to the initiation of sexual activity significantly increases its efficacy and reduces HPV infections.

Viral Suppression

Medical viral suppression is available for genital herpes as a method of prevention of transmission, in addition to symptomatic relief for the patient. In a study of heterosexual herpes-discordant couples, taking valacyclovir 500 mg once daily reduced transmission over the course of 8 months from 3.6% to 1.9%. Additionally, the affected partner had a decrease in outbreaks.[28]

Male Circumcision

By removing the foreskin and thus eliminating a moist environment where infection can proliferate, male circumcision significantly reduces the risk of HPV, HIV, and HSV transmission.[29] Randomized controlled trials on adult men in Kenya showed a 50%–60% reduction in the rate of HIV acquisition as well as a significantly reduced risk of high-risk HPV (14.8% decreased from 22.3%), a trend to lower rates of trichomoniasis infection, and no effect on gonorrheal infection. These data may potentially be extrapolated to neonatal circumcision as well. Although circumcision is clearly not a complete solution to the prevention of STIs, it may play a role. Furthermore, the decision to perform a male circumcision is influenced by surrounding cultural and religious practices.

SCREENING

Sexual History

The first step in screening any patient for STIs is to take a sexual history. This can allow for targeted screening of asymptomatic patients according to risk group. Of utmost importance is creating a nonjudgmental open environment in order to obtain the essential information. The CDC has developed a five-part questionnaire for this purpose (Table 71.2).[30]

Risk Factors

The sexual history allows the provider to identify a patient's risk factors and counsels the patient appropriately. Statistically significant risk factors for current infection include younger age (less than 17 years old) at the time of evaluation, younger age at first intercourse, multiple sexual patterns, history of prior STI and/or PID, low socioeconomic

TABLE 71.2
Five Ps of Sexual History Taking According to the CDC

1. Partners
   - Do you have sex with men, women, or both?
   - In the past 2 months, how many people have you had sex with?
   - In the past 12 months, how many people have you had sex with?
2. Prevention of pregnancy
   - Are you or your partner trying to get pregnant? If not, what are you doing to prevent pregnancy?
3. Protection from STIs
   - What do you do to protect yourself from STIs including HIV?
4. Practices
   - Have you had vaginal sex, meaning "penis in the vagina" sex?
     - Do you use condoms never, sometimes, or always? If never, why not? If sometimes, in what situations or with whom do you not use condoms?
   - Have you had anal sex, meaning "penis in the rectum/anus sex"?
     - Do you use condoms never, sometimes, or always? If never, why not? If sometimes, in what situations or with whom do you not use condoms?
   - Have you had oral sex, meaning "mouth on the penis/vagina"?
5. Past history of STIs
   - Have you ever had an STI?
   - Have any of your partners had an STI?

Additional questions
- Have you or any of your partners ever injected drugs?
- Have you or any of your partners exchanged money or drugs for sex?
- Is there anything else about your sexual practice that I need to know about?

status, race, tobacco use, and exposure during menses.[30–33] It is difficult to assign a precise rate of elevated risk to each of these variables as these numbers have varied widely in the literature. Thus, these risk factors must be considered in a clinical context for any given patient. Considerations such as a recent new partner or potential exposure may influence screening decisions. At any time, a patient may request screening without indicating his or her reasons.

Screening Guidelines

The U.S. Prevention Services Task Force has made a series of recommendations regarding routine screening for STIs.[34] Their most recent recommendations in 2007 call for all women under age 25 to be screened for chlamydia annually as well as all those patients above this age limit who are at a higher risk based on their risk factors. The risk factors they cite include "previous chlamydial infection or other STIs, new or multiple sexual partners, inconsistent condom use, and sex work." These guidelines apply to both pregnant and nonpregnant women. Given the lower prevalence of gonorrheal infection, they recommend screening for this infection only in high-risk populations.[35]

The ACOG recommend that patients undergo "routine HIV screening" with an opt-out policy as part of their routine gynecologic care.[36] A single negative test may be sufficient if subsequent sexual histories identify no new risk factors. However, for those identified to be at high risk, annual HIV screening should be performed.

Outside of chlamydia, gonorrhea, and HIV screening, there is little in the way of guidelines for STI screening. If a patient initiates a request for screening, a complete panel might include a cervical swab for chlamydia and gonorrhea, a serum sample for HIV, syphilis, and hepatitis B immune status, and any other testing as indicated by the patient's particular history. For example, for a patient with known IV drug use, or who had sex with those with IV drug use, consideration should also be given for testing for hepatitis C.

Special Populations

Adolescents

As noted earlier, adolescents are at increased risk for STIs. The ACOG recommends that chlamydia, gonorrhea, and HIV be tested at the patient's first gynecologic visit if the patient is sexually active.[37]

Pregnant Patients

Pregnant patients may be thought of as two separate patients: the mother and the fetus. Therefore, screening is not only directed at the mother with consideration of her pertinent risk factors but also directed toward the fetus. Given the risk of congenital infection, there are several additional screens that are considered routine during pregnancy. At the initial prenatal visit, women should be screened for hepatitis B, chlamydia, gonorrhea, syphilis, and HIV as well as clinically examined and questioned regarding genital herpes.[38]

Lesbians

Women who have sex with women represent a unique population, although there are no separate screening guidelines currently available.[39] A thorough history should ascertain if shared penetrative sex items are used, as these may act as a fomite for STIs. This might in part explain the high rate of bacterial vaginosis as well as the concordant strains of HPV that have been isolated in monogamous female partners.[40,41] Also of note, 53%–99% of women who have sex with women have had intercourse with men and may continue to do so.[42] This emphasizes the importance of a thorough sexual history in determining the need for screening for STIs in women who report female partners, but may have had heterosexual relationships in the past or will have them in the future.

Sexual Assault Victims

A post-assault examination should be conducted by a trained provider. The CDC recommends obtaining a swab for chlamydia and gonorrhea from any attempted sites of penetration, as well as a wet mount for trichomoniasis. The wet mount can also be examined for yeast or bacterial vaginosis as indicated by the physical examination. A serum sample should be collected for HIV, hepatitis B, and syphilis.[30]

DIAGNOSIS AND TREATMENT

General Principles

There are several general principles for evaluation and management of STIs. Previously, it was thought that patients should return to the clinic for a "test of cure." Current treatment regimens are, in general, quite efficacious and a "test of cure" is no longer recommended. The exception to this guideline is for pregnant women, as well as any patient in whom noncompliance is suspected, symptoms persist, or reinfection is suspected.[30] Repeat testing should be in no less than 3 weeks, as nucleic acid amplification tests (NAATs) may yield a false-positive due to the presence of dead organisms. Reinfection may be symptomatic or asymptomatic, requiring clinical judgment to assess which cases are high risk and thus merit rescreening. In 2006, of 1236 women seen at an STD clinic who had initially screened positive, 25.8% had one or more new infections.[43] Of these patients, 66.2% reported no symptoms. A similar study of women aged 15–19 showed slightly higher rates (41.1%) of reinfection within 1 year of initial diagnosis.[44] This study also showed that nearly 10% of this population was reinfected with more than one organism, an indication for complete repeat screening. Thus, for high-risk populations, including adolescents, screening for reinfection with chlamydia, gonorrhea, and trichomoniasis 3 months after initial diagnosis is indicated.

After being diagnosed and treated for an STI, it is of crucial importance that the patient's partner also be screened and treated prior to reinitiating sexual relations. The optimal method of notification and treatment of partners is not clear, and it is complicated in many locations

by legal barriers. In 2005, a group in Seattle, Washington, enrolled partners of infected patients in an expedited treatment program by giving them therapy without a clinical examination. The patients in the expedited treatment group had significantly reduced persistent and recurrent infections (relative risk 0.76) and patients were more likely to report all of their partners.[45] If using expedited therapy, the partner must receive written instructions on how to take the medication, as well as information on potential side effects, general health counseling, and indications to seek further care, including signs and symptoms of PID in female partners. Regardless of the mechanism of treatment, there should be a period of abstinence usually of 1 week's duration after both partners have been treated to allow for complete treatment of the infection.[46]

Reporting requirements for STIs vary by state; however, syphilis, gonorrhea, chlamydia, chancroid, HIV, and acquired immune deficiency syndrome (AIDS) are reportable diseases in all 50 states.[30] The local department of public health can be contacted for more information regarding guidelines in specific locations. Records of infection are kept confidentially and protected from subpoena by nearly all states.

Pelvic Inflammatory Disease

PID is an acute infection of the upper genital tract in women. PID is a potential complication of an STI, particularly chlamydia and gonorrhea. It is important to recognize this potential complication at the time of diagnosis of an STI, as PID carries the risk of future infertility.[47] Of those women with laparoscopically confirmed PID who desired conception, 16% had infertility compared with 2.7% of those with a normal laparoscopic exam. Of those in the infertility group, 67.6% were diagnosed with tubal factor infertility. As would be expected in a group with increased tubal factor infertility, there is a higher rate of ectopic pregnancy after PID. In the same cohort study, 7.8% of the study group had an ectopic pregnancy compared with 1.3% in the control group.

The diagnosis of PID is largely clinical; however, laboratory results may confirm the diagnosis. Diagnostic guidelines from the CDC can be seen in Table 71.3.[48]

STIs, including *Neisseria gonorrhoeae* and *Chlamydia trachomatis*, are universally implicated in the pathogenesis of PID although bacterial vaginosis is present in up to two-thirds of cases. Thus, most cases are considered polymicrobial.[49,50] There are a number of different inpatient and outpatient regimens recommended for PID although all regimens are designed for broad coverage including coverage for the most commonly indicated STIs. As an outpatient, a single dose of ceftriaxone 250 mg intramuscularly as well as doxycycline 100 mg orally twice daily for 14 days with or without metronidazole 500 mg orally twice daily is recommended. As an inpatient, cefoxitin 2 g intravenous every 6 h with doxycycline 100 mg orally twice daily can be given.[30] There are a number of alternative regimens available if a patient has known allergies.

TABLE 71.3
Diagnostic Criteria for PID

Clinical PID

Cervical motion tenderness, uterine, or adnexal tenderness with lower abdominal pain, plus one or more of the following:

- Oral temperature >101°F (38.3°C)
- Abnormal cervical or vaginal mucopurulent discharge
- Presence of abundant number of white blood cells on saline microscopy of vaginal secretions
- Elevated erythrocyte sedimentation rate
- Elevated C-reactive protein

Confirmed PID

Pelvic pain or tenderness, plus one or more of the following:

- Acute or chronic (plasma cell) endometritis or acute salpingitis on histological evaluation of a biopsy
- Demonstration of *N. gonorrhoeae* or *C. trachomatis* in the genital tract
- Gross salpingitis visualized at laparoscopy or laparotomy
- Isolation of pathogenic bacteria from a clean specimen from the upper genital tract
- Inflammatory/purulent pelvic peritoneal fluid without another source

Definitive PID

Pelvic pain or tenderness, plus one or more of the following:

- Histological evidence of endometritis on an endometrial biopsy
- An imaging study revealing thickened fluid-filled tubes with or without free pelvic fluid or tuboovarian complex
- Laparoscopic abnormalities consistent with PID (e.g., tubal erythema, edema, adhesion; purulent exudate or cul-de-sac fluid; abnormal fimbriae)

Source: Centers for Disease Control and Prevention, *MMWR Recomm. Rep*. 55(RR-11), 1, 2006.

Chlamydia

Chlamydial infection is caused by the bacteria *C. trachomatis*. It is the most common STI in the United States with 579.98 infections per 100,000 women, as reported by the CDC in 2008.[1] Although it is a reportable disease in all 50 states, this number is probably an underrepresentation as not all infected women present for care. Patients may present with vaginal discharge and vague lower abdominal pain; however, nearly 50% of infected women will be asymptomatic.[51] On physical examination, a friable erythematous cervix with mucopurulent discharge may be observed.[52] Chlamydial infection may present with more disseminated infection including urethritis causing dysuria and pyuria, perihepatitis causing Fitz-Hugh–Curtis syndrome, or PID. Less commonly invasive serovars L1, L2, and L3 *C. trachomatis* can cause lymphogranuloma venereum, an inflammation of the lymphatics and inguinal lymph nodes.

There are several methods of laboratory detection for chlamydia infection. Perhaps most commonly, the provider collects a cervical swab that then undergoes NAAT; however, there are multiple other collection and detection methods. As an alternative to the office examination, the patient may collect her own vaginal swab or provide a urine specimen.

Patients and adolescents in particular may feel more comfortable with these less invasive screening methods. Once the specimen is collected, the test may be performed using one of many laboratory methods, such as NAAT, ligase chain reaction, polymerase chain reaction, or gene probe, which are all DNA based or using an enzyme immunoassay (EIA). A 2002 meta-analysis compared these methods and found DNA-based tests to be more accurate than the EIA tests regardless of specimen type.[53] For the PCR assay, the sensitivity and specificity were 83% and 99.5% for urine samples and 86% and 99.6% for cervical samples.[54]

There are two recommended treatment regimens. Azithromycin 1 g orally one time may be administered under direct observation to ensure compliance. Alternatively, doxycycline 100 mg twice daily for 7 days may be given. Both of these regimens have an excellent efficacy (97% and 98%).[55] In pregnancy, the same azithromycin regimen may be used or amoxicillin 500 mg three times daily for 7 days. For patients with allergies, there are a number of other acceptable regimens including 7 days of any of the following: erythromycin base 500 mg four times daily, erythromycin ethylsuccinate 800 mg po once daily, ofloxacin 300 mg po twice daily, or levofloxacin 500 mg po once daily. Untreated chlamydia leads to PID in approximately 30% of cases.[56]

Gonorrhea

Gonorrheal infection is caused by the bacteria *N. gonorrhoeae*. It is the second most common STI with 117.85 cases per 100,000 women as of 2008.[1] As with chlamydia, approximately 50% of women with an active gonorrheal infection are asymptomatic.[57] Of those patients with symptoms, complaints usually consist of mucopurulent discharge and/or vaginal pruritus. Abdominal pain is more indicative of PID and would not be expected in uncomplicated gonorrheal infection.

Gonorrhea can infect multiple mucosal surfaces, including the cervix, urethra, anal mucosa, and oropharyngeal mucosa. In a high-risk population, *N. gonorrhoeae* may be responsible for up to 10% of urethral infections.[58] Physical exam findings include purulent urethral discharge, which should be collected for gram stain and culture on Thayer–Martin agar. Alternatively, urine DNA testing is available but may have a lower sensitivity and specificity as compared with a traditional urethral sample.[54] Infection is also possible in the anal mucosa, although patients are generally asymptomatic as one study found in 97% of cases; rarely these patients report anal itching, rectal discharge, rectal fullness, and painful defecation.[59] One investigation examined 127 women with known exposure to gonorrhea. In this population, 50% had an active gonorrheal infection in the genital region. Of this group, 46% had gonorrhea isolated from the rectum as well as the cervix and/or urethra while 6.3% had gonorrhea isolated from the rectum without concomitant vaginal infection.[60] Rectal disease can be identified using a blind swab technique.[61] Lastly, gonorrheal infection may be present in the oropharyngeal mucosa. The prevalence of pharyngeal gonorrhea varies widely from less than 1% to as high as 22.5%, depending on the risk level of the population.[62] Those reporting orogenital sexual activity had increased rates of colonization and infection with particularly high infection rates in pregnant women. Pharyngeal culture remains the laboratory testing standard as gram stain is frequently contaminated.

The CDC recommends that laboratory evaluation for cervical disease be performed with NAAT.[30] Using this method, samples can be stored at room temperature for days prior to testing and once tested offers rapid results. As compared with the gold standard diagnosis on modified Thayer–Martin culture medium, NAAT has an excellent sensitivity and specificity, 95.2% and 99.4%, respectively.[63] This method, however, has a significantly lower sensitivity (ranging from 56% to 91% depending on the technique) for urine specimens and thus is not recommended by the CDC. Furthermore, urine specimens are not approved by the FDA for use on nongenital sites.[54]

Gonorrhea can be treated swiftly in the office with one dose of 125 mg of intramuscular ceftriaxone.[64] Over the past decade, increasing resistance to fluoroquinolones has been seen, and this is no longer recommended as an appropriate treatment regimen. Similarly, resistance has been seen for many other alternative regimens, including cefixime, which is given 400 mg orally once. In 2001, there were three cases of cefixime-resistant gonorrhea.[65] For this reason, providers should be aware of local microbiology and treat accordingly.

Syphilis

Syphilis, caused by the spherocyte *Treponema pallidum*, was once called "the great imitator" as a result of its nonspecific clinical presentation as well as its prevalence. The peak incidence in the United States was in 1946 when there were 66.6 new cases of syphilis diagnosed per 100,000 people.[66] Since then, the prevalence has fallen drastically through the widespread use of penicillin therapy and focused eradication efforts. In 2008, the incidence was 8.51 per 100,000 people.[1] Although this trend is overall reassuring, exploring the data from recent years has revealed that the number of cases of primary and secondary syphilis as well as congenital syphilis is slowly on the rise again.[67]

The clinical presentation of syphilis can be described according to its stage. Classically, primary syphilis presents as a singular painless lesion on the genitals after an incubation period of 2–3 weeks. This lesion originates as a macule and then progresses to a papule until it ulcerates and drains serous fluid. There may be associated non-painful inguinal lymphadenopathy. Generally, this will heal spontaneously in about 4–5 weeks. This lesion may occur in an inconspicuous site such as the vagina, so it may not be recognized by the patient.[68] Secondary syphilis may be seen 4–8 weeks later. Symptoms include a macular–papular rash on the palms and soles associated with general lymphadenopathy and malaise. Treatment is commonly sought at this time if not earlier; however, symptoms should spontaneously improve in 3–6 weeks if the patient remains untreated. Syphilis that remains

untreated can progress to early or late latent syphilis, which includes neurosyphilis and cardiovascular syphilis.

Diagnosis of syphilis is made by either serologic or direct testing. Serologic testing uses a series of tests: a screen and a confirmatory test. First a nontreponemal test such as Venereal Disease Research Laboratory or Rapid Plasma Reagin is performed by testing the patient's serum for reactivity against a cardiolipin–cholesterol–lecithin antigen. If this test is positive above a critical titer (generally 1:32), a specific treponemal test such as fluorescent treponemal antibody absorption (FTA-ABS) is reflexively sent. Although less commonly used, the diagnosis may be made by direct visualization of *T. pallidum* by dark-field microscopy or histopathologic staining using direct fluorescence antibody testing. These methods are limited by specific preparation requirements as well as the availability of trained technicians.[69]

Syphilis is easily treated in its early stages. Patients with primary, secondary, or early latent disease may be treated with 2.4 million units of intramuscular penicillin G once.[70] Patients with late syphilis require three doses at weekly intervals. If the duration of infection is unknown, it is presumed to be late, and the patient is treated with three doses of penicillin accordingly. Penicillin desensitization remains the optimal therapy for patients with penicillin allergies as there have been no reports of penicillin resistance. For those unable to tolerate penicillin, the suggested alternative regimen is doxycycline 100 mg orally twice daily for 14–28 days depending on the stage of disease. Previously macrolides, such as azithromycin, were commonly used; however, multiple resistant strains have emerged and thus this is no longer recommended.[71] The Jarisch–Herxheimer reaction is a known complication of therapy that occurs within the first 24 h. This acute febrile reaction associated with headache and myalgias is thought to result from lipopolysaccharides released from dying spirochetes. Patients are treated supportively.

Hepatitis B Virus

There is a relatively low prevalence of HBV in the United States with approximately 1.25 million chronic HBV infections and 200,000–300,000 new cases annually.[72] This represents approximately 0.2% of the U.S. population compared with endemic areas, such as Sub-Saharan Africa, where approximately 8%–25% of the population has an active infection.

HBV is transmitted by percutaneous, sexual, and perinatal contacts. In the United States, it is most commonly acquired in adolescence or young adulthood by percutaneous routes during IV drug use or sexual intercourse. There is an incubation period of 4 weeks to 6 months although approximately 50% of patients with HBV infection remain asymptomatic.[70] Those who do present for care note nonspecific symptoms, such as fatigue, anorexia, and jaundice. Physical examination will reveal hepatomegaly as well as splenomegaly. Of note, 5%–10% of patients may present with a serum sickness-like illness and rarely patients may present with fulminant liver failure.

Diagnosis is made by a series of serologic tests. The presence of hepatitis B surface antigen (HBsAg) is the marker for current infection. Antibody status to hepatitis B core (HBc) can differentiate acute from chronic disease. Those patients with IgM anti-HBc have an acute infection while those patients with IgG anti-HBc have a chronic infection. Hepatitis B e antigen (HBeAg) is a marker of high infectivity and is seen at the peak of viral load. This is replaced by anti-HBe within 2–3 months. Lastly, patients with anti-HBs, anti-HBe, and/or anti-HBc without a positive HBsAg have cleared the disease and are immune by prior infection. Of note, one would expect a vaccinated patient to have an isolated anti-HBs antibody.

Patients with HBV are generally referred to a hepatologist rather than managed by a primary care provider. Generally, the prognosis is encouraging. Ninety-five to ninety-nine percent of infected patients have a complete recovery. Without complete recovery, patients progress to chronic HBV with deleterious sequelae, such as hepatocellular carcinoma and cirrhosis. Risk factors for this progression include comorbid illnesses such as diabetes mellitus, congestive heart failure, immunosuppressive disease such as HIV, as well as young age.

Hepatitis C Virus

Hepatitis C virus (HCV) is most commonly an asymptomatic chronic disease. There are 2.7–3.2 million chronic HCV infections in the United States with less than 30,000 new cases annually.[72,73] These statistics highlight the near-universal incidence of chronic disease and the low clearance rate in those who are infected. In fact, HCV is the leading cause of chronic liver disease and the number one indication for liver transplant in the United States.

The spread of HCV is primarily through exposure to infected serum. The high-risk population includes IV drug users, recipients of blood transfusion or clotting factors prior to 1992, patients who have been on hemodialysis, and rarely health care workers with occupational exposures. There is a low rate (approximately 5%) of perinatal transmission. HCV appears to be transmitted sexually as well, but there is a much lower efficacy of seroconversion. For example, otherwise low-risk spouses of patients with chronic HCV infection have only a 1.5% conversion rate.[74] Screening for HCV has a place in STI screening, as 15%–20% of HCV patients report no exposure other than sexual contact.[75]

The incubation period for HCV is 2–12 weeks. As with HBV, most patients are asymptomatic but those who do present commonly complain of fatigue, fever, nausea, and vomiting. Chronic HCV will develop in 60%–85% of infected patients. Liver function tests (LFTs) will fluctuate in these patients; however, at any given time, approximately 60%–70% of chronically infected patients will have elevated LFTs.

Diagnosis is confirmed by serologic testing. Anti-HCV antibody represents prior exposure and usually develops within 8–9 weeks although may take up to 6 months. This test is performed by EIA and has 99% specificity and sensitivity,

although in immunosuppressed patients this antibody may never develop. Detection of HCV RNA confirms active infection. HCV RNA is quantified according to the World Health Organization international units (IU) per milliliter. This allows differentiation between high- and low-level diseases based on whether a patient's HCV RNA exceeds 800,000 IU/mL. The last laboratory test available, HCV genotyping, is not diagnostic but prognostic for a patient.

Patients with confirmed HCV should be evaluated and treated by a hepatologist. There are several treatment options including interferon, pegylated interferon, and ribavirin depending on a patient's genotype and comorbidities as these therapies have significant side effects. With regard to prognosis, 20% of patients will develop cirrhosis over two to three decades of infection. Once a patient develops cirrhosis, 1%–4% of cirrhotics will develop hepatocellular carcinoma annually.

Human Immunodeficiency Virus

HIV was first recognized by the CDC in 1981 with the first five cases diagnosed in Los Angeles. Since then, there has been a dramatic rise in the number of infections and a similarly impressive response from the research community allowing for effective treatment and drastically improved prognosis for these patients. Rates of HIV infection in the United States have not been directly measured, but advanced modeling estimates an incidence of 56,000 cases per year and a prevalence of 1.1 million patients as of 2006.[76,77] An estimated 21% of these cases are undiagnosed. These same models show a significantly increased risk of infection among black and Hispanic populations, as well as men who have sex with men.

HIV is transmitted by exposure to blood, vaginal secretions, semen, breast milk, as well as vertical transmission from mother to child. Approximately 31% of new infections are acquired through heterosexual contact, while 53% of new infections are acquired through male homosexual contact. Injection drug users represent 12% of new infections. Overall, women represent 27% of new infections.

Diagnosis is made by assessing HIV antibody status. Antibodies appear between 2 and 12 weeks after exposure. Initial testing is performed by EIA, which has a high sensitivity (>99.5%), and then confirmed by Western blot. There are a number of direct tests available, including the p24 antigen capture assay. This assay is used when initial testing is non-diagnostic and when infection must be detected prior to the development of antibodies such as in blood donors, as well as in a research capacity. Once infection is confirmed, a patient's disease course is followed by $CD4^+$ count and HIV RNA, indicating viral load.

HIV is a retrovirus that infects $CD4^+$ helper T cells resulting in immunodeficiency. Infection can be described in four stages: incubation, acute infection, latency, and AIDS.[78] The incubation stage, a period of 2–4 weeks, includes the time from exposure to initial symptoms. Acute infection is a manifestation of HIV viremia lasting approximately 4 weeks. Patients generally present with nonspecific viral symptoms including fever, generalized lymphadenopathy, pharyngitis, rash, and oral sores. During latency, patients are generally asymptomatic. This stage has a greatly variable duration, lasting from 2 weeks to indefinitely in a small group of patients termed "long-term nonprogressors." Generally, the median duration of latency is 10 years. HIV may then progress to its final stage, AIDS. This progression is defined by a decrease in $CD4^+$ cells to less than 200 cells/μL of blood or 14% of all lymphocytes as well as the presence of AIDS-defining illnesses (Table 71.4).[79]

TABLE 71.4
List of AIDS-Defining Illnesses

Candidiasis of bronchi, esophagus, trachea or lungs	Kaposi sarcoma
Cervical cancer that is invasive	Lymphoma that is Burkitt type, immunoblastic, or that is primary and affects the brain or central nervous system
Coccidioidomycosis that has spread	*Mycobacterium avium* complex or disease caused by *Mycobacterium kansasii*
Cryptococcosis that affecting the body outside the lungs	*Mycobacterium tuberculosis* in or outside the lungs
Cryptosporidiosis affecting the intestines and lasting more than a month	Other species of mycobacterium that has spread
CMV disease outside of the liver, spleen, or lymph nodes	*Pneumocystis jiroveci*, formerly called *carinii*, pneumonia
CMV retinitis that occurs with vision loss	Pneumonia that is recurrent
Encephalopathy that is HIV related	Progressive multifocal leukoencephalopathy
Herpes simplex including ulcers lasting more than a month or bronchitis, pneumonitis, or esophagitis	Salmonella septicemia that is recurrent
Histoplasmosis that has spread	Toxoplasmosis of the brain, also called encephalitis
Isosporiasis affecting the intestines and lasting more than a month	Wasting syndrome, caused by HIV

Treatment of HIV is directed by an infectious disease specialist. Since 1995, highly active antiretroviral therapy (HAART) has been the principal treatment. Recommendations from the U.S. Department of Health and Human Services are constantly evolving as the virus and the pharmaceutical industry progress. In general, HAART initiation may be considered in acute HIV syndrome, all pregnant women, patients with symptomatic disease, and patients with asymptomatic disease with $CD4^+$ T cell counts less than 350 cells/μL. Life expectancy is significantly increased with HAART, and recent studies have suggested that earlier initiation of this therapy may further prolong life expectancy.[80]

Herpes Simplex Virus

Infection with HSV results in genital and labial herpes. Approximately 50 million people, or one in four over the age

of 30, have genital HSV, although many infected persons are unaware.[81] Previously, HSV-1 was strongly associated with oral lesions while HSV-2 was associated with genital lesions. As a result of changing sexual practices, nearly 50% of new genital herpes is caused by HSV-1.[82] Transmission occurs by contact with the mucosal surfaces both while active lesions are present and through asymptomatic viral shredding.[83]

The incubation period is approximately 4 days. At the time of primary infection, patients present with painful genital lesions as well as tender inguinal lymphadenopathy. Classically lesions will form as macules and progress to form vesicles. Those on mucosal surfaces will ulcerate while those on keratinized skin will scab.[84] Constitutional symptoms such as fever and malaise appear in 40% of patients during a primary outbreak.[85] Rarely, significant neurological complications such as aseptic meningitis may be present at the time of primary outbreak. Of note, up to 25% of patients presenting with initial clinical infection may in fact be presenting with recurrent infection.[86] After resolution of the primary infection, the virus remains dormant in the neuronal bodies until it is reactivated. HSV is never cleared. Recurrent outbreaks may be preceded by prodromal symptoms such as pain or tingling.[87] Generally, these outbreaks are much milder with fewer lesions (6 vs. 16 lesions) and shorter duration (4 days vs. 11 days) as compared with primary infections.[85] Recurrence decreases over time, HSV-1 to a greater extent than HSV-2.[88]

Diagnosis is generally made by viral culture of an active lesion. Higher yield results from a primary vesicular lesion as compared with a recurrent or ulcerated lesion. PCR testing is available, which has a higher sensitivity and faster result than viral culture. Most institutions continue to use viral culture due to lower cost; however, when assessing for more acute conditions such as HSV meningitis, PCR is frequently used as an alternative. Serologic testing may be performed to evaluate whether disease is caused by HSV-1 or HSV-2; however, the mean time to antibody formation is 22 days and presumably these antibodies would be negative at the time of initial presentation.[89]

There is effective episodic treatment and prophylaxis available for HSV. At the time of presentation with a primary infection, patients should be treated with a 7–10 day course of oral antiviral therapy, such as acyclovir 400 mg three times daily, valacyclovir 1000 mg twice daily, or famciclovir 250 mg three times daily.[90] If neurological involvement is suspected, admission and workup by a neurologist are indicated. After the primary episode, patients should be counseled on the options for either episodic or suppressive therapy. Options for episodic therapy consist of acyclovir 400 mg three times daily, valacyclovir 500 mg twice daily, or famciclovir 125 mg twice daily all for 5 days. Another option includes suppressive therapy, which reduces outbreaks by 80% and reduces transmission by about 48%.[91] To reduce vertical transmission to the neonate, suppressive regimens are recommended by the ACOG for women with known HSV during the third trimester of pregnancy. Options for suppressive therapy include acyclovir 400 mg twice daily, valacyclovir 500 mg once daily, or famciclovir 250 mg twice daily.

Condylomata Acuminata

Condylomata acuminata, or genital warts, are caused by the HPV. Although there are over 100 strands of HPV, types 6 and 11 are responsible for 90% of anogenital lesions.[92] Exposure to this virus is extremely common. In fact, over 50% of sexually active women will be exposed to HPV over the course of their lifetime; however, not all exposed women will have clinically apparent disease.[93] The incidence of clinical disease is unclear as women do not always present for care; however, the CDC estimates that 1% of the sexually active population has active genital warts at any given time.[94] Risk factors for acquisition of HPV include new sexual partners, tobacco use, and oral contraceptive use.[95] After exposure to HPV, the incubation period is estimated at 1–3 months, but may be quite variable, making identification of the source of infection difficult for the patient.[96]

Diagnosis is made primarily by physical examination (Figure 71.1).[97] Lesions may appear on the external genitalia including vulva, perineum, and perianal skin, as well as on mucosal surfaces including cervix, vagina, urethra, and anal tissue. Lesions have a characteristic keratotic cauliflower-shaped appearance.[94] Biopsy and/or HPV testing is not required for diagnosis unless the diagnosis is unclear clinically.

Treatment is directed at elimination of all visible disease. There are multiple treatment options available, and the

FIGURE 71.1 Extensive bilateral Condylomata acuminata. (Reprinted from *Am. J. Obstet. Gynecol*., 189, 3 Suppl., Gunter, J., Genital and perianal warts: New treatment opportunities for human papillomavirus infection, S3–S11. Copyright 2003, with permission from Elsevier.)

treatment of choice will depend on the extent and the location of disease as well as patient preference. The first category of therapy is chemical destruction. Podophyllin and podophyllotoxin are antimitotic agents applied topically. The former is applied in the clinic by a physician once or twice a week while podophyllotoxin is applied by the patient with the following regimen: daily for 3 days with 4 days respite. This method is limited by neurotoxicity and chemical burns. It is contraindicated in pregnancy and on mucosal surfaces. Another method in the same category of chemical destruction is 80%–90% trichloroacetic acid. Again, this is irritating to the surrounding skin but may be used on mucosal surfaces and during pregnancy. Lastly, lesions can be treated with 5-fluorouracil gel, which acts as a pyrimidine antimetabolite. The second category of treatment is immune modulation. Imiquimod is a topical therapy that acts by induction of a cytokine response. It has both high clearance and low recurrence rates; however, it cannot be used on mucosal surfaces and it causes local erythema.[98] Interferon alpha is used for treatment of genital warts; however, it is not FDA approved for this purpose and is limited by its many associated side effects. Lastly, condyloma can be removed surgically using cryotherapy, laser, or excision. Excision allows examination of the tissue by a pathologist if there is concern for neoplasia or alternative diagnoses. Rate of recurrence after treatment is approximately 30%–70% after 6 months.[99]

Trichomoniasis vaginalis

Trichomoniasis is a form of vaginitis caused by the flagellated protozoa *Trichomoniasis vaginalis*. The incidence is around three to five million cases a year with higher rates in non-Hispanic black women and lower rates in non-Hispanic white women.[100] It is transmitted by sexual intercourse, although male partners have transient infection only. In vitro studies suggest that the incubation period is 4–28 days.[101]

Classically, patients present with green frothy malodorous vaginal discharge accompanied by pruritus and dysuria. Physical examination reveals discharge as described as well as punctate "strawberry hemorrhage" on the cervix.

Diagnosis can be made in the office with physical examination and wet mount microscopy, with the pH of the vagina elevated to 5.0–6.0. Saline microscopy reveals an inflammatory response with multiple leukocytes as well as mobile trichomonads. Trichomonads on wet mount may be absent in 30%–50% of cases.[102] If trichomoniasis is suspected but not confirmed with microscopy, culture may be sent on Diamond's medium or specimen may undergo rapid testing by DNA probe or monoclonal antibody depending on availability. Lastly, diagnosis may be made incidentally on liquid-based Pap tests. Although the sensitivity is low (61%), the specificity is high (99.4%) and thus a positive finding is an indication for treatment.[103]

Trichomoniasis is treated effectively with metronidazole or tinidazole.[104] Metronidazole regimens include 2 g orally once or 500 mg twice daily for 7 days. There are no established regimens for patients with allergies to 5-nitromidazoles and desensitization is recommended. Similar treatment regimens are used during pregnancy as metronidazole is not teratogenic although may cause significant nausea. Active trichomoniasis during pregnancy is associated with preterm delivery and preterm rupture of membranes; however, many clinicians do not treat asymptomatic pregnant women as this has not been shown to reduce these obstetric complications.[105]

Molluscum Contagiosum

Molluscum contagiosum is a viral skin infection caused by a virus in the *Poxviridae* family.[106] It can be transmitted by skin-to-skin contact and thus is commonly seen in school-aged children on exposed skin, although it avoids palms and soles. It is also transmitted during sexual activity resulting in genital and upper thigh lesions. There are few studies exploring the prevalence of molluscum as an STI. In patients with AIDS, there is a prevalence of 5%–18%.[107] Lesions are generally asymptomatic aside from cosmetic complaints. Physical exam reveals clusters of lesions that are 2–5 mm in diameter with a pearl appearance and central umbilication. Given their unique appearance, diagnosis is made clinically although skin biopsy may be used to confirm.

Providers have tried a variety of treatments including salicylic acid and tretinoin; however, no therapy has proven beneficial.[108] Lesions generally clear spontaneously in months in those with a healthy immune system. Individuals with immunosuppression are known to have a more recalcitrant infection. For this population, a provider may consider interventions similar to those available for genital warts, specifically topical imiquimod, optical podophyllotoxin, or excision.[109]

Pediculosis Pubis

Pediculosis pubis or pubic lice is caused by *Phthirus pubis*, the crab louse. The louse is 0.8–1.2 mm and may be seen with the naked eye upon close examination or more easily with microscopy (Figure 71.2).[110] Each louse lives for 3–4 weeks

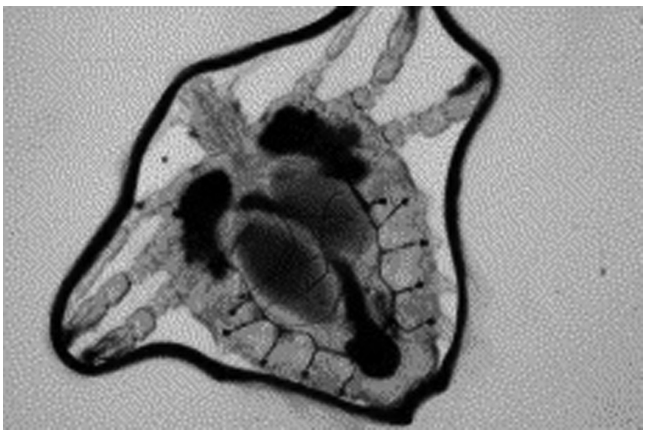

FIGURE 71.2 Crab louse in oil immersion. (Reprinted from *J. Am. Acad. Dermatol*., 50, Ko, C.J. and Elston, D.K., Pediculosis, 1–12. Copyright 2004, with permission from Elsevier.)

and lays approximately 25 ova. Pediculosis pubis is spread by sexual contact with an infected partner. Patients present with itching and occasionally maculae ceruleae, which are 5–10 mm bluish macules related to the bites of the louse. Diagnosis is made clinically with the assistance of microscopy. Treatment as recommended by the CDC consists of either topical permethrin (1%) or pyrethrins with piperonyl butoxide. Additionally, all bedding and clothing should be cleaned in hot water.

Chancroid

Chancroid is caused by a bacteria *Haemophilus ducreyi*, which results in painful genital ulcerations. Infection is rare; 14 women were diagnosed and reported to the CDC in 2008.[1] Lesions present after a 4–7 day incubation period. Lesions start as an area of erythema that evolves into a pustule and then into a non-indurated painful ulcerated lesion, approximately 1–2 cm in diameter. Women present with multiple vulvar lesions with a mean of 4.5 lesions, unlike men who generally present with a singular lesion.[111] Fifty percent of patients have tender unilateral inguinal lymphadenopathy. Occasionally, constitutional symptoms may be reported. Diagnosis is difficult as the *H. ducreyi* is difficult to culture, and few tests are commercially available. Culture has been the gold standard, but PCR is proving to be more sensitive (98% vs. 74%).[112] Given the difficulty of diagnosis, the CDC has developed guidelines for diagnosing definite versus probable disease.[113] Definite disease requires isolation of the organism whereas probable disease requires only an appropriate clinical history with confirmed exclusion of syphilis and HSV. Adequate treatment may be achieved with a single dose of either 1 g azithromycin orally or 250 mg ceftriaxone intramuscular. Given the high efficacy of these single-dose regimens, few providers are using multi-dosing regimens although they may be considered in the case of allergies or other contraindications.

INTRODUCTION

Bladder health is an important part of healthy aging. Lifestyle factors such as weight and diet can affect bladder health, so the primary care provider should have a basic understanding of the pelvic floor and bladder-related disorders. As our population ages, bladder health issues are becoming more common, and they can greatly impact a healthy lifestyle. An estimated 24% of women in the United States have some type of pelvic floor disorder. Pelvic floor disorders included urinary incontinence, pelvic organ prolapse (POP), and pelvic pain syndromes.[1] This is probably a conservative figure given that these disorders are widely underreported by both patients and physicians. It is also estimated that 10% of women in the United States have surgery for urinary incontinence, POP, or both during their lifetime.[2] These disorders carry tremendous psychosocial, medical, and financial burdens to patients and society[3] and increase with each decade of life. Therefore, with the lengthening of women's lifespan and the aging population, the incidence and relevance of these problems increase. To fully understand the pathology and treatment of pelvic floor disorders, one must first understand the anatomy of the pelvis. Therefore, this chapter will begin with a review of basic pelvic anatomy. This will be followed by a discussion of the three major pelvic floor disorders: urinary incontinence, POP, and pelvic pain syndromes.

PELVIC ANATOMY

The female pelvis consists of a group of muscles, ligaments, vasculature, and nerves, which work together to provide support and function to the pelvic organs: the bladder, urethra, uterus, vagina, ureters, and rectum. The bony structures include the ilium, ischium, pubis, sacrum, and coccyx. Ligaments, muscles, and fascia attach to various points on the bony pelvis.

The pelvis is composed of the minor and major pelvis. The pelvic diaphragm resides in the minor pelvis. It is composed of the levator ani and coccygeus muscles. The pubococcygeus, puborectalis, and iliococcygeus muscles together comprise the levator ani muscles. The pelvic diaphragm stretches between the pubic bone and the coccyx. The arcus tendineus is a dense connective tissue structure from which the levator ani originates. It runs from the pubic ramus to the ischial spine, extending along the surface of the obturator internus. The muscles of the pubococcygeus and puborectalis form the urogenital hiatus through which the urethra, vagina, and rectum pass. The levator ani consists of both type I (slow-twitch) and type II (fast-twitch) fibers. This allows for constant baseline tone, which supports the pelvic viscera, and voluntary contractions. Enervation of the levator ani muscle is primary from the third and fourth sacral nerve roots via the pudendal nerve.[4]

The perineum is made up of a superficial and deep compartments separated by the perineal membrane that provides support to the vagina and urethra, which pass through it. The boundaries of the perineum are the ischiopubic rami, ischial tuberosities, sacrotuberous ligaments, and coccyx. The muscles of the perineum include the bulbospongiosus muscles, superficial and deep transverse perinea, ischiocavernosus muscle, and posterior vaginal muscularis.[5–7]

Pelvic organ support is primarily from the pelvic muscles, while the connective tissue stabilizes the organs in their correct position. DeLancey and others have described the various levels of connective tissue that support the vagina. Level I is the uterosacral/cardinal ligament complex attaching the cervix to the sacrum and lateral pelvic sidewalls. This maintains the vaginal axis nearly horizontal so the lavatory plate can

support it. Level II consists of the paravaginal attachments to the arcus tendineus keeping the vagina midline. Level III is the most inferior support of the vagina and includes the perineal body, the perineal membrane, the perineal muscles, and endopelvic fascia.[4]

URINARY INCONTINENCE

Normal urinary continence involves a complex interaction of neuronal signaling pathways and muscle activity. As the bladder fills, afferent signals activate the sympathetic pathways, which stimulate smooth and striated sphincters and inhibit detrusor contraction. Continence is also enabled by pelvic floor musculature, which compresses the urethra when intra-abdominal pressure increases.[8] Urinary incontinence is defined as the complaint of involuntary leakage of urine.[9] There are several different categories of urinary incontinence including stress, urge, mixed, and other. This section will discuss factors that are common to all types of incontinence and then focus on the three most common types: stress, urge, and mixed. There are several other types of incontinence that are rare and require specific intervention. These will not be addressed in this chapter.

The prevalence of urinary incontinence increases with age, as do most pelvic floor disorders. Approximately 25% of women less than 50 years old demonstrate urinary incontinence compared with 34% of women over 50 years of age. This is likely an underestimation, as the condition is often embarrassing for both patients and physicians to discuss. The disorder is three times more common in women than in men until approximately age 80 when the rates become nearly even.[10] The financial cost of urinary incontinence is estimated to be higher than other medical disorders including breast cancer and eating disorders.[11] In the year 2000, approximately $20 billion dollars was spent in the United States alone on this disorder.[12] There are also the psychosocial implications of incontinence for patients, with adverse effects on women's quality of life, productivity, sexual function, and emotional well-being.[3] Studies have shown that the severity of incontinence is associated with increasing incidence of major depressive disorder.[13]

Although incontinence can occur in any age group and population, there are several risk factors that are common to all types of urinary incontinence. Childbearing and obesity are both well-known risk factors for incontinence.[14,15] Similarly, functional impairment is a risk factor more commonly seen in the elderly and handicapped populations, which increases their likelihood of incontinence.[16] High-impact physical activity, chronic straining, diabetes, stroke, depression, fecal incontinence, episiotomy, estrogen depletion, gynecologic surgery, pelvic radiation, and a childhood history of enuresis are other factors that have been demonstrated in population studies to have significant association with having urinary incontinence.[17,18]

Age is a particularly strong risk factor for urinary incontinence, although this is thought to be secondary to several factors. First, it is known that there is increased detrusor overactivity in the elderly population. Similarly, detrusor contractility, bladder sensation, and urethral pressure decline with age.[19,20] The elderly suffer from striated muscle loss, which impacts pelvic floor muscles and sphincter tone. In addition, postmenopausal women are often in a chronic state of low estrogen levels. This has been theorized to lead to atrophy of the urethral mucosal epithelium creating an atrophic urethritis leading to symptoms of urgency and frequency and a theoretical risk of diminished urethral seal due to decreased vascular flow.[21] It is valuable to recognize a patient's risk factors when beginning an evaluation of urinary incontinence.

The assessment of patients with complaints of urinary incontinence begins with obtaining a thorough medical history, including comorbidities, medications, and any recent changes. Concomitant anorectal or sexual dysfunction should be queried at the same time. A voiding diary can also be helpful in diagnosis.[22] The physical exam should include calculation of patient's BMI and cardiovascular exam to search for evidence of volume overload. An abdominal exam is recommended to locate any hernias that may be a sign of tissue weakness, masses, or muscle abnormalities. A neurological exam is important to investigate sacral nerve deficits such as loss of anal wink or bulbocavernosus reflex as chronic neurologic disorders can also impact urinary continence. In elderly patients, ambulation and manual dexterity should be checked to identify any functional impediments to continence.[23]

During the genital exam, atrophy or milder hypoestrogenism should be evaluated. Skin irritation may suggest the presence of prolonged incontinence. Vaginal infections, or other disease states, such as lichen sclerosis or lichen planus, could also impact patient symptoms. Bimanual exam will demonstrate any masses or tenderness that could be causing urinary symptoms. The physician can also evaluate the pelvic floor strength and anterior or posterior wall defects. A tender, hypertonic pelvic floor should also be noted. Presence of prolapse or urethral diverticulum should also be assessed. The rectal exam will evaluate for sphincter tone, masses, or fecal impaction.[4]

There are several simple and inexpensive tests that can be performed in the office to further evaluate a patient with urinary incontinence. An empty supine stress test (ESST) can be carried out during the pelvic examination. With an empty bladder, the patient is asked to perform a provocative maneuver such as cough or strain either supine or standing. The physician then observes the urethra for any leakage of urine. A positive ESST has been thought to indicate increased severity of leakage. Immediate loss of urine may signify stress incontinence while a delayed leak often indicates uninhibited bladder contractions.[22] If there is a question, based on the history and physical, about whether the patient is in fact leaking urine, a pyridium pad test is also a simple and inexpensive way to distinguish between urine and other types of discharge. In this test, the patient takes oral pyridium and then wears a pad. She is asked to monitor her pad for orange staining indicating leakage of pyridium-stained urine. The Q-tip test is another inexpensive test that

can help look for urethral hypermobility. During this test, a lubricated Q-tip is inserted into the urethra to the level of the urethrovesical junction while the patient is in lithotomy. The angle between the Q-tip and horizontal is measured. The patient is asked to strain and the angle is measured again. Normal change is 30°. If the change is greater than 30°, this can suggest hypermobility of the bladder neck and therefore stress urinary incontinence (SUI). Although it can be helpful to quantitatively assess mobility, this test can be uncomfortable, and some women demonstrate hypermobility without incontinence symptoms.[24]

Checking a post-void residual volume in patients is a simple way to ensure that urinary retention of obstructive or neuropathic etiology is not the cause of the patient's incontinence. Volumes less than 50 mL are considered normal and greater than 100 mL are generally considered abnormal, although older women are often given more leeway and measurements up to 150 mL may be considered normal in some elderly patients. Volumes between 100 and 200 mL should be repeated. Finally, a urine analysis and culture is an inexpensive test to look for urinary tract infection (UTI) or other abnormality. A UTI can cause symptoms of urgency, frequency, and incontinence.

For more complicated clinical pictures, urodynamics can be utilized to provide further information on bladder function. Similar, cystoscopy can be considered if there is any concern of malignancy or other bladder abnormality, especially if symptoms are of sudden onset or accompanied by hematuria in the absence of UTI.[24] Urodynamics can be performed if a patient is contemplating surgery or there is a complicated clinical picture.

Therapy for incontinence varies depending on the type of incontinence. However, there are several noninvasive approaches that can be initiated regardless of the incontinence type. Weight loss, for example, has been demonstrated to help obese and overweight women suffering from urinary incontinence.[25] Dietary changes to eliminate known bladder irritants such as alcohol, carbonated beverages, coffee, and tea can also be helpful. Similarly, fluid intake modification may also address patients' complaints of frequency, urgency, nocturia, or nocturnal enuresis. Bladder retraining with timed, frequent voiding and learning pelvic mechanisms to inhibit urges are often useful in addressing incontinence.[26,27] Pelvic floor muscle physical therapy has been demonstrated to be helpful in the treatment of urinary incontinence in a variety of settings.[28] The success of physical therapy has been well demonstrated in women suffering from incontinence during pregnancy, postpartum, as well as other phases of life. The main obstacles with this therapy are often the time commitment required and locating a trained pelvic floor physical therapist in the area, as well as issues with adequate insurance coverage.[29,30] Setting up the environment for older women to facilitate access to the bathroom and prevent falls is also helpful.

Prevention is important and can make a difference in bladder health. Educating patients on good bladder habits and methods can prevent some urinary incontinence. This can begin with general lifestyle modifications, which improve their overall health. Weight loss, smoking cessation, increased exercise, dietary modifications, and treatment of chronic coughs and constipation are all helpful in the prevention of urinary symptoms. The patient can also perform pelvic floor muscle strengthening exercise such as Kegels as a preventive measure. Management or prevention of associated comorbidities, such as diabetes and other neurologic disorders, can also help prevent the development of urinary incontinence. Finally, instruction on healthy voiding habits is quite important, with an emphasis on adequate but moderate fluid intake, avoidance of straining with voiding or bowel movements, and regular soft bowel movements, which are all helpful in preventing the development of urinary incontinence in patients.[31]

STRESS INCONTINENCE

SUI is defined as the complaint of involuntary leakage of urine on effort or exertion, or on sneezing or coughing.[9] It is most often secondary to bladder neck hypermobility along with weakening of the striated sphincter with or without intrinsic sphincter deficiency.[24] During increased intra-abdominal pressure, the bladder and neck and proximal urethra drop below the retropubic space, and there is uneven distribution of abdominal pressure to the bladder but not the urethra due to loss of anatomic support. Often described as a hammock, the anterior vaginal wall and endopelvic fascia are attached laterally to the arcus tendineus and levator ani muscles creating a support structure for the urethra and urethrovesical junction. This hammock can be damaged during events such as childbirth. This leads to failure of optimal urethral compression with increased intra-abdominal pressure and resulting leakage of urine.[32] Intrinsic sphincter deficiency refers to failure of the urethral sphincter to close appropriately during times of stress. There are multiple factors that can cause this including trauma during childbirth, hypoestrogenism, neurologic disease, radiation exposure, scarring from prior surgery, and medications.[33]

The treatment of SUI varies depending on severity and patient goals. Conservative treatment can begin with the modifications mentioned earlier including treatment of medical comorbidities, decreased fluid intake to 2–3 L a day, avoidance of bladder irritants, and pelvic floor physical therapy. Biofeedback has not been demonstrated to produce any added benefit to physical therapy.[34] Elderly patients may elect to simply use absorbent pads.

Vaginal devices such as pessaries or urethral inserts are other treatment options for patients with SUI. The pessaries come in a wide range of styles and sizes; however, the ring type is often the most useful.[35] They sit under the neck of the bladder for support. Urethral occlusive devices are less popular, but can be inserted into the urethral meatus to achieve mechanical occlusion of the urethra. However, they can be irritating and pose a risk for infection. These options are often helpful for women who wish to avoid or delay surgical intervention.[36]

Medical management of SUI is another option although modestly effective. Although hypoestrogenation is thought to be a contributor to SUI in postmenopausal women, the data on estrogen replacement for treatment have been varied. Data on oral hormone replacement have demonstrated that it can actually worsen symptoms of urinary incontinence.[37] The role of topical estrogen remains unclear.[38] Alpha-adrenergics are a class of medications that act on sympathetic nervous system to increase the tone of the urethra and bladder neck. These have been associated with only modest improvements in symptoms and significant systemic side effects including hypertension, anxiety, headaches, and insomnia.[39] Duloxetine is a combination of serotonin and norepinephrine reuptake inhibitors, which had been shown to enhance the external urethral sphincter contraction.[40] However, a Cochrane clinical review demonstrated that any beneficial effects of the medication are transient and side effects can be quite serious.[41]

Urethral bulking agents are an attractive option for women who are not candidates for surgery or who have failed surgery. This can be done via local anesthesia in the office. The injections are transurethral or via paraurethral through perineal injections. There are multiple bulking agents available including silicone, saline, and collagen. Although the majority of women experience an initial relief of symptoms after treatment, many agents are biodegradable; therefore, the effect is transient.[42] Short-term cure rates are as high as 70%, and long-term rates fall to around 20%–30%. Women also require repeat injections.[43] When compared to surgical method of treatment, bulking treatment is less effective.[44]

Surgery for SUI is the most common treatment as it offers the most sustainable results. Several considerations should be evaluated prior to initiation of surgery. Coexistent urge incontinence is not a contraindication for surgical correction of SUI; however, patients should be counseled that the procedure could in fact worsen their other symptoms. In addition, women with concomitant POP should have both anti-prolapse and anti-incontinence procedures performed simultaneously because this will afford improved outcomes.[43–45]

There are a variety of surgical options available for women. Abdominal retropubic suspension procedures have been utilized for decades in the treatment of SUI. These surgeries work by elevating and fixing the bladder neck and proximal urethra in a retropubic position to enhance support. There are three main variations of the repair: the Burch, Marshall–Marchetti–Krantz, and paravaginal defect repair.[46] The most widely utilized approach is the Burch colposuspension; it also has the highest long-term success rates.[47] Given the higher success rates and lower complication rates, the Burch procedure is preferred to the Marshall–Marchetti–Krantz and paravaginal defect repair.

Vaginal approaches to SUI include anterior colporrhaphy with suburethral plication to elevate the bladder neck. This procedure has been shown to have limited long-term success rates.[24] Bladder neck needle suspension procedures are another option in which sutures are passed through the periurethral tissue near the bladder neck and then to the suprapubic space and rectus fascia. The sutures are tied over the rectus fascia to suspend the proximal urethra and bladder neck. This also has been shown to have poor long-term success rates and therefore is no longer a favored option of treatment. A Cochrane systemic review demonstrated that the open retropubic colposuspensions have lower failure rates than bladder neck needle suspensions, anterior vaginal repairs, and laparoscopic suspensions.[47] Other methods include bladder neck slings, mid-urethral slings, and injection of urethral bulking agents. The bladder neck slings involve placement of a sling under the bladder neck and urethra and fixation of the ends to the anterior rectus fascia.[24]

Tension-free mid-urethral sling procedures have been shown to be highly effective with minimal complications and are rapidly becoming the surgical treatment of choice for SUI, rapidly replacing Burch procedures. There are two different techniques: the tension-free vaginal tape (TVT) and the tension-free transobturator tape (TVT-O).[48] In the TVT procedure, small midline suburethral incisions are made in the vaginal mucosa. A synthetic polypropylene tape is placed at the level of the mid-urethra and extended bilaterally behind the pubic symphysis and through the fascia and suprapubic dermis using thin trocars. TVT-O differs by avoiding the retropubic space and passing through the obturator foramen. The latter method has been demonstrated to have lower rates of urinary tract injury, voiding dysfunction, and blood loss when compared with the TVT.[49] Mid-urethral slings are as effective as other surgical treatments for SUI but with shorter operative time and fewer postoperative complications, therefore the surgical treatment of choice for many surgeons.[48] Risks however include the risk of mesh erosion or infection as well as thigh pain with TVT-O.

URGE INCONTINENCE

Urge incontinence is defined as the involuntary leakage of urine accompanied by or immediately preceded by urgency. This differs from overactive bladder, which is a symptomatic diagnosis where patients have symptoms of urgency with or without urge incontinence.[9] This disorder is largely due to detrusor over activity.[50] A related disorder in the elderly is detrusor hyperactivity with impaired contractility. These patients experience urgency in combination with a high postvoid residual.[51]

There are multiple etiologies for urge incontinence. Neurologic diseases such as multiple sclerosis, Parkinson's disease, or spinal cord injuries can lead to detrusor hyperactivity. Local bladder or urethral irritants such as sutures or malignancies can be a cause. Medications, particularly parasympathomimetics, can cause a sensation of urinary urgency. Bladder outlet obstruction can also lead to symptoms of urgency; this is often seen in patients with advanced POP. Unfortunately, the vast majority of cases are due to an unknown etiology. There is likely a myogenic dysfunction of the detrusor muscles leading to spontaneous contractions.[52]

There are a variety of treatment options available for patients suffering from urge incontinence. Prior to initiating

treatment, patients should be counseled that up to 5.6% of patients suffering from urge incontinence experience spontaneous remission per year.[53] Intervention can be conservative at first with fluid management, bladder retraining, and physical therapy.[54] Pharmacologic therapy is primarily antimuscarinics, which increase bladder capacity and decrease urgency.[55] These medications have consistently been shown to be more effective than placebo in multiple randomized control trials, with a 40% or higher cure rate.[56] There is no definitive literature to suggest that one antimuscarinic is better than another.[57] Unfortunately, discontinuation rates are high, averaging around 60% at 6 months, given the multiple systemic side effects patients experience.[58] Common side effects include dry mouth, vision changes, tachycardia, drowsiness, and constipation. Constipation and dry mouth can often lead patients to increase fluid intake and strain, which may worsen their urinary symptoms. These medications are also contraindicated in patients with gastric or urinary retention and angle closure glaucoma. There is controversy regarding using this class of medication in elderly patients with dementia due to concern for aggravation of symptoms. If prescribed for the elderly, the lowest dosage possible should be utilized.[59]

Botulinum toxin A injected into the detrusor muscles is a newer therapy for urge incontinence patients with symptoms refractory to oral pharmacologic and behavioral therapy. The exact mechanism of action of botulinum toxin in the bladder is unclear, although evidence suggests that it may work by preventing the presynaptic release of acetylcholine from the parasympathetic innervations to the bladder and may have an effect on sensory mechanisms. The data are limited primarily to case series but results have been encouraging.[60] The concern with this treatment is urinary retention and need for intermittent self-catheterization; therefore, proper counseling of this risk is important prior to initiation of treatment.[61]

There are various neurologic stimulation therapies that can be utilized to treat urinary urge incontinence by stimulating or modulating pelvic and/or detrusor muscles. The most noninvasive option is a removable stimulation device in the vagina or the anus. It is thought to work by stimulating the periurethral striated muscles and the pudendal nerve, which thereby inhibits detrusor muscle activity. Results have been inconclusive with no clear benefit over behavioral therapy.[62]

Sacral nerve stimulation has had higher success rates. The stimulators are thought to act by innervation of afferent fibers to the detrusor, which inhibit spinal and supraspinal signals, leading to muscle relaxation. However, the exact mechanism of action is unclear. In this procedure, percutaneous electrodes are placed adjacent to the S3 dorsal roots. Patients then undergo a 1–2 week trial. If they have an improvement in their symptoms, patients return for permanent lead implantation and placement of a pacemaker-like stimulator under the skin of the buttock. Cure rates have been reported to range between 47% and 56% among patients who have failed other therapeutic options.[63] Unfortunately, the majority of the data available are from case series rather than randomized control trials. Adverse events are uncommon but include migration of the electrodes, pain, infection from placement, and occasional transient electric shock.[64]

Percutaneous stimulation of the tibial nerve stimulation is another alternative for patient refractory to other therapies. The data on the efficacy are limited. Most studies suggest limited benefit over pharmacologic management.[65]

Surgical treatment is generally not an option for patients suffering from urge incontinence as the procedures have limited success and high morbidity. For patients who have failed all other treatments, bladder denervation, bladder augmentation, and urinary diversion may be attempted. However, these are procedures of last resort, and their usefulness remains controversial.

MIXED INCONTINENCE

Mixed incontinence is the complaint of involuntary leakage of urine associated with urgency and also with exertion, sneezing, or coughing.[9] Patients exhibit components of stress and urge incontinence. It is often challenging to determine which therapeutic option is most appropriate for these patients. Treatment usually begins with conservative measures, which are common treatments for all types of incontinence, such as pelvic floor physical therapy. Electrical stimulation has also been shown to be helpful in this population.[66] The majority of these patients have one symptom that is more bothersome and generally receives treatment for that symptom, or a combination of treatments to address all their symptoms.

PELVIC ORGAN PROLAPSE

POP is defined as the herniation of one of pelvic organs (uterus, vaginal apex, bladder, rectum, or small bowel) from its normal location. The degree of prolapse is graded on a 0–4 scale in relation to the hymenal ring, with 0 being no prolapse and 4 complete prolapse often referred to as procidentia. There are various types of prolapse including upper vaginal prolapse (uterus or vaginal vault), anterior vaginal wall prolapse (bladder or urethra descent or pelvic fascia defect), or posterior vaginal wall prolapse (descent of the small bowel or rectum or perineal deficiency).[67] Twenty-four percent of women in the United States are estimated to suffer from POP.[1] There are an estimated 200,000 prolapse repair surgeries per year, with an annual cost exceeding $1 billion.[68,69]

There are multiple risk factors for POP. There appears to be a genetic predisposition to the disease. Parity, particularly vaginal births, occipital posterior position, and instrumental delivery are known risk factors.[70] There are some data that a cesarean delivery may be protective when compared to vaginal delivery; however, other data suggest that pregnancy itself, regardless of mode of delivery, is a risk factor.[71] Like many other pelvic floor disorders, obesity and advanced age increase the likelihood of developing POP.[72] Estrogen deficiency, connective tissue disorders, and prior pelvic surgery have also been associated with POP. Chronic increased intra-abdominal pressure such as chronic constipation or

cough (COPD) can also be associated with POP.[73] Women with hypermobile joints have been shown to have a higher prevalence than women with normal joints, suggesting that collagen abnormalities may contribute to prolapse.[74]

Patients exhibit a variety of symptoms depending on the location of prolapse. The most common complaint is a feeling of heaviness or pressure in the vagina. Urinary symptoms are often indicative of anterior wall prolapse, which comprise approximately 40% of prolapse.[75] Symptoms of defecatory dysfunction usually imply posterior wall prolapse, which occurs about 7% of the time. The majority (47%) of patients have a combination of anterior, posterior, or apical prolapse.[2]

Physical examination should be done with patients in both lithotomy and upright to visualize the maximal prolapse descent. The Pelvic Organ Prolapse Quantification system (POP-Q) is the standardized prolapse grading mechanism. Various points are recorded both at rest and with Vaslava to create a map to grade patients prolapse and measure treatment response. A rectovaginal exam should always be included to look for evidence of an enterocele, rectovaginal connective tissue defects, perineal deficiency, or masses.[76]

Prior to initiating treatment for POP, the clinician must first ascertain patient goals. The primary predictor of patient satisfaction is achievement of individual patient goals.[77] Mild prolapse has been shown to spontaneously resolve in some women or at least not be as symptomatic. Conservative management begins with weight loss, pelvic floor physical therapy, and behavioral modification including bladder retraining as needed and dietary modifications to improve bowel function and decrease chronic straining.[78]

There are multiple surgical options available for patients suffering from POP. The choice of procedure depends on the severity and location of prolapse, urinary or bowel symptoms, general health of the patient, sexual function of the patient, surgeon experience, and need for additional procedures. There are laparoscopic, vaginal, and abdominal techniques that can be utilized. One of the most common repair procedures is an anterior colporrhaphy. This entails placating the vaginal muscularis and adventitia overlying the bladder or plicating and reattaching the paravaginal tissue to reduce to the protrusion of the bladder and vagina. Cochrane review analysis has demonstrated that the anterior repair with the use of vaginal mesh may confer more successful repair than that without mesh.[67] However, vaginal mesh erosion rates have been reported between 2% and 11%, which can cause pain, bleeding, and need for reoperation. Therefore, it is imperative for physicians to counsel patients on the risks of the procedure prior to initiating surgery.[79]

Another option is a paravaginal repair. In this procedure, the detached lateral vagina is reconnected to the normal place at the level of the arcus tendineus. This can be accomplished vaginally or via a retropubic approach. Long-term results of these procedures have been disappointing.

Similar procedures are available for posterior defects. For instance, a posterior colporrhaphy is a procedure in which the tissue underlying the vaginal mucosa is plicated in the midline, increasing the fibromuscularis tissue in the midline of the posterior vaginal wall. A variant on this procedure is a site-specific defect repair. As the name implies, defects in the fibromuscularis are individually isolated and repaired. Graft augmentation is another variation to augment support of the posterior vaginal wall. Perineorrhaphy is often done with a posterior repair. During this procedure, the bulbospongiosus muscles and the transverse perineal muscles are plicated in order to recreate or fortify the perineal body.[67] These procedures are most helpful for localized defects or distal stool trapping requiring splinting.

Laparoscopic, vaginal, and abdominal approaches are possible for apical prolapse. Vaginal procedures offer relatively quick recovery when compared to abdominal procedures. The best studied vaginal procedure for apical prolapse is a sacrospinous ligament suspension. This procedure has a low failure rate (2%–11%) when performed for apical prolapse.[80] During this procedure, the sacrospinous ligament is sutured to the posterior vaginal muscularis.[81] The procedure is traditionally performed unilaterally. The most common complication is bleeding usually arising from the pudendal vessels, which are in close contact with ligament. Pain has also been reported due to the proximity of the pudendal and sciatic nerves. Subjective success rates have been reported to be as high as 90% from this procedure.[82] Iliococcygeus suspension is a similar procedure that secures the posterior vaginal muscularis to the iliococcygeus fascia rather than the sacrospinous ligament. It was thought that this procedure has less incidence of anterior vaginal wall prolapse recurrence than sacrospinous ligament fixation; however, studies have demonstrated that the two procedures have equal success and recurrence rates.[83] McCall culdoplasty is a technique often done at the time of vaginal hysterectomy to repair an enterocele and close the redundant cul-de-sac. It has also been shown to provide apical support by bringing the posterior vaginal cuff and peritoneum to the uterosacral ligaments bilaterally, thereby obliterating the dependent portion of the cul-de-sac. The most frequent serious complication of a McCall Culdoplasty is damage to the ureters.[24]

Uterosacral ligament suspension is another apical prolapse repair procedure in which the vaginal apex is elevated via attachments to the uterosacral ligaments. This procedure can be performed laparoscopically, abdominally, or vaginally. Subjective success rates have been reported up to 98% for apical prolapse.[84] A sacral colpopexy is the most common abdominal prolapse procedure and can also be performed laparoscopically. It is the most durable procedure due to the use of mesh for attachment and is considered by many to be the gold standard for prolapse repair. During this procedure, a Y-shaped graft is attached to the anterior and posterior vagina, and the arm of the graft is then attached to the anterior longitudinal sacral ligament. Success rates of up to 95% have been reported at 2 years postoperatively.[85] Various materials have been used for the graft in colpopexy, both natural and synthetic. Most studies indicate that cadaveric fascia is associated with a higher rate of recurrent prolapse than synthetic mesh (ref). However, increased durability comes with a 3%–4% mesh erosion and other mesh complications. Mesh

erosion rates can be as high as 14% when mesh is placed following a total hysterectomy.[22] For this reason, supracervical hysterectomy has become more common when planning for a sacrocolpopexy. Intraoperative complications are rare but can be serious such as bleeding, which can be difficult to control.[67] Also delayed bowel issues such as ileus, obstruction, or other intra-abdominal issues can be encountered with this route of repair.

With advancements in technology and surgical tools, more procedures formerly done via an abdominal incision are performed laparoscopically. This same trend is also evident with pelvic floor reconstructive procedures. Laparoscopic surgery offers the advantages of shorter hospital stay, decreased postoperative pain, and improved cosmesis.[86] Robotic surgery is another minimally invasive method to perform these procedures. There has been minimal prospective literature on this method; however, the results of numerous small studies on robotic sacrocolpopexy are encouraging.[86]

Vaginal mesh procedures have also been performed with increasing frequency. Although anatomic cure and durability are good, there remain questions on complications such as more common mesh erosions and intractable pain.

There are also obliterative procedures for women who do not desire future vaginal intercourse and/or have poor general health. In comparison with reconstructive surgery, postoperative patient satisfaction rates are similar.[87] The procedure consists of removing all the vaginal epithelium. The leading edge of prolapse is identified and successive interrupted sutures are used to reduce the prolapse until it lies above the levator plate, obliterating the vaginal canal. A wide perineorrhaphy is then created with a "butterfly"-shaped incision and the levator muscles are reapproximated, closing the area from above the rectum to the urethrovesical junction. Possible complications included SUI, which is likely secondary to incidentally pulling the posterior urethra down when suturing the anterior and posterior vagina.[88]

Studies comparing different surgical options demonstrate that each has its own strengths and weaknesses. For instance, a meta-analysis comparing abdominal sacral colpopexy versus vaginal sacrospinous colpopexy found that the abdominal procedure was better than the vaginal sacrospinous colpopexy in terms of recurrent vault prolapse, postoperative dyspareunia, urinary retention, and postoperative urinary stress incontinence. However, the abdominal procedure was also associated with longer operative time, recovery time, and increased cost.[89]

Given the multitude of surgical options, it is the responsibility of the provider to advise which procedure would be most appropriate for a particular patient with appropriate informed consent and to offer choices with regard to approach. For instance, a medically unstable patient who is not sexually active would most be best treated with an obliterative procedure. However, a young active women may prefer a laparoscopic sacrocolpopexy given its fast recovery time and durability. In addition, it is important to discuss potential complications and issues that are related to the use of mesh for pelvic reconstructive surgery.

INTERSTITIAL CYSTITIS/PAINFUL BLADDER SYNDROME

Interstitial cystitis (IC) or painful bladder syndrome (PBS) is a poorly defined syndrome of bladder pain associated with filling and/or emptying and is usually accompanied with urgency, frequency, and nocturia.[90] It is a disease of exclusion with a poorly understood etiology, which has led to an unclear consensus on treatment.[91] It is difficult to estimate the incidence of the disorder given that there are variable definitions. Estimation of prevalence ranges from 10 to 865 cases per 100,000 people.[92] The National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) attempted to create a standardized criterion in 1987. However, it is estimated that this criterion misses an estimated 60% of patients. The NIDDK criterion is primarily used in research settings, and often the diagnosis is made clinically using patient symptoms and exam findings.[93] IC/PBS patients are usually middle aged with a mean age of diagnosis of 42–45 years old.[94] However, patients can be of any age. There is also an association between IC/PBS and other chronic pain disorders including, endometriosis, vulvodynia, irritable bowel syndrome, fibromyalgia, chronic fatigue syndrome, and allergies.[95]

The pathophysiology behind IC/PBS is poorly understood. The etiology of IC/PBS is likely multifactorial; however, multiple theories exist. One hypothesis is that there are urothelial abnormalities, particularly a deficiency of the glycosaminoglycan layer (GAG), which are visualized on bladder biopsy, and these abnormalities lead to patient symptoms. However, it is difficult to establish a causal relationship and assume that the disease itself did not cause the urothelial abnormalities.[96] Another theory is that these patients have an increased sensory awareness making them more sensitive to normal bladder filling, as in allodynia. Central neurological upregulation and increased activation of bladder sensory neurons may initiate and propagate patient's symptoms and heighten sensitization.[97]

Patients suffering from IC/PBS often present with complaints of urgency, frequency, and pain around the area of their bladder. The pain may be modified by voiding habits, intercourse, or foods. It can wax and wane with periods of flair and remission. The first diagnostic step is to rule out other possible causes for the patients' symptoms including infections, mass, urinary stone, or malignancy. Tests to consider include a urinalysis with possible cytology and cystoscopy to look for any masses or physical abnormalities. In the past, hydrodistension was thought to be necessary to look for characteristic markers of IC including glomerulations and Hunner's patches. However, these findings are now considered to be nonspecific as they are found in 45% of healthy patients; therefore, hydrodistension is no longer necessary for diagnosis.[98] Similarly, the potassium sensitivity test is also no longer recommended for diagnosis given that the results are nonspecific. In this test, the bladder is filled with water, drained, and then filled with potassium chloride. Increased pain with potassium chloride is considered suggestive of IC/PBS. However, up to 46% of patients with negative

potassium sensitivity tests still have IC/PBS.[99] Therefore, given the lack of sensitivity and the discomfort associated with the test, it is no longer recommended.[100] Bladder biopsies are done if necessary to exclude other disorders.[101] Currently, investigations are under way to look for biomarkers that may help with diagnosis.[102]

Prior to initiating treatment, patients should be asked to complete a voiding diary and symptoms scale. The voiding diary will help establish a baseline for frequency, urgency, and bladder pain. A symptoms scale will help quantify the patient's symptoms and evaluate their response to treatment. There are various validated symptoms scales including the O'Leary IC Indices, the University of Wisconsin IC Scale, and the Pelvic Pain and Urinary Urgency and Frequency Scale.[24]

Currently, there is no "cure" for IC/PBS. However, treatment options are available that can effectively mediate symptoms and provide long-term relief. Given that this is a chronic pain disorder, many patients benefit from support groups. Patients can immediately begin with behavioral therapy such as bladder retraining with timed voiding for frequency symptoms. Avoidance of exacerbating triggers such as spicy foods or other patient-identified foods or activities can be initially helpful. Pelvic floor physical therapy has also been shown to be helpful in this patient population.[103]

Pharmacologic treatment modalities include pentosan polysulfate. This medication may be helpful in reconstituting the GAG layer, which is believed to be leaky in these patients.[103] Meta-analysis of randomized control trials of the agent has found it to be modestly more effective than a placebo. Another oral therapy used is amitriptyline. Often used to treat other chronic pain syndromes, several randomized control studies of this medication have demonstrated an improvement in patient symptoms.[104] Gabapentin is becoming increasingly used to treat pain in IC/PBS patients; however, data are still very limited on its efficacy.[105] Since some theories have suggested that mast cells cause the release of neuroactive and vasoactive agents responsible for IC/PBS symptoms, treatment directed at mast cells have been tried to alleviate this inflammatory response. However, recent data on medication such as hydroxyzine demonstrated that it has no clear benefit over placebo.[106] Cimetidine was found to have a minor benefit, but this was only seen in small studies.[107]

As hydrodistension has be used for diagnosis, it has also been used as a form of treatment for some patients. Thirty to fifty-four percent of patients have improvement of symptoms after hydrodistension of the bladder. Patients who have improvement for 6 months or greater are candidates for repeat therapy.[108] However, since symptoms often recur quickly and there have been concerns about distension injury to the bladder, hydrodistension is much less commonly used.

Bladder instillations are the next line of treatment for patients who fail oral therapy. The instillations are done via a catheter and usually left in the bladder for 20–30 min. Treatments are usually given once a week for a series of 6 weeks. Dimethyl sulfoxide (DMSO) is the only Food and Drug Administration-approved intravesical treatment of IC. It was shown to be beneficial in two randomized control trials reviewed in a review paper on pharmacologic treatment of IC.[109] DMSO has anti-inflammatory and analgesics effects. It is also thought to cause muscle relaxation and mast cell inhibition. It can be used alone or in combination with heparin, triamcinolone, and sodium bicarbonate.[110] Sodium pentosan polysulfate can also be used as a bladder instillation. This has equal efficacy as the oral method, although symptoms are relieved faster.[111] Steroids have also been utilized in this fashion with the thought that that they can help IC symptoms with their immunosuppressive properties. Heparin and local anesthesia can be used in combination or alone. Heparin may help replenish the GAG layer in the bladder's urothelium. Local anesthetics such as lidocaine produce a significant response but are generally short-lived improvement in symptoms. Instillations of various "cocktails" are often used for symptom relief. Patients who respond to these instillations can be taught to catheterize and administer them at home. Intravesical hyaluronic acid has shown to have a significant response rate for up to 6 months. It is thought to coat the lining of the bladder and protect it from irritating substances. Bacillus Calmette-Guerin is an immunogenic agent used to treat bladder cancer and is under investigation for instillation therapy. Randomized control trials fail to show a statistically significant improvement in symptoms among patients treated with the medication.[112] Botulinum A toxin has been utilized as a possible intravesical treatment option. In one study comparing hydrodistension versus hydrodistension with botulinum toxin, greater improvement in symptoms was found among patients treated with botulinum toxin. However, botulinum A toxin for IC remains investigational.[113]

Multiple small studies have investigated sacral neuromodulation as a treatment option for patients refractory to the earlier-mentioned treatment options. There have been mixed results with some prospective studies on sacral neuromodulation demonstrating promising results, while a prospective randomized control trial on tibial nerve stimulation demonstrating no difference from placebo.[114,115] Surgical therapy is considered a last resort for patient, given the morbidity and poor efficacy. Surgical options include laser fulguration of Hunner's ulcers, cystectomy, and bladder augmentation. All have low success rates and high rates of recurrence and morbidity.[24]

CONCLUSION

Pelvic floor disorders affect women of all ages, races, and backgrounds. This chapter focused on the preventive lifestyle and health modifications to maintain bladder health and the evaluation and treatment of the three most common pelvic floor conditions: incontinence, prolapse, and pain. These disorders have significant and important effects on the quality of life for many women. Simple preventive strategies include control of constipation, chronic coughs, or chronic straining. Pelvic floor muscle strengthening can also preempt these disorders. The treatments discussed in this chapter can be initiated only after the disorders are properly diagnosed. It is the responsibility of physicians to inquire about pelvic floor issues and symptoms as patients are often reluctant to report them.

Increased awareness and education of both physicians and patients about the frequency of these disorders, bladder health-related lifestyle modifications, and the array of available treatment options will bring increased prevention, detection, and effective treatment. As our patient population grows older, knowledge about bladder health can bring improved quality of life to healthy aging. Although significant advances have been made, more research is needed in the field to address the varied needs of the growing patient population.

INTRODUCTION

Cancer is the second leading cause of death for women in the United States. Several women's cancers can potentially be caught early through screening. These include breast, endometrial, ovarian, and cervical cancers. Risk factors, guidelines for screening, and modifiable lifestyle factors are discussed.

BREAST CANCER

Epidemiology/Risk Factors

Breast cancer is the most common cancer among women in the United States, excluding non-melanoma skin cancer, and is the second leading cause of death from cancer. Approximately one in eight women will develop breast cancer during her lifetime.[1]

Various reproductive factors affect the risk of breast cancer, probably due to hormone exposure and changes in breast tissue as part of pregnancy and lactation. Delivering a child before age 30, increased parity, and increased duration of breast-feeding are all associated with reduced risk of breast cancer. By some estimates, every birth confers an approximate 7% reduction in risk, 4.3% with every year of breast-feeding.[2] Early menarche and late menopause are associated with an increased risk, with a relative risk of 2–3.[3]

There is a small increased risk of breast cancer with the use of oral contraceptive pills (OCPs), but this attenuates after discontinuation, and overall most experts agree that the risk does not outweigh the other potential benefits of oral contraceptive use (contraception and reduction of ovarian and endometrial cancer risk). A meta-analysis examined data from 54 studies with a combination of 53,297 women with breast cancer and 100,239 controls. Results demonstrated a relative risk of breast cancer of 1.24 in women currently taking contraceptive pills and in the 10 years after discontinuation of use, with attenuation of risk with years from use (e.g., relative risk of 1.16 at 1–4 years after stopping). However, at 10 years from discontinuation of use, risk returned to baseline with a relative risk of 1.01. Duration of use, age at first use, and type/dose of medication were not found to be significant.[4]

Similarly, use of postmenopausal hormone replacement therapy (HRT) confers a small increased risk of breast cancer that resolves with discontinuation of therapy. The same group analyzed a number of studies regarding the risk of breast cancer with use of HRT. Data on 52,705 women with breast cancer and 108,411 women without the disease from 51 different studies were analyzed. Among current or recent (within 1–4 years) users of HRT, relative risk for breast cancer was increased by 1.023 for each year of use. For those using HRT for 5 or more years, the relative risk was 1.35. Risk returned to baseline at 5 years from discontinuation of HRT.[5]

Screening

Screening for breast cancer is most commonly performed through mammography. In certain high-risk populations, additional imaging with ultrasound or breast MRI may be appropriate. Other modalities for the detection of breast cancer include breast self-exam and clinical breast exam by a physician.

Mammography is accepted as the current best method of early detection of breast cancer. Meta-analyses of randomized clinical trials demonstrated a 26%–27% reduction in breast cancer mortality. Another meta-analysis reported a sensitivity of 83%–95% and false-negative rates of 0.9%–6.5%, making it a good screening tool.[1] Results regarding the utility of clinical and self-breast examination are more equivocal. Data from the National Breast and Cervical Cancer Early Detection Program were analyzed with regard to clinical breast exams. In 752,081 clinical breast exams that were assessed, 6.9% were coded as abnormal. A total of 5 cancers were found per 1000 breast exams. A sensitivity of 58.8% and a specificity of 93.4% were reported.[6] For breast self-examination, efficacy is even less. A Shanghai trial randomized 266,064 women to either breast self-examination or a control group without any instruction in self-examination. The group instructed in self-examination received reinforcement training as well as reminders to perform self-examination and supervision of their technique during office visits. Mortality from breast cancer was the same in both groups, and women in the self-examination group underwent more biopsies for benign disease.[7]

The U.S. Preventive Services Task Force (USPSTF) recommendations regarding screening mammography include the following:

- At age 50, start routine biennial screening with mammography
- At ages 40–49, routine mammography screening not recommended
- At age 75 or older, insufficient evidence to assess risks/benefits of screening mammography
- Teaching breast self-exam not recommended
- Insufficient evidence to assess risks/benefits of the clinical breast exam

The rationale behind these altered guidelines was to attempt to reduce unnecessary additional testing and procedures for younger women, as false-positive results are higher.[8]

However, these guidelines are the source of some recent controversy. The USPSTF found that the net benefit for women is similar in their 40s and 50s, but that women in their 40s incur more harm through additional imaging and biopsies for abnormalities on imaging that are eventually found to be benign—and that this is potentially more common in younger women due to denser breast tissue. The American Cancer Society argues that when taking a broader view of the literature in existence, there is strong evidence to continue supporting the initiation of screening at a younger age, and more frequently. The American College of Obstetrics and Gynecology (ACOG) also endorses more frequent screening, and at a younger age.

The American Cancer Society recommendations for screening are as follows[9]:

- At age 40, start routine annual screening with mammography
- Clinical breast exam recommended at least every 3 years for ages 20–40, annually after 40
- Breast self-exam risks/benefits discussed, teach technique if a woman chooses to perform self-exam

The ACOG recommendations for screening are as follows[1]:

- Ages 40–49, routine screening with mammography every 1–2 years
- At age 50, routine annual screening with mammography
- Annual clinical breast exam for all women as part of the physical examination
- Breast self-exam may have some utility in detection of cancer, and may be recommended

Women with BRCA mutations should be screened earlier and more frequently than the general population. Currently recommended surveillance strategies include semiannual clinical breast examination, and both annual breast MRI and mammography, starting at age 25 or sooner, depending on family history and the earliest age of onset.[10] Please see the Section on Ovarian Cancer for a discussion of indications for BRCA testing.

Lifestyle

Some correlation has been found between obesity and the development of breast cancer, particularly in postmenopausal women. In a systematic review and meta-analysis examining the role of body mass and various cancers, a relative risk of 1.12 for postmenopausal breast cancer was found in obese women. The relative risk of premenopausal breast cancer in obese women from the study was 0.92.[11] A prospective cohort study within the Nurses' Health Study noted a relative risk of 0.43

for women who had lost 10 kg or more since menopause and maintained their lower weight.[12]

Data from the Nurses' Health Study supports the role of exercise in risk reduction of breast cancer. Baseline physical activity was assessed at the start of the prospective study, as well as at regular intervals. Over 16 years of follow-up, 3137 cases of breast cancer were identified, with 1036 premenopausal and 2101 postmenopausal. Women reporting higher levels of physical activity had a reduced relative risk of 0.82, when comparing those engaged in 7 or more hours of activity per week to those reporting less than 1 h of physical activity per week. There was a trend toward dose–response (higher levels of activity correlating with decreasing risk) that was statistically significant.[13] Another study looked at a large cohort of postmenopausal women as part of the American Cancer Society Cancer Prevention Study. In that study, 72,608 postmenopausal women completed a questionnaire, including assessment of physical activity, with 1,520 cases of breast cancer identified over 5 year follow-up. The women who were the most active had a 29% reduction in risk compared to the least active women. Measures of physical activity included both recreational and non-recreational activities, such as housework and gardening.[14]

Alcohol consumption, even in moderate quantities, has been linked to an increased risk of breast cancer. In the Million Women Study in the United Kingdom, 1,280,296 women were prospectively followed for the development of cancer and surveyed regarding various habits and characteristics. The authors estimated that for every additional drink per day (if consumed regularly), the risk of breast cancer increases by 11 per 1000 women.[15] The Women's Health Study in the United States found similar results. In that, 38,454 women provided dietary information and were followed for an average of 10 years, with subsequent diagnosis of 1484 cases of breast cancer. Analysis of the results found increasing risk of breast cancer correlating to increasing drinking, with a 9% increased risk for women consuming one drink daily and a 43% increase in those consuming more than three drinks daily.[16] A meta-analysis of 38 studies of alcohol consumption and its relation to breast cancer confirmed a modest increase in risk, with an 11% increased risk in women who consumed one drink daily.[17]

Smoking has also, in some studies, been correlated with an increased risk of breast cancer. However, a recent meta-analysis of 53 epidemiologic studies suggests that those results may have been confounded by alcohol use. Women who had smoked at any point in their lives were more likely to have higher alcohol intake. When smoking was analyzed separately from alcohol consumption, no increased risk was noted, with a relative risk of 1.03 for women who had smoked at some point during their lifetime and 0.99 for current smokers.[18]

High intake of dietary fat has been suggested to increase the risk of breast cancer. A review of the literature examined the available meta-analyses of various cohort and case–control studies. One meta-analysis reported a positive correlation between increased risk and both total and saturated fat intake. However, within another large study in Sweden, no association was found. Additional cohort studies did not report an association with total fat intake but did find a possible trend toward increased risk with higher saturated fat intake. However, in the same Swedish study, in subgroup analysis, women over 50 who had the highest consumption of mono- and polyunsaturated fats had a 50% reduction in risk compared to women with the lowest consumption. Overall, the evidence is mixed but suggests some role in reducing the risk of breast cancer through modification of certain fats within the diet.[19]

There is some evidence that vitamin D may be protective against breast cancer, but study results have been inconclusive. Generally, increased vitamin D intake or sunlight exposure proximal to the time of diagnosis has been more correlated with decreased risk when compared to assessed vitamin D status remote from diagnosis. However, vitamin D levels may be affected by hormonal status and may be affected by the cancer itself or by age. Additionally, most studies have been conducted in populations of Caucasian women and may not be applicable to other ethnicities.[20]

Soy products have been discussed as both possibly contributing to and protecting against the development or recurrence of breast cancer, due to estrogen-like activity. A recent meta-analysis of prospective studies showed a protective effect with soy consumption, but only in Asian populations, among whom the relative risk was 0.76. Western populations showed no effect, with a relative risk of 0.97.[21] Similarly, another meta-analysis that included case–control studies found a positive association between soy intake and reduced risk of breast cancer. The odds ratio for women in the lowest soy intake group was 0.88 and was 0.71 in the group with highest consumption, in Asian populations. Western population studies showed no effect, but the authors pointed out that in those studies, women in the highest soy consumption groups still consumed much lower quantities of soy isoflavones than the typical reported Asian diet. They suggested that high levels of soy, as in traditional Asian diets, may be protective against breast cancer.[22]

Evidence is mixed for other dietary factors, including green tea consumption. Some animal studies have demonstrated antitumor effects from compounds contained in green tea. A meta-analysis of studies examining a correlation between green tea intake and breast cancer reported heterogeneous results. A total of 5617 cases of breast cancer were studied. Case–control studies suggested a reduced risk with green tea consumption, with an overall odds ratio of 0.81. However, cohort studies found no association.[23] A review of meta-analysis examining the possible role of coffee in cancer reduction found no association with breast cancer.[24]

Intervention/Prevention

There is currently no role for the use of medications for prevention of breast cancer in the general population. However, for women at high risk, chemoprevention with tamoxifen (a selective estrogen-receptor modulator) has been approved

by the FDA. In a National Surgical Adjuvant Breast and Bowel Project study of 13,388 women at increased risk of breast cancer, tamoxifen reduced breast cancer risk by 49%–50% as compared to placebo. Tamoxifen does, however, have adverse effects such as increased risks of endometrial carcinoma and thromboembolic disease. For patients with known BRCA mutations, risk-reducing salpingo-oophorectomy, in addition to the reduction of ovarian cancer risk, also decreases the risk of breast cancer. Women with BRCA mutations, who undergo risk-reducing salpingo-oophorectomy, have been reported to have odds ratios of 0.44–0.57 for the development of breast cancer. Preventive measures in high-risk women, as they have other health ramifications, should be carefully considered, with full discussion of risks and benefits for the individual woman.[25]

OVARIAN CANCER

Epidemiology/Risk Factors

Ovarian cancer is the leading cause of death in women with gynecologic malignancies. Approximately 1.3% of American women will develop ovarian cancer during their lifetime. Its etiology remains poorly understood; proposed mechanisms include malignant transformation of cells engaged in turnover during ovulation, inflammation, and gonadotropin or hormonal influence.

Risk factors that have been identified fall into reproductive, genetic, and environmental categories. The most significant risk factor is a family history of breast and ovarian cancers, as up to 10% of women with ovarian cancer may have a hereditary predisposition. Women of Ashkenazi Jewish heritage are particularly at risk. Of women diagnosed with ovarian cancer, approximately 35%–40% of those with an Ashkenazi Jewish background have a BRCA mutation.[26]

For reproductive risk factors, parity seems to be the most significant. A large population, case–control study examined 563 cases of ovarian cancer in the New England area, with controls matched by age. Parity was associated with a reduced risk of ovarian cancer, as was having breast-fed. Increasing parity conferred additional risk reduction, but duration of breast-feeding did not. Women who had never had children had approximately twice the risk as women who had delivered a child. Early pregnancy losses and abortions were not found to be significantly associated with the risk.[27] A smaller case–control study in Taiwan also found an inverse association between ovarian cancer and parity, as well as trend toward protection with breast-feeding for over a year.[28] Early menarche and later menopause have been suggested as increasing risk of ovarian cancer. In at least one of the studies described earlier, those factors were not found to be significant although increasing age at menarche seemed to be protective among premenopausal women.[27] These identified reproductive risk factors lend credence to the theory of malignant transformation during cellular turnover, as many factors that seem to be protective suppress ovulation and subsequent turnover of ovarian epithelium.

For hormonal and gonadotropin effects, evidence regarding the risk for ovarian cancer is mixed. The Million Women Study was a UK study of women's health in those aged 50 or older. It reported a 2.2 per 1000 women incidence of ovarian cancer over 5 years in those not using HRT versus a 2.6 per 1000 women incidence in those using HRT (statistically significant), with a decrease in risk to that of controls with cessation of hormone use. Thus, the initial conclusion was that postmenopausal use of HRT was associated with an increased risk of ovarian cancer that could resolve with discontinuation.[29] However, a subsequent paper pointed out that the attributable risk for incidence of ovarian cancer associated with HRT use was only 4 per 1000 women and that the small increase in diagnosed ovarian cancer could be due to occult cancers that were then stimulated by hormone therapy and then able to be diagnosed.[30] The NIH-AARP Diet and Study Health Cohort examined over 90,000 women. Use of unopposed estrogen for fewer than 10 years was not associated with increased risk of ovarian cancer, although use for greater than 10 years conferred a relative risk of 1.89.[31] With regard to infertility and assisted reproductive therapy, a case–control study conducted in the southern United States found an increased risk for women diagnosed with infertility who had never had children. Among parous women, a history of infertility was not associated with an increased risk of ovarian cancer, nor was use of ovulation-inducing drugs. The reason that infertility would confer additional risk beyond nulliparity alone is unclear.[32] However, a recent Cochrane review of the use of clomiphene citrate (Clomid) for stimulation of ovulation noted that an up to threefold increase in ovarian cancer has been reported with the use for more than 12 cycles.[33]

Talc, used by some women as a powder in the genital area for personal hygiene, has been implicated in some studies as a risk factor for ovarian cancer. Structurally similar to asbestos, some have noted similarities in histologic characteristics between mesothelioma and serous adenocarcinomas. Inflammation and reactive changes in ovarian epithelium have been postulated to be a possible mechanism, with travel of talcum powder up the reproductive tract and to the ovaries. A meta-analysis examined 16 observational studies and found a statistically significant increased relative risk of 1.33 with the use of talcum powder, about a 33% increased risk of developing ovarian cancer. However, further analysis showed that hospital-based studies showed no association, whereas population-based studies did show an increased risk. Thus it is difficult to draw a clear relationship between talcum powder use and ovarian cancer.[34]

Endometriosis, polycystic ovarian syndrome (PCOS), and pelvic inflammatory disease (PID) are conditions in the literature that have also been associated with an increased risk of epithelial ovarian cancer. Endometriosis has particularly been linked to the endometrioid and clear cell histologic subtypes of ovarian cancer. One case–control study in Washington state found a threefold increase in risk of clear cell or endometrioid ovarian cancer with a history of endometriosis.[35] Studies have been mixed regarding the association between

PCOS and ovarian cancer, although the trend toward associated risk was stronger for those not using OCPs or who were thin.[36] A case–control study conducted in Canada found an increased risk of ovarian cancer with at least one episode of PID compared with never having had PID, with an increased risk if also associated with nulliparity or earlier diagnosis of PID.[37] Conversely, a similar Italian case–control study found no increased risk with a history of PID.[38]

Screening

A screening test should, ideally, be highly sensitive and highly specific and should uncover early disease at a point that intervention could result in a significant difference in morbidity or mortality. There is currently no recommendation for routine screening for ovarian cancer in the general population, as available screening methods neither have the required specificity to justify unnecessary procedures based on false-positive results nor are very successful at identifying early-stage disease.

Ovarian cancer generally presents at an advanced stage, and it was previously thought that women were asymptomatic until the disease became clinically apparent. This has been challenged; Goff et al. found in a survey of 1725 ovarian cancer patients that 95% reported having symptoms prior to their diagnosis, with 30% subsequently diagnosed as having stage I or II disease. This was a survey dependent on patient recall, but the results are still compelling. Only 11% of stage I or II patients, and 3% of stage III or IV, reported no symptoms prior their diagnoses. Symptoms were primarily abdominal or gastrointestinal (i.e., bloating, constipation, indigestion) rather than pelvic.[39] The study may have been affected by recall bias, but these types of symptoms should be noticed and could help triage patients to further testing.

Two modalities for testing are currently widely available—CA-125 serum level and transvaginal ultrasound. The University of Kentucky screened 25,327 women who were asymptomatic and either older than 50 or older than 25 with a family history of ovarian cancer, with annual ultrasounds from 1987 to 2005. Those who had an abnormal imaging study had CA-125 levels drawn and had a repeat ultrasound 4–6 weeks later. Of that, 364 (1.4%) eventually went on to have surgery, with 35 primary invasive ovarian cancers and 9 serous tumors of low malignant potential discovered. Of these, 64% were stage I, and the authors felt that transvaginal ultrasound could be an effective screening method. However, 313 (86%) of the masses removed were benign. Nine women developed ovarian cancer within 1 year of a negative screen, and three of those women died of their disease within the study period.[40] It has yet to be shown conclusively that transvaginal ultrasound identifies enough early-stage disease to justify the arguably unnecessary procedures for ultimately benign pathology.

CA-125 is a well-studied biomarker for ovarian cancer that, by itself, also has not been shown to be a valuable screening tool for asymptomatic women. It can be elevated by myriad other conditions including endometriosis and can also be affected by smoking, obesity, age, and race. CA-125 combined with transvaginal ultrasound has not been validated as a screening tool either, due to the high false-positivity rate leading to unnecessary procedures. For example, the Prostate, Lung, Colorectal, and Ovarian (PLCO) trial screened women annually with CA-125 for 6 years and transvaginal ultrasound for 4 years. A total of 28,746 women were screened with either test; 1,675 abnormalities were found. Eventually, 566 surgeries were performed, with 18 invasive ovarian cancers detected. Then, 31.4 surgeries were performed for every cancer discovered, and 83% of the cancers discovered were advanced stage. This improved with subsequent screenings, but after four cycles of screening, the ratio of surgeries performed to cancers discovered was still 19.5–1, with 72% of the cancers already advanced.[41] There are ongoing studies examining the use of different algorithms to evaluate risk of cancer, rather than a one-time CA-125 measurement or imaging study. The Risk of Ovarian Cancer Algorithm (ROCA) is based on serial CA-125 levels taken at set intervals of time. By calculating the rate of change (slope), a risk assessment is generated; when the ROCA score exceeds a 1% risk of ovarian cancer, further evaluation is undertaken with transvaginal ultrasound. The ROCA is undergoing trials in the United States and the United Kingdom; data from the initial screening of 202,638 women are available, as part of the UK Collaborative Trial of Ovarian Cancer Screening. ROCA CA-125 screening with directed transvaginal ultrasound based on the ROCA score was found to have 89.5% sensitivity and 99.8% specificity, which was higher than the annual transvaginal ultrasound alone. The studies are ongoing to determine whether this algorithm will result in a clinically valid screening tool.[42]

Biomarker panels and proteomics represent another avenue of investigation into screening modalities. Mass spectrometric protein profiling and proteomic techniques have been used to identify differential patterns between cancer and control samples and subsequently to generate biomarker panels that could be used to identify clinically unapparent malignancies. These biomarkers include leptin, prolactin, and osteopontin, in addition to a variety of other markers in conjunction with CA-125. One example of a recently released biomarker panel is the OvaSure test, which was removed from the market after a few months due to lack of clinical validation. The Society of Gynecologic Oncologists has issued a statement regarding both OvaSure and OvaCheck, a similar panel, recommending additional clinical study of those and other new biomarker panels before making the tests widely available.[26]

The discovery of a genetic locus for familial breast and ovarian cancer syndrome has made a significant difference in the targeting of screening tests and prophylactic procedures. However, one should keep in mind that there may be unknown familial syndromes or other genetic foci that could confer risk. Testing should ideally first be performed in a family member who has breast or ovarian cancer. If the test is positive, then a family member subsequently testing negative can be more assured of a risk similar to that of the

general population. If the index family member with cancer tests negative for the BRCA mutations, then a negative result for your patient is less reassuring.

Additionally, risk for breast and ovarian cancers as part of the Lynch (or hereditary non-polyposis colorectal cancer/HNPCC) syndrome must be considered. Please see the Section on Endometrial Cancer for a discussion of indications for Lynch syndrome testing.

The ACOG guidelines for genetic evaluation are outlined in the following and are based on a Society of Gynecologic Oncologists Education Committee statement.[10]

Patients with the following characteristics have a greater than 20%–25% risk of having an inherited predisposition to breast and ovarian cancer, and testing should be recommended:

- History of both breast and ovarian cancer
- History of ovarian cancer and a first- or second-degree relative with ovarian cancer, pre-menopausal breast cancer, or both
- History of ovarian cancer and Ashkenazi Jewish ancestry
- History of breast cancer at age 50 or younger and first- or second-degree relative with ovarian cancer or male breast cancer at any age
- First- or second-degree relative with a known BRCA mutation

Patients with the following characteristics have a greater than 5%–10% risk of having an inherited predisposition to breast and ovarian cancer, and testing may be helpful:

- History of breast cancer at age 40 or younger
- History of ovarian, primary peritoneal, or fallopian tube cancer of high-grade, serous histology at any age
- History of bilateral breast cancer (particularly if first cancer diagnosed at age 50 or younger)
- History of breast cancer at age 50 or younger and a first- or second-degree relative with breast cancer at age 50 or younger
- History of breast cancer at age 50 or younger and Ashkenazi Jewish ancestry
- Breast cancer at any age and two or more first- or second-degree relatives with breast cancer at any age (particularly if at least one case was diagnosed at age 50 or younger)
- First- or second-degree relative that meets the aforementioned criteria

First- and second-degree relatives are parents, siblings, aunts, uncles, nieces, nephews, grandparents, and grandchildren.

There is no consensus regarding screening for BRCA or Lynch/HNPCC mutation carriers or those with a strong familial history of malignancy. However, some form of screening should be considered—one suggested method is pelvic exam, CA-125, and transvaginal ultrasound every 6 months starting at age 35 or 5–10 years before the youngest age of diagnosis in the family.[43] For women with a Lynch/HNPCC-associated mutation, current NCCN guidelines for screening are for annual transvaginal ultrasound, colonoscopy, and endometrial biopsy.[44]

Lifestyle

Various lifestyle and dietary factors have been implicated as risks for the development of ovarian cancer, but the evidence is mixed.

In terms of body mass, higher body mass index (BMI; overweight or obese) was associated with an increased risk of ovarian cancer in an Australian meta-analysis of case–control studies.[45]

Smoking, in meta-analyses, seems to be associated with an increased risk of mucinous tumors in particular.[46] However, there are some studies that did not find a correlation,[47] and others that noted an eventual return to baseline risk with smoking cessation.[48] Similarly, alcohol (heavy consumption) has been associated with mucinous tumors[49] but in several other studies has not been found to impact the risk of developing ovarian cancer.[50]

Population-based cohort studies of alcohol use and ovarian cancer have yielded mixed results. The Iowa Women's Health Study found a decreased risk, while the California Teachers Study did not find a correlation between total consumption and risk. However, having at least one glass of wine daily in the year prior to diagnosis was associated with a 43% risk of developing malignancy. Other cohort studies have reported no association. Some case–control studies have reported an increased risk, while others have found a reduced risk of ovarian cancer. Approximately half of case–control studies have found no correlation. Overall, there is no clear evidence to support alcohol consumption as a significant risk factor in the development of ovarian cancer.[51]

The effect of dietary patterns on ovarian cancer risk has also been found to be overall negligible. The European Prospective Investigation into Cancer and Nutrition (EPIC) study included 325,731 women from across Europe. At recruitment, patients were given country-specific food frequency questionnaires or diet histories. Subgroups of meat (fish, chicken, red meat) and dairy products (milk, cheese, and yogurt) were examined. None of the food groups was found to be associated with a significant change in risk, despite previous case–control studies suggesting a link between red meat consumption and development of ovarian cancer.[52] Although some studies have also suggested a reduced risk with the consumption of antioxidants, fiber, and carotene, results from the Women's Health Initiative (WHI) suggest otherwise. Assessment was done on 133,614 women enrolled in the WHI for intake of carotenoids and antioxidants, including vitamins A, C, E, and selenium using food frequency questionnaires. An eventual 851 cases of ovarian cancer were identified over approximately 8.5 years of follow-up, with no significant association found between dietary intake and development of ovarian cancer.[53]

A prospective cohort study of 49,613 Canadian women administered food frequency surveys did not find any correlation between dietary fiber intake and subsequent development of ovarian cancer.[54]

A recent study examined exercise among those diagnosed with ovarian cancer in Washington State. 812 patients were interviewed, with exercise level assessed both by average number of hours and by metabolic-equivalent (MET) hours per week, as well as the number of years during which the patient engaged in regular recreational activity. The risk of invasive ovarian cancer, but not borderline tumors, was reduced among active women as compared to those who denied performing regular exercise during adulthood. Higher-intensity activity (greater MET hours) was associated with greater risk reduction, with the most active women having 60% the serous invasive ovarian cancer risk as nonactive women. However, that same group of women was noted to have an increased risk of endometrioid and clear cell invasive tumors, making the results inconclusive.[55] Another prospective study did not find an overall significant association between exercise and risk of ovarian cancer, although there was a trend toward inverse association.[56]

A meta-analysis of studies investigating the relationship between soy (which contains phytoestrogens that have been postulated to have an estrogen-like effect on tissues) and gynecologic cancer reported a protective effect. The odds ratio for the development of ovarian cancer was 0.52 when comparing those in the highest soy intake group versus the lowest. The authors concluded that there could be a protective effect from soy intake and that additional prospective studies are needed to investigate this further.[57]

Caffeine has been reported to increase, decrease, and have no effect on the risk of ovarian cancer. Tea, due to its antioxidant properties, has been suggested as having a beneficial effect.[58]

Intervention/Prevention

OCP use has been strongly associated with a decreased risk of ovarian cancer, presumably through the inhibition of ovulation.[59–61] The duration of use required and the length of protection conferred have been more clearly delineated by recent studies. As part of the U.S. Nurses' Health Study, OCP use as well as other contraceptive methods was investigated for an association with ovarian cancer in 107,900 participants. Follow-up extended for 28 years, with 612 cases of invasive epithelial ovarian cancer. In attempting to adjust for other influencing factors, women with a greater than 10 year history of OCP use were more likely to be parous, to have had tubal ligation, and to have used postmenopausal HRT as compared to women reporting no OCP use. Increasing length of OCP use was associated with decreased ovarian cancer risk, with benefit seen after at least 5 years of use. Age at use was not significant when adjusted for duration of use. The authors reported an approximate 38% risk reduction with 10 years or greater of OCP use. There was a trend toward decreasing benefit with greater length of time since discontinuation, particularly with a period of more than 20 years since last OCP use. The study also found a 34% risk reduction in women reporting a history of tubal ligation.[62]

Tubal ligation has been associated with risk reduction for ovarian cancer, perhaps by preventing the transmission of environmental/inflammatory factors from the lower genital tract into the abdomen.[63,64] Prophylactic, or risk-reducing, salpingo-oophorectomy confers at least an 80% risk reduction for BRCA mutation carriers,[65,66] although the incidence of incidentally found invasive ovarian, fallopian tube, or primary peritoneal carcinoma found during that surgery ranges from 2% to 17%[67,68] in various studies. Removal of the ovaries also confers a risk reduction for ovarian cancer, of up to 70%.[69,70] The benefit of hysterectomy is not as clear; in theory, there could be residual tubal tissue left at the cornua of the uterus, which increases the risk. However, studies have yet to show a clear correlation with remnant tissue on the uterus developing into malignancy in those undergoing risk-reducing salpingo-oophorectomy. By contrast, women with a Lynch/HNPCC-associated mutation clearly benefit from hysterectomy with bilateral salpingo-oophorectomy due to their increased risk of endometrial cancer, with a risk reduction of nearly 100%.[71] Risk-reducing surgery should be offered at the completion of childbearing or by age 40 for those with a BRCA or Lynch/HNPCC-associated mutation or with a very strong familial history.[26]

ENDOMETRIAL CANCER

Epidemiology/Risk Factors

Endometrial cancer is the most common female genital tract malignancy, with an estimated 2.62% of women in the United States developing uterine cancer within their lifetime. The majority of those diagnosed with endometrial cancer will present at an early stage, as abnormal or postmenopausal bleeding is an early manifestation of the malignancy. Approximately 72% of women will be diagnosed with stage I disease. The most common histologic type of endometrial cancer, the endometrioid subtype, is clearly associated with several risk factors, largely related to increased circulating levels of hormones. The more aggressive papillary serous and clear cell subtypes are not clearly associated with defined risk factors. Risk factors include older age, nulliparity, menstrual irregularities, diabetes, and obesity.[72]

For example, an Australian case–control study surveyed women younger than 50 regarding their medical and reproductive histories. A total of 156 cases were matched to 398 controls. Women with PCOS, which is associated with anovulation and menstrual irregularities, had a fourfold increase in the risk of endometrial cancer as compared to those without PCOS. This risk decreased when adjusted for BMI but was still elevated with an at least twofold increased risk.[73]

The following list describes relative risk of the provided factors for the development of endometrial cancer[74,75]:

Nulliparity	2–3
PCOS	2–3 (evidence mixed)
Obesity (BMI > 27)	2–4
Diabetes (independent from BMI)	1.3–2.7
Late menopause (after 55)	2
Hormone replacement therapy (unopposed estrogen)	4–5
Tamoxifen therapy	1.7–2.5

Most women diagnosed with endometrial cancer will be postmenopausal. However, in various studies, 5%–30% will be younger than 50 years of age at the time of diagnosis. A retrospective cohort study conducted at the MD Anderson Cancer Center examined characteristics of 1531 patients treated for endometrial cancer between 1989 and 2003 at the institution. Of these 12% were younger than 50, with an average age of 41 at diagnosis 58% had a BMI of 30 or greater, 55% were nulliparous, and 39% reported irregular menstrual cycles—these factors may be the most significant when evaluating the risk of endometrial cancer, particularly in younger women.[76]

The use of HRT confers an increased risk of endometrial cancer, particularly therapy with estrogen alone. In a meta-analysis analyzing HRT, women receiving estrogen alone had a relative risk of 2.3 for the development of endometrial cancer, as compared to women not taking hormones. If use was continued for 10 years or greater, relative risk increased to 9.5 and remained elevated even after the discontinuation of estrogen therapy for approximately 5 years. However, if progesterone was given in combination with estrogen, relative risk was reduced to 0.8. Another study found that if progesterone was given for 10 days/month, there was no increased risk of endometrial cancer, nor if combined HRT was given continuously.[77]

Approximately 5% of all cases of uterine cancer can be attributed to a hereditable cause.[78] Careful attention should be made to family history and the possibility of an inherited predisposition to malignancy, especially Lynch/HNPCC (hereditary non-polyposis colorectal cancer) syndrome. The presence of a Lynch/HNPCC-associated mutation confers an approximate 40%–60% lifetime risk of endometrial cancer, in addition to (most commonly) colon and ovarian cancers. The syndrome also predisposes to gastric, small bowel, ureter, and renal cancers classically, in addition to several others such as bladder, brain, and skin.[72] The Amsterdam criteria, originally created in 1991 and revised in 1999, can be used to aid in identifying individuals whose family history could indicate a high index of suspicion for Lynch/HNPCC syndrome.

The Amsterdam criteria are as follows:

1. At least three relatives with Lynch/HNPCC-associated cancer (colon, endometrium, small bowel, renal pelvis, or ureter).
   a. Of note, not included in this list is stomach, ovary, bladder, brain, or skin.
2. One affected person is a first-degree relative of the other two.
3. At least two successive generations are involved.
4. One person was diagnosed below the age of 55.
5. Familial adenomatous polyposis has been excluded.
6. Tumors have been verified by a pathologist.

In at least one study, a sensitivity and specificity of 72% and 78%, respectively, have been documented. However, the Amsterdam criteria do not take into account patients who present with a gynecologic malignancy or who have small family pedigrees, and this should be taken into account when considering referral for genetic counseling and/or testing.[79]

Guidelines for genetic testing, incorporating both family and personal history, are outlined in the following and are based on a Society of Gynecologic Oncologists Education Committee statement.[80]

Patients with the following characteristics have a greater than 20%–25% risk of having an inherited predisposition for colon, endometrial, and other malignancies and genetic testing should be recommended:

1. Endometrial or colon cancer and with the criteria listed in the following:
   a. At least three relatives with a Lynch/HNPCC-associated cancer (colon, endometrial, ovarian, small bowel, ureter, renal) in one lineage
   b. One should be a first-degree relative of the other two
   c. At least two successive generations affected
   d. At least one cancer diagnosed before age 50
2. Synchronous or interval development of endometrial and colorectal cancer with the first cancer diagnosed before age 50
3. Colorectal or endometrial cancer with evidence of a mismatch repair defect
   a. Microsatellite instability
   b. Immunohistochemical loss of expression of MLH1, MSH2, MSH6, or PMS2
4 First- or second-degree relative with a known mismatch repair gene mutation

Patients with the following characteristics have a greater than 5%–10% risk of having an inherited predisposition for colon, endometrial, and other malignancies, and genetic testing may be helpful:

- Endometrial or colorectal cancer diagnosed prior to age 50
- Endometrial or ovarian cancer with a synchronous or metachronous colon or other Lynch/HNPCC-associated tumor at any age
- Endometrial or colorectal cancer and a first-degree relative with a Lynch/HNPCC-associated tumor diagnosed prior to age 50

- Colorectal or endometrial cancer diagnosed at any age with two or more first- or second-degree relatives with Lynch/HNPCC-associated tumors regardless of age
- First- or second-degree relative that meets the aforementioned criteria

First- and second-degree relatives are parents, siblings, aunts, uncles, nieces, nephews, grandparents, and grandchildren.

Screening

Routine screening in the general population, if asymptomatic, is not currently recommended as early endometrial cancer is generally symptomatic, with abnormal or postmenopausal bleeding the most common presenting sign.

As the risk of endometrial cancer increases with age, particularly after age 35, any woman over the age of 35 with irregular bleeding should have the endometrium evaluated. Consideration should be given to those younger if risk factors are present, using clinical judgment. Any postmenopausal woman with vaginal bleeding should be evaluated for endometrial cancer. With any type of abnormal bleeding, other etiologies should be considered, such as lesions of the cervix or vagina. Imaging with transvaginal ultrasound prior to endometrial sampling is reasonable; blind office endometrial biopsy is useful for detecting a process that globally involves the endometrium, but may miss focal lesions. If a thin, distinct endometrial echo of 4 mm or less is present on imaging, the ACOG guidelines report a very low (1 in 917) risk of endometrial cancer and state that endometrial biopsy is not necessary. If the endometrium is globally thickened, then an office endometrial biopsy is warranted. However, if the endometrium appears to be focally thickened, visual evaluation with hysteroscopy and removal of the lesion and/or curettage would be appropriate. Sonohysterography is a valuable adjunct if the endometrial cavity is difficult to define or if there is a question of a focal lesion, such as a polyp.[81]

For asymptomatic women with incidentally found endometrial thickening or endometrial polyps, there is evidence to support expectant management, as the risk of underlying malignancy has been found to be quite small in the absence of symptoms, depending on the actual thickness of the endometrium. An analysis was conducted of studies examining postmenopausal women over 50, not on hormone therapy, who had transvaginal imaging to assess the endometrial echo (sometimes referred to as the stripe). In a postmenopausal woman without vaginal bleeding, the risk of malignancy with an endometrial strip of <11 mm was estimated at 0.002%, whereas risk was assessed to be around 6.7% with a thickness >11 mm. For postmenopausal women with vaginal bleeding, a concerning endometrial thickness is >5 mm, although consideration for biopsy should be given for any symptomatic woman.[82] Another study found that in 82 women with an incidentally found suspected endometrial polyp on imaging, who subsequently underwent evaluation with operative hysteroscopy, no malignancy was found. Sixty-eight polyps were found, of which one contained simple endometrial hyperplasia. No premalignant conditions such as complex atypical hyperplasia were found. The overall complication rate reported was 3.6%.[83] A larger study examined 1152 women who underwent hysteroscopic removal of polyps found during sonohysterography. The women were all asymptomatic and postmenopausal. There was one endometrial cancer in a polyp (<0.1%) and three other endometrial cancers that were not in a polyp but were found to by polypoid in appearance and focal and were thus mistakenly thought to be a polyp (<0.3%).[84] Thus in the absence of bleeding, an incidental finding on imaging does not need to automatically trigger further evaluation, but this should be adjusted based on the individual patient and her risk factors for malignancy.[81]

For women with Lynch/HNPCC syndrome, some form of screening should be undertaken. The average age that women with the syndrome develop endometrial cancer is 48, and ultrasound evaluation of the endometrial stripe can be limited in premenopausal women due to cycle variations. The National Comprehensive Cancer Network currently recommends annual endometrial biopsy for screening, based on expert opinion.[78]

Lifestyle

Obesity is one of the most significant risk factors for endometrial cancer, hormone dependent/endometrioid particularly, and is a potentially modifiable factor. Some estimate that up to 70%–90% of patients with hormone-dependent endometrial cancer are overweight or obese. Other comorbid conditions, such as hypertension and diabetes, also put patients at increased risk of mortality after treatment for endometrial cancer.[75] A recent meta-analysis found a strong correlation between increasing BMI and the risk of endometrial cancer.[11]

Conversely, a recent meta-analysis showed a correlation between increasing physical activity and decreased risk of endometrial cancer. Physical activity has been postulated to be protective both by maintenance of a healthy body weight with increased lean body mass (decreased aromatization of circulating hormones to estrogen in adipose tissue) and increased serum levels of sex-hormone-binding globulin (increased binding of estrogen and thus less active circulating estrogen). The meta-analysis did not examine the effects of exercise independent of BMI, as a reduction in BMI is a likely mechanism for the benefits and found that increased physical activity was highly correlated with reduced risk.[85] A case–control study matched 472 cases to controls and assessed approximate lifetime physical activity. In general, patients with endometrial cancer had an overall lower level of physical activity, were nulliparous, or were obese. Risk decreased in proportion to the level of physical activity, although when results were stratified by BMI, the risk reduction was limited to overweight and obese women.[86]

A cohort study from the Swedish Twin Registry investigated the effects of various lifestyle factors, including dietary intake, smoking, and alcohol consumption, on the risk of endometrial cancer. In the study, 133 cases of endometrial

cancer were observed. Increasing physical activity was associated with a significant risk reduction, with women in the highest exercise category having a relative risk 0.2 in comparison with women reporting little or no regular exercise. There was a trend toward very low fruit and vegetable intake increasing risk, but this did not reach significance. There was no clear association between smoking or alcohol consumption and endometrial cancer risk.[87] A meta-analysis suggested an inverse relationship between vegetable consumption and the risk of endometrial cancer. The study included both cohort and case–control studies and reported overall risk reduction with vegetable consumption, particularly cruciferous vegetables (broccoli, cauliflower, bok choy), but not as significant of an association with fruit intake. The pooled odds ratio was 0.71 for those in the group of highest vegetable consumption compared to those in the lowest.[88] An Italian case–control study found that in 454 women treated for endometrial cancer, as matched to 908 controls, there was an increased risk associated with consumption of red meat and decreased risk associations with consumption of coffee and vegetables.[89] However, a prospective study examined the possible preventive effects of fruits and vegetables on the development of endometrial cancer and did not support those results. In the study, 41,400 postmenopausal women were surveyed regarding their dietary habits and were then followed for approximately 10 years, with one survey to update dietary information in the intervening time. There were 435 cases of endometrial cancer, with no association found with fruit or vegetable consumption.[90]

A recent analysis of several cohort studies suggests a reduced risk of endometrial cancer correlated with soy intake, with an odds ratio of 0.67 for the development of endometrial cancer in the group of women reporting the highest soy intake, with a trend toward inverse dose–response.[57]

A recent meta-analysis examining coffee consumption and the risk of various cancers found a consistent association between coffee consumption and a reduced risk of endometrial cancer. In the aforementioned Italian case–control study, endometrial cancer risk in the group of women with the highest consumption was approximately half that of women with the lowest consumption.[89] A Japanese study found a linear inverse relationship correlating coffee consumption with reduced risk, with increasing reduction in risk as the number of cups consumed per day increased. Additional Swedish and Japanese studies also found statistically significant associations between coffee consumption and reduced risk, with reports of a relative risk of 0.4 with a consumption of three or more cups of coffee per day.[20] Another Japanese case–control study found an inverse, dose–response relationship between the consumption of green tea and the risk of endometrial cancer. In this study, endometrial cancer cases were specifically limited to the endometrioid subtype. The decreased risk of endometrial cancer was observed even when analysis was controlled for other factors such as obesity and menopausal status.[91]

A recent study summarized the results of various studies examining the effect of alcohol consumption on gynecologic cancers. Cohort studies in North America, Sweden, and the United Kingdom did not show a consistent correlation between alcohol consumption and the development of endometrial cancer. One study, the Iowa Women's Health Study, showed a reduced risk in alcohol users as compared to those who did not drink. In the Multiethnic cohort, however, those who drank two or more drinks per day had a significantly increased risk. Other cohort studies showed no correlation. Results from case–control studies were similarly inconsistent. Sixteen studies carried out in North America, Japan, and Western Europe were examined. In 10 of the studies, no significant association between alcohol consumption and endometrial cancer was observed. Several other studies showed a trend toward increased risk with alcohol consumption, with one study reporting a decreased risk with alcohol users compared with those who abstained. Overall, there is no clear evidence that alcohol use increased the risk of endometrial cancer.[51]

Intervention/Prevention

Use of OCPs is protective against endometrial cancer. A recent review compiled information from 4 large cohort studies and over 15 case–control studies that demonstrated an overall 50% reduction in the risk of endometrial cancer with the use of combined oral contraceptives. This is reported to be independent of pill formulation, and risk is overall reduced in correlation with duration of use. A meta-analysis found that reduced risk of 50% remained at 5, 10, and 20 years after cessation of use. Of note, these results were found with combined OCP users. In the studies that address the subgroup, users of progesterone-only contraceptive pills were too small in number to generate significant findings.[92]

The use of intrauterine devices (IUDs) can also be protective against endometrial cancer. The two IUDs currently available in the United States are a nonhormonal copper IUD (Paragard) and a progesterone-containing/levonorgestrel IUD (Mirena). Several studies, including the Cancer and Steroid Hormones study of the Centers for Disease Control and Prevention, showed an association between reduced risk of endometrial cancer and use of the nonhormonal IUD.[93] The levonorgestrel IUD was approved by the FDA in 2000, so long-term data are not available. However, there are several studies examining its use in the treatment of endometrial hyperplasia and as a means of preserving fertility and treating early-stage endometrial cancers in young women. A European study, where a similar device was approved earlier, recently released follow-up results after 15 years of IUD use to treat endometrial hyperplasia. Patients having all forms of hyperplasia, from simple to complex/atypical, were included. Of that, 94% had regression to atrophic endometrium based on tissue sampling at the end of treatment.[94] In recent case series from Australia, three patients with early endometrial cancer were treated with the Mirena IUD, nine patients were treated with the IUD and an oral progesterone, and four were treated with an oral progesterone only. A 63%

response rate was reported.[95] Endometrial hyperplasia, particularly atypical/complex hyperplasia, is a precursor to malignancy. Studies demonstrating a response to treatment with the progesterone-containing IUD, whether hyperplasia or cancer, suggest that there may be a protective effect on the endometrium.

Several retrospective studies have demonstrated the value of risk-reducing surgery for women with Lynch/HNPCC syndrome. For 210 women who did not undergo hysterectomy, 69 developed endometrial cancer compared to no endometrial cancers in 61 women who did have a hysterectomy. Additionally, 12 ovarian cancers developed in women who did not have concurrent bilateral salpingo-oophorectomy, while no ovarian cancers were diagnosed in those who did, although those results did not reach statistical significance.[78]

CERVICAL CANCER

Epidemiology/Risk Factors

Cervical cancer in the United States has steadily declined in recent years, largely due to improved access to screening with the Papanicolaou, or Pap test, and a long preinvasive disease phase that is treatable. However, cervical dysplasia still represents a significant burden to health care in the United States, and worldwide cervical cancer continues to cause significant morbidity and mortality as the second most common cancer among women.[96]

The link between human papillomavirus (HPV) and cervical cancer has now been well established. Up to 75% of women will be infected with HPV in their lifetime. However, many younger women will clear their infection, and there are myriad strains of HPV, some of which are associated with malignancy and some of which are associated with genital warts, with strain distribution depending on the population. Risk reduction of cervical cancer is aimed at reducing factors that could contribute to persistent infection, decreasing acquisition of high-risk strains, and establishing guidelines for regular screening.[97]

The predominant risk factor for HPV infection is the number of lifetime sexual partners. Young age is also a significant factor, with the highest prevalence of infection in the early 20s, decreasing until around age 35, with a plateau and then a further decrease after age 50. The pattern is reflective of a sexually acquired infection, with the second decline at age 50 perhaps reflective of immunity or decreased exposure.[98] There may be different risks for high-risk versus low-risk HPV. Non-oncogenic HPV may be more associated with short-term sexual activity, as the infections tend to be more transient, while high-risk HPV is more associated with cumulative behaviors.[99]

Vulvar and vaginal cancers, while uncommon, may be associated with similar risk factors as those for cervical cancer, including HPV infection and smoking. Women with lichen sclerosis and other inflammatory skin disorders of the vulva are also at increased risk of malignancy.[100]

Screening

The 2009 screening guidelines for Pap testing from the ACOG are outlined as follows[101]:

Screening should begin at age 21

1. Women aged 21–29, screening every 2 years
2. Women aged 30 or older, with 3 consecutive normal tests, screening every 3 years
3. More frequent screening is indicated if the following factors are present:
   a. HIV
      i. Twice in the first year after diagnosis and annually thereafter
   b. Immunosuppression
   c. History of diethylstilbestrol (DES) exposure in utero
   d. Women previously treated for CIN 2, 3, or cervical cancer
      i. Annually for 20 years post-treatment or after post-treatment surveillance
4. May discontinue screening at age 65–70
   a. If three consecutive normal tests, no abnormal test in >10 years
5. May discontinue screening post-hysterectomy if for benign disease, no history of CIN 2 or 3
   a. If history of CIN 2 or 3, or undocumented screening history, continue screening
6. Women who have received vaccination should be screened according to the same guidelines
7. HPV testing may be used to stratify risk for women with ASC-US or LSIL results
8. HPV testing may be used for women older than 30 as a co-test with the Pap smear
   a. If both results are negative, testing should be spaced to every 3 years

Women with cervical dysplasia and HPV infection are also at risk for vulvar and vaginal dysplasia and cancers, and attention should be paid to those areas during examination. There is no routine screening for vulvar and vaginal cancers, but clinicians should have a high index of suspicion if lesions are noted.

Lifestyle

Genital HPV is transmitted sexually, through contact with skin, body fluids, or mucous membranes of an infected individual. Genital HPV subtypes have been isolated from the skin and nails of those with genital warts; transmission may be possible through manual–genital or non-penetrating genital–genital contact.[102] Condom use is protective, as a latex condom covers many areas of the male genitalia where HPV tends to reside. However, any area of genital skin, or bodily fluids, may harbor HPV and thus a condom is not completely protective, particularly if it should slip or break.[103] Studies examining the efficacy of condoms have been mixed,

probably because HPV infection can be latent and intermittently nondetectable, making it difficult to assess whether an infection is newly acquired. Protection has been shown for non-oncogenic subtypes and genital warts, but for a reduction of cervical dysplasia, the evidence has been mixed.[97]

Parity and oral contraceptive use have been reported to be associated with cervical dysplasia. In a study that pooled data from eight case–control studies, women with invasive or in situ cervical carcinoma, with HPV, were compared to controls. Increasing parity was directly associated with increasing risk of squamous cell carcinoma of the cervix (the most common sub-type), while not correlated with adenocarcinoma. The odds ratio for a woman with—one to two term pregnancies was 2.3, and for a woman with greater than seven term pregnancies, it was 3.8.[104] A meta-analysis of cervical cancer and oral contraceptive use studies showed a relative risk of 1.9 for those using oral contraceptives for more than 5 years versus those who had never used them. The risk was noted to decline after cessation of use and to return to baseline after approximately 10 years. While the study adjusted for age, number of sexual partners, age at first intercourse, parity, smoking, and screening, it did not address HPV infection.[105] A Swedish case–control study looked at those with cervical intraepithelial neoplasia (CIN) 2 and 3 and controlled for past and present HPV exposures during the study. Women diagnosed with CIN 2 or 3 through the local screening program, and who had been tested for HPV, completed questionnaires regarding sexual and reproductive history, dietary intake, smoking, and use of oral contraceptives. A significant period of oral contraceptive use (>5 years) was associated with an increased risk of CIN 2 or 3, but this finding disappeared after adjustment for age, smoking, and HPV infection. In the adjusted analysis, a history of pregnancy was associated with increased risk. A dose-dependent significantly increased risk with smoking was reported, which was found to be present even after adjustment for HPV exposure.[106]

Tobacco smoking has been implicated as a significant risk factor in the development of high-grade cervical dysplasia and cervical cancer. This may be mediated either by direct carcinogenic activity on cervical cells or through suppression of the immune system's ability to clear HPV infection. A 10 year prospective study in Oregon enrolled 1812 identified to have infection with high-risk HPV at enrollment and completed a survey regarding smoking, oral contraceptive use, and reproductive history. Oral contraceptive use and parity were not associated with the development of high-grade dysplasia (CIN 3) or cervical cancer. Final analysis demonstrated an increased risk of CIN 3 or cervical cancer for current or former smokers, with odds ratios 2.9–4.3, with the highest risk in those smoking more than 1 pack per day.[107]

Several cohort studies have examined alcohol use and risk of cervical cancer and found increased risk; however, many did not adjust for confounding factors such as HPV infection, number of sexual partners, smoking, or access to Pap screening. Several of those studies were also performed in select populations (waitresses, alcohol abusers). In the Million Women Study, which was conducted in the general population and controlled for the aforementioned confounding factors, reported no association between alcohol consumption and risk of cervical cancer. Case–control study results have been mixed, with no overall clear association but a positive trend toward increased risk with increased alcohol consumption.[51]

In prior studies, higher intake of fruits and vegetables and certain micronutrients has been associated with a decreased risk of cervical dysplasia, although the evidence is largely from observation and is not overwhelming. A recent case–control study compared 231 women diagnosed with CIN 3–453 controls. Significantly reduced fruit and vegetable intake was noted when those with CIN 3 were surveyed, compared with controls. Smokers in both groups reported lower overall fruit and vegetable consumption. Sexual history and reproductive factors were similar among both smokers and nonsmokers in the CIN 3 group. Lower fruit and vegetable intake was associated with an increased risk of high-grade cervical dysplasia, with an odds ratio of 1.14. However, smokers with a higher intake of fruits and vegetables had a higher risk, with an odds ratio of 1.83. The study suggests a weak association with dietary intake, but a stronger effect of smoking on the development of cervical dysplasia.[108] There have been some studies showing benefit from vitamins C and E, carotene, and lycopene in ameliorating HPV persistence. Additionally, folate, retinol, vitamin B_{12}, lutein, and cryptoxanthin have been discussed as protective against cervical neoplasia. However, most analyses do not demonstrate strong evidence for dietary protection when HPV is taken into account.[109]

Intervention/Prevention

A recent development in the prevention of cervical cancer has been the introduction of the vaccines Gardasil and Cervarix. Both are protective against the high-risk HPV strains 16 and 18, which have been implicated as being the most frequent strains associated with cervical cancer in the United States. Gardasil adds additional protection against HPV strains 6 and 11, which are low risk for the development of cervical cancer but cause genital warts. In approximate 3 year follow-up of the vaccines, the efficacy of Gardasil has been reported to be near 100% for HPV 16 and 18 CIN 2/3, adenocarcinoma in situ, vulvar intraepithelial neoplasia 2/3, and vaginal intraepithelial neoplasia 2/3 (high-risk dysplasia or carcinoma in situ). Similarly, 99%–100% efficacy for genital warts was reported. Cervarix was found to have a rate of 93% protection for HPV-16 and -18-associated lesions. Both have also demonstrated cross-protection for several other strains of HPV. Even if sexual activity has been initiated, it should not preclude administration of the vaccine, as women may not have been exposed to any or all strains of HPV covered by the vaccines. The vaccines are currently approved for routine vaccination of girls aged 11–12 years, at the physician's discretion at ages 9–10, and for catch-up vaccination at ages 13–26. Gardasil has also been approved for males aged 9–26 for the prevention of genital warts, but could potentially also reduce the burden of HPV transmission.[110]

INTRODUCTION

Helping patients achieve and maintain a healthy lifestyle includes allowing them to be equal partners who take ownership of their health care. Such a partnership has benefits for both patient and physician and has the potential to decrease medical errors, which in turn enhances health. In the course of a busy day, the average clinician has many opportunities to make mistakes. While only some of these will lead to harm, the value of error prevention in delivering health care is unquestionable. If left only to the skill, alertness, or memory of individuals, there would be little hope of preventing medical errors. But by redesigning systems to eliminate the occasion for errors, danger can be averted.

The focus of this chapter will be the use of thoughtful and efficient systems that can make women's health care safer. Several common errors related to screening and preventive health care for women are explained, along with algorithms to improve outcomes. These serve as examples for other situations when clinicians are poised to identify vulnerabilities and embed systems into their everyday workflow. Such systems will prevent errors and put women's health care in the vanguard of sound practice by placing the patient at the center of her own care.

In his "Swiss cheese model," the psychologist James Reason asserted that adverse events can be traced to one or more levels of failure: organizational influences, unsafe supervision, preconditions for unsafe acts, and the unsafe acts themselves.[1] In Reason's thinking, the ideal system is like a stack of Swiss cheese slices, each slice a different step in the process, each hole another opportunity for errors to creep in, and the cheese itself a defensive wall that prevents errors from reaching the patient. An error that passes through one layer is usually caught at the next step, where the holes are in different places. For harm to occur, the holes need to be lined up in a way that allows a persistent error to pass through and reach the patient. Thus, if a system allows all the holes to line up, the system is the problem. For Reason, a well-designed system has many defenses to stop errors (i.e., many slices of Swiss cheese) and few opportunities for error (small holes in the cheese).

Reason's model considers both active and latent errors. Active errors include the unsafe acts that can be directly linked to an adverse event, such as administering a medication to a person with a known allergy. Latent failures are features of a system—such as ineffective communication, fatigue, inadequate supervision, or illegible handwriting—that may lie dormant until they collide to produce a catastrophic result. Adverse events do not occur because of one failure; they occur when several problems come together in a way that allows errors to persist—when all the holes in the Swiss cheese line up. Only well-designed systems can prevent multiple levels of failure, individuals alone cannot.

Consistent with Reason's thinking, the patient safety movement has emphasized system correction, not individual punishment.[2] At the root of this philosophy is the belief that embedding good systems can lead to widespread improvement in a way that targeting individuals never will. The medical community's attitude toward the value of systems began to change in 2000 when the Institute of Medicine (IOM) published its seminal report, "To Err is Human," which estimated that 98,000 Americans die each year as a result of medical errors.[3] A year later, the IOM followed up with a proposal to redesign the health care system for the new millennium.[4] It saw the patient as a potential defensive barrier who could protect against error and suggested that shifting control to her was a pivotal step toward a safer health

care environment. To that end, the report recommended that patients be provided with information and the opportunity to control decisions that affect them. Patients, then, provide an additional defense against error—another slice of Reason's Swiss cheese.

Women's health care presents an ideal arena in which to push forward with patient safety, because women often function as caregivers for the people they live with or for other relatives or friends. One out of four people is a caregiver for a family member or friend; in the absence of an able spouse, a daughter or daughter-in-law is most likely to assume the role of caregiver.[5] Approximately 75% of caregivers for older family members and friends are female.[6] Of the 2.4 million grandparents who live with and are responsible for grandchildren, 63% are women. Clearly, women have a huge footprint in the health care network and are well positioned to provide a safety net for their nuclear and extended families.[7]

ERROR: MISSING AN ECTOPIC PREGNANCY

Whether a pregnancy is planned or unplanned, confirming an intrauterine gestation is a key initial step for the clinician and patient. Life-threatening ectopic pregnancy remains a possibility until this takes place.

It is estimated that approximately 2% of pregnancies in the United States are ectopic.[8] If not addressed, ectopic pregnancy can lead to hemorrhage, transfusion, and death. The approach to minimizing risk related to ectopic pregnancy rests on two principles: engaging the patient in her own care by educating her about early warning signs and understanding the ability of different tests to discriminate between normal and abnormal early pregnancies.

Patients who present for preconceptual counseling or initiate care early in the first trimester provide an opportunity for the clinician to discuss, among other things, early warning signs of abnormal pregnancy. Such signs may include pain, bleeding, or light headedness. Alerting the office to these symptoms, should they occur, may help to prevent complications of ectopic pregnancy.

If pregnancy is diagnosed by urine or serum testing, the clinician should review the patient's history to identify risk factors for ectopic pregnancy. These may include endometriosis, tubal infection, cigarette smoking, previous history of ectopic pregnancy, or the presence of an intrauterine device. After a physical exam, the remainder of the evaluation and plan is dependent on the quantitative level of serum human chorionic gonadotropin (beta-HCG).

The discriminatory threshold (or cutoff) is that level of beta-HCG at which evidence of an intrauterine gestation can be visualized by transvaginal ultrasound, with sensitivity approaching 100%.[9,10] The discriminatory threshold is determined by individual institutions based on experience and expertise and is commonly between 1500 and 2500 IU/L. When no evidence of intrauterine gestation is seen on transvaginal ultrasound, and the beta-HCG level is above the discriminatory threshold, ectopic pregnancy should be suspected. Treatment of ectopic pregnancy may include medical or surgical options, but prompt attention is crucial.

In order to detect an ectopic pregnancy, offices must have tracking systems for pregnancy tests. When a pregnancy test is ordered, an electronic or paper alert should be sent to the clinician, who contacts the patient. If risk factors for ectopic pregnancy are present, and quantitative HCG is above the discriminatory threshold for an intrauterine gestation, an ultrasound should be performed.

If quantitative HCG is below the discriminatory threshold for pregnancy, and risk factors for ectopic pregnancy exist, the patient should be evaluated promptly. It is also important to engage the patient in her own care, including a clinician–patient agreement to monitor beta-HCG levels until reaching the discriminatory threshold.

Below the discriminatory threshold, serial measurements of quantitative beta-HCG, along with monitoring of patient signs and symptoms, may help confirm a normal intrauterine pregnancy (thus, excluding an ectopic pregnancy). In a normal pregnancy, the beta-HCG concentration doubles about every 2 days. An increase over 48 h of at least 66% is commonly used as a cutoff for normalcy.[11–14] However, this must be viewed within the clinical context, as Barnhart et al.[15] found that some patients with a 53% increase in serum beta-HCG levels over 48 h were later found to have a viable intrauterine pregnancy. Thus, caution is required when using serial beta-HCG measurements below the discriminatory threshold to monitor a desired pregnancy, as one risks incorrectly diagnosing nonviability.

A clinical pathway that involves both patient and provider in the confirmation of normal early pregnancy will prevent unrecognized ectopic pregnancy. Figure 74.1 is an example of such a clinical pathway.

ERROR: ABNORMAL CERVICAL CANCER SCREENING TESTS LOST TO FOLLOW-UP

Cervical cancer screening, or the PAP test, is a routine yet important aspect of well-woman care. However, providers can be inundated with results of these tests. An estimated 30.2 million PAP tests were ordered at physician offices and hospital outpatient departments in the United States from 2003 to 2005.[16] The follow-up of PAP test results is particularly susceptible to error; lost in a sea of normal results, the lone abnormal finding goes easily unnoticed unless every test is tracked in a closed-loop system that begins the moment the test is ordered.

Revised recommendations in recent years for follow-up of abnormal cervical cancer screening tests have altered the schedule and the volume of tests that are performed.[17] Additionally, the clinician may now be presented with not only cytologic information, but also data regarding the human papillomavirus (HPV) carrier status of the patient. Any additional piece of information received, as well as changes in recommendations for follow-up, presents opportunities for confusion, miscommunication, or lack of communication with patients and eventually losing track of patients.

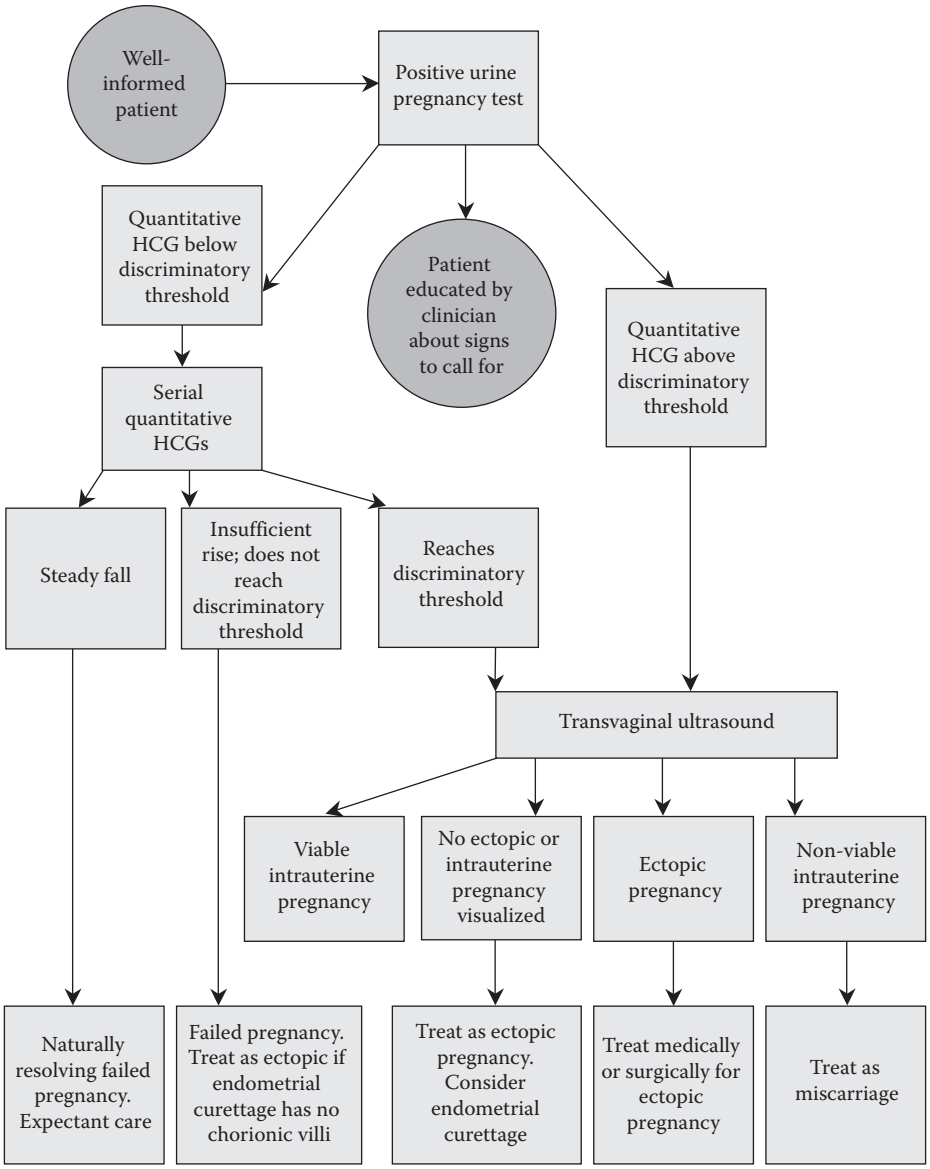

FIGURE 74.1 Example algorithm to prevent missing an ectopic pregnancy.

Engaging the patient in the prevention of cervical dysplasia and cervical cancer begins before the initiation of cervical cancer screening. This discussion should include details about safer sex practices and vaccination for the prevention of HPV infection.

The Centers for Disease Control and Prevention recommend vaccination for HPV at age 11 or 12. Therefore, at a time when adolescents are on the cusp of beginning sexual activity and may be receptive to information about potential hazards of unsafe sexual practices, a discussion regarding vaccination for HPV may be most productive. HPV vaccines are most effective for both males and females when given before exposure to HPV through sexual contact. HPV4 (quadrivalent vaccine) or HPV2 (bivalent vaccine) is recommended for the prevention of cervical dysplasia and cancers in females, while HPV4 is recommended for the prevention of cervical, vaginal, and vulvar precancerous lesions and cancers, as well as genital warts in females. Vaccinations are a routine part of preventive care; the HPV vaccine is no exception.[18]

Regardless of whether a patient has received the HPV vaccine, an abnormal PAP test or positive test for HPV needs to be explained to the patient. Patient care is at risk when communication breaks down; according to the American College of Obstetricians and Gynecologists, these breakdowns can include delay in care, failure to follow up on abnormal results due to workload, and failure to establish a tracking system.[19]

Once a patient is screened for cervical cancer, an office reminder system must be triggered in order to provide the patient with timely, accurate follow-up recommendations. This system should not rely on an individual's memory, but must be incorporated in a sustainable way into office workflow. While effective tracking can be accomplished either electronically or manually, recent data suggest that electronic tracking is preferred in an at-risk urban population because it accelerates the resolution of abnormal results and increases

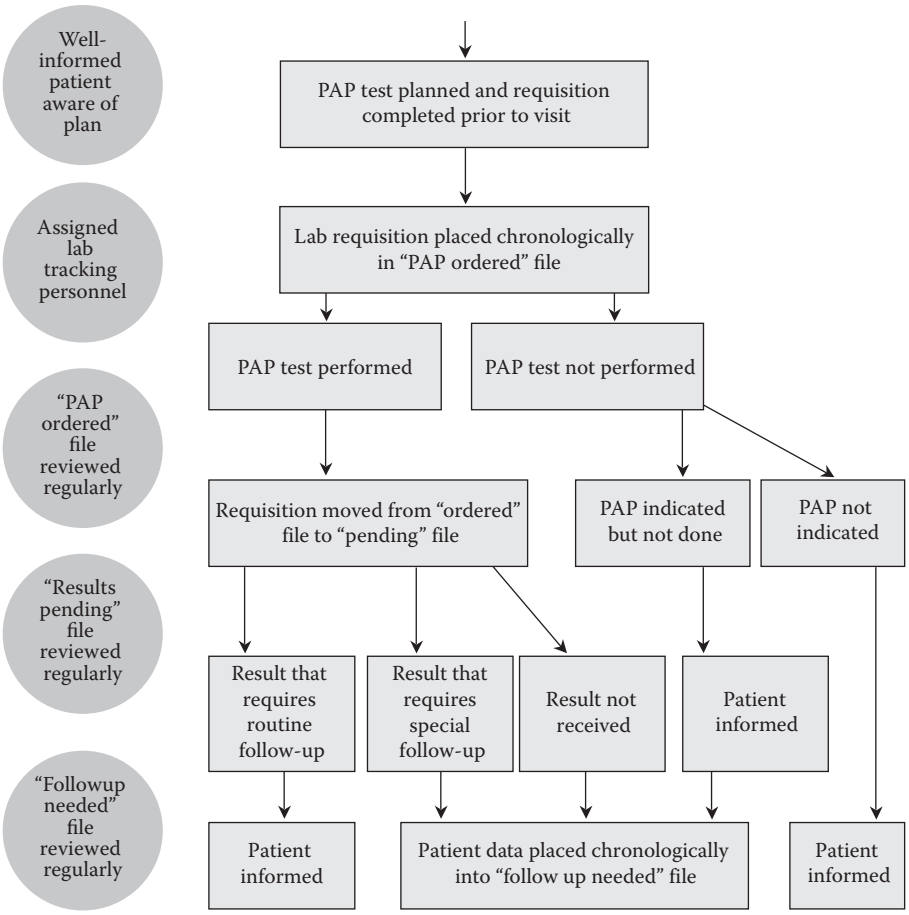

FIGURE 74.2 Example algorithm to prevent abnormal cervical cancer screening tests lost to follow-up. Note "PAP" refers to cytologic or HPV testing. The circles at left represent necessary background conditions and organizational structure that must exist in order for the algorithm to prevent error.

the number of women who achieve diagnostic cure.[20] For the many offices without access to an electronic system, however, paper tracking is possible and effective. Tracking systems for cervical cancer screening tests may be adapted according to the individual office's patient population, the level of the provider monitoring the tracking, and the anticipated lag time in the receipt of results. Figure 74.2 is an example of such a tracking system.

ERROR: FAILURE TO SUSPECT CANCER BASED ON ULTRASOUND OF THE OVARIES

There currently is no effective way to screen for ovarian cancer. However, clinicians are often faced with interpreting pelvic ultrasound results in order to determine which ones might be suggestive of ovarian cancer. The vast majority of pelvic ultrasounds reveal either entirely normal findings or findings suggestive of a benign process; as an example, several studies have shown that simple cysts (those without internal echoes on ultrasound) up to 10 cm are highly likely to be benign, with malignancy rates of less than 1%.[21–23] However, there is evidence that women with ovarian cancer whose care is managed by a physician with advanced training, such as a gynecologic oncologist, have improved overall survival rates when compared with those treated without such collaboration.[24–26] The challenge, then, is to properly utilize the information from a torrent of ultrasounds and avoid missing or under treating ovarian cancer by failing to refer the case to a specialist.

There are specific ultrasound results that warrant surgical consultation. For those women who are experiencing symptoms including, but not limited to, pelvic pain or abnormal uterine bleeding, surgery may be indicated even if the suspicion for cancer is very small. Likewise, for those women with solid tumors diagnosed on ultrasound, prompt surgical consultation is absolutely necessary.

The more difficult decision-making involves the patient who is not experiencing symptoms and does not have a solid tumor, but an adnexal cyst is discovered incidentally on pelvic ultrasound. The Society of Radiologists in Ultrasound convened a panel of specialists in 2009 from gynecology, radiology, and pathology to arrive at a consensus regarding the management of ovarian and other adnexal cysts imaged sonographically in asymptomatic women. Its consensus statement guides management diminishes the likelihood of overlooking cancer and identifies the characteristics that are most worrisome for malignancy (thick septations 3 mm or more, solid elements with flow at Doppler ultrasound, and focal

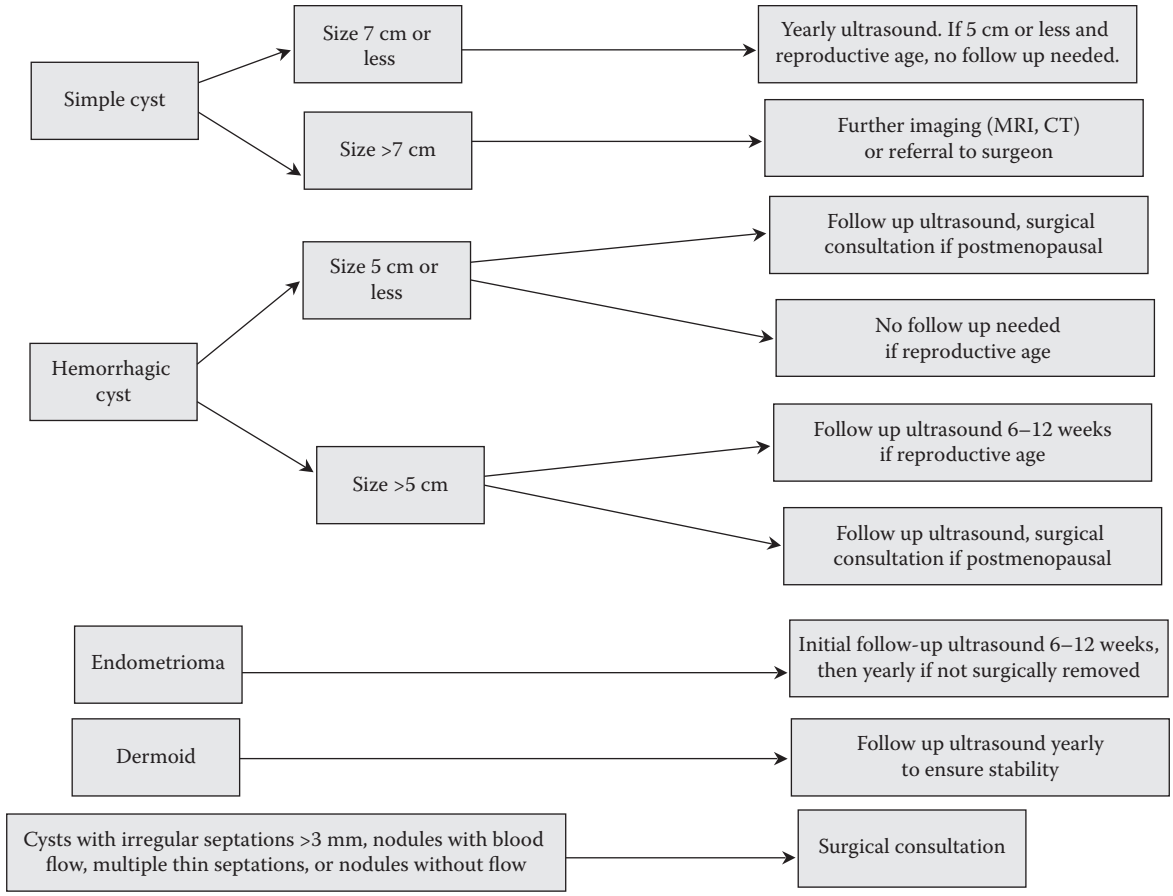

FIGURE 74.3 Example algorithm to prevent failure to suspect ovarian cancer based on ultrasound, based on recommendations from the Society of Radiologists in Ultrasound Consensus Conference Statement. (From Levine, D. et al., *Radiology*, 256(3), 943, 2010.)

areas of wall thickening 3 mm or more).[27] With these parameters, it is possible to effectively triage the management of asymptomatic adnexal cysts in order to minimize the risk of undetected cancer and maximize patient safety.

A clinical pathway that engages the patient in her follow-up after pelvic ultrasound, particularly in the asymptomatic patient who may be less likely to advocate for herself, will help with the timely detection of ovarian cancer. Such a pathway begins with ordering the ultrasound. A patient should be instructed to expect a result, and the clinician must have a system to trigger this, either electronically or on paper. The ultrasound exam should be considered incomplete until a patient is informed of the result, regardless of how she is feeling. Figure 74.3 is an example of such a clinical pathway.

ERROR: INCOMPLETE WORKUP OF POSTMENOPAUSAL BLEEDING

One of the most common reasons women seek medical attention is because of a change in their uterine bleeding pattern. Cancer of the endometrium is the most common type of gynecologic cancer in the United States, and bleeding is the presenting sign in more than 90% of postmenopausal patients.[28] Menopause is defined as the absence of menstrual periods for 1 year not due to pregnancy or medication, and bleeding that occurs after menopause must prompt a workup. Several modalities are available to investigate.

The ability of transvaginal ultrasound to diagnose or exclude endometrial cancer has been extensively studied and found to have an extremely high negative predictive value.[29–33] As a result, transvaginal ultrasound can be used to exclude the diagnosis of endometrial cancer for postmenopausal women who experience bleeding. An endometrial thickness of greater than 4 mm, however, does not yield a specific diagnosis and cannot be relied on to exclude pathology.[34]

Endometrial biopsy may be used as part of the workup for postmenopausal bleeding. However, studies have demonstrated that entrance to the uterine cavity may not always be possible, and attempts at retrieval of sufficient tissue for pathologic diagnosis are prone to failure.[35] In such cases, a normal transvaginal ultrasound demonstrating an endometrial thickness equal to or less than 4 mm may eliminate the need for more invasive testing; however, the problem must be addressed again if bleeding recurs or persists.

Postmenopausal bleeding can have a variety of clinical presentations, ranging from brown spotting to frank blood. Failure to investigate this complaint squanders an opportunity for early detection of cancer, and it is an error. Figure 74.4 is an example of an algorithm for the workup of postmenopausal bleeding.

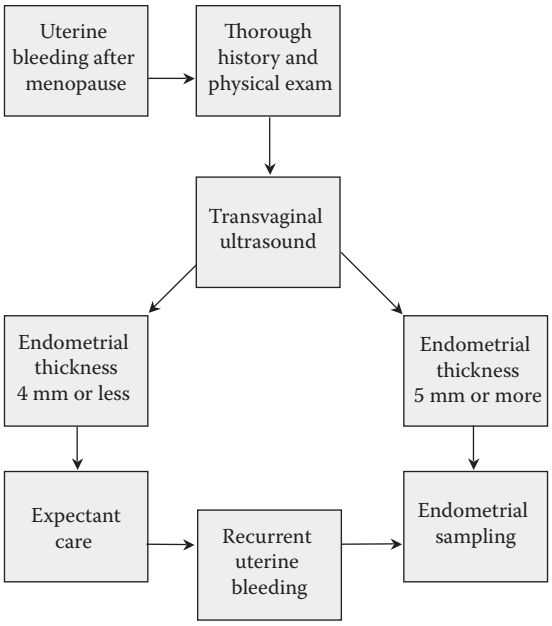

FIGURE 74.4 Example algorithm for the evaluation of postmenopausal uterine bleeding.

ERROR: PALPABLE BREAST LUMP, NORMAL IMAGING, LOST TO FOLLOW-UP

Breast cancer is the single most common female malignancy and a leading cause of cancer deaths in the United States.[36] Screening and early detection can make a difference in outcomes. Breast cancer may be detected during a clinician breast exam, through imaging, or sometimes, by the well-informed patient herself.

Commonly, women seek medical attention when they detect a change in their breast through self-examination. This is a cause of great anxiety, and patients look for immediate reassurance from a clinician's exam, or from mammography or ultrasound. This is the opportunity to educate the patient that the evaluation of a breast mass, particularly in a woman over 30, does not stop with imaging. As the patient leaves the office, she should expect to need an additional diagnostic workup for a palpable breast mass—even if imaging results are reassuring. The prevalence of breast cancer among women with a breast lump is relatively high (10%) compared with those who are asymptomatic, and about 15% of women with palpable cancer have a diagnostic mammogram that is normal.[37]

In women under 30 who have dense breast tissue, evaluation of a mass may begin with an ultrasound performed by a practitioner with training and expertise in breast imaging. For older women, the evaluation of a breast mass should include diagnostic mammography and may be augmented with breast ultrasound. With a palpable breast lump, screening mammography is inadequate as a single test to exclude cancer.[38,39] Therefore, if a patient is found to have a breast mass, workup should proceed even if she has had a recent normal screening mammography.

In order to obtain the most valuable information from breast imaging, a careful history and physical examination should be performed; any pertinent positive or negative findings should be conveyed to the patient and the imaging professional.[40] Important pieces of information include the timing of onset of the mass, changes in its size or shape, changes in skin texture, and the relationship of these changes to the menstrual cycle.[41]

Physical exam findings should be conveyed to the imager as precisely as possible. Noting the location of the mass by its clock-face location and distance in centimeters from the nipple, as well as its diameter, mobility, texture, and presence or absence of tenderness, can aid the imaging professional in arriving at a likely diagnosis. This is important when ordering either ultrasound or diagnostic mammogram. The patient herself must be fully informed and prepared to describe the location of a palpable breast lump to the imaging professional; without such information, the quality and usefulness of a report may be limited.

Communication with the patient in this clinical setting is paramount. According to the Risk Management Foundation (RMF) of the Harvard Medical Institutions,[42] several steps should be part of a system to make sure the patient understands the importance of follow-up for breast abnormalities. These include making follow-up or test appointments before the patient leaves the office, creating a system to recall and track patients who need follow-up, and reducing noncompliance by reminding patients of their appointments. Many radiologists are able to inform the primary provider when a patient does not appear for a scheduled test. Redundant safety steps can assure that no patient with a palpable breast lump is lost to follow-up so that breast cancer can be detected early.

Complete evaluation of a breast mass includes a well-informed patient, a thorough history and physical exam, precise interdisciplinary communication in a closed-loop fashion, high-quality imaging, the possibility of a return office visit to confirm resolution, and often a cytologic or histologic diagnosis. Figure 74.5 is an example of an algorithm for the evaluation of the palpable breast mass.

ERROR: UNSAFE MEDICATION PRESCRIBING

Safe prescribing and use of medications is a vital part of health care. The frequency of medication errors and preventable adverse drug events is a very serious cause for concern. The Institute of Medicine estimated in a 2006 report on preventing medication errors that approximately 450,000 preventable adverse drug events occur each year and that the rate of medication errors in hospitalized patients is approximately one medication error per patient per day. The report emphasized that medication safety is everyone's responsibility, and it proposed a move toward a patient-centered system. There should be openness—including with patients and families—regarding errors and problems, and information is made available to patients and their families that anticipates their needs and allows them to make informed decisions when choosing among alternative treatments.[43]

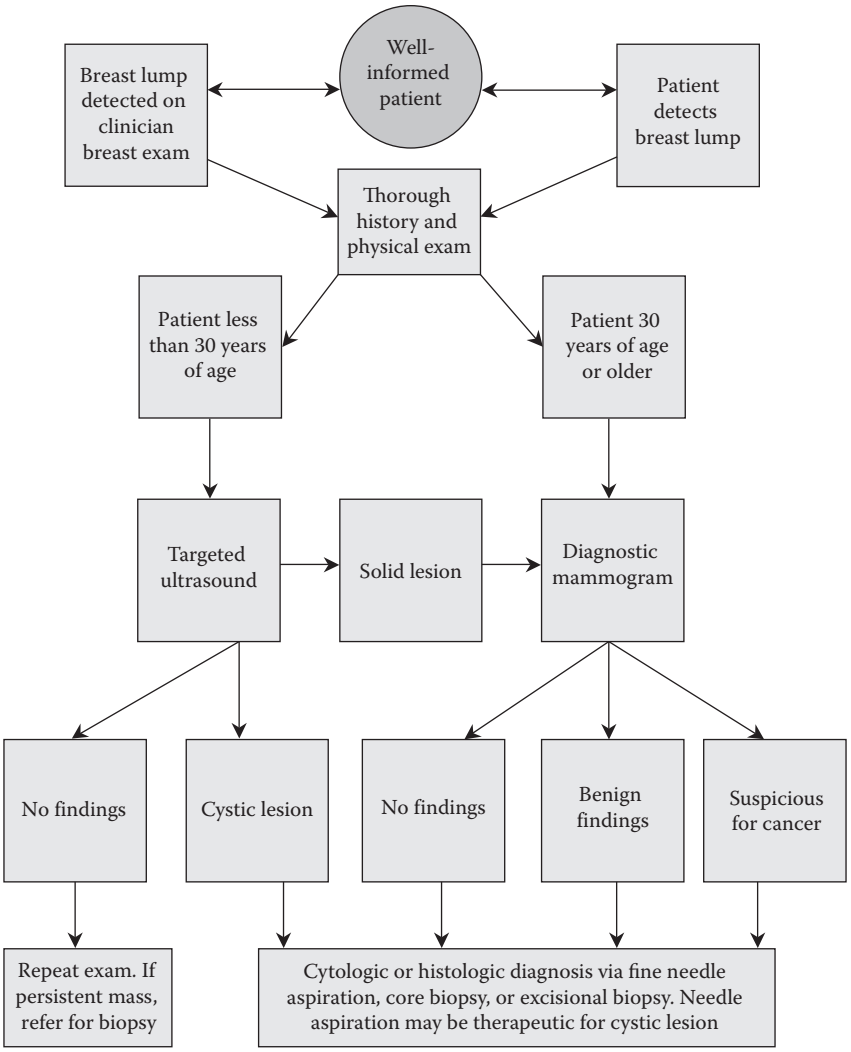

FIGURE 74.5 Example algorithm for evaluation and investigation of palpable breast mass.

In the labor and delivery setting, there are ample opportunities for errors in the transitions from triage to pre-procedure areas, labor rooms, and operating rooms, then to recovery and postpartum units. These mistakes may include poorly chosen drugs, inappropriate dosing, improper dosing intervals, or failure to prescribe a medication when it is indicated (an error of omission). The fatigue, stress, and production pressure that often accompany obstetric emergencies add to the vulnerability when using medications to care for patients with massive hemorrhage, sepsis, or fetal compromise. Often, such medications are ordered verbally and administered rapidly.

Similarly, medication errors are also common in ambulatory practice. Evidence reveals a preventable adverse drug event rate of 3 per 100 patients.[44] In the outpatient setting, medication orders are not usually checked, either in an electronic system or on paper, by pharmacists or nurses before dispensing and administration. Ambulatory practices often do not have policies for prescribing high-risk medications such as insulin or methotrexate, and there is no infrastructure to ensure read-back of prescriptions phoned into pharmacies or for deciphering illegible handwriting.

An additional hazard in the ambulatory women's health practice involves the risk of unknowingly prescribing a contraindicated medication to a patient with an undiagnosed pregnancy. While many medications can be used safely during early gestation, some drugs are preferable to others based on longevity of use and the historical lack of proof of human teratogenicity. The overbooked office schedule, task disruption, and burdensome outpatient documentation expectations increase the possibility of making such an error; however, an empowered patient who feels part of the care team and is therefore more likely to volunteer information, along with enhanced provider awareness and caution, will decrease the likelihood of unsafe medication practices.

In order to improve medication safety, providers need to take an active role. It should be routine to verify the patient's current medication list during each visit to ensure that it is accurate and up to date. Patient education before prescribing, allowing time for questions and answers, is essential. The name of the medication, a basic description of its mechanism of action, side effects, dosing schedule,

and drug–drug interactions should be reviewed. In this way, partnering with patients and engaging them in the medication-use process serve as a safety net in the ambulatory care practice.[45,46]

In many inpatient settings, and some outpatient, electronic prescribing is available. These systems ensure prescription completeness and are often able to be sent electronically to an outpatient pharmacy. They may be printed out, avoiding dispensing errors from illegibility. Many electronic prescribing systems are capable of decision support and can be integrated into the patient's electronic medical record. This creates an additional barrier to an incorrect medication or dosing interval or a potentially dangerous drug combination.

Medication safety in women's health rests on several key systematic preventive measures: routine and thorough patient education, attentive medication reconciliation and identification of allergies, scrutiny during the prescribing and dispensing process, and, most importantly, engagement and empowerment of the patient so that she becomes a valued member of the care team.

PUTTING THEORY INTO ACTION

As long as human beings are the ones who provide health care, the possibility of errors will exist. Concentrating only on those human errors, though tempting, is exceedingly unlikely to lead to a safer environment. Learning from error and creating sustainable systemic improvement are possible only when one steps back and looks at error in a different way.

All too often, those responsible for quality oversight, root cause analysis, and regulatory compliance function much like a firefighter. Caught in a barrage of everyday problems, well-intentioned nurses, physicians, medical assistants, and their managers focus on individual events or incidents. They quickly determine an immediate cause and eliminate it, exactly the way the firefighter responds to a desperate 911 call with a huge shower of water. The first responders cannot worry about whether the fire was caused by an unattended cigarette or an outdated electrical wiring system—the fire just needs to be extinguished. It is someone else's job to determine the reason for the fire; still others decide whether to update building codes or step up inspections that might help prevent a similar fire.

The health care analogy follows naturally: an elderly patient has a urine culture ordered at an office visit, the result never finds its way to a clinician's desk, and no antibiotics are prescribed. Three weeks later, the patient develops pyelonephritis and urosepsis, necessitating a prolonged intensive care unit admission. A likely reaction is to look at the clinician's habits, advise him or her to be more careful, and care for the patient's complication. The analysis and corrective action ends there; everyone is just too busy to look at this any differently, and bystanders are likely to say, "That wouldn't happen to me." A more holistic analysis of this error, though, would include consideration of the lab-reporting system, the office's paper reconciliation process, and the general approach toward educating the patient about being on the alert for notification of results. All would be considered aspects of process improvement. When the event is viewed this way, and improvements are aimed at root causes, the next patient will be less likely to be harmed by a similar mistake. Learning should be expected to follow errors or adverse outcomes.

In order to learn from an adverse event or error and make improvements, one must first understand how it happened. The error may be discovered through voluntary reporting or from analyzing a process or adverse event. One study in women's health that looked at voluntary reporting of medical errors showed that in a large tertiary care hospital, 38 of 82 medical errors reported during the study period represented potential adverse events.[47] The important point is that, in order to truly be successful at process improvement, errors and adverse events must be looked at as opportunities for generalized learning, not as things to be feared. There must be a change in the collective attitude.

Sharing the details of events is an important part of changing that attitude. Debriefs are a way to share information after an adverse or sentinel event has occurred, or even on a routine basis following a typical day's work. Debriefs are generally facilitated rather than led and work best when conducted within an organization that embraces a "just culture," originally described by David Marx, an attorney and expert in human error management[48]:

> It is through the lessons of our everyday errors that we can design our work environment to be less error prone and more error tolerant. Few people are willing to come forward and admit to an error when they face the full force of their corporate disciplinary policy, a regulatory enforcement scheme, or our onerous tort liability system. To collect productive investigative data, we must promote a culture in which employees are willing to come forward in the interests of system safety.

Debriefs are practical ways to gather information. They do not substitute for careful analysis but will facilitate corrective actions. Often, well-conducted debriefs will provide information that might, in another setting at another time, go undetected.[49]

Once the facts are known, through a debrief or other means, a simple way to analyze an event and elicit potential learning points and improvements is to utilize a question-asking method called "The 5 Whys." This technique developed by Sakichi Toyoda has been used within the Toyota Motor Corporation and the now-famous Toyota Production System, which is widely respected for its focus on continuous improvement, respect for people, and belief that the process that leads to the root cause of a problem will produce the right results. When faced with an adverse event, answers to "The 5 Whys" will uncover systemic

issues and lead to process improvement. The following example illustrates the technique:

1. The problem: The patient had emergency surgery and a fallopian tube was removed.
   a. Why? She had a ruptured ectopic pregnancy.
   b. Why? She did not phone the doctor when she had increased pain 3 days earlier.
   c. Why? She was not given instructions to call for this symptom when an early pregnancy was diagnosed and an ultrasound failed to show a normal pregnancy 2 weeks earlier.
   d. Why? The patient did not speak English and an interpreter was not available.
   e. Why? It was a weekend when she was initially diagnosed with a pregnancy, and interpreters do not work on the weekend.

Looking only at the outcome in this example, one can see the temptation to blame the provider. However, a quick analysis yields a few opportunities for systematic improvements: making interpreters available on the weekend, perhaps by telephone, having printed instructions available in a variety of languages, and creating a callback system for patients diagnosed with early pregnancy when follow-up is critical. When viewed in this way, it is apparent that although the provider did not adequately follow up with the patient, there were systematic deficiencies that enabled the whole mistake to happen.

We must look at the way we provide care in a way that points us toward continuous improvement, not continuous blame. In *Chasing the Rabbit*, Steven Spear, a senior fellow at the Institute for Healthcare Improvement, suggests ways to start process improvement projects that are likely to successfully reduce error and avoid adverse events[50]:

- Start with a small project. Improve a process that you know well and is in the control of just a few people; in this way, the chance for sharing ideas as improvements are made will be high.
- Solve a problem that really matters. Do not pick something people do not care about.
- Real learning comes to life as you walk through a process. As you decide to make improvements, do not just stand by—get involved and know the work.
- Stay safe. Improve things in a way that does not put anyone at risk.
- Budget time every day for designing a work process in order to see its problems, for solving those problems, and for sharing what you learn with others to whom the new insights may be useful.

Women's health care presents countless chances for mistakes, but it also offers an ideal environment for systems that can prevent error and improve in both inpatient and outpatient settings. A commitment to examining error in a nonpunitive way, addressing adverse events as opportunities to learn and improve, and reworking systems deliberately and persistently will create a safer environment for women.

OVERVIEW

The skin is a vital organ in the human body, and as with any other organ, proper nutrition can help improve function and longevity. Improper diet can exacerbate or cause disease states that can severely impact the skin and the entire body. The appearance of the skin can also be significantly affected. Therapeutic and preventative dietary measures are important for skin health just as they are for other bodily organs. For example, people with heart conditions carefully monitor salt intake and balance other nutritional requirements in order to control their cardiac disease and to improve their prospects of healthy longevity. Even people without a diagnosed cardiac condition are attempting to be more "heart smart" in order to prevent the development of cardiovascular disease. Being "skin smart" is also very important because the skin is constantly bombarded with environmental stressors like UVA and UVB radiation, and the nutritional requirements needed to prevent skin damage and increase the overall health of the skin should be considered. The internal ravages of smoking and its ability to cause lung cancer are well known, but it is also easy to see the impact of smoking in a smoker's lax and wrinkled skin. So both health and beauty of the skin are influenced by dietary choices.

The concept that a healthy inside is equal to a healthy outside is gaining momentum, and evidence is growing daily that the presence or absence of certain foods in the diet can improve or worsen skin conditions [1]. The appearance of the skin is also reflected by nutritional state, and just as people aspire to "healthy longevity" for their body, another useful goal is to achieve a lifetime of healthy skin. While encompassing the diseases related to skin nutrition, this chapter will also attempt to give a broader understanding of why certain nutrients are needed in the skin and where they can be obtained in the diet.

Change in Dietary Habits

In modern society, "fast" food is abundant. Foods are highly processed and chemicals are added to them on a routine basis to act as preservatives, artificial flavorings, or colorings. Dietary fat and sugar intake is high, and overindulgence of fried foods and sweetened drinks and snacks is common. In short, people are eating more and more of the wrong things and less of the beneficial things needed to promote healthy skin. A recent review of the food consumption in America over the last 100 years (1909–2008) by the USDA demonstrated the average citizen eats 37% more processed food now than they did 100 years ago. Even more disturbing is the consumption levels of high-fructose corn syrup, which is the predominant sweetening agent in processed foods. It is estimated that the average consumption of high-fructose corn syrup, as of 2003, is 61 lb/year, the average sugar consumption is 142 lb/year, and the average soft drink consumption is 46 gal/year [2]. The average consumption level (in pounds of food per year) has also increased from 177 to 251 lb. As of 2008, the average American on a 2000 cal diet consumes 130% of the recommended grain servings and 120% of the recommended meat servings per day. To go along with this overconsumption of meat and grain, the average consumer gets only 70%, 60%, and 40% of the recommended vegetable, dairy, and fruit servings per day [3].

As previously stated, the most common outward appearance of premature aging and poor skin nutrition is characterized by loose, wrinkled, and dyschromic skin (often appearing as spots of hyperpigmentation). However, aging skin is also a combination of genetics, disease, progressive deterioration, body composition, and environmental stress [4]. The importance of nutrition in skin and overall health can be seen in a recent study for caloric restriction in monkeys. The study demonstrated that calorically restricted monkeys had not only better looking skin and fur (in both texture and fur color) but also reduced amount and severity of disease as the monkeys aged [5]. By contrast, a longtime rhesus monkey researcher said the (at one time) largest monkey on record, "Fat Albert," ate nothing but the American Heart Association-recommended diet [6]. This illustrates that one diet may not work for all situations and that optimal nutrition for skin health will take into account all factors and attempt to provide the proper nutrients in the proper amount to keep the skin healthy and all defensive and repair mechanisms running smoothly.

Nutritional Guidelines and Supplementation

The most popular set of nutritional guidelines is the recommended daily allowance or RDA. The RDA was created in 1941 by the Food and Nutrition Board and was designed to represent values that would be acceptable to 97%–98% of the healthy population in each group based on gender, age, and health stage. The RDAs were generally updated every 5–10 years. More recently, there have been a number of other additions to the nutritional guidelines for different purposes, which we will summarize here. The reference daily intake (RDI) is used for nutrition labeling by the FDA and was initially based on the highest 1968 RDA value to ensure that the needs for all groups were met. The most current nutritional guidelines (as of November 2010) in use are the dietary reference intake (DRI) established by the Food Nutrition Board of the Institute of Medicine. The DRI is composed of several measurements: (1) the estimated average requirements, which is expected to satisfy the needs of 50% of the selected age group based on the review of the scientific literature; (2) the RDA (previously described); (3) the adequate intake, which is an intake level believed to cover all members of the group and is used where no RDA exists; and finally (4) the tolerable upper intake level, which is the highest level of consumption that the current literature or data show to be safe. It should be noted that the DRIs are currently based on pooled opinion and literature review and not on randomized, controlled clinical studies [7]. So, as evidenced here, most people use general guidelines, which, while ensuring that basic nutritional levels are met for most healthy individuals, have little focus on the unique needs of an individual based

on the many previously mentioned factors. In general, under the current system of guidelines, an elite athlete or a chronically ill person would require the same nutrient levels as an average, healthy person. While this will keep the individuals free from disease caused by deficiency, it is obvious the nutrient requirements are vastly different.

It is currently estimated that per year use of dietary supplements and the dietary supplement production and sales of over 150 million Americans is a $26.9 billion industry. The industry is regulated by the FDA and the Federal Trade Commission through the Dietary Supplement and Nonprescription Drug Consumer Protection Act [8]. The sheer volume of products competing in the marketplace almost assures varying levels of efficacy. Consumers need to be aware of how products are tested and what the results of those tests truly mean for them. For instance, products containing conjugated linoleic acid showed the ability in vivo and in animal studies to produce a loss of fat mass and increase in lean muscle tissue. In human trials, little evidence was found of reducing body weight or repartitioning of body fat and fat free mass; it is possible that the increase in LDL:HDL ratio may result in an adverse effect on human health, in this case a higher cardiovascular risk [9]. The final variable found in dietary supplements is that the actual nutritional content may vary from what is described on the label, sometimes at levels over the upper limits or at reduced levels [10].

VITAMINS IMPORTANT FOR HEALTHY SKIN

Vitamin C

Vitamin C is the common terminology for L-ascorbic acid or L-ascorbate. It is a vitamin, antioxidant, and enzymatic cofactor in at least seven important cellular reactions, several of which involve the synthesis of collagen, which is vital in maintaining skin health. Collagen synthesis, aside from its importance in skin appearance and health, also plays a vital role in the healing of wounds (Office of Dietary Supplements, 2010) [11]. The most severe symptoms of scurvy (a disorder caused by vitamin C deficiency) stem from inability to synthesize collagen. Vitamin C is made internally by most organisms, with humans and primates being the most notable exceptions. Synthesis of vitamin C requires L-gluconolactone oxidase (GLUO), which is lacking in the human and primate body, making it essential that enough vitamin C be taken in through the diet. Vitamin C functions in an antioxidant role in the body. As L-ascorbic acid, it has reducing agent properties and is converted to L-dehydroascorbate (oxidized vitamin C). This molecule is then recycled to active L-ascorbate through enzymatic reactions involving glutathione [12].

Vitamin C is absorbed from consumed food via the intestine through sodium-dependent active transport and simple diffusion. The mechanisms regulating the bioavailability of vitamin C are complex and not fully understood. After absorption from food, any excess vitamin C is excreted in the urine making vitamin C toxicity a rare occurrence, but reinforcing the need for meeting the daily requirements for good health and healthy skin. Relating to healthy skin, it has been shown that outer layers of the skin itself (epidermis) store vitamin C at higher levels than deeper layers, such as the dermis [13]. Other areas of the body that demonstrate higher levels (100× more than in serum) of vitamin C are the adrenal gland, pituitary gland, thymus, corpus luteum, and retina. The brain, spleen, lung, testicles, liver, lymph nodes, small intestinal mucosa, leukocytes, pancreas, kidney, and salivary gland demonstrate levels of vitamin C 10–50× greater than serum [14].

There are multiple forms of vitamin C, both natural and synthetic, and the bioavailability and rate at which they are absorbed through the skin can often vary. One form is ascorbic acid 2-phosphate, which when given to human dermal fibroblasts increased the gene expression levels of genes associated with DNA replication and repair, showed faster repair of oxidatively damaged DNA, and increased proliferation and cell motility in the context of wound healing. This is a good indication that a topical application of a stable vitamin C derivative can serve to protect the main components of skin from reactive oxygen species (ROS) and aid in repair/wound healing [15]. Percutaneous absorption of vitamin C studies have shown that the L-ascorbic acid form demonstrates over 400-fold greater absorption than vitamin C palmitate or Mg ascorbyl phosphate [16]. There are ways to increase the absorption of vitamin C through the skin: one such method demonstrated that pretreatment with lasers can increase the amount of vitamin C derivatives across the dermis by 82- to 117-fold in the case of 3-*O*-ethyl ascorbic acid and 181- to 277-fold in the case of another derivative, ascorbic acid 2-glucoside [17]. Bioavailability of vitamin C is another factor that can vary, particularly in amount available following an oral dose. It has been demonstrated that vitamin C in doses of 15 mg has an 89% bioavailability, at 100 mg there is 80%, at 200 mg there is 70%, at 500 mg there is 63%, and at 1250 mg there is 46% bioavailability, indicating that increased dosage does not ensure a greater amount of bioavailable vitamin C [18].

The highest recorded concentrations of vitamin C have been found in Kakadu Palm, CamuCamu, rose hip, acerola, and sea buckthorn. Other plant sources with good vitamin C concentrations include green chili pepper, guava, black currant, red pepper, papaya, strawberry, orange, kale, garlic, cauliflower, and raspberry. Animal sources of vitamin C are less common and have a much lower concentration than plant sources, but some examples are raw oysters and fried livers (raw beef, chicken, and calf livers contain more vitamin C, which is damaged during cooking, but raw liver is far less palatable than cooked). If not enough vitamin C is obtained through the diet, a deficiency can result. The most recognizable disorder tied to vitamin C deficiency is scurvy. Scurvy left untreated is fatal and is incredibly rare in modern times since all that is needed for treatment is to resume adequate levels of vitamin C. The symptoms of scurvy demonstrate the significance of insufficient collagen synthesis on the health of the skin. It commonly causes dry and splitting hair; gingivitis and other gum inflammations; rough, dry, and scaly skin; easier

bruising; and decreased wound healing rate. Other symptoms not directly related to skin include anemia, nosebleeds, swollen and painful joints, decreased ability to fight infection, and possible weight gain through slower metabolism [19].

Vitamin E

Vitamin E is the collective name for a group of important fat-soluble antioxidants. There are eight chemical forms: alpha, beta, gamma, and delta tocotrienol and a coinciding set of tocopherols with varying levels of biological activity. Originally, alpha tocopherol was thought to be the only form recognized as able to meet human requirements, but it is the preferred form in the body [20]. The American diet consists of mainly gamma tocopherol, while the European diet is mainly alpha tocopherol, which is also the primary form used in nutritional supplements. While alpha tocopherol is predominantly thought to be the "best" form, new research is pointing toward the applications of other forms like delta tocopherol, which has recently been shown to be more active than the alpha or gamma forms at inhibiting tumorigenesis in an in vivo mouse model. Delta tocopherol was shown to reduce oxidative DNA damage while enhancing apoptosis in tumor cells to a greater degree than either alpha or gamma tocopherol [21]. Vitamin E, particularly in alpha tocopherol form, primarily functions as a peroxyl radical scavenger; by doing this, it maintains the integrity and bioactivity of long-chain polyunsaturated fatty acids found in cell membranes and damaged through oxidative stress [22]. The tocotrienol forms of vitamin E are a new area of research, but are thought to be even more potent antioxidants than the tocopherols, as well as being more active against cancer, cholesterol, and brain cell damage.

The primary use of vitamin E in relation to skin health is in the area of UV protection. As early as 1985, researchers discovered that vitamin E could confer some protective effects against UV exposure [23]. Topically applied vitamin E has a significant effect on protecting from UVB radiation, but has not been shown to have a large effect on UVA radiation. A 5% vitamin E cream applied to the skin prior to a 30 J UVA exposure demonstrated no change in the melanin index over the 12 week study [24]. However, when skin with topically applied vitamin E is exposed to UVB radiation, it demonstrates reduced erythema, less sunburn cells (SBCs), reduced chronic UVB-induced skin damage, and photocarcinogenesis in most studies. It was also determined that only high oral doses of vitamin E show a significant photoprotective effect, but a synergistic effect between vitamin C and E does exist [25]. This synergy for skin protection is demonstrated even further in a study of 45 volunteers supplemented with vitamin C, vitamin E, and vitamin C + E exposed to UVB radiation. The minimal erythemal dose (MED) in subjects with vitamin E supplementation increased from 60 to 65 mJ/cm^2, and in the vitamin C + E group the MED increased from 50 to 70 mJ/cm^2 [26]. As previously described, vitamin E contributes to healthy skin mainly in its role as an antioxidant by protecting skin from UVB damage and raising the overall photoprotective level. It can also help regulate the levels of vitamin A in the body and shows some anti-inflammatory capacity through the regulation of PKC. These anti-inflammatory properties are why it has been used, with varying degrees of success, to treat inflammatory skin disorders like psoriasis.

The best sources of vitamin are nuts, seeds, and oils, more specifically wheat germ oil, sunflower seeds, almonds, hazelnuts, sunflower oil, and saffron oil. Another effective source is fortified breakfast cereals which have been shown more effective than some capsule supplements [27]. Common plant sources include tomatoes, mangoes, spinach, broccoli, and kiwi fruit. Animal sources are generally poor sources for vitamin E.

Vitamin E deficiencies in the American and European diets are rare, but diseases that prevent the absorption of fat, such as Crohn's disease, cystic fibrosis, or liver disease, may interfere with the absorption and ability to process vitamin E and may require supplementation. When deficiencies do occur, they can cause neurological conditions stemming from impaired nerve conduction and anemia/hemolysis. The effects on the skin can include decreased sun protection (which results in higher levels of oxidative stress, DNA damage, and the like) and easier bruising.

Vitamin A

Vitamin A is a generic term for a number of related compounds collectively known as retinoids and carotinoids. The compounds are composed of retinyl groups, and the most commonly known is beta carotene, which comprises two joined retinyl groups. One of the compounds under the vitamin A umbrella is retinoic acid (a converted form of retinal aldehyde), which is important in skin health. It regulates gene expression levels that allow keratinocytes to mature into endothelial cells. It (in the form of all *trans* retinoic acid) has also been shown to reduce the activity of collagen-degrading enzymes like MMP-1 by reducing the post-UVB activity of the transcriptional factors AP-1 and NFKB [28]. It is this stimulation of immature skin cells that has led the cosmetic industry to use retinoic acid for the improvement of fine lines and wrinkles, as well as to treat psoriasis. The mechanism of retinoid action on skin health is not well known, but they remain popular in the treatment of many skin-related diseases. For example, 13-*cis*-retinoic acid, commercially known as Accutane, is used to reduce the size and activity of the sebaceous glands. A second prescription retinoid, called tazarotene, is approved for use in the treatment of acne, psoriasis, and sun-damaged skin. It is commonly sold in a gel or cream form at concentrations of 0.05% or 0.1%. The effects of vitamin A compounds are not limited to the skin; another compound, retinol alcohol, accumulates in the retina and plays a role in the formation of the visual pigment rhodopsin. Vitamin A is also involved in cellular differentiation, differentiation of white blood cells, the integrity/function of skin/mucosal cells, and the expression of growth hormone [29].

The precursor of vitamin A is beta carotene, and this compound is also a singlet oxygen quencher, which has been shown to inhibit MMP-1 and MMP-10 expression in keratinocytes [30]. Vitamin A is a lipid-soluble vitamin, and excess vitamin A is not easily removed from the body, which can allow buildup to toxic levels. Dietary vitamin A is obtained from preformed vitamin A (i.e., retinyl esters from animal foods, fortified foods, and pharmaceutical supplements) as well as from provitamin A carotenoids from plant sources. Preformed vitamin A is efficiently absorbed and utilized by humans at absorption rates of 70–90% (Penniston K., Tanumihardjo S., [31]. However, the intake of dietary fat needs to be evaluated as studies have had conflicting results indicating improved vitamin A absorption [32] and other studies that indicated no noticeable effect of dietary fat intake on the absorption levels [33]. Disregarding the dietary fat effect on absorption, the most common plant sources for vitamin A compounds are carrot, sweet potato, kale, spinach, pumpkin, collard greens, cantaloupe, mango, and butternut squash. Animal sources are also viable sources of vitamin A and can include milk, butter, eggs, liver (beef or poultry), and cod-liver oil.

Vitamin A deficiencies can be either a primary deficiency, in which not enough vitamin A is consumed in the diet, or a secondary deficiency where the individual cannot absorb lipids or is in a state of continuous exposure to oxidative stress (e.g., cigarette smoking or alcoholism). Vitamin A deficiencies are unfortunately quite common in children under the age of 5 around the globe and can result in blindness. These instances are highest in Southeast Asia and Africa, where hunger and malnutrition continue to be problems [34]. The good news is that simple supplementation with vitamin A can decrease the mortality levels of these children by 23% [35]. Along with its effect on children, vitamin A is also important in prenatal care, but should come from whole sources and not supplements [36]. This is due to high oral doses having been shown to affect the developing fetus, resulting in side effects ranging from a serious disruption of cephalic neural activity to a transient carotenodermia or orange-yellow tinting of the skin.

In adults, vitamin A can be over- or underconsumed, with both states resulting in disorders and disease states. Toxic levels of vitamin A symptoms include muscle weakness or pain, nausea, irritability, blurry vision, and headaches. A chronic state of excess often leads to dry skin, fever, fatigue, bone fractures, hair loss, and diarrhea. Deficiencies in adults commonly cause blurred vision, night blindness (even actual blindness), and lowered protection from ROS and oxidative stress. This reduction in ROS protection leads to an increase in the photodamage to the skin and poor bone health.

Vitamin K

Vitamin K is another fat-soluble vitamin, which has two types of natural versions, K_1 or K_2, and three synthetic versions, K_3, K_4, and K_5 (commonly used in the food industry). Both natural forms are naphthoquinone derivatives, with K_1 being obtained from outside the body and K_2 is synthesized in the gut by normal intestinal flora. Vitamin K is primarily responsible for blood clotting, but is also involved in the posttranslational modifications of proteins and metabolic pathways for bone and tissues. It also converts glutamate in proteins, which then bind calcium and affect the previously described pathways [37]. Oral vitamin K absorption occurs in the intestinal tract and is mediated by the amount of free bile present. Penetration of vitamin K into the skin is low, with the majority of the penetrated molecule located in the stratum corneum and a lesser portion being found in both the dermis and the epidermis 12 h post-topical application [38].

Vitamin K_1 is obtained through the diet primarily from green leafy vegetables. Viable sources of vitamin K_1 are spinach, Swiss chard, beet greens, asparagus, broccoli, collard greens, kale, parsley, and olive, soybean, and canola oils (although the oils would require too large a caloric intake to give the full RDA) [39]. It is thought that cooking sources of vitamin K with fat increases the bioavailability of vitamin K. Vitamin K_2 sources are found primarily in animal sources like meat, eggs, and dairy products [40].

Vitamin K, while being fat soluble, has no known toxic levels (K_1 and K_2), but deficiencies can occur. Though they are rare in adults, they are more common in newborns due to their underdeveloped intestinal flora. Deficiency causes easy bruising and bleeding (particularly from the gums), which can be severe and life-threatening in infants. Lack of sufficient vitamin K in the skin can result in dark circles under the eyes and increased ease of bruising. Vitamin K in conjunction with retinol is used in antiaging regimens. It has been used to treat rosacea and can be applied topically after cosmetic injections to help prevent or reduce the severity of bruising.

Vitamin B Complex

Originally thought to be 1 vitamin, it was later determined that there are many different chemical structures (roughly 28) that are often present in the same food. Vitamin B must be obtained from the diet as it is not synthesized by the body. There are eight major forms of B vitamin that are often referred to as the B complex. The following eight compounds form the B complex:

Vitamin B_1: Thiamine

Used primarily for protein binding, most serum thiamine is bound to albumin in erythrocytes. Vitamin B_1 is absorbed through carrier-mediated transport at low concentrations and passive diffusion at high concentrations. Sources of vitamin B_1 are commonly whole grains. Most of the thiamine is found in the germ layer, which is removed in the processing of rice and flour. To combat this, most Western countries must put the thiamine back into processed white rice and bread. Other sources of thiamine are other fortified grains (common in breakfast cereals), lean pork, milk, oatmeal, asparagus, cauliflower, and kale [41].

Thiamine deficiency results in a disease called beriberi, which can be termed "dry," "wet," or "infantile." It is not common for beriberi to have skin effects other than a slight

rash or swelling in the extremities; however, it is possible. Dry beriberi affects the nervous system and causes symmetric impairment sensory, motor, and reflex functions in the distal limbs. Wet beriberi not only affects the cardiovascular system but can also cause neuropathy, tachycardia, edema, mental confusion, muscular atrophy, and congestive heart failure. Infantile beriberi affects babies who are being nursed by thiamine-deficient mothers (who may not themselves show symptoms of thiamine deficiency) and has symptoms akin to wet beriberi, which can result in death if not treated.

Vitamin B_2: Riboflavin

Vitamin B_2 is what imparts the yellow color common to the vitamin. It is the main component of key oxidoreductase cofactors (FAD and FMN), which are vital to the energy metabolism of fats, proteins, and carbohydrates. Riboflavin is destroyed by exposure to light. Vitamin B_2 is naturally found in milk, cheese, tomatoes, almonds, mushrooms, and green leafy vegetables [42]. It is also removed in the processing of grains, flours, and cereals and must be added back post-processing. Items that have had the riboflavin added back in are labeled as "enriched."

Riboflavin is a water-soluble vitamin, so it is continuously excreted in the urine. Dietary insufficiency can easily lead to a deficient state known as ariboflavinosis. Common in alcoholism, one of the symptoms is angular stomatitis, which is cracking of the lips and edges of the mouth. In addition, the skin can be affected in other ways, such as seborrheic dermatitis (particularly around the scrotum or labia majora). Other symptoms common to riboflavin deficiency are glossitis (purple, atrophied tongue) and redness/swelling of the mucosa in the throat and mouth. Riboflavin deficiency in pregnant women is 4.7 times more likely to cause preeclampsia or hypertension due to pregnancy [43].

Vitamin B_3: Niacin

This vitamin exists in two alternate forms, nicotinamide and inositol hexanicotinate, which have different physiological effects than niacin. Niacin is important in metabolism, nervous function, and production of sex- and stress-related hormones. Recently, niacin has been used to lower elevated LDL levels and raise HDL levels [44]. Niacin is most often found in dairy products, lean meats, fish, nuts, eggs, and legumes and, like many other vitamin B compounds, is added back to processed grains, flours, and cereals. A niacin deficiency, also known as pellagra, is caused through dietary insufficiency or inability to absorb the vitamin. This is common in alcoholism and gastrointestinal disease sufferers. Symptoms of pellagra include scaly skin sores, mental confusion, delusions, diarrhea, and inflamed mucous membranes [45].

Vitamin B_5: Pantothenic Acid

Pantothenic acid is essential to all forms of life and is found in cells as coenzyme A. Coenzyme A is a cofactor in energy metabolism, synthesis of essential fats, steroids, acetylcholine, and heme. Heme is a component of hemoglobin, which binds oxygen in the blood. The main function coenzyme A performs in the previously mentioned processes is acetylation of key compounds [46]. Vitamin B_5 has been shown to accelerate the closure of wounds and increase the strength of the scar tissue in animals. In human skin fibroblast cultures, it has demonstrated increased number and speed of wound migrating skin cells, but clinical trials in humans remain inconclusive to date [47]. Coenzyme A is primarily found in animal muscle tissues, the outer layer of whole grains (which is often lost through processing and not added back in items labeled enriched), mushrooms, avocados, and broccoli [48].

As essential as coenzyme A is, deficiencies are not only fortunately rare but also poorly understood and studied. There is a broad range of symptoms associated with lack of vitamin B_5 in the diet. Typical of most B vitamin deficiencies, it results in lower energy output due to the important role coenzyme A plays in energy metabolism. This decreased energy output manifests as fatigue, apathy, or irritability. There can also be neurological symptoms like numbness, stinging of the feet or hands, muscle cramps, nausea, and in a few rare instances, adrenal and hepatic problems [49].

Vitamin B_6: Pyridoxine

Pyridoxine, again like most B vitamins, plays a role in the energy metabolism of food. Additionally, it also aids in the formation of red blood cells, antibodies, and proteins and in maintaining the integrity of healthy skin. Vitamin B_6 is most common in fortified, ready-to-eat cereals. It can be found in potatoes, bananas, garbanzo beans, pork loin, roast beef, trout, salmon, tuna, and chicken breast [50]. Like vitamin B_5, deficiencies of pyridoxine are also uncommon, although it most frequently appears in alcoholics due to their impeded ability to absorb the enzymes and overall diet deficiency. Vitamin B_6 deficiency is also noted in infants, manifesting as seizures or irregular EEG patterns. In more severe cases, the lack of proper vitamin B_6 in the body can also cause irritability, confusion, and sores/ulcers of the skin and at the corners of the mouth [51].

Vitamin B_7: Biotin

Biotin is essential for cell growth and production of fatty acids, plays a key role in the citric acid cycle, and assists carbon dioxide transfer. One of the biological activities of vitamin B_7 is the biotinylation of histones, which may have a role in affecting replication and transcription of DNA [52]. While it is required by all organisms, it is synthesized only by bacteria, yeast, molds, algae, and some plant species [53]. Vitamin B_7 comes from a variety of sources, but very few would be considered "biotin rich." Egg yolks have high biotin content when raw, but cooking and consumption with the egg whites mitigates the bioavailability. Other sources include yeast, raspberries, avocado, pork, salmon, and cauliflower [54].

Since biotin is synthesized in the body by intestinal flora, deficiencies are uncommon. In the rare instance the intestinal flora does not produce enough biotin or enough is not taken in from the diet, disorders can result. The symptoms, other than the neurological and energy metabolism-based ones, are

common to the skin. Biotin deficiency, as exhibited in the skin, has been known to cause alopecia (including the eyelashes); scaly, red rash around the mucous membranes; and unusual fat distribution in the face. Systemically, it can cause numbness in the extremities, lethargy, depression, and even hallucinations [55].

Vitamin B_9: Folate/Folic acid

Vitamin B_9 occurs naturally as folate, and not folic acid. The biologically activating step of folate occurs in the liver and involves the transformation of folate into dihydrofolic acid [56]. Bioactive vitamin B_9 is important in the synthesis, methylation, and repair of DNA. It also has a key role in the production of red blood cells and recently has been shown to potentially prevent changes that are commonly associated to lead to causation of cancer [57]. Supplementation of folate in pregnant women has been shown to significantly reduce the risk of neural tube defects [58]. Green, leafy vegetables and citrus fruits are excellent sources of folate. Other common sources include asparagus, lentils, and lima beans. The FDA has also required addition of folic acid to any already enriched and refined grain products like pasta, rice, or bread in an effort to ensure that the proper nutrient levels are met for the population [59]. Folate deficiency is more common than the other B vitamin deficiencies and occurs most commonly when an increased need for folate is not matched through the dietary intake. States requiring a higher folate intake include pregnancy/lactation, alcoholism, and kidney dialysis. Medications can also interact and cause a need for folate, particularly anticonvulsants, barbiturates, and drugs used to control inflammation in Crohn's disease or colitis [60].

Vitamin B_{12}: Cyanocobalamin

Vitamin B_{12} is the most common and air-stable form of vitamin B, found in some foods but commonly used as a food additive in most others. Vitamin B_{12} is not actually usable by the body, but can be converted into active cofactors like methylcobalamin and 5′-deoxyadenosylcobalamin [61]. Through these and other cofactors, vitamin B_{12} is involved in the formation of red blood cells and of genetic material (commonly DNA) and is an important cofactor in methionine synthesis. Methionine is required to create compounds that serve as methyl-donating species in over 100 reactions in the body. When taken orally at a 1 mcg dose, approximately 56% of the dose is absorbed. The absorption of vitamin B_{12} decreases drastically when the capacity of the intrinsic factor is exceeded, usually around 1–2 mcg of B_{12} [62].

Sources of vitamin B_{12} are lean meats (turkey, mutton, liver, and chicken demonstrated average bioavailability from 40% to 89%), milk, shellfish, eggs, tea leaves/drinks, cabbage, spinach, celery, broccoli, soybeans, and edible algae, aka nori in Japanese cooking [63]. B_{12} is also added to fortified cereals, like many of the other B complex vitamins. Vitamin B_{12} deficiency is more prone to occur in vegans/vegetarians since the primary natural sources are meat based. A deficiency can also be caused through malabsorption, common in disorders like gastritis. Symptoms include anemia and neuropathy [64]. Cutaneous manifestations can be hyperpigmentation, vitiligo, angular stomatitis, hair loss/changes, and unresolving/unexplained skin lesions [65].

Vitamin D

Vitamin D is a fat-soluble vitamin that must be metabolized into biologically active forms and is synthesized in the skin following UVB exposure. The vitamin D (D_3 or cholecalciferol) synthesized in this fashion must be obtained through the diet if UVB exposure is low, as vitamin D is a key component in maintaining normal calcium metabolism, which is important for bone growth and bone density and in keeping serum calcium levels in the narrow range required for proper nervous system function [66]. Vitamin D can also function as an immunomodulator and promoter of cellular differentiation and proliferation.

Aside from being generated by sunlight in the skin, vitamin D, since not many foods contain vitamin D, can also be obtained in the diet by supplements or with more difficulty through consumption of egg yolks; salmon, mackerel, and sardines; and fortified milk, cereals, and juices. Severe deficiencies of vitamin D have been known to be serious for a long time, but lesser states of deficiency can exist, and knowledge of risk factors for vitamin D deficiency is becoming more important. The known risk factors involved in vitamin D deficiency are infants who are exclusively breast-fed (they do not receive the vitamin in fortified milk), people with dark skin (since less UVB radiation penetrating the skin means less D synthesis), fat malabsorption syndromes, inflammatory bowel disease, aging, and lack of sun exposure (due to covering the skin or using sunscreens whenever outside). A sunscreen of SPF8 will reduce the amount of vitamin D synthesis by as much as 95% [66]. Recently, the American Academy of Dermatology (AAD) has released a position paper reinforcing both the need for getting vitamin D through the diet and preventing UV radiation overexposure.

In fact the AAD recommends

> an adequate amount of vitamin D should be obtained from a healthy diet that includes foods naturally rich in vitamin D, foods/beverages fortified with vitamin D, and/or vitamin D supplements. Vitamin D should not be obtained from unprotected exposure to ultraviolet (UV) radiation [67].

Severe vitamin D deficiency is also known as rickets in infants and children and osteomalacia in adults. Both disorders affect the bones; in the case of rickets, the bones continue to grow, but without adequate mineralization they become bowed. In adults the bones lose minerals and density and can become painful.

ESSENTIAL FATTY ACIDS

Essential fatty acids are labeled as "essential" because they are not made by the body or intestinal flora and must be taken in from the diet. The human body lacks the enzyme

required to place a *cis* double bond at the *n*-3 (omega 3) or *n*-6 (omega 6) position on the chemical structure of a fatty acid. Essential fatty acids are macronutrients indicating they need to be obtained in far larger quantities per day than vitamins or other micronutrients, often in gram amounts per day. Also known as "good fats" or polyunsaturated fats, they are involved in the maintenance of cell membrane integrity and the transfer of waste and water through those membranes. The ratio of omega 3 to omega 6 fatty acids in the early human diet was 1:1, but in the modern Western diet, that ratio is more like 10–30:1, mainly due to the increase in the use of vegetable oils and the reduction in fish consumption [68].

Omega 3

The parent version of the omega 3 fatty acid is alpha-linoleic acid (ALA) and is an 18-carbon fatty acid with the first *cis* double bond located at position *n*-3. ALA is hydrolyzed from fats by pancreatic enzymes before being absorbed in the small intestine [69]. ALA functions in the cell itself by being incorporated into phospholipids that compose the bilayer of the cell membrane. This adds structural support, while still retaining the membrane's ability to be flexible and permeable and to affect the activity of membrane-bound enzymes. Docosahexaenoic acid (DHA) is synthesized from ALA and has critical roles in vision through the regeneration of rhodopsin. Rhodopsin is required to convert the light signals received on the retina to visual images in the brain; therefore, it is not unexpected that DHA is highly concentrated and conserved in the retinal cell membrane [70]. DHA is also present in high ratios in the phospholipids of the gray matter in the brain indicating a function in the central nervous system, quite possibly regulating the availability of neurotransmitters and function of ion channels or membrane receptors. There is also evidence that both omega 3 and omega 6 fatty acids can regulate gene expression relating to inflammation and fatty acid metabolism by interacting with PPAR and LXR receptors. Omega 3 addition results in the suppression of NFkB, which results in the inhibition of inflammatory cytokines [71], and a second study confirmed the anti-inflammatory potential of omega 3 fatty acid [72]. ALA is currently being used in the oral treatment of arthritis and in products designed for skin health and acne. It is this anti-inflammatory effect, and possibly related increase in blood flow, that will keep the skin producing elastin and collagen, which can prevent sagging and wrinkle formation. Meta-analyses have also shown that ALA supplementation decreases overall mortality and mortality due to myocardial infarction and sudden cardiac death in patients with cardiovascular disease [73].

Sources of omega 3/ALA include walnuts, flaxseed, canola oil, and tofu [74]. Other plant sources of omega 3s are lingonberry, black raspberry, pecans, and hemp. The most common animal sources for obtaining omega 3 are generally fish and fish oils, with a higher proportion being found in fish from cold-water climates. The fish most associated with ALA content are salmon, flounder, grouper, herring, shark, oysters, sardines, trout, and tuna. If enough omega 3 is not ingested, there are many health issues that can result, although not all of them have solid research behind the association. Some of the issues associated with less than sufficient levels of ALA include acne, prematurely aging skin, arthritis, Alzheimer's disease (clinical trials are currently under way to determine whether ALA supplementation can help [75]) cancer, depression, eczema, vision disorders, rheumatoid arthritis, ulcerative colitis, psoriasis, obesity, and mental illness. Vision problems can occur in infants if the mothers do not receive enough ALA during pregnancy, while in adults, the most common symptoms are fatigue, depression, dry skin, poor circulation, and memory.

Omega 6

The parent form is linoleic acid and consists of an 18-chain fatty acid that has the first double bond at the *n*-6 position and absorbed by the body and converted into di-homo-gamma linoleic acid (DGLA) and arachidonic acid (AA). Conversion of GLA to DGLA requires other nutrients like magnesium, vitamin B_3 and B_6, vitamin C, and zinc. These are then converted into prostaglandins (PGE1 or 2, respectively). These prostaglandins are involved in the inflammatory response, with PGE2 being responsible for clotting and having pro-inflammatory effects, and PGE1 prevents clotting and is anti-inflammatory. When the levels of AA or PGE2 are out of balance with PGE1 and PGE3, the pro-inflammatory nature of PGE2 becomes evident. In most Western diets, the majority of the omega 6 is of the AA form and this pro-inflammatory boost is causing poor skin health and inflammatory diseases.

The sources of omega 6 commonly found are unheated and unprocessed vegetable oils, like corn, sunflower, sesame, and soy. Another common set of plant sources are legumes, nuts, gooseberry, black currant seeds, evening primrose, raw nuts, and leafy greens. Most problems associated with omega 6 fatty acids are caused by overconsumption and not a deficiency. Overconsumption leads to excess production of eicosanoids, which is associated with heart attacks, thrombotic stroke, arthritis, osteoporosis, inflammatory disease, mood disorders, cancer, and obesity [76]. Most medications treating these conditions focus on curtailing the efficacy/activity of arachidonic acid, which forms the basis for the mechanism of action for the COX1 and 2 anti-inflammatory medications [77].

ANTIOXIDANTS IMPORTANT FOR HEALTHY SKIN

Lycopene

Lycopene is a nonessential carotenoid, but it has no vitamin A activity. It is fat soluble, absorbed in the stomach (so ingesting with oil aids in the absorption process), and is transported by lipoproteins through the blood. Lycopene in tomato products, unlike most other vegetables, has increased bioavailability when processed. Lycopene may be one of the

most powerful quenchers of singlet oxygen (the primary form of oxidative stress and cause of skin aging) following exposure to UV radiation. UVA-generated singlet oxygen mediates photoaging-related mitochondrial deletions [78]. Studies have shown the antioxidant activity of lycopene to have some effect on cancer, diabetes, cardiovascular disease, sunburn cell formation (following a 10 week placebo-controlled study, the lycopene supplemented group had lower numbers of SBC following 2 MED of UVA/UVB radiation), and skin texture. Relating to skin texture, a recent study demonstrated that higher levels of the antioxidants in the skin may correlate to lower levels of skin roughness/wrinkles [79]. While rarely deficient in most diets, overconsumption can cause lycopenodermia, a reversible orange-yellow tinting of the skin.

Grape Seed Extract

Grape seed extract is rich in proanthocyanidins, a class of flavonols. Flavonols generally correlate to high ORAC (oxygen radical absorbency, which is a measure of the ROS quenching ability of a compound commonly measured in trolox equivalents/unit) values. When administered to Japanese women suffering from chloasma, 83% of the women demonstrated improved skin lightening and melanin index scores at 6 months [80].

Coffeecherry Extract

An extract made from the actual semi-ripe fruit of the coffee plant (the flesh surrounding the bean). Coffeecherry extract contains a multitude of antioxidant compounds such as chlorogenic acid, caffeic acid, quinic acid, and ferulic acid. Processed coffee is the most common antioxidant source in adults, and it is estimated that 1300 mg of antioxidants in 1.6 cups of coffee, on average, are consumed daily.

Polypodium Leucotomos

Polypodium leucotomos is a fern that contains phenolic antioxidant compounds, including *p*-coumaric, ferulic, caffeic, vanillic, and chlorogenic acids. The antioxidant-rich extract is taken orally and has been found to reduce the erythema, sunburn cell counts, DNA damage/dimers, and mast cell infiltration following UV exposure [81]. It has also been shown to inhibit MMP and may reverse the loss of elastic fibers through intrinsic aging in fibroblast and keratinocyte cultures exposed to UV radiation. It is currently being used as treatments for psoriasis and vitiligo.

Cocoa Powder

When dry and unsweetened, this powerful antioxidant has a total ORAC score of 80,933 µmol TE/100 g. The processing of chocolate removes the naturally high flavonol content from the raw cocoa product and renders it less effective at protecting from ROS-induced damage. A good quality cocoa can deliver 5000 ORAC units in about 20 g/day. Processed chocolate also has antioxidant capacity (the higher cocoa content the better), but to a lesser extent than the raw form.

Green Tea/Black Tea/White Tea

Green, black, and white tea all come from the *Camellia sinensis* plant, but at varied stages of crushing and drying; green tea is unprocessed. All are excellent sources of antioxidants in the form of polyphenols and flavonols, primarily catechins, epicatechins, and thearubigins. There has been evidence showing that green tea polyphenols can cause an increase in IL-12-mediated DNA repair, which aids in preventing the formation of UVB-induced skin tumors [82].

Alpha Lipoic Acid

Alpha lipoic acid (LA), aka thioctic acid, is synthesized in the mitochondria of plants and animals from octanoic acid. It functions as an enzymatic cofactor in several mitochondrial complexes for energy production and is important in the catabolism of alpha keto and amino acids [83]. It also functions as an antioxidant by directly scavenging free oxygen and nitrogen radicals (demonstrated in vitro, but not confirmed in vivo) and indirectly through acting as a reducing agent for other oxidized free radical scavengers, chelating ROS forming metal ions, and inducing glutathione synthesis, particularly in aged animals [84]. LA is commonly found in food bound to the protein lysine forming lipoyllysine. Food sources with larger amounts of LA include organ meats, spinach, broccoli, tomatoes, peas, and Brussels sprouts. Supplements of alpha lipoic acid contain unbound or "free" lipoic acid and typically contain far greater amounts than can be obtained through the diet. There have been no known instances of lipoic acid deficiency since the body seems capable of synthesizing enough on its own or getting enough through the diet. Toxic levels are also not known, but higher doses of oral supplementation have demonstrated some cases of gastrointestinal problems and allergic reactions (hives, skin rashes, etc.).

Resveratrol

A polyphenolic compound present in red grapes, red wine, peanuts, and some other berries, resveratrol is a stilbene, which is produced by some plants in response to stress, injury, fungal infection, or UV radiation. This compound is fat soluble, has direct antioxidant activity (through free radical scavenging and inhibition of LDL oxidation), and is well absorbed orally, but the bioavailability is low since it is rapidly metabolized. Resveratrol has demonstrated the ability to induce cell cycle arrest, inhibit proliferation, and induce apoptosis in cancer cells [85]. Resveratrol has a wide variety of effects on cells in culture, such as inhibition of inflammatory enzymes, inhibition of at least one type of metalloproteinase, stimulation of eNOS activity, and increase in the activity of NADPH:quinone reductase. Not all of these in vitro findings have been repeated in vivo, and cultured

cells were not exposed to the metabolites of resveratrol (as would occur in the body) and often in levels much higher than would be found in circulation. However, in yeast, fruit flies, and nematodes, resveratrol supplementation extended the lifespan of the organisms in a manner similar to caloric restriction [86]. Resveratrol supplementation (usually in the form of red wine extract or *Polygonum cuspidatum* extract) is still in the early stages, and very few controlled clinical studies have been conducted. There are currently no known adverse effects of high-dose resveratrol, but pregnant women are advised to avoid alcohol as a means for resveratrol supplementation and individuals suffering from estrogen-dependent cancers should also avoid resveratrol as little is known about the estrogenic activity of resveratrol.

Curcumin

A yellow, curcuminoid (polyphenolic compound) found in the rhizomes of a member of the ginger family, curcumin is what gives the spice turmeric its yellow color. While studies have shown that the bioavailability of curcumin is low, it is possible to achieve biologically active levels in the gastrointestinal tract through oral supplementation. Curcumin, in vitro, has demonstrated free radical scavenging ability of both ROS and RNS, inhibition of inflammatory enzyme activity, and increase of glutathione synthesis [87]. Like resveratrol, curcumin is being studied for its anticancer potential, and clinical trials are still in the very early stages. It is also being used to treat skin disorders like scleroderma, psoriasis, skin cancer, and possibly wound healing [88]. There have been no recorded instances of serious adverse effects in individuals on high doses of curcumin, and it is generally recognized as safe by the FDA.

Pomegranate

The juice of the pomegranate aril (the water-laden pulp surrounding the seed) contains large amounts of vitamin C, vitamin B_5, potassium, and polyphenols. The juice contains a wide variety of polyphenols like, ellagitannins, punicalagins, catechins, gallocatechins, and anthocyanins. One of the compounds, egallic acid, is metabolized very quickly in the body when taken orally. This same compound when applied topically to SKH-1 hairless mice exposed to UVB radiation demonstrated diminished production of pro-inflammatory cytokines, blocked macrophage infiltration, and attenuated UVB-triggered skin wrinkle formation and epidermal thickening [89]. Using the same mouse model, a study involving oral supplementation of pomegranate fruit extract, prior to UVB radiation, inhibited edema, hyperplasia, leukocyte infiltration, peroxidation of lipids, peroxide generation, and ornithine decarboxylase (ODC) activity, indicating a substantial protective effect to UVB-induced photodamage [90]. A final study using cultured human skin fibroblasts demonstrated that pomegranate extract increased synthesis of collagen and decreased synthesis of MMP-1 [91]. Preliminary data exist indicating that pomegranate extract has a positive effect on several types of cancer, coronary artery diseases, oxidative stress, diabetes, and the common cold.

TRACE ELEMENTS AND MINERALS IMPORTANT FOR HEALTHY SKIN

Trace elements are only needed in small amounts in the diet, and toxic levels could easily result through overconsumption.

Zinc

Zinc must be ingested daily as it is not stored by the body. The most common source of zinc is red meat or poultry, but is also found in pumpkin seeds, beans, nuts, and whole grains (but it is most highly concentrated in raw oysters). Zinc is involved in many body processes including wound healing, DNA synthesis, protein synthesis, cell growth and division, and catalytic activity for enzymatic reactions. Zinc is currently found in sunscreens since it physically blocks UV rays, it is also used to treat acne, seborrheic dermatitis, and dermatitis herpetiformis. Another study has shown possible use as a treatment for age-related macular degeneration [92]. Toxic levels can result despite the inability of the body to store excess zinc, and the result is usually gastrointestinal injury, fever, and kidney failure [93].

Selenium

A nonmetal trace element related to sulfur, selenium forms selenoproteins in the body, such as glutathione peroxidases (five types) and thioredoxin reductase. These enzymes are key mediators in the reduction of damaging ROS, like hydrogen peroxide or lipid hydroperoxides, and in the regeneration of antioxidants like vitamin C, making it vital in the pro-oxidant/antioxidant balance. It is a known stimulator of the immune response [94]. The richest known sources of selenium are Brazil nuts, followed by organ meats and seafood such as crab, shrimp, salmon, and halibut. Selenium doses over 400 μg/day can result in toxicity, which can cause shakiness, vomiting, redness of the face, irritability, brittle hair/nails, and possible cardiac arrest [95].

Copper

Copper is an important metal involved in creating energy for the cell inside the mitochondria through interaction with the copper-dependent enzyme cytochrome c oxidase. Copper also plays a vital role in the scavenging of free radicals and in redox reactions as a part of superoxide dismutase (SOD). Copper is required in the cross-linking of collagen and elastin fibers and aids in myelin formation, neurotransmitter synthesis, and melanin formation [96]. Copper-rich foods include organ meats, oysters, clams, cashews, crabmeat, hazelnuts, almonds, and raw mushrooms. Copper toxicity, while possible, is rare, and copper deficiency often presents as anemia since copper functions as a key mediator in iron

absorption. Wilson's disease is another form of copper toxicity, which is caused by abnormal copper accumulation from birth, although the first symptoms often do not occur until late childhood or early adolescence. The primary damage is usually to the liver, and this is reflected in the skin by the appearance of jaundice, hypermelanotic pigmentation, and other signs of liver disease like spider veins.

Silicon

Silicon is a common metalloid found in apples, raw cabbage, cereals, peanuts, carrots, onions, cucumber, pumpkin, honey, and oranges. Its status as an important trace element is currently being debated with proponents listing many yet-to-be-accepted benefits like preventing brittleness in hair and nails, strengthening the connective tissues in the skin (silicon is most commonly found in skin connective tissue), and reduced skin wrinkling (silicon plays a role in collagen synthesis).

Ubiquinone/Idebenone

Ubiquinone is also known as coenzyme Q10 and is an oil-soluble compound vital to the mitochondria and production of ATP. The majority of the body's energy is generated through the electron transport chain, and coenzyme Q10 serves a critical role as an electron carrier from complex I to complex II. It also serves a function as an antioxidant through its ability to undergo redox reactions in the cell and is very effective against the damaging singlet oxygen radical. Food sources include organ meats, pork and beef, sardines, salmon, tuna, soybean oil, peanuts, parsley, and avocado. Deficiencies can be caused by reduced biosynthesis due to aging, increased utilization by the body, disease conditions like cancer, or insufficient dietary intake. There are no known skin-specific symptoms of ubiquinone deficiency, but supplementation has been shown in some studies to increase the longevity of rats and nematodes through reduced oxidation and DNA damage [97].

As a synthetic version of coenzyme Q10, idebenone must be obtained as a supplement because it does not occur in nature. It has been shown to have an antiaging effect and, like ubiquinone, when applied topically, can improve the appearance of photodamaged skin [98]. It has also been used orally in the treatment of many neurological disorders like Alzheimer's disease and Friedreich's ataxia [99].

Chromium

Found commonly in nature as trivalent chromium (III) or hexavalent chromium (VI) and generally recognized as an essential mineral, the actual mechanism or function of chromium in the body is poorly understood. The reason for the uncertainty on chromium function is the lack of sensitive and accurate testing methods for its nutritional status. Chromium III is commonly found in food sources and is the bioactive form preferred by the body; while chromium VI is convertible to usable chromium III, it is thought to be an irritant and carcinogen. Chromium interacts with insulin and aids in glucose metabolism in the body. Common chromium sources include processed meats, whole grain products, broccoli, grape juice, green beans, apples, and bananas. A chromium deficiency has rarely been reported; however, inhalation of chromium VI has been shown to increase the risk of lung cancer, and exposure to the skin has demonstrated the ability to cause dermatitis. There has been no known risk associated with chromium III, but caution against long-term high-level intakes is encouraged.

Calcium

As the most common mineral found in the human body, calcium interacts with a number of other compounds and biological systems. Primarily forming the bones and teeth, calcium is also important in the maintenance of voltage-sensitive ion channels in cell membranes and muscle function, and the binding of calcium activates vitamin K-dependent clotting of coagulation [100]. Calcium in the skin (epidermis) is believed to help regulate the turnover of skin cells, affect skin color through stimulation of melanocytes, help control inflammation, and keep the skin full and healthy as skin cells without calcium can result in fragile, thin-appearing skin. Calcium is most commonly found in dairy products like milk, yogurt, and cheeses. It can also be obtained in tofu, white beans, rhubarb, and spinach. Supplementation of calcium is usually reserved for certain nutritional disorders as most health care providers encourage individuals to get the required amounts of calcium from natural sources and foods because natural calcium is often accompanied by other nutrients that help the body utilize calcium more efficiently. Calcium deficiency is usually associated with osteoporosis, but can also be related to parathyroid malfunction, chronic kidney failure, and vitamin D deficiency. It is reflected cutaneously by dry skin and brittle hair and nails. Toxic levels of calcium can be achieved and is known as hypercalcemia. Cases of mild hypercalcemia can show no symptoms or include nausea, vomiting, constipation, frequent urination, dry mouth, and thirst, while more severe hypercalcemia can be characterized by confusion, delirium, coma, and death if left untreated. Increased secretion of calcium in the urine, called hypercalciuria, can result in a greater likelihood of kidney stone development.

CONCLUSION

A lifetime of healthy skin begins on the inside through proper diet and nutrient intake. Optimizing mitochondrial function and having the proper nutrients available for repair of environmental damage and chronologic aging keep the skin looking youthful and resilient and minimize the risk of preventable diseases. As this chapter has shown, proper nutrition must take into account many factors in an individual's lifestyle such as age, activity level, current health status, and environmental/oxidative stress level. To do this, it is important to understand the function of the more important nutrients for skin health as well as the bioavailability

and structural form required for each. Most experts agree that natural food sources are generally ideal, but that there is also an important role for proper supplements. Another important factor is selection of the nutrient source and preparation for consumption. In some instances, processing or improper cooking method can damage or remove potential health benefits, but this is not always the case. For example, with regard to total ORAC levels, a raw, unprepared sweet potato has an ORAC of 902 µM TE/100 g, while a sweet potato that has been baked in the skin has a total ORAC of 2115 µM TE/100 g [101]. Finally, bear in mind that most nutritional guidelines are set at the intake level required to prevent a deficiency or disease for 95% of the population and is not tailored to an individual, so there are instances where more of a specific nutrient or supplementation may be required (in the case of alcoholism or malabsorption disorders). So these nutritional guidelines to prevent disease are not the guidelines for producing optimal skin health.

Life expectancy in both developed and developing nations is continuing to increase as advances in health care and accessibility continue to expand. This means that across the world, the proportion of older people is increasing. By 2030 in the United States, 31% of the population is expected to be 55 years of age or older [1]. As a result, it will be indispensable for physicians and health care providers to recognize and address age-related changes in every organ system of the body, including the skin.

Aging in the skin reflects an interaction between two processes: intrinsic aging and photoaging. Intrinsic aging occurs throughout the entirety of the skin and is caused by several factors including gradual oxidative damage and reduction in the rate of skin cell replication. Photoaging is the result of chronic, lifelong exposure to ultraviolet radiation, which superimposed on intrinsic aging, causes most of the visible age-related changes in the skin [2]. In addition to gradual skin aging, several dermatologic disorders increase in incidence with age, including cutaneous neoplasms and certain skin infections [2].

INTRINSIC SKIN AGING

Intrinsic skin aging, caused by the passage of time alone, is considered universal and unavoidable. This type of aging results in characteristic histologic, functional, and physical changes in the skin. In the epidermis, histologic changes are numerous and include flattening of the dermal–epidermal junction (DEJ), variable or decreased thickness, variable cell size and shape, and fewer melanocytes and immune cells; in the dermis, there are fewer fibroblasts, fewer mast cells, fewer blood cells, and atrophy [2]. Functional changes include reductions in barrier function, DNA repair, immune responsiveness, mechanical protection, cell replication, vitamin D production, and wound healing [3]. Physical changes include dryness, roughness, wrinkling, delayed healing, and an increased incidence of cutaneous malignancies [2].

Mechanisms of Intrinsic (Chronologic) Aging of the Skin

Several theories have been proposed to explain the specific mechanisms behind the intrinsic aging of skin. A major and widely accepted theory [4] involves the formation of free radicals and their deleterious effects on cellular integrity of the skin. Cellular aerobic metabolism continuously exposes skin cells to reactive oxygen species (ROS) that gradually damage biomolecules, including DNA. The accumulation of this damage increases the risk of tumorigenesis and results in apoptosis or senescence causing skin aging.

ROS and oxidative stress cause upregulation of inflammatory cytokines such as interleukin-1 (IL-1), IL-6, and tumor necrosis factor (TNF)-alpha [2]. These immune-modulating molecules [5] are thought to play a major role in cellular aging partly through stimulating expression of matrix-degrading metalloproteins [6].

In addition, oxidative stress affects terminal portions of chromosomes in eukaryotic cells known as telomeres. They consist of a repetitive sequence of nucleotides that are conserved within a species. As a cell replicates, telomeres are gradually shortened due to inability of DNA polymerase to fully replicate the end of a linear strand of DNA, known as the end-replication problem [7]. The telomerase enzyme replenishes telomeres; however, its expression is reduced dramatically with age resulting in gradual erosion of telomeres [7]. As telomeres shorten with each replication cycle, they reach a critical length that signals for cell death or senescence [7]. One mechanism by which oxidative stress may cause damage to telomeres and ultimately result in cutaneous aging is through activation of these same signaling pathways [8,9]. Under normal conditions, the 3′ end of a telomere is longer than the 5′ end and is "buried" and protected beneath the loop configuration of the telomere [7]. It is believed that during the repair of oxidation-induced telomere damage, as well as when telomeres reach their critically short length, the 3′ end of the telomere becomes exposed, activating a cellular signaling cascade involving p53 that eventually results in apoptosis or senescence [8,9].

Oxidative damage also hinders cellular function by altering protein composition. Generation of ROS causes the development of carbonyl groups (C=O) on cellular proteins. These abnormal proteins are typically degraded by proteasomes whose function declines with age, leading to buildup of the altered and often nonfunctional proteins [10].

In order to counteract free radical accumulation, cells contain a variety of enzymatic antioxidant molecules, including glutathione peroxidases, catalases, and superoxide dismutases. Nonenzymatic protection against ROS in primarily mediated by antioxidants such as vitamin E and coenzyme Q10. Despite their existence and efficacy in youth, these antioxidant systems are far from perfect and tend to depreciate with age [11].

Another mechanism that contributes to intrinsic aging is cellular senescence. A senescent cell has an extremely limited ability to divide; it has critically short telomeres and is resistant to apoptosis and altered differentiation. In addition, cells in senescence overexpress genes that encode for proteins such as fibronectin and proteases that modulate the extracellular matrix and contribute to skin aging [12–14]. Finally, modification of amino acids within proteins is another mechanism that plays a role in intrinsic aging. Within proteins, D-amino acids undergo racemization to form L-amino acids; these changes can render whole proteins nonfunctional and resistant to degradation, which in turn leads to their intracellular accumulation and ultimately interference with cellular function [2].

Epidermis

The skin is composed of three distinct layers that are all affected by the aging process: the epidermis, dermis, and subcutaneous tissue. The epidermis is the outermost layer of the skin; it is a stratified squamous epithelium composed of keratinocytes, but also houses melanocytes, Langerhans cells, Merkel cells, and inflammatory cells. The innermost epidermal layer, the stratum basale, consists of fairly proliferating basal cells that attach to the underlying basement membrane and dermal connective tissue; cells of the basal layer differentiate to form the overlying spinous and granular cell layers [15]. The outermost epidermal layer consists of anucleate and terminally differentiated keratinocytes that form the basis of the stratum corneum, which serves as the main environmental barrier of the epidermis [15].

Within the epidermis, signs of aging are most pronounced and consistent in the DEJ. The most salient histologic change is a flattening of the DEJ, with effacement of the dermal papillae and epidermal rete pegs. The loss of the dramatic wave-like form of the epidermis results in less surface area contact between the epidermis and dermis [2]. In addition to a presumed decrease in intercommunication and nutrients, this loss of contact surface area most likely weakens the strength of epidermal attachment to the dermis and explains why the elderly are more prone to tears, abrasions, and blisters after minor trauma [16].

It is estimated that epidermal turnover rate declines between 30% and 50% between the third and eighth decades. The rate of stratum corneum replacement correspondingly increases. Not surprisingly, epidermal repair after injury slows down and growth rates for hair and nails decline as well [2].

In addition, the epidermis undergoes a thinning of 10%–50% between the ages of 30 and 80 years [17]. Not only does this thinning occur almost inevitably, but it also occurs unevenly throughout the skin resulting in variability in epidermal thickness. An increase in variability of keratinocyte size is also seen. Evidence exists that implicates aged keratinocytes as inherently predisposed to malignant transformation: these cells ultimately enter a senescent state, become resistant to apoptosis, and sometimes accumulate mutations that increase their risk for malignant transformation [2]. Studies have also shown a gradual decrease in stem cells in the epidermis with the passage of time [18]. Aged epidermal skin also displays disruptions in cohesion between keratinocytes and a decrease in adhesion of the basal layer to the underlying dermis [17].

Despite the eventual increase in variability in epidermal thickness of aged skin, the thickness of the stratum corneum seems to remain constant over the years, even though individual cell sizes within the stratum corneum increase [2]. Also age affects the transcutaneous delivery of certain medications across the stratum corneum. Hydrophilic compounds have been shown to be less well absorbed percutaneously in older skin than in younger skin while absorption of hydrophobic substances is not affected by skin aging [19]. Furthermore, as epidermal skin ages, stratum corneum lipid generation and activities of enzymes necessary for synthesis of these lipids decline. This is presumably caused by reduction in gene expression of these enzymes and/or aberrant autocrine/paracrine signaling within aging keratinocytes [20]. The decrease

in lipid composition of the stratum corneum is clinically significant because the slowed replacement of lipids in the cornified layer leads to a delay in repair and restoration of its integrity after any damaging insults [21].

Aging epidermal skin also undergoes a gradual decrease in filaggrin content. In elderly patients, this is most notable in the lower extremities where the skin tends to appear dry and scaly. In patients with ichthyosis vulgaris, similar histologic findings are noted, and the lack of filaggrin in both conditions is thought to cause the characteristic appearance of the skin [22]. In addition, the number of active melanocytes decreases by approximately 10%–20% per decade as the epidermis ages [2]. This in turn decreases melanin production and the protective barrier against ultraviolet radiation [2].

With increasing age, the immunologic barriers of the epidermis are also affected. Langerhans cells (LCs) are dendritic cells that are found in the epidermis, lymph nodes, and other organs. LCs process and present antigens to T-lymphocytes, resulting in modulation of immune responses. As the epidermis ages, the number of Langerhans cells decreases 20%–50% between early and late adulthood. The remaining LCs have been shown to demonstrate abnormal morphologies, such as fewer and shorter dendrites, as well as decreased antigen-presenting capability [23]. All of these changes in the cutaneous immune system contribute to age-associated decreases in skin immunity.

The skin's endocrine functions are also impaired as aging ensues, the most important of which is vitamin D production. Vitamin D production decreases with age [24]. Deficiency in vitamin D causes osteomalacia and has been associated with diabetes, hypertension, and malignancy [25]. Both the lack of dietary intake and insufficient sunlight exposure contribute to vitamin D deficiency. However, studies have shown that even provitamin D_3, the precursor to vitamin D_3, tends to decrease by about 75% in the skin between early and late adulthood [24]. This finding emphasizes the importance of dietary vitamin D intake [26].

Dermis

Beneath the epidermis lies the dermal layer. The dermis is connected to the epidermis through a number of specialized junctions that are responsible for mechanical integrity, cell–cell communication, and nutrient exchange between these two layers. The dermis is composed of a connective tissue milieu of collagen and ground substance, composed of glycosaminoglycans and proteoglycans. It also contains elastic fibers, cells of the immune system, fibroblasts, blood and lymphatic vessels, nerve fibers, hair follicles, and eccrine and apocrine glands. The dermis is generally divided into the superficial papillary dermis and the deeper reticular dermis. The papillary dermis houses smaller, finer, looser collagen fibrils whereas the reticular dermis is composed of larger, denser, interwoven collagen fibrils. The dermis provides the skin with its tensile strength, elasticity, and malleability—qualities that are modified in aging skin. It also holds sensory receptors, aids in thermal regulation, and protects the deeper structures from mechanical injury [15].

With aging, the dermis, which represents the thickest layer of the skin, gradually begins to lose volume. The dermal layer thins by about 20% as one approaches late adulthood, with the most significant thinning corresponding to the most sun-exposed areas [2]. Older skin demonstrates depletion of cellularity, reduction in vasculature, and an age-related loss of elastic fibers and dermal collagen [27].

In old age, the skin begins to lose its pliability resulting in an increase in rigidity that is due to biomedical changes in collagen, elastin, and the ground substance. It is estimated that collagen content decreases by 1% every year throughout adult life [28], and the remaining collagen loses its organization, becomes more compact and granular, and displays increased cross-linking [2]. The increase in cross-linking is thought to be due to a decrease in collagen synthesis, defects in collagen processing, and an increase in collagenases [17].

As early as young adulthood, elastic fibers begin to decrease in size and number. By late adulthood, as elastin is degraded, elastic fibers lose their structural integrity and become more fragmented, especially at the DEJ [29]. Similar to collagen, elastic fibers display more cross-linking and may become progressively calcified. Not only do elastic fibers undergo structural changes, but they also endure compositional changes, showing decreases in numerous components including elastin and fibrillin [2]. One of the earliest age-associated changes is a decrease in fibulin-5, an extracellular protein that provides a support base for elastic fibers. Studies have shown that decreases in fibulin-5 expression occur before other changes are observed in aging skin, suggesting that fibulin-5 might be a suitable early marker for skin aging [30].

The dermal ground substance is composed of glycosaminoglycans (GAGs), proteoglycans, and mucopolysaccharides. The content of these components, especially hyaluronic acid, decreases with age likely due to either decreased hyaluronic acid extractability or decreased hyaluronan secretion [2]. Proteoglycans bind about 1000 times their own weight in water and affect collagen deposition and size; thus, changes in the composition of these substances most likely adversely affect skin turgor and pliability [31].

The elderly exhibit decreased cutaneous inflammatory responses most likely due to decreased cytokine production and release, decreased inflammatory effectors, impaired endothelial response to inflammatory signals, and impaired endothelial capacity to induce leukocyte adhesion [2]. In the dermal vasculature of the middle-aged, blood vessel walls display mild thickening, especially in the lower extremities [32]. This is thought to be due to gravitational effects [32]. As aging progresses, vessel walls display thinning to less than one half of a young adult and this most probably results in vascular fragility. Elastin depletion and deterioration of elastic fibers in arteriole walls contribute to vascular rigidity in the skin [2]. The typical clinical appearance of elderly skin,

including pallor, decreased temperature, and decreased blood flow results from losses of vascular beds, especially in the dermal papillae and increases in distance between the existing vasculature and the epidermis [33].

Preservation of dermal vasculature is aided by epidermal VEGF that appears to induce anti-apoptotic proteins in endothelial cells; the age-associated decrease in VEGF most likely contributes to endothelial apoptosis and ongoing destruction of dermal vasculature [32]. In addition, angiogenic homeostasis is disturbed and compromised in older skin [34]. Aging gradually impairs the skin's ability to respond to heat or cold, by impairing the aged vessels' abilities to contract, dilate, or shunt [32]. The elderly are also predisposed to heat stroke and hypothermia. This may be due in part to impaired thermoregulation in addition to subcutaneous fat loss. The decrease in hair follicles and associated adnexal structures in the dermis may also be in part due to the loss of the vasculature supplying vital nutrients to these structures resulting in their subsequent degeneration and fibrosis [2].

Several observations have displayed that transdermal absorption of substances decreases with age [35], probably due to changes in both the underlying vasculature and the extracellular milieu [2]. Elderly skin has displayed prolonged time to producing a tense blister after exposure to ammonium hydroxide application, indicating a decrease in transudation rates due to injury. Several studies have also demonstrated impaired transfer of cells and solutes between the extravascular and intravascular dermal spaces [2]. Finally, dermal lymphatic vessels show age-associated gradual loss in density and size, increased rigidity, and impaired lymphatic drainage, partly due to loss of surrounding elastic fibers [32].

The biochemical changes in dermal cellularity, elastic composition and organization, ground substance composition, vasculature, and lymphatics all contribute to changes in the global mechanical functioning of skin as a whole. The skin gradually loses its elastic recovery, consistent with the deterioration of elastic network [2]. Observations using ultrasound have displayed differences in water distribution in the dermis between older and younger skin, which affects skin pliability, flexibility, and elasticity [36]. All the biochemical changes the dermis endures over time render it rigid, inflexible, and less capable or responding to stress or injury.

Hypodermis

The hypodermis, or subcutaneous tissue, is the layer below, and clearly demarcated histologically from, the dermis. The hypodermis is composed mainly of adipocytes, organized into lobules that are separated by fibrous septa. Vessels, lymphatics, and nerves run within the septa. The hypodermis provides insulation, cushioning, and protection of the underlying structures from trauma. It allows for the skin's unhindered mobility over the underlying structures and plays a major role in the cosmetic form of the face and body [17].

With the passage of time, there is a progressive atrophy and resulting redistribution of the subcutaneous fat within the hypodermis. Not only does this deterioration of adipocytes affect the skin's insulating capabilities, but its altered distribution throughout the body contributes significantly to the typical appearance and cosmesis of elderly skin [2]. Fat is depleted from certain facial areas such as the periorbital, forehead, and perioral regions, whereas there is a prominent increase in fatty tissue in other areas such as the jowls, the submental area, and the nasolabial folds. These changes in fat distribution of older skin along with gravitational effects contribute to sagging and drooping of older skin [37].

In addition to facial fat, the musculature of the face undergoes specific age-associated changes that contribute to the appearance of aged skin. Muscle cells gradually become damaged, as is signaled by the accumulation of lipofuscin, a pigment used as a marker for cellular damage. The progressive decrease in neuromuscular control, compounded with decrease in muscle cellularity, contributes to wrinkle formation [38]. Finally, facial skin appearance is also affected by bone resorption. Like the rest of the skeleton, facial bones constantly undergo remodeling, with a preponderance of resorption and bone mass loss occurring in later ages. Bone mass loss occurs primarily in the frontal, maxillary, and mandibular areas of the face. Loss of this bony scaffolding for the skin augments facial droopiness and contributes to the eradication of the distinct demarcation between the jawline and the neck that is so prevalent in younger individuals [39].

Glands and Nerves

The skin contains three types of glands. Eccrine glands are found on most of the body and produce sweat in response to acetylcholine-mediated stimuli, playing a major role in thermoregulation. Apocrine glands are also sweat-secreting glands that are located in the axillae, areolae of the nipples, and the genitoanal region and respond to adrenergic stimuli. Sebaceous glands are associated with hair follicles and produce oily sebum.

Total eccrine glands decrease by an average of 15% during adulthood in most areas of the body, and sweating is reduced by over 70% in older individuals when compared to younger subjects [2]. This is mainly caused by a decrease in sweat production per gland and contributes to the elderly predisposition to heatstroke. Apocrine glands also decrease in size and function with aging [2]. Observations have shown that sebaceous gland size and number do not seem to change with age; however, sebum production decreases significantly, possibly due to a decrease in circulating adrenal and gonadal hormones in older age [40].

Furthermore, the elderly experience significant decreases in sensory perception secondary to changes in the network of nerves contained within the skin. With age comes a decreased sensation to light touch, vibration, and corneal stimulation; special acuity; and ability to discriminate two points [41,42]. Pacinian and Meissner's corpuscles are the

end receptors responsible for pressure and light touch perception. They show greater size variability and structural abnormalities, and their density decreases to approximately one-third of their original density between the second and ninth decades of life [2].

Hair

Hair shows several changes with advancing age. By the beginning of around the age of 50, approximately half the population has at least 50% gray scalp hair, with almost every individual displaying some degree of graying; this change is due to the progressive loss of melanocytes in hair bulbs [43]. Melanocyte loss becomes evident more rapidly and dramatically in hair than in interfollicular epidermis due to the fact that melanocytes within the hair bulb proliferate and secrete melanin at maximal rates when compared to the relatively inactive epidermal melanocytes [2]. One study suggests that melanocyte loss in the epidermis might increase oxidative stress in the keratinocytes of the hair bulb, compromising their function and viability [44]. In addition, atrophy and fibrosis cause a significant decrease in hair follicles; remaining hairs are smaller in diameter, finer, and grow more slowly. Also, there is an increase in proportion of hair follicles in telogen or the resting phase [2].

Hair also exhibits changes in structure and distribution secondary to alterations in circulating hormones with advancing age. The process known as "balding" is primarily androgen dependent; thick and dark scalp hairs are gradually converted to lightly pigmented, fine, and short hairs [2]. This process tends to affect men more severely than women [2]. In women, menopause causes decreased estrogen levels and estrogen–androgen ratio, resulting in hair loss and mild facial hirsutism. Testosterone or progestin supplements that may be present in hormone replacement therapy may aggravate these changes [45].

Menopause and the Skin

Menopause is a pivotal change in a woman's life in which her development, physiology, and biological balance are altered. Estrogens play a chief role in female development and reproductive life and also impact hair and nails [2]. Menopause normally occurs in a woman's early 1950s, but may occur anytime after the age of 40 [46]. As life expectancy in the United States continues to approach 80 years [47], it is estimated that a woman will spend nearly one-third of her life in the postmenopausal state. Thus the dermatologic changes secondary to menopause deserve special mention.

In the premenopausal state, estradiol, the principal circulating estrogen, is produced by the ovaries and plays a critical role in female physiology. With the onset of menopause, estradiol levels decrease by more than 90% [48]. Progestin and androgen levels also decrease strikingly after menopause, and it is hypothesized that the decrease in estrogens and androgens and/or the decreased sensitivity of skin cells to these circulating hormones augments the age-associated changes seen in skin such as delayed wound healing, impaired barrier function, and altered immune-regulation [2].

Certain changes in the skin occur as a result of the onset of menopause rather than chronologic age alone [49]. Reduced levels of estrogens are associated with decreased skin elasticity, decreased collagen levels in the dermis, and increased skin extensibility. Also menopausal skin exhibits reduced water-holding capacity, reduced sebum levels, increased dryness, and increased fine wrinkling [2]. It is reported that menopausal women not receiving hormone replacement therapy experience more pronounced wrinkling than those receiving hormone treatment [2].

Normally, estrogen and progesterone play roles in cutaneous inflammation modulation. They also enhance proliferation of keratinocytes and collagen synthesis, decrease the activity of matrix metalloproteinases (MMPs), and increase the production of dermal ground substance [45]. Therefore, shifts in circulating levels of these hormones in menopause undoubtedly play a role in the loss of these critical components to skin's structure and function.

PHOTOAGING

As previously mentioned, skin aging is due in large part to the interaction of two processes: intrinsic skin aging and the photoaging. Photoaging is the result of chronic, lifelong exposure to ultraviolet (UV) radiation that superimposes on and compounds the effects of intrinsic aging, causing the typical physical appearance associated with old skin. Elastosis is a salient feature of photoaged skin: visible clinically as yellow, pebbly skin (Figure 76.1) and histologically as tangled deteriorated elastic fibers [2]. Even though

FIGURE 76.1 (See color insert.) Photoaging versus intrinsic aging. Consistently sun-exposed skin above the collar shows prominent wrinkling and laxity, in contrast to the sun-protected skin below the collar. (From Yaar, M. and Gilchrest, B.A., Aging of skin, in *Fitzpatrick's Dermatology in General Medicine*, 7th edn., K. Wolff et al., eds., McGraw-Hill Companies, Inc., New York, http://www.accessmedicine.com, 2008.)

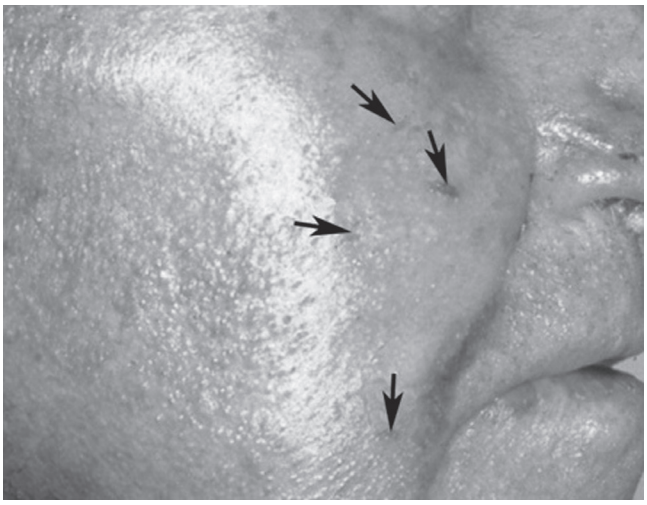
fibrillin remains abundant in the elastotic substance in the deeper zones of the dermis, it becomes significantly reduced in the upper zone of the dermis, at the DEJ [50]. Also the amount of ground substance, composed of GAGs and proteoglycans, increases in photoaged skin as the amount of collagen decreases. Photodamaged skin, in contrast to sun-protected skin of the same chronologic age, exhibits a multiplication in the number of hyperplastic fibroblasts and inflammatory cells [2]. In addition, UV radiation seems to induce a pro-inflammatory state, manifested by recruitment of inflammatory cells including histiocytes, mast cells, and other mononuclear cells; in addition, sun-damaged skin observed in immunohistologic studies displays an increase in the number of dermal CD4+ T cells. This state of chronic mild inflammation may be referred to as dermatoheliosis [2]. Mild sun damage also tends to cause vascular wall thickening, whereas in significant sun-damaged skin, dermal vasculature displays vascular wall thinning and dilations (telangiectases) consistent with changes observed with skin aging [2]. Table 76.1 summarizes features of photoaged skin.

Sun damage can affect skin of all types, from fair-skinned individuals to individuals with darker skin with a history of significant sun exposure. The manifestation and severity of UV-induced skin changes vary from individual to individual, suggesting that photodamage depends on the susceptibility and repair capacity of each individual's skin [2]. Although UV damage tends to affect the same areas including the face, neck, and upper extremities, it tends to manifest differently in skin phototypes I and II than in darker skin types. Lighter skin tends to become more atrophic and dysplastic, exhibiting more actinic keratoses and epidermal malignancies, whereas darker skin tends to display hypertrophic changes that manifest as furrowing, lentigines, and coarseness (Figure 76.2) [2].

Photoaging affects skin of various ethnicities, including Caucasians, Asians, Hispanics, and Africans, but skin changes induced by photoaging are manifested differently between these ethnicities due to inherent differences in UV defense mechanisms [2]. In Asians, Hispanics, and Africans, melanin plays a critical role in UV protection, whereas in whites, stratum corneum thickening plays a more significant role in defense than melanin [52]. Epidermis with high melanin content provides a greater sun protection factor compared to epidermis with low melanin content. One study reported that epidermis from darker individuals transmitted to the dermis approximately 6% of UVB and 18% of UVA light, compared to epidermis from light individuals that transmitted approximately 30% of UVB and more than 55% of UVA light [53].

In Asian skin, photodamage manifests clinically as solar lentigines and mottled pigmentation. Melasma in Asians is considered a clinical sign of photoaging [54]. Similar to lighter skin patients, the aging Asians present clinically with moderate to severe wrinkling, but only in the sixth decade of life and only in individuals who spent significant time in the sun [55]. Finally, lighter-skinned Hispanics and Africans may show clinical signs of photodamage, including fine wrinkles and mottled pigmentation, earlier in life than darker-skinned individuals of the same ethnicity [54].

TABLE 76.1
Clinical and Histologic Traits of Photodamaged Skin



Clinical	Histologic Findings
Xerosis	Increased compaction of stratum corneum, increased thickness of granular cell layer, reduced epidermal thickness, reduced epidermal mucin content
Actinic keratoses	Partial thickness atypia, loss of orderly, progressive keratinocyte maturation; irregular epidermal hyperplasia and/or hypoplasia
Irregular pigmentation	
Solar lentigines	Elongation of epidermal rete ridges; increases in number and melanization of melanocytes
Idiopathic guttate hypomelanosis	Reduced number of melanocytes
Diffuse irreversible hyperpigmentation (bronzing)	Increased number of DOPA-positive melanocytes and increased melanin content per unit area and increased number of dermal melanophages
Wrinkling	
Fine surface lines	No histologic changes detected
Deep furrows	Contraction of septae in the subcutaneous fat
Stellate pseudoscars	Histologically same as a scar; absence of epidermal pigmentation, altered dermal collagen bundles
Solar elastosis	Nodular aggregations of fibrous to amorphous material in the papillary dermis
Telangiectasia	Ectatic dermal vessels often with atrophic walls
Venous lake	Single dilated vascular channel often with atrophic walls
Purpura	Extravasated erythrocytes and increased perivascular inflammation
Actinic comedones	Dilated pilosebaceous follicular orifice
Sebaceous hyperplasia	Hyperplasia of sebaceous glands

Mechanisms of Photoaging

Signaling

Photoaging employs distinct molecular mechanisms from those involved in intrinsic aging of the skin. One such mechanism involves the upregulation of membrane and nuclear

(A)

(B)

FIGURE 76.2 (See color insert.) (A) Photoaging. The skin of a lighter individual displays atrophic photoaging with relatively few wrinkles but with several actinic keratoses (arrows). (B) Photoaging. The skin of a darker individual displays hypertrophic aging with deep wrinkles, furrowing, and coarseness. (From Yaar, M., The chronic effects of ultraviolet radiation on the skin: Photoaging, in *Principles and Practice of Photodermatology*, H. Lim, ed., Taylor & Francis Group LLC, New York, p. 99, 2007.)

signaling. Under circumstances of oxidative stress, reactive oxygen species (ROS) inhibit phosphatases that normally retain cell surface receptors in an inactive state [56]. UV radiation, partly by generating these ROS, causes the activation of cell surface receptors that results in an intracellular signaling cascade culminating in the activation of the nuclear transcription complex AP-1 [57]. AP-1 activity serves to decrease collagen synthesis through a number of mechanisms. First, AP-1 inhibits transforming growth factor β (TGFβ), a cytokine whose function is to stimulate collagen gene expression. This inhibition of TGFβ impairs the production of dermal collagens I and III [57]. Next, AP-1 reduces the number of TGFβ receptors, thereby decreasing collagen synthesis even further [58]. AP-1 also reduces collagen synthesis by interfering with the retinoic acid functions in the skin [2]. Finally, AP-1 augments activity of enzymes that degrade extracellular matrix, including MMP-1 (collagenase), MMP-3 (stromelysin-1), and MMP-9 (92-kd gelatinase) [57]. UV light also induces the degradation of extracellular matrix by activating the nuclear factor kappa B (NFκB) transcription factor that among other actions increases the levels of MMP-1 and MMP-9, thereby increasing extracellular matrix degradation [59]. This process is further aggravated by the release of MMP-8 by neutrophils that infiltrate into UV-irradiated skin [60]. Notably, the activity of tissue inhibitors of metalloproteinases is increased concurrently; however, it is presumed that their upregulation is not sufficient to protect the skin from damage to collagen by UV light [61]. Interestingly, collagen degradation due to UV damage tends to be somewhat incomplete, yielding debris of partially degraded collagen fragments in the dermis [57]. It has been shown that the accumulation of partially degraded collagen fragments inhibits new collagen synthesis, exacerbating the generalized decrease in collagen synthesis seen in UV-irradiated skin [62].

Mitochondrial Damage

Mitochondria are the major energy-producing cellular organelles in eukaryotic cells. Mitochondria use oxygen to generate energy in the form of adenosine triphosphate (ATP). This function predisposes these organelles to constant oxidative stress through the production ROS. Despite the presence of antioxidant systems in mitochondria, oxidative damage is still a major cause of damage to mitochondrial DNA (mtDNA). Also, due to lack of repair capacity, mtDNA accumulates mutations at a significantly higher rate than nuclear DNA [2]. UV radiation seems to exacerbate mtDNA mutations, as photodamaged skin seems to show higher rates of mtDNA mutation than sun-protected skin [63–66]. Damage to mtDNA results in disruption of mitochondria, further ROS accumulation, and reduced ATP production in the cell. Impaired mitochondrial function, in turn, seems to correlate with increased MMP levels, further intensifying collagen breakdown and worsening skin aging [63–66].

Protein Oxidation (Smoking)

Smoking plays a major role in skin aging by directly affecting the cells of the dermis and epidermis and intensifying effects of UV-associated changes in the skin. There is a significant increase in wrinkling and discoloration of the skin due to smoking, with the severity of these changes correlating directly with the amount of cigarettes smoked [67,68]. In general, features of photoaged skin present more severely in smokers than in nonsmokers with comparable risk factors [69]. Smokers' skin displays histologic features similar to that of photoaged skin. Elastic fiber fragmentation seen in photodamaged dermis is found to penetrate deeper in the dermis of smokers [70]. Smoking induces a pro-inflammatory state, recruiting neutrophils with increased elastase activity that is presumed to contribute to the deep dermal elastosis in smokers' skin [71]. In addition, the elastosis is exacerbated by constant ischemia and oxidative stress caused by smoking [67,68]. Smoking also seems to decrease the water content and estrogen levels in the skin, possibly contributing to dryness and atrophy [68].

Additionally, smoking impairs wound healing and increases the risk of cutaneous neoplasia [72].

NEOPLASIA

With advancing age, the incidence of benign and malignant neoplasia increases in nearly every organ system, including the skin. Certain benign growths are characteristically present in nearly every adult over the age of 65, and these include acrochordons (skin tags), cherry angiomas, lentigines (sun spots), and seborrheic keratoses [2].

Seborrheic keratoses are benign lesions that may be considered biomarkers of intrinsic skin aging as their numbers increase with aging, regardless of sun exposure [73]. Their appearance varies greatly in size and color, but they often present as flat, warty lesions, appearing to be "stuck onto" the skin's surface. Seborrheic keratoses result from the proliferation of keratinocytes and are not considered premalignant lesions [74]. The pathogenesis of these benign growths is not completely understood.

As humans age, there is an exponential increase in the incidence of malignant cutaneous neoplasms, including melanomas [75]. Over a lifetime, human skin cells are repeatedly exposed to oxidative stress and carcinogens in addition to experiencing normal cell turnover and replication; these factors in combination predispose DNA to mutation [2]. It has been shown that with aging, there is a gradual decrease in cells' ability to repair mutated DNA [76] and a decrease in the immune system's capacity to detect and destroy neoplastic cells [77].

Sun exposure is the major factor in the pathogenesis of skin cancer. Cumulative exposure to UV radiation over a lifetime, especially in fair-skinned people, predisposes to the development of actinic keratosis squamous cell carcinoma (SCC) and basal cell carcinoma (BCC). Actinic keratoses are premalignant lesions that may go on to develop into SCC [78]. In addition, total cumulative sun exposure, as well as a history of sporadic, intense sunburns, increases the risk of development of malignant melanoma [79]. The etiology causing this difference in the pathogenesis of malignant melanoma when compared to non-melanoma skin cancer is not completely understood.

With increasing age, there is an increased incidence of all types of melanoma (Figure 76.3) [75]. The incidence of lentigo maligna melanoma is particularly increased in individuals 60 years or over [80]. As a whole, melanomas in the older population are usually thicker than those in younger adults. This is thought to be due to the lack of proper skin examinations, poor vision, and other medical problems, including those that can compromise the elderly individual's immunologic surveillance [2]. Also, men over the age of 50 have an increased risk of mortality from melanoma in comparison to women or younger men, likely due to late diagnosis [2]. Finally, there is an increased incidence of Merkel cell carcinoma, a rare tumor that develops from cells of neuroendocrine lineage [82,83]. Incidence of angiosarcoma, a rapidly growing vascular tumor, of the head and neck is also increased with age [84]. Angiosarcoma is an aggressive malignancy that metastasizes early, usually causing death within 2 years of diagnosis [85].

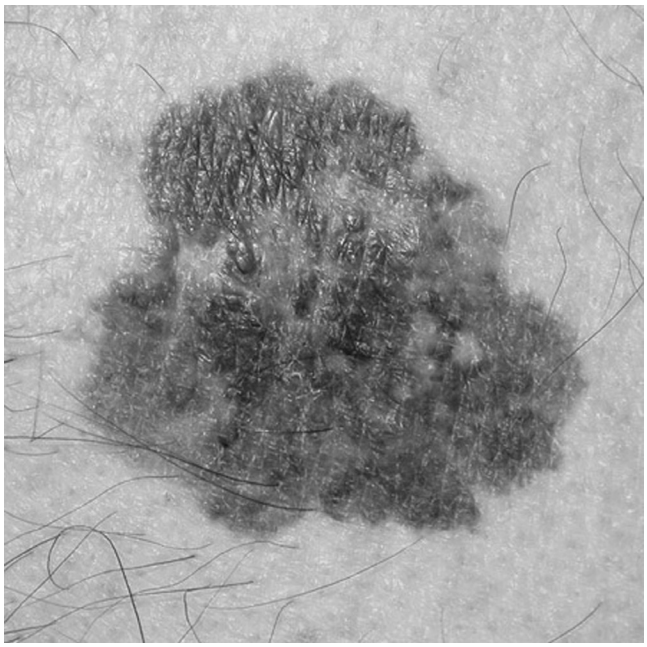

FIGURE 76.3 (See color insert.) Melanoma, with classic asymmetry, irregular borders, blotchy color, large diameter, and central elevation. (From Paek, S.C. et al., Cutaneous melanoma, in *Fitzpatrick's Dermatology in General Medicine*, 7th edn., K. Wolff, et al., eds., McGraw-Hill Companies, Inc., New York, http://www.accessmedicine.com, 2008.)

INFECTIONS

Skin infections caused by bacteria, viruses, or fungi can occur in any age group; however, special considerations must be acknowledged when dealing with the elderly population. Impetigo is most commonly associated with the pediatric age group; however, it must be noted that impetigo and follicultis do present in the elderly population. Impetigo is typically caused by *staphylococci* and should be cultured and treated with appropriate systemic antibiotics [86].

Cellulitis is an infection that involves the dermis and subcutaneous tissue and may be caused by *streptococci* or *staphylococci*. Traits that are more prevalent in the elderly population and predispose this age group to cellulitic infections include chronic lower extremity edema, poor circulation, chronic fungal infections of the feet (tinea pedis), surgical wounds, and diabetes mellitus [2].

Methicillin-resistant *Staphylococcus aureus* (MRSA) carriage is extremely prevalent in the age group of 80 or above [87], and infection by MRSA can present as impetigo or cellulitis [2]. Hence, practitioners should be aware of this

pathogen as a causative agent when dealing with skin and soft-tissue infections in this age group.

The major viral cutaneous infection that affects the elderly is caused by reactivation of the varicella-zoster virus, also known as shingles. The incidence of herpes zoster peaks at age 75 [2], and post-herpetic neuralgia is estimated to occur in 40% of adults aged from 60 to 69 years and in 50% of individuals over the age of 70 and can be debilitating [86]. The reason for the increased incidence of post-herpetic neauralgia is not entirely clear; however, impaired cellular immunity and wound healing might be implicated [2].

Recurrent or uncontrollable *Candida albicans* infections in the elderly population may represent a more serious underlying disease process such as a malignancy, poorly controlled diabetes, or severe immunosuppression [87]. Fungal nail infection (onychomycosis) is present in 40% of individuals greater than the age of 60, and tinea pedis is present in about 80%, sometimes so severe and ulcerated that it can predispose to more serious consequences like bacterial cellulitis [88].

CONCLUSION

Although much research is still needed to further understand the biological mechanisms involved in skin aging, large advances have been made in understanding this process. Skin aging is believed to be a result of two mechanisms: the presumably inevitable intrinsic aging and the superimposed effects of UV photoaging. As the proportion of aging population continues to increase, it is essential for practitioners to be able to understand and recognize the normal and expected changes of skin aging and, in doing so, be able to differentiate abnormal findings that may need further investigation.

Exposure to ultraviolet radiation (UVR) from the sun and artificial ultraviolet (UV) sources is now recognized to be associated with the development of premature skin aging and skin cancer [1,2]. Basal cell carcinoma (BCC) accounts for 75% of all non-melanoma skin cancer (NMSC) and is the most common malignant tumor in white populations [3]. Squamous cell carcinoma (SCC) comprises the majority of remaining cases. Although BCC is more prevalent, SCC has a higher mortality rate due to metastasis. It has been estimated that 84% of BCC and 74% of SCC are found at chronically sun-exposed sites [4]. Compared to the NMSC, melanoma is much less common, but it accounts for the vast majority of all skin cancer-related fatalities due to its metastatic rate and resistance to chemotherapy and radiation [5].

This chapter will provide an overview on the physics of UVR, followed by discussions of the physiologic and pathologic relationships between sunlight and skin. The pathologic reaction to UVR includes NMSC, melanoma, immunologically mediated photodermatoses, inherited photodermatoses, phototoxic and photoallergic reactions, as well as photoaggravated dermatologic conditions. Lastly, methods of effective photoprotection will be discussed.

ELECTROMAGNETIC RADIATION FROM THE SUN

Sunlight is a form of electromagnetic radiation; as it reaches the surface of the earth, it comprises the UV, visible light (VL), and infrared (IR) spectra, with UVR being approximately 6.8% of solar radiation [6]. UVR is further divided according to wavelength: UVC (200–290 nm), UVB (290–320 nm), UVA II (320–340 nm), and UVA I (340–400 nm). UVA accounts for 95%–98% of the UVR reaching the earth, while UVB accounts for the rest. UVC is largely absorbed by stratospheric ozone [7]. Depletion of the ozone layer has led to an increase in UV transmission to the earth's surface [8]. Other factors such as time, season, latitude, altitude, presence of fog, clouds, water, snow, sand, concrete, and even air pollution can influence one's exposure to UVR [9].

PHYSICS OF UV

Energy in UVR is packaged as photons. According to Planck's theory, the amount of energy in a photon is directly proportional to the frequency of the radiation and inversely proportional to the wavelength. As a result, radiation of shorter wavelength has

greater energy per photon. The depth of penetration, however, is proportional to the wavelength. Based on these principles, UVA has lower energy but is able to reach deeper into the skin when compared with UVB [10]. Although UVB is 1000 times more biologically active and has more energy compared with UVA, the biologic effect of UVA is significant for two reasons. First, the proportion of UVA to UVB in sunlight as it reaches the surface of the earth is approximately 20:1. Second, because UVA has greater ability to penetrate through cloud cover, it has a more constant presence throughout the daylight hours compared to UVB [11].

Biologic effects occur only when photons of UVR and VL are absorbed by skin chromophores, which are molecules that absorb electromagnetic radiation. Endogenous chromophores in the skin include water, hemoglobin, melanin, protein, pyrimidine and purine, urocanic acids, and 7-dehydrocholesterol [12]. Exogenous compounds can also serve as chromophores in the skin, producing phototoxic or photoallergic reactions. Absorption of photons by chromophores can induce biochemical responses involving signal transduction, ultimately altering levels of transcription factors, synthesis of proteins, and secretion of cytokines and inflammatory factors, all of which contribute to the physiologic and pathologic cutaneous changes associated with sun exposure [10].

TABLE 77.1
Major Properties and Physiologic Effects of UVR, VL, and IR

	Wavelength (nm)	% in Solar Radiation	Physiologic Effects
UVR[a]	200–400	6.8	Inflammation, immediate and PPD, delayed tanning, vitamin D synthesis, immunosuppression, DNA damage and repair, photoaging, photocarcinogenesis
VL	400–700	38.9	Immediate and PPD in darker skin color
IR	700–3000	54.3	Photoaging, photocarcinogenesis

[a] Further divided into UVC 200–290 nm, UVB 290–320 nm, UVA II 320–340 nm, UVA I 340–400 nm.

PHYSIOLOGIC REACTION TO UVR, VL, AND IR RADIATION

Physiologic reactions upon UVR exposure can be conveniently divided into acute and chronic effects, which represent a continuum. Acute effects include inflammation (sunburn), pigmentary changes, vitamin D synthesis, immunosuppression, and DNA damage and repair, while chronic changes include photoaging and photocarcinogenesis.

While the effects of UV have been extensively studied, recent data have shown that VL and IR also have biologic effects (Table 77.1). VL, used for general illumination purposes, has been demonstrated to induce pigmentation in dark-skinned, but not in light-skinned individuals [13]. IR, which is responsible for the warm sensation that one gets with sun exposure, is involved in carcinogenesis and can upregulate metalloproteinases responsible for skin aging [6].

Inflammation

Sunburn, an inflammatory reaction with increased vascular permeability and blood flow, is characterized by erythema (redness), warmth, pain, and swelling and is the most well-recognized acute cutaneous response to UVR; it peaks 24 h after sun exposure. UVB is the main contributor of sunburn, with a minor contribution from UVA II. Mast cells contain mediators such as histamine and tumor necrosis factor, which are important in the development of erythema [14]. Other pro-inflammatory cytokines, chemokines, complement, and adhesions molecules are also upregulated after UVR exposure [7]. Neutrophils and T lymphocytes appear as early as 3 h after UVB exposure, further contributing to the inflammatory reaction [15].

TABLE 77.2
Skin Types

Skin Types[a]	Skin Reaction after Sun Exposure/Skin Phenotypes
I	Always burn, never tan
II	Always burn, sometimes tan
III	Sometimes burn, always tan
IV	Never burn, always tan
V	Moderately pigmented skin
VI	Darkly pigmented skin

[a] Skin types I–IV determined by history. V and VI determined by exam.

The degree of inflammation and erythema produced is determined by the total dose of UVR energy received. Since UVR energy is inversely related to its wavelength, the erythemal effect of UVR rapidly decreases with increasing wavelength. This explains how the small amount of UVB reaching the earth's surface actually accounts for the majority of solar radiation erythemal effect [7]. An individual's ability to tan or burn constitutes his/her skin type (Table 77.2). Individuals with skin type I have a higher skin cancer risk than individuals with skin type VI.

Skin Pigmentation

Sun exposure induces pigmentary alterations, which include immediate pigment darkening (IPD), persistent pigment darkening (PPD), and delayed tanning. IPD is a grayish color induced by UVA and VL; it occurs immediately after exposure and resolves in 10–20 min. IPD blends into PPD, which is noticeable within 10–20 min of

exposure and lasts for 2 h. Both IPD and PPD are due to photooxidation of existing melanin and redistribution of existing melanosomes to more peripheral melanocyte dendrites; there is no new melanin synthesis. Delayed tanning, by contrast, occurs days after UV exposure. It is the result of new melanin production via enhanced activity in tyrosinase, the rate-limiting enzyme in melanogenesis, as well as an increase in the number and activity of melanocytes. There are also increases in the number and size of melanosomes. Neither IPD nor delayed tanning demonstrates effective photoprotection [7].

UVR also stimulates melanin-stimulating hormone (α-MSH) locally from keratinocytes and regulates the expression of its receptor, melanocortin 1 receptor (MC1R), on melanocytes. The binding of α-MSH and MC1R activates the cAMP pathway and regulates the synthesis of melanin [16]. Furthermore, the paracrine secretion of α-MSH plays a critical role in local inflammation and immunosuppression (see UV-induced DNA damage and carcinogenesis) [17]. Polymorphism of MC1R has been associated with the risk of NMSC and melanoma [18,19].

Immunosuppression

UVA and UVB both cause immunosuppression in humans. The relationship between immunosuppression and the development of skin cancer is further highlighted by the frequent development of NMSC and melanoma in organ transplant patients who are iatrogenically immunosuppressed [20–22].

UVR causes immunosuppression through downregulation of cell-mediated immunity. The balance between CD4+ Th1 and Th2 subtypes is regulated delicately by various cytokines. A vigorous Th1 response is required for destruction of tumor cells, while a Th2 response has been linked to tolerance. It has been shown that patients with progressive melanoma elicit a Th2 response, while those who respond to therapy show a Th1 immune response [23]. UVR also generates regulatory T cells that suppress the immune response in an antigen-specific manner [24].

Langerhans cells (LCs) are dendritic cells in the skin that play a critical role in the induction and maintenance of specific T-cell immunity. Alteration of the number and the function of LCs will therefore change host immune response. It has been shown that UVA irradiation reduced the ability of LCs to stimulate lymphocytes, and UVB irradiation, even at low doses, can deplete human epidermal LCs [11].

A further immunosuppressive effect of UVR is that of the isomerization of urocanic acid. Urocanic acid normally exists in its *trans* isoform in the stratum corneum. With UVB irradiation, it is transferred to its *cis* isomer, which has an immunosuppressive property [25]. The complex nature of UVR-induced immunosuppression is compounded by the ability of UVR to induce various growth factors and cytokines. For example, platelet-derived growth factor is thought to be pivotal in both UVB- and psoralen-UVA (PUVA)-induced immunosuppression [26].

UV-Induced DNA Damage and Carcinogenesis

The relationship between solar exposure and NMSC and to a lesser extent, melanoma, has long been established by extensive epidemiologic studies. There are considerable biologic differences between the two common types of NMSC, SCC and BCC. While SCC is clearly associated with cumulative sun exposure, the association between BCC and the amount or timing of personal sun exposure appears to be more complex. It has been shown that infrequent, intense, and intermittent sun exposure before the age of 20 years increases the risk of BCC more than if a similar dose was delivered more continuously over the same period [27,28].

The molecular events involving the progression from UVR-induced DNA damage to the development of NMSC and melanoma are complex. The details of such pathways are beyond the scope of the current discussion. Only important players will be discussed.

UVA radiation, while not a major contributor to sunburn, has now been demonstrated to play a role in the pathogenesis of skin cancer [29]. UVA is capable of exciting endogenous chromophores and generating reactive oxygen species (ROS), resulting in the formation of oxidative products. By producing singlet oxygen, UVA causes oxidative modifications at guanine bases, leading to generation of a premutagenic compound, 7, 8-dihydro-8-oxoguanine (8-oxoG) [30]. Analysis has shown that G → A and G → T are the major mutations induced by UVA [31].

DNA is believed to be a direct chromophore for UVB radiation [32]. UVR photons absorbed by DNA can produce excited electron states, leading to direct DNA damage, or they can generate toxic by-products, leading to indirect DNA damage. After DNA is exposed to UVB, a photochemical reaction occurs between pyrimidine dimers, leading to formation of two specific photoproducts. If a covalent binding between C5 and C6 carbon atoms is formed, cyclobutane pyrimidine dimers (CPDs) are produced. On the other hand, a pyrimidine 6–4 pyrimidone photoproduct is formed if the covalent binding occurs between C6 and C4 positions [33]. In a perfect world, the DNA repair machinery recognizes and corrects these UVB-induced photoproducts. However, DNA repair is not error proof. Incorrect repair of the damaged DNA leads to mutations in the epidermal cells, thus initiating the development of cancer. When UVB-induced CPDs and pyrimidine 6–4 pyrimidone photoproducts are incorrectly repaired, the signature mutations formed are C → T and CC → TT [30]. More recently, it was suggested that UVA may also trigger DNA damage via CPD formation similar to that induced by UVB [34]. As one ages, the skin also becomes less effective at removing CPDs [35].

UVB irradiation also induces early epidermal apoptosis in the form of highly characteristic sunburn cells (SBCs). These apoptotic SBCs are thought to represent a way to eliminate keratinocytes that have failed to adequately repair DNA.

The *p53* gene itself is also a direct target of UV radiation. It has been postulated that UVR-induced *p53* mutations result in a decreased number of SBCs, which gives rise to a

selection bias toward clonal expansion of *p53*-mutated cell lines, which then progress to various skin cancers [36]. Clones of mutant cells carrying *p53* mutations with UVR signature mutations have been found in chronically UVR-exposed skin, BCC, actinic keratosis (AK), SCC, and to a lesser degree in melanoma [36–38]. In the situation where DNA damage is sustained, *p53* triggers both intrinsic and extrinsic apoptotic pathways [39]. In addition to *p53* mutations, mutations in the *PTCH* gene have been found in 30%–40% of sporadic BCC.

While certain UV-induced mutations are shared between NMSC and melanoma, it is important to remember that melanocytes are fundamentally different from keratinocytes. When compared with keratinocytes, melanocytes are highly differentiated cells with poor proliferation ability; they live much longer and are more resistant to apoptosis [40]. The longevity of melanocytes increases their chance to acquire and accumulate mutations over time due to repetitive sun exposure. The presence of a few severe sunburns during childhood or early adolescence is thought to cause mutations that represent a first hit in melanocytes. With repetitive sun exposure, further hits accumulate and result in melanoma formation [41,42].

Although details of the response of melanocytes to UV radiation are far from being completely understood, it is now well accepted that this response is mediated to a large extent by a network of paracrine factors that is activated upon UV exposure [43]. While melanocytes provide photoprotection for keratinocytes by donating melanin-containing melanosomes, keratinocytes synthesize biochemical mediators that stimulate melanin synthesis and ensure the survival and genomic stability of melanocytes following UV exposure.

The search for common melanoma susceptibility genes is ongoing. One of the most susceptible genes for melanoma, especially familial melanoma, is *CDKN2A*, which encodes for two different but related proteins regulating cell cycle checkpoints [44].

Photoaging

Photoaging, defined as accelerated aging from UVR exposure, is distinct from intrinsic chronological aging. However, the two may share similar molecular events. UVA is a greater contributor to photoaging than UVB, because of its ability to penetrate deeper into the dermis and its greater abundance in sunlight [45]. Photoaging is clinically characterized by deeply wrinkled, inelastic, leathery skin with telangiectasias and irregular pigmentation [7].

UVR activates multiple signal transduction pathways, which converge to stimulate the transcription factor activator protein-1 (AP-1). Matrix metalloproteinase (MMP) and procollagen expressions are regulated by AP-1 [46]. MMPs are a family of zinc-dependent endopeptidases that degrade structural proteins such as collagen and elastin. UVR-induced production of MMPs thus participates in photoaging via matrix and basement membrane degradation [47,48]. UV-enhanced matrix degradation is also accompanied by decreased collagen production [46].

Vitamin D Synthesis

Not all UVR-induced molecular events are detrimental. One such beneficial effect of UV exposure is the synthesis of vitamin D, a fat-soluble vitamin. The most well-documented role of vitamin D in maintaining human health is its role in regulating calcium and bone homeostasis. More recently, low vitamin D has also been implicated, by epidemiologic studies, in unfavorable outcome in cardiovascular diseases, autoimmune diseases, neurological diseases, cancer, and overall mortality [49–54].

Vitamin D can be obtained through three sources: exogenous acquisition of vitamin D through dietary intake, ingestion of oral supplements, and endogenous vitamin D synthesis induced by UVR in the skin. Sources of dietary vitamin D include egg yolk, cod-liver oil, as well as oily saltwater fish such as salmon, sardines, tuna, and mackerel. Milk, yogurt, orange juice, and many other food products are also fortified with vitamin D in the United States and other countries [55].

The action spectrum of vitamin D synthesis in the skin falls in the UVB range. After UVB exposure of the skin, 7-dehydrocholesterol (provitamin D_3) is converted to previtamin D_3 at the basal and suprabasal layer of the epidermis [56]. Pre-vitamin D_3 then undergoes nonenzymatic isomerization to form vitamin D_3 (cholecalciferol). Vitamin D_3 enters the circulation and is carried by vitamin D-binding protein to the liver where it is hydroxylated by 25-hydroxylase to 25-hydroxyvitamin D [25(OH)D], which is the major measurable circulating form. 25(OH)D is transported to the kidney by vitamin D-binding protein, where it is further hydroxylated by 1α-hydroxylase to its active form, 1,25-dihydroxyvitamin D [1α, $25(OH)_2D$]. Conversion of 25(OH)D to 1α, $25(OH)_2D$ also occurs at other sites of the body, although these are not thought to contribute significantly [57]. Intrinsic skin factors also influence vitamin D synthesis: aged skin synthesizes vitamin D less efficiently than younger skin, and darker skin synthesizes less vitamin D than lighter skin due to the more abundant presence of UV-absorbing melanin [58,59].

The serum level of 25(OH)D is used to assess overall vitamin D status. In November 2010, the Institute of Medicine (IOM) of the U.S. Academies recommended a daily vitamin D intake of 400–800 IU, based on the age of the individual (Table 77.3; [60]). This recommendation was made according to data on skeletal health only, as the IOM judged

TABLE 77.3
Recommended Dietary Vitamin D Intake Based on Age

Age (Year)	Recommended Daily Vitamin D Intake (IU/Day)
0–1	400
1–70[a]	600
>71	800

[a] Including pregnant and lactating women.

that extra-skeletal data were inconsistent and insufficient for making recommendations, and was based on the assumption of minimal or no sun exposure. IOM further recommended that serum 25(OH)D levels of 20 ng/mL (50 nmol/L) be considered sufficient.

Recently, concerns regarding the effects of regular sunscreen use on decreased vitamin D levels have been raised. A 2009 literature review on all published evidence regarding this matter showed that while sunscreen use under strictly controlled conditions may reduce vitamin D production significantly, normal use of sunscreen does not result in vitamin D insufficiency [61]. This could be explained by the fact that in actual use, individuals apply sunscreens at concentrations lower than that used in SPF testing (2 mg/cm^2) (see the section on Photoprotection).

Because of the carcinogenic effect of UVR on skin, and the variability of UVR exposure with environmental and intrinsic skin factors, UVR exposure is an unreliable and risky method for obtaining vitamin D [62,63]. The readily available dietary sources and vitamin D supplements make oral intake a much safer and reliable method for obtaining a sufficient amount of vitamin D.

PATHOLOGIC REACTION TO LIGHT

In addition to the carcinogenesis discussed earlier, UVR also results in other pathologic conditions. These conditions can be divided into immunologically mediated photodermatoses, inherited photodermatoses, phototoxic reactions, photoallergic reactions, and photoaggravated dermatologic conditions. Correct diagnoses of these conditions require detailed history, physical examination, laboratory workup, phototesting, and possible photopatch testing. Referral to a dermatologist is often necessary for diagnosis and management. Details of the evaluation of a photosensitive patient are beyond the scope of the current discussion but are reviewed elsewhere [64]. Each of the pathologic reactions to light will be briefly discussed here. Photoprotection is important in all photosensitive patients.

Immunologically Mediated Photodermatoses

This group of diseases with wide clinical presentations is thought to be mediated by the immune system. However, the exact molecule responsible for initiation of the photochemical reactions has not been completely elucidated. These diseases, their frequency, age of onset, and action spectrum are summarized in Table 77.4.

TABLE 77.4
Immunologically Mediated Photodermatoses

Diseases	Frequency	Age Onset	Sex	Action Spectrum
Polymorphous light eruption (PMLE)	Most common	Adult	Female > male	UVA, UVB, rarely VL
Actinic prurigo	Common in Native American	Childhood	Female > male	UVA, UVB
Chronic actinic dermatitis	Uncommon	Adult	Male > female	UVA, UVB, rarely VL
Solar urticaria	Rare	Adult	Female > male	UVA, UVB, VL. May change as the disease progresses
Hydroa vacciniforme	Rare	Childhood	Male > female	UVA

Inherited Photodermatoses

Inherited photodermatoses usually have an early onset of photosensitivity due to defect in DNA repair mechanism or chromosomal abnormality. This group includes xeroderma pigmentosum, Cockayne syndrome, trichothiodystrophy, Bloom syndrome, and Rothmund–Thomson syndrome [64]. Kindler syndrome, a syndrome with combined features of photosensitivity and epidermolysis bullosa, shows distinct mutation in an actin cytoskeleton-associated protein. The photosensitivity in patients with Kindler syndrome tends to improve with age [65].

Phototoxicity and Photoallergy

Photosensitivities can be induced by endogenous or exogenous chemicals. Exogenous photosensitizers can be from agents either topically applied or systemically absorbed. PUVA therapy, which is used to treat various dermatoses, takes advantage of the phototoxicity of an exogenous agent, psoralen. Phototoxic reactions present as a sunburn-like reaction due to direct tissue injury caused by the phototoxic agent and radiation. This reaction can occur after the first exposure and often happens within minutes to hours after exposure. A photoallergic reaction, by contrast, represents an eczematous reaction that is mediated by type IV-delayed hypersensitivity reaction. It occurs only in previously sensitized individuals, hence does not happen after first exposure. Time from reexposure to onset of eruption ranges from 24 to 48 h [66]. Numerous topical and systemic agents can cause phototoxic and photoallergic reactions. A partial list includes diuretics (thiazides, furosemide), tetracyclines (especially doxycycline), NSAIDs, quinolones, and antiarrhythmics (amiodarone, quinidine). A comprehensive list can be found elsewhere [64,66]. Ironically, some sunscreen ingredients can elicit photoallergic responses (see the section on Photoprotection).

Photoaggravated Dermatologic Conditions

The heterogeneous group of disorders mentioned in this section shares one common feature: precipitation or exacerbation by exposure to UVR. These, however, are not true

photodermatoses as they do develop without exposure to UVR. Photoaggravated dermatoses include acne, atopic dermatitis, carcinoid syndrome, cutaneous T-cell lymphoma, dermatomyositis, disseminated superficial actinic porokeratosis, erythema multiforme, familial benign pemphigus, granuloma annulare, Darier disease, lichen planus, lupus erythematosus, pellagra, pemphigus foliaceus, pemphigus erythematosus, pityriasis rubra pilaris, psoriasis, reticulate erythematous mucinosis, rosacea, seborrheic dermatitis, Grover disease, and viral infection such as herpes simplex [64,67].

PHOTOPROTECTION

Because of the previously mentioned deleterious effects of UV exposure, it is crucial to modify one's behavior to minimize damage from UV radiation. This behavior modification can potentially have a tremendous impact on health care cost and morbidity and mortality relating to skin cancer.

One of the most popular methods of photoprotection when engaged in outdoor activities is sunscreen. Ideal sunscreens should not only provide protection from both UVA and UVB radiation but also maintain this protection during the entire period of exposure to the sun. In the United States, sunscreens are regulated by the Food and Drug Administration (FDA) as over-the-counter drugs. Sunscreen formulations in different countries vary due to regulations and approval of UV filters. In general, because of the availability of more UV filters, sunscreen manufacturers from Europe, Australia, and Japan have more options for UV filters compared with manufacturers in the United States. Only the commonly found FDA-approved sunscreen filters will be discussed.

Sunscreen filters can be divided into two groups: inorganic (physical) filters and organic (chemical) filters. Inorganic filters work by both scattering and absorbing UVR. There are two FDA-approved inorganic filters, titanium dioxide and zinc oxide. Inorganic filters offer several advantages. First, both are photostable, producing a predictable degree of photoprotection after UV exposure. Second, both have low allergic potential, therefore, low rates of sensitization. Furthermore, the newer technology of incorporating nanosized (<100 nm in diameter) particles has contributed tremendously to the cosmetic acceptability of these inorganic sunscreens compared with early-generation products [8]. While nanoparticle-contatining sunscreens are safe to use on normal skin, the significance of its absorption on inflamed skin remains unclear.

Organic filters work by absorbing UV radiation through their conjugated aromatic rings. Organic filters can be further divided into UVA and UVB filters (Table 77.5). Although widely found in sunscreens in the United States, oxybenzone has been implicated in many cases of contact and photoallergic dermatitis [68,69]. In addition, it is not photostable and can generate oxygen radicals upon UV exposure [70]. As a result, most European sunscreens have replaced oxybenzone in their formulations [8]. Avobenzone is the most efficient long-wave UVA organic filter available in the United States because its protection extends into UVA1 range. However, similar to oxybenzone, avobenzone is also intrinsically photolabile and significant degradation can occur after less than 1 h of UV exposure [71]. Photostabilizers such as octocrylene and diethylhexyl 2,6-napthhalate can be added to increase the stability of avobenzone upon UV exposure [8]. Avobenzone should not be combined with octinoxate, a widely used UVB filter. After absorbing UV radiation, the excited and unstable avobenzone can react with octinoxate to form a new compound, destroying the photoprotective property of both during the process [72,73]. In contrast to the photounstable oxybenzone and avobenzone, ecamsule is photostable. It is also water resistant and has low percutaneous absorption because of its high molecular weight [8].

TABLE 77.5
FDA-Approved UVA and UVB Organic Filters

UVA filter

Benzophenone:
- Oxybenzone (benzophenone 3)
- Sulisobenzone (benzophenone 4)
- Dioxybenzone (benzophenone 8)

Avobenzone (Parsol 1789, butyl methoxydibenzoylmethane)

Ecamsule (Mexoryl SX or terephthalylidene dicamphor sulfonic acid)[a]

Methyl anthralinate (Ensilizole, meradimate)

UVB filter

Aminobenzoates:
- Para-aminobenzoic acid (PABA)
- Octyl dimethyl *p*-aminobenzoic acid (padimate O)

Cinnamates:
- Octinoxate or octyl methoxycinnamate
- Cinoxate or ethoxy-ethyl-*p*-methoxycinnamate

Salicylates:
- Octisalate (octyl salicylate)
- Homosalate (homomethyl salicylate)
- Trolamine salicylate

Octocrylene (2-ethylhexyl-2-cyano-3,3-diphenylarylate)

Ensulizole (phenylbenzimidazole sulfonic acid)

[a] Approved as part of a New Drug Application process.

Currently there is no global consensus regarding the labeling and testing standards for measuring UVA protection. In the United States, the FDA has proposed using both *in vitro* and *in vivo* testing results for rating the overall UVA protection. The lowest category determined by either test will be used in product labeling. A five-category four-star system (i.e., no star to four stars) has been proposed to be assigned to products, with 4+ rated products offering the highest UVA protection [8]. However, this proposal has not been finalized by the FDA at the time of this writing.

There are five classes of FDA-approved UVB filters in the United States, aminobenzoates, cinnamates, salicylates, octocrylene, and ensulizole (Table 77.5). Para-aminobenzoic

acid (PABA), a compound in the aminobenzoates class, was the first UVB filter widely used in the United States [74]. However, because of the yellow discoloration that stains clothing and its potential for photoallergic reaction, PABA has largely fallen out of favor [8]. Padimate O is the most potent UVB absorber [75].

Within the class of cinnamates, two compounds are available, octinoxate and cinoxate. Octinoxate is the most potent UVB absorber used worldwide [8]. Its advantages include low skin irritancy and its water-resistant property [76]. The major drawback of octinoxate is its incompatibility with avobenzone as previously mentioned.

The third class of UVB filters available is salicylates. Currently, octisalate, homosalate, and trolamine salicylate are approved by the FDA. As a class, they have low sensitizing potential. Both octisalate and homosalate are water insoluble and retain their effectiveness after water exposure and perspiration [8]. Trolamine salicylate is water soluble and has been used in hair products. Salicylate compounds also play a minor role in stabilizing and preventing photodegradation of oxybenzone and avobenzone [77]. Octocrylene has an excellent safety profile with low irritation, low phototoxicity, and low photoallergic potential [76]. In addition, it is considered the best photostabilizer for avobenzone [8]. Ensulizole is water soluble and it is used in product formulated to feel lighter and less greasy [75].

In contrast to the different labeling systems for UVA protection from different countries, sun(burn) protection factor (SPF) has become the worldwide standard for labeling sunscreen regarding its protection from UVB. It is an in vivo test and is defined as the ratio of the least amount of UV dose required to produce a minimal erythema on sunscreen-protected skin, compared to the amount of dose required to produce the same erythema on unprotected skin, with the sunscreen applied at an even rate of 2 mg/cm^2. The 2 mg/cm^2 coverage translates to about 1 oz of sunscreen to cover the entire body. In the United States and Australia, water resistance of a sunscreen can be claimed only if the full SPF is retained after defined water immersion tests [78].

Recently, the SPF of available sunscreens has crept up to triple digits, which leads to tremendous confusion among consumers. The bottom line is that if adequately applied (2 mg/cm^2), sunscreens with sky-high SPFs offer slightly better protection against UV-induced erythema than SPF 30 sunscreens [78]. However, the increase in protection from an SPF 50 to an SPF 100 sunscreen is minimal; as such, SPF 50 sunscreens, if properly applied and reapplied, should be sufficient for the vast majority of individuals.

Unfortunately, in real life, most people do not apply the product evenly, leaving parts of the body uncovered. Furthermore, most individuals use only about 0.5–1 mg/cm^2 [79]. As a result, a consumer who uses an SPF 30 product may only receive an SPF of 15 or less. In a recent sunscreen knowledge assessment of the general public, only 18% of respondents knew the correct amount of sunscreen needed for each application [80].

In addition to applying a sufficient amount, another important issue regarding sun protection with sunscreen is applying it correctly. In order to achieve the desired protection level stated on the product label, sunscreen needs to be applied 30 min before going outdoors and reapplied every 2 h, especially when coming into contact with water or sweat. In a survey assessing sunscreen knowledge, only 32% of respondents reported the need to apply sunscreen 30 min before going outdoors and likewise, and only 30% reported the need to reapply them every 2 h [80]. It is also important to choose a sunscreen that offers both UVA and UVB protection; these products are now labeled as "broad-spectrum" sunscreens in the United States. Unfortunately, until the FDA makes a final decision on the proposed UVA labeling, consumers will not be able to differentiate different levels of UVA protection in a particular "broad-spectrum" product.

Behavior modifications, in addition to sunscreen application, are also important in UV protection. It has been found that when discussing photoprotection, many physicians recommend sunscreen use while omitting the message of shade seeking, use of sun-protective clothing and wide-brimmed hats, and wearing sunglasses [81,82]. One should seek shade from 10 AM to 4 PM when the UVR is most intense. It has been shown that shade reduces UV radiation from the sun by 50%–90%, with dense foliage providing superior UV reduction to a beach umbrella [83].

Wearing clothing and broad-brimmed hats has also been emphasized as an important means for photoprotection [84]. The wearing of protective garments offers several advantages. First, clothing and hats offer a balanced and uniform protection for both UVA and UVB. Second, they offer a more reliable protection as long as users wear them. Third, clothing and hats offer immediate and prolonged protection, as they avoid the needs of application prior to sun exposure and reapplication. Therefore, wearing sun-protective garments may have better compliance. Fourth, clothing and hats are less costly than sunscreens. Lastly, clothing and hats are devoid of any complications such as photoallergic contact dermatitis [8,84].

To accurately and quantitatively measure UV protection by garments, most regulatory agencies use UPF (UV protection factor) as a standard measurement. To obtain the UPF of any clothing item, the amount of UV transmission through the clothing is measured with a spectrophotometer. UPF is then calculated based on the amount of UV transmission at each wavelength and the erythema response from each spectra of the UVR [8]. Because erythema is the end point, UPF, similar to SPF, is a better reflection of UVB, rather than UVA, protection. As expected, the degree of UV protection offered by garments varies greatly depending on several factors. Fiber characteristics such as material, thickness, color, and the type of weave all influence the UPF of clothing (Table 77.6; [85–89]. When clothing is wet, the presence of water eliminates the scattering of UV light at the fabric–air interface. As a result, moisture and wetting can decrease UPF. This effect is especially important for

TABLE 77.6
Fiber Characteristics That Influence the UPF of Clothing

	Increased UPF	Decreased UPF
Fabric material	Polyester, wool	Cotton, linen, rayon
Fiber thickness	Thicker fiber	Thinner fiber
Fiber weave	Tightly woven	Loosely woven
Fiber color	Darker color	Lighter color

light-colored clothing, since scattering rather than absorption is the dominant protection mechanism [78,90].

Washing, especially after the first wash, makes certain fibers shrink, thereby decreasing the gaps between the individual fibers and making them thicker. As a result, a higher UPF is obtained [91]. The effect of washing on UPF is most pronounced on garments made from cotton, rayon, and flax materials [84]. Chemical treatment of garments with optical brightening agents, UV absorbers, and bleaching agents can also alter UPF measurements. Optical brighteners increase UPF values by absorbing UV energy and reemitting this energy in the form of VL. They are found in many household laundry detergents [84]. Similar to optical brighteners, UV absorbers such as Tinosorb FD also increase UPF via chemical binding to individual fibers with each wash [8]. It has been demonstrated that the UPF of cotton fabric can be increased by several 100-fold with the addition of UV absorbers [8]. Harsh treatment damages fabric materials and decreases UPF by either creating new or enlarging existing interstices, allowing more UV transmission [8]. Bleaching also reduces UPF [85].

Aside from its deleterious effect on the skin, UV exposure can also directly damage the cornea, conjunctiva, lens, and retina. Most ocular damage from UV radiation results from scattered and reflected light from the periphery [66]. Sunglasses can protect the eye from UV damage. However, while protecting the anterior and superior sides of the eyes, most sunglasses do not adequately shield the lateral and inferior portions. Although much less fashionable, an ideal pair of sunglasses should wrap closely to the eyes. Currently, in the United States, there is no mandatory standard to categorize the different types of sunglasses according to the degree of shading and UV absorption profile. A pair of sunglasses may offer shade without adequate UV protection. Price, brand, and polarizing lenses also do not ensure adequate UV protection [8].

Because most public education emphasizes avoidance of midday sun, one may generalize and assume that eye protection can be ignored during off-peak hours. However, in fact, most ocular damages occur during the morning and late afternoon hours when the incident rays are parallel to the pupil axis. During these times, the UV incident angle is low and the UV rays bypass the defense of the brow ridge and eyelid. In addition, squinting and papillary constriction mechanisms are not initiated due to lower light intensity, allowing more UV radiation to be transmitted. To ensure adequate protection of eyes from UV radiation, sunglasses need to be worn throughout the day [8]. The most effective photoprotection should employ combinations of shade seeking, sunscreens, sun-protective clothing, broad rim hats, as well as sunglasses.

INDOOR TANNING

In recent decades, indoor tanning booths have emerged as another significant source of UV radiation. The utilization of indoor tanning facilities continues to rise with the highest rates of reported use in young adult females [92,93]. Epidemiologic data have demonstrated a clear association between use of indoor tanning and melanoma as well as NMSC. In an analysis performed by the International Agency for Research on Cancer (IARC), the relative risk of melanoma among individuals who first used indoor tanning before 35 years of age was 1.75. The same study also found that ever-use of indoor tanning equipment was associated with a 2.25 relative risk of SCC [2]. Although the IARC analysis did not find sufficient evidence to support an association between indoor tanning and BCC, a population-based case–control study demonstrated an odds ratio of 1.5 for BCC with any use of tanning device. This study also confirmed the IARC finding of increased SCC in tanning bed users [95].

Behaviors that motivate indoor tanning are complex and involve both physiologic and psychologic responses. There is evidence suggesting the presence of an opiate-like addiction in tanning [94–97]. This could be explained by the fact that MSH production in tanning is accompanied by the release of β-endorphin, as both share a common precursor, proopiomelanocortin (POMC). Some advocate indoor tanning as a way to obtain vitamin D. However, this is erroneous, as the action spectrum for vitamin D synthesis is in the UVB range and most modern tanning equipment emits predominantly UVA. Of note, the FDA does not regulate the relative amounts of UVA and UVB in tanning devices [98]. Many countries have banned indoor tanning for individuals under the age of 18. Some states in America have also enacted restriction of access to tanning facilities for minors, but many states have not. Indoor tanning should be strongly discouraged across all age groups [99,100]. Furthermore, a tight regulation of the tanning industry is needed. Such regulation will have a profound impact on skin cancer prevention.

SUMMARY

NMSC and melanoma are unique in that few human cancers demonstrate such tightly linked associations to known and preventable environmental carcinogens. Primary care physicians are in a unique position in aiding dermatologists to provide patient education regarding the detrimental effects of excessive UVR and the importance of photoprotection.

INTRODUCTION

As individuals increase their participation in exercise, they also unfortunately experience untoward effects on their skin. Most of the skin-related conditions related to sports result in self-limited minor ailments, while some dermatoses result in significant morbidity, loss of practice time, and even infectious epidemics. This chapter reviews the traumatic, inflammatory, infectious, and environmental cutaneous ailments of sports participation. The early recognition and treatment of these dermatoses minimize exercise loss; this chapter also focuses on preventative approaches that should limit the interference of skin problems in one's dedication to exercise.

TRAUMATIC CONDITIONS

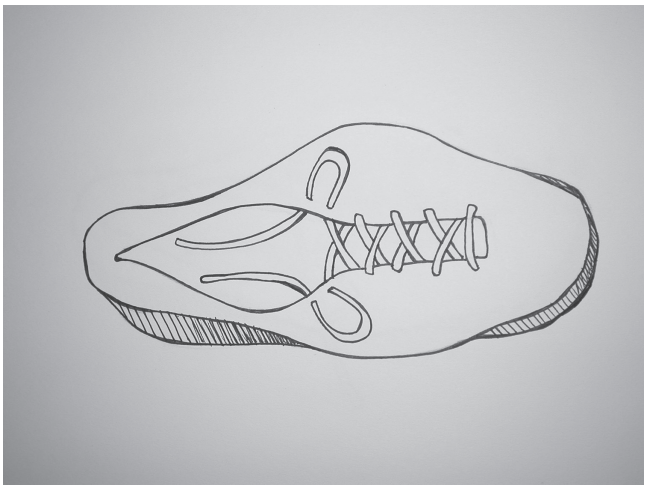
Blisters

Bulla, which represent one of the most common skin conditions related to exercise, result from repeated friction between athletes' skin and their equipment. Sporting implements cause friction bulla on the hands, whereas shoes and socks create blisters on the feet (Figure 78.1). Factors that increase the likelihood of friction bulla include moisture, frequency of the repeated rubbing, tightness of fit or coarseness of the implement or clothing material, and heat [1]. Frequently, athletes will acutely recognize a warm sensation that portends the development of a bulla. Rarely, some young athletes who often do not know that they have an unusual form of a genetic blistering condition called epidermolysis bullosa simplex (Weber–Cockayne variant) will present with severe blisters [1].

Proper treatment of bulla allows continued participation in sports activity. The bulla should be punctured with a sterile needle at one focal point so that the blister roof remains intact and can act as a biologic dressing [2]. As fluid recurs in the blister space, the athlete should repeat the lancing procedure.

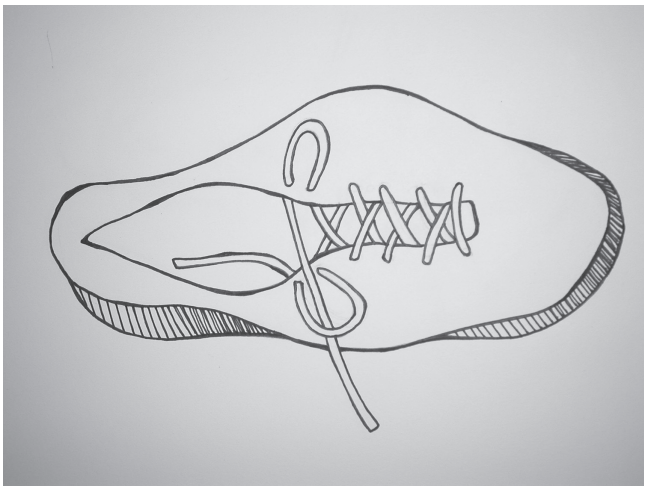
Prevention remains the key for athlete's blisters. Sports participants must wear non-coarse, moisture-wicking clothing; cotton retains moisture and increases the probability of blister formation. Synthetic moisture-wicking socks, shirts, shorts, and undergarments, readily available in many retail establishments, keep the skin relatively dry and minimize friction. Furthermore, athletes can apply petroleum jelly at maximal friction points. Athletes who continue to develop blisters, despite employing these techniques, can also wear two layers of synthetic moisture-wicking socks with petroleum jelly applied to the socks corresponding to the areas most at risk for blisters. In all instances, athletes need properly fitted footwear though lacing techniques can mitigate the effects of poorly fitted footwear [1] (Figure 78.2).

FIGURE 78.1 **(See color insert.)** Friction bullae result from chronic friction on athletes' skin.



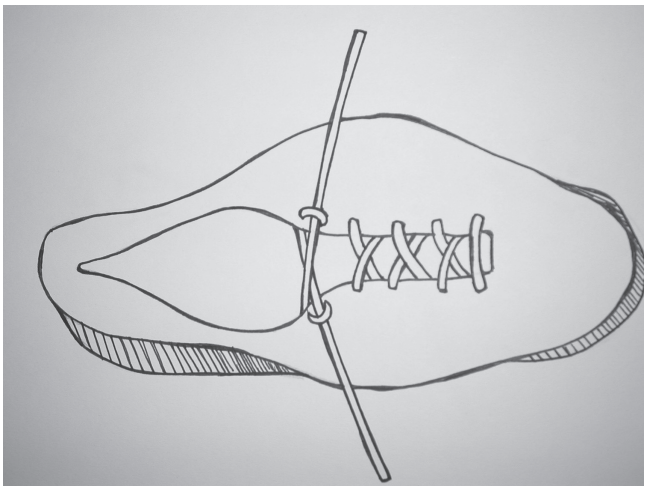
Calluses

Areas that chronically develop blisters often become callused. Occasionally, clinicians will confuse calluses for verruca or corns or vice versa. Clinicians must pare all apparent calluses in athletes. Calluses retain the typical skin markings upon paring, whereas corns will demonstrate a central core and verruca will display pericapillary hemorrhages (Figure 78.3). Occasionally, athletes also develop verruca within preexisting calluses.



While these calluses protect the athlete from repeated blisters, some enthusiasts will desire therapy. An optimal approach to callus therapy includes soaking the affected area for 10 min in lukewarm water, thereafter rubbing the area with an abrasive element, such as a pumice stone, applying urea cream, and finally covering with an occlusive dressing such as plastic wrap or duct tape [1]. The preventative techniques employed for bulla also work well for calluses.

Runner's Nipple



Friction between an athlete's nipple and clothing causes an erosive skin condition termed runner's nipple [3]. While the cutaneous signs often appear subtle, the athlete frequently experiences intense sensitivity and pain. Occasionally, bleeding from the lesions results in two parallel, linear, red streaks on a long-distance runner's pale colored shirt. Several factors increase the likelihood of developing runner's nipples including increased moisture, coarse fiber shirts (i.e., cotton), and increased frequency and intensity of friction between the nipple and the clothing [4]. Ointment-based products such as petroleum jelly, polysporin, and aquaphor not only minimize the discomfort and accelerate the healing but also prevent runner's nipples. Athletes should wear synthetic moisture-wicking clothing; cotton clothing conversely retains moisture and heat that promotes the development of runner's nipples [4]. Commercially available waterproof pads also exist that cover and protect the nipple.

FIGURE 78.3 **(See color insert.)** Paring of this callous-like lesion ultimately reveals a central core characteristic of a corn.

Athlete's Nail

Sports enthusiasts endure many different types of nail changes that vary with the type of athletic activity. Nail changes result from constant slamming of the most distal toes into the toe box such as those that occur with long-distance running [5] from abrupt forces into the toe box, which occur in sports with quick starts and stops such as basketball or tennis; or from singular, strong, explosive forces experienced while kicking a ball in sports such as soccer and football [1]. The range of nail changes includes discolored nail plate, onycholysis, ridging, periungual callosities, and onychomadesis (Figure 78.4). Athletes must ensure that the toe box has adequate room by wearing properly sized footwear and should cut their nails straight across without curving the edges. A curve nail plate experiences greater force when it slams into the toe box. Unique lacing techniques, which also minimize friction bulla, help prevent athlete's nail [4].

FIGURE 78.4 **(See color insert.)** This dystrophic nail demonstrates discoloration and transverse ridging typical of athlete's toenail.

Piezogenic Pedal Papules

Pressure on the posterior–medial aspect of the heel may induce piezogenic pedal papules in susceptible athletes. It appears that athletes more often experience pain with these lesions that represent protrusions of subcutaneous fat into the dermis. The pain theoretically results from impingement of either the vasculature or nerves as the fat protrudes into the upper layers of the skin [1]. The lesions, often demonstrable only upon standing on one foot, exhibit well-defined, skin-colored to yellow papules. Multiple therapies for piezogenic pedal papules exist and include intralesional steroid injections [48], compression therapy [6], and acupuncture [7]. The use of heel cups can also provide pain relief.

Talon Noire

Talon noire, also known as black heel or calcaneal petechiae, represents asymptomatic, minute bleeding into the epidermis [8]. Constant sheering forces on the heel create these many, small, closely set, punctate, and black macules that mimic verruca (Figure 78.5). Many different types of athletes experience this skin condition including runners and tennis, lacrosse, and basketball players [1]. Clinicians may confuse talon noire not only for verruca but also for acral melanoma; a biopsy confirms the later diagnosis. Heel cups may help prevent talon noire, but affected athletes do not require therapy [4].

Athlete's Nodules

Some athletes develop nodules at pressure points between their skin and their sports equipment. Surfers may acquire these nodules, also known as surfer's nodules or surfer's knots, on their knees and lower legs [9]. Some of these nodules result from a foreign body reaction to sand and wax (used to minimize slippage while surfing) that get embedded in the athlete's skin. As surfers kneel on the board while paddling out to catch waves, they apply a great deal of pressure on their knees that causes the sand and wax on the board to become embedded. Conversely, other athletes such as runners, figure skaters, and hockey players develop athlete's nodules at sites corresponding to areas of constant tight rubbing with equipment (most often footwear) [10]. The biopsy of these athlete's nodules reveals a collagenoma. Clinically, athlete's nodules appear as well-defined thick, often erythematous, scaling nodules at sites of pressure (Figure 78.6).

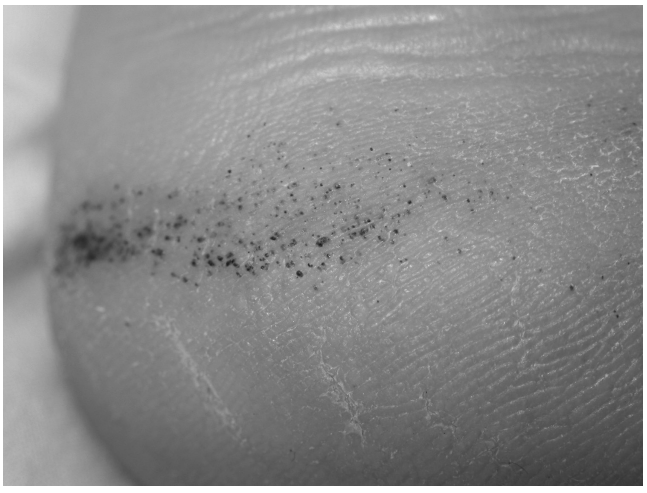

FIGURE 78.5 **(See color insert.)** Clinicians may confuse these black dots of talon noire with the pericapillary hemorrhages of verruca.

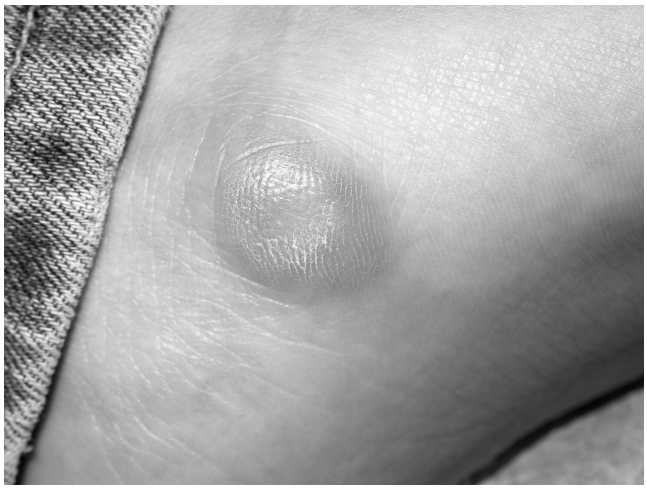

FIGURE 78.6 **(See color insert.)** This figure skater's foot developed an athlete's nodule while wearing markedly too small skates.

Either type of athlete's nodule clears with surgical excision or intralesional triamcinolone injections. Occasionally, these nodules resolve without therapy when the athletes discontinue their sporting activity. At-risk athletes should ensure that their sports footwear fits properly; extra padding also decreases the friction and pressure experienced by the skin [10].

Alopecia

Some athletes acquire alopecia from constant friction between their hair and the sporting environment. Gymnasts risk alopecia from traction applied to their scalp hair while on the beam, while some water slide enthusiasts may develop round, symmetrical, alopecic patches on the posterolateral aspects of their legs while they speed down the slide [11]. Discontinuation of the activity allows the hair to regrow.

Acne Mechanica

While most of the traumatic cutaneous ailments of athletes relate to one specific type of force, acne mechanica results from a compilation of friction, heat, pressure, and moisture. This type of acne can occur in athletes with or without a prior history of acne vulgaris and affects athletes with occlusive

FIGURE 78.7 (See color insert.) The chin of this football player displays the papules and pustules of acne mechanica that occur beneath chin straps.

equipment such as helmets and protective pads [1,12]. The distribution of the erythematous papules and pustules, typical of acne mechanica, corresponds to the occlusive equipment worn [13]. For example, football and hockey players acquire lesions on the chin and posterior scalp and shoulders corresponding to their helmets and shoulder pads, respectively (Figure 78.7). Wrestlers and volleyball players frequently develop acne mechanica on their knees that relate to their use of kneepads.

Clinicians may confuse acne mechanica with infectious folliculitis especially due to its atypical distribution. Acne mechanica does not respond as well to typical therapy for acne vulgaris; topical tazarotene, benzoyl peroxide, and clindamycin as well as oral antibiotics help assuage lesions. To prevent acne mechanica, athletes should place synthetic moisture-wicking material between their skin and the equipment and shower immediately after practice or competition.

INFLAMMATORY CONDITIONS

Allergic Contact and Irritant Dermatitis

Athletes develop allergic and irritant contact dermatitis from items that they encounter in the practice of their sport (Table 78.1) [14]. Allergic contact dermatitis represents a type IV delayed hypersensitivity reaction to an allergen, while irritant contact dermatitis does not require any immunologic sensitization. Both conditions cause well-defined (often uniquely patterned), erythematous, vesicular papules and plaques. In the subacute form, both types of dermatitis will lack vesicles, exhibit less intense erythema, and possess more scaling than the acute variety.

Affected athletes should use topical steroids to clear the eruption. The choice of strength of the topical steroid depends on the anatomical location of the dermatitis. The face (especially the eyelids), groin, and axilla require less potent topical steroids to avoid adverse events associated with their use. The choice of vehicle within which the active steroid ingredient resides depends on athlete preference and the presence of hair in the affected location. Occasionally, in severe reactions, clinicians may need to use systemic steroids. Many equipment alternatives exist for sensitized athletes (Table 78.1).

TABLE 78.1
Contact Dermatitis in Athletes

Equipment	Rash Location	Allergen	Alternate Equipment
Helmets	Forehead, scalp	Epoxy resins	Silicone

Sailing wishbone	Hands	Thiorams	Aluminum
Analgesic cream	Focal	Eucalyptus	Hot/cold packs
Shin pads	Shins	Urea formaldehyde	Barrier between guard and skin
Maggots	Hands of fishers	Dyes	Non-dyed

Exercise-Induced Anaphylaxis

Epidemiologic research reveals that runners appear particularly prone to develop exercise-induced anaphylaxis, although the mechanism by which exercise causes the condition remains unclear [15]. Most athletes with exercise-induced anaphylaxis do not experience pulmonary or vascular collapse but nearly universally complain of pruritus [16] (Table 78.2).

Affected athletes should take oral antihistamines and epinephrine if they experience respiratory or circulatory collapse. Exercising in extreme temperatures (either cold or hot) or after eating places athletes at increased risk to develop exercise-induced anaphylaxis; athletes who avoid these triggers can avert outbreaks 50% and 33% of the time, respectively [1,15].

Urticaria

In part related to increased core body temperature and the environments wherein practice and competition occurs,

TABLE 78.2
Prevalence of Various Symptoms in Exercise-Induced Anaphylaxis

Symptom	Prevalence (%)
Pruritus	92
Urticaria	86
Angioedema (palms and soles)	72
Dyspnea	50
Chest tightness	33
Nausea or diarrhea	25

athletes experience various types of urticaria including cholinergic, cold, aquagenic, and solar.

Cholinergic Urticaria

Cholinergic urticaria represents the most common type of urticaria among athletes. Runners appear particularly susceptible, but any athlete can develop cholinergic urticaria as a result of increased core body temperature. Affected athletes demonstrate small edematous and erythematous wheals that resolve spontaneously within minutes to hours. Lesions that persist greater than 24 h should prompt investigation of urticarial vasculitis. Oral antihistamines can both treat and prevent outbreaks of cholinergic urticaria in susceptible athletes.

Cold Urticaria

Athletes who compete in outdoor winter or cold water sports risk developing cold urticaria, which presents as urticarial plaques on exposed skin. To confirm the diagnosis, clinicians should perform an ice cube test. A positive test reveals a wheal as the skin rewarms after an ice cube is removed from the forearm and helps the clinician differentiate this type of urticaria from the cholinergic and aquagenic varieties. Cyproheptadine effectively prevents cold urticaria; additionally, winter athletes should minimize exposed skin while they practice their sport [1].

Aquagenic Urticaria

While exceedingly rare, aquagenic urticaria affects water sport athletes. Contact with water, regardless of temperature, causes urticarial plaques and has resulted in some cases of anaphylaxis. A positive test reveals an urticarial plaque on the forearm after the clinician applies room temperature water. To prevent this condition, susceptible athletes should apply inert oils on the exposed skin and take oral antihistamines; these athletes should never swim alone [1].

Solar Urticaria

Athletes occasionally also develop wheals from ultraviolet (UV) light within minutes of exposure, but resolve within hours. Phototesting confirms the diagnosis, and broad-spectrum sunscreen helps prevent solar urticaria [1].

INFECTIONS

Athletes acquire skin infections more commonly than nonathletes for a variety of reasons. First, many sports involve intense skin-to-skin contact that promotes the spread of infection among athletes. Second, sweating, inherent to athletic activity, macerates the epidermis and allows for easier penetration of the microorganisms into the skin. Third, trauma related to sports competition further facilitates the entry of microorganisms. Last, athletes routinely share equipment on and off the field. This frequent sharing often results in epidemics [1,17].

Prevention remains paramount as it relates to athletes who acquire skin infections from repeated skin-to-skin contact. Athletes must minimize the amount of exposed skin during practices; loose fitting, synthetic, moisture-wicking clothing keeps the skin relatively dry and cool, while it covers and protects the athlete's cutaneous barrier. Athletes also should not share personal items (such as towels and soap), equipment (such as helmets, gloves, clothing, and pads), or clothing (such as spandex). Athletic trainers and other medical professionals should carefully cleanse their hands between caring for athletes. These same medical professionals should perform careful skin examinations of their athletes, bandage infected skin during practices, and encourage daily laundering of athletic equipment and clothing. Athletic facilities require proper cleansing to eliminate bacterial contamination of common areas [1,17].

Bacterial

The majority of bacterial infections in athletes are caused by the methicillin-sensitive variety of *Staphylococcus aureus* (MSSA); however, increasing numbers of bacterial infections result from methicillin-resistant strains [18]. In addition, occasionally *streptococcal* species cause these bacterial infections. The majority of these infections result from skin-to-skin contact. As such, the at-risk sports include basketball, football, hockey, rugby, soccer, and wrestling [18]. Some sports without intense skin-to-skin contact, however, also have documented epidemics; fomite transmission likely causes these outbreaks in sports such as cross-country, fencing, gymnastics, and weight lifting.

Recent research has documented a high prevalence of methicillin-resistant *S. aureus* (MRSA) on the surfaces of the athlete's environment [19]. All studied high school athletic facilities had positive MRSA cultures. Ninety percent of mats, 78% of benches, and 20% of the doorknobs to athletic training rooms possessed MRSA. Additionally, a longitudinal, 1-year study of one division I college's women's lacrosse and men's football teams revealed a prevalence of MRSA in the nares ranging from 4% to 24% [20]. Because MRSA infects athletes at epidemic levels, clinicians should consider performing nares cultures on all infected athletes to determine carrier status. While no studies confirm the effectiveness of controlling epidemics by clearing nasal carriage, mupirocin twice daily to the nares clears MRSA/MSSA carriage for 4–5 months. Many epidemics of MSSA and MRSA in athletes appear in the literature, and several epidemiologic investigations note many risk factors [21–23] (Table 78.3).

Clinically, MSSA- and MRSA-related skin infections appear quite differently based on the specific location of infection within the different portions of the skin. Superficial infection of hair follicles results in folliculitis,

TABLE 78.3
Football Risk Factors for the Development of Staphylococcal Skin Infections

Risk Factor	Relative Risk of Infection
Adjacent locker	60
Shared towels	47
Cornerbacks	17.5
Shared soap	15
Wide receivers	11.7
Turf burns	7.2
Body shaving	6.1

while superficial infection of the epidermis creates impetigo. Furunculosis occurs when *S. aureus* infects deeper portions of the follicle.

For these bacterial infections, athletes should apply warm water soaks to affected areas three times daily for 5–10 min. Studies confirm that athletes treated empirically with antibiotics risk reoccurrence 33 times more likely than athletes for whom clinicians prescribe antibiotics based on the results of culture sensitivity testing [24]. Oral dicloxacillin and cephalexin effectively clear athletes' skin infections related to MSSA. Trimethoprim–sulfamethoxazole and the tetracycline family of antibiotics most often clear MRSA [1,18]. Even though resistance has increased in prevalence, most MRSA still responds to topical mupirocin. To prevent transmission and thwart epidemics of folliculitis, impetigo, and furunculosis, athletes should receive 72 h of antibiotics before returning to practice or competition [1]. Athletes may return to practice, during therapy, as long as the trainer can safely cover the infected skin site with a bandage that won't dislodge. Without an adequate duration of oral antibiotics, wrestlers cannot compete with bandages.

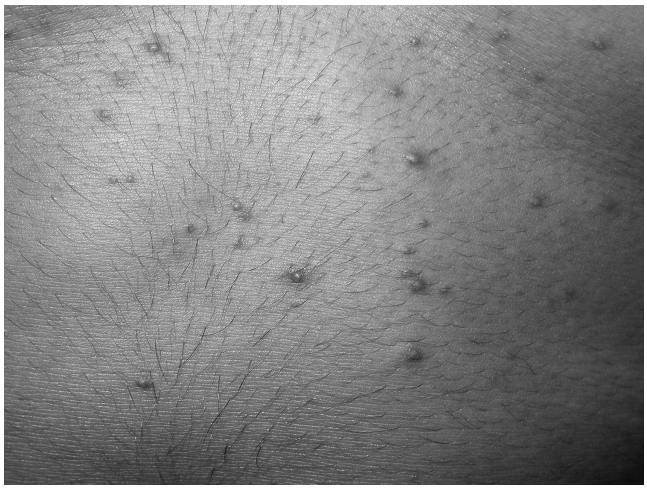

FIGURE 78.8 **(See color insert.)** Pustular eruption on the chest of a collegiate football player typifies folliculitis.

FIGURE 78.9 **(See color insert.)** A wrestler who has acquired impetigo contagiosum.

Folliculitis

Folliculitis, caused by both MSSA and MRSA, appear as follicular pustules and occur primarily at sites of skin-to-skin contact. Clinicians can easily confuse MRSA or MSSA folliculitis with other types of folliculitis such as *Pityrosporum*, *Pseudomonal*, acneiform, steroid, and eosinophilic (Figure 78.8). Usually a combination of biopsy, cultures, and history taking help differentiate among these conditions [25].

Impetigo

Athletes infected with impetigo present with honey-colored crusted papules and plaques on exposed skin (Figure 78.9). While most mature lesions of impetigo do not pose diagnostic difficulty, a typical lesion early in the course of the disease exhibits a nonspecific, erythematous papule. As such, impetigo early in the course of disease appears similar to early lesions of tinea corporis gladiatorum, herpes gladiatorum, dermatitis, acne, and lupus erythematous [17,25]. Performing cultures and taking a careful history confirms the diagnosis. Only rarely do clinicians need to perform biopsies.

Furunculosis

Furunculosis presents as tender, erythematous nodules on exposed skin surfaces. The differential diagnosis includes other infections (deep fungal infections, cutaneous myiasis), inflammatory conditions (inflamed cyst, arthropod bite reaction), and neoplasms (amelanotic melanoma, squamous cell carcinoma (SCC) cutaneous lymphoma) [17,25]. In addition to using the treatments that exist for folliculitis or impetigo, clinicians should also perform incision and drainage on all furuncles.

FIGURE 78.10 (See color insert.) Craterlike pits on the sole characterize pitted keratolysis.

FIGURE 78.11 (See color insert.) This scaling, mildly erythematous eruption on the lower sides of the foot, illustrates the moccasin variant of tinea pedis.

Pitted Keratolysis

Caused by gram-positive organisms (*Corynebacteria* or *Micrococcus*), pitted keratolysis occurs in athletes more commonly than nonathletes secondary to exertional hyperhidrosis and occlusive footwear [26]. Affected athletes have small, round, craterlike pits on the soles, particularly the weight-bearing aspects (Figure 78.10). Often, clinicians mistake pitted keratolysis for tinea pedis. Topical clindamycin and topical benzoyl peroxide clear the eruption. Benzoyl peroxide not only acts as an antibacterial agent but also dries the sole, making it a less hospitable environment for the bacteria. Athletes can prevent pitted keratolysis by wearing synthetic, moisture-wicking socks and by applying aluminum chloride solution to the sole before athletic activity [1,25].

Fungal

Tinea Pedis

Tinea pedis, otherwise known as athlete's feet, occurs far more frequently in athletes compared to nonathletes [27–31] (Table 78.4). This increased risk results from the warm, moist, and dark environment of the athletic footwear as well as exposure to shower and locker room floors colonized by fungal organisms. The three clinical types of tinea pedis include interdigital, moccasin-like, and inflammatory. The interdigital and moccasin variants, most often caused by *Trichophyton rubrum*, present with asymptomatic scaling plaques in the interdigital spaces and the soles, respectively (Figure 78.11). The inflammatory (or vesicular) type, which results most often from *Trichophyton mentagrophytes* infection, presents with pruritic vesicles and scaling plaques on the soles (particularly the instep) [1,25].

Clinicians often mistake the scaling variants of tinea pedis for xerosis and the vesicular variants for dermatitis. Athletes may develop allergic or irritant dermatitis from contact with compounds found in their athletic footwear, clothing, or other protective equipment. A potassium hydroxide examination of the scale reveals hyphal structures and confirms the diagnosis of tinea pedis; rarely must the clinician perform cultures. Depending on the severity of the eruption, clinicians may prescribe topical allylamines (such as ciclopirox or terbinafine) with or without oral antifungal agents (such as terbinafine or griseofulvin). To prevent tinea pedis, all athletes must wear synthetic moisture-wicking socks and don sandals in the locker room, showers, or pool decks. Antifungal powders shaken into the footwear can also not only decrease moisture that facilitates fungal growth but also destroy any present fungal elements [1].

TABLE 78.4
Prevalence of Tinea Pedis among Sports

Sport	Prevalence
Basketball players	39% (24/61) [28]
Runners	45% (66/147) [30]
	55% (20/36) [28]
Soccer	12.5% (7/56) [29]
	44% (35/79) [28]
	69% (22/32) [31]
Swimming	22% (22/150) [27]
	55% (17/31) [28]

Onychomycosis

In addition to acquiring tinea pedis, athletes also frequently develop fungal infection of their nails. Affected nails demonstrate nail plate thickening, discoloration (most often yellow), onycholysis, and subungual debris. Clinicians can confuse onychomycosis with athlete's toenail [25]. Permanent clearance presents challenges as oral therapies only clear toenails in a minority of the cases. As such, athletes and their medical staff should pay careful attention to prevention using the same techniques discussed for tinea pedis.

Tinea Corporis

Epidemics of tinea corporis, termed tinea corporis gladiatorum (also known as ringworm) in wrestlers, have occurred for decades. The prevalence ranges from 24% to 77% and varies based on study methodology [25,32–35]. In the study with the lowest prevalence, the investigators examined a wrestling team without a known epidemic and found that nearly one-quarter of the wrestlers had tinea corporis gladiatorum [35]. While *T. rubrum* remains the most likely causative organism of tinea corporis in non-athletes, *Trichophyton tonsurans* (typically cultured from tinea capitis) causes tinea corporis gladiatorum [25,35]. These interesting epidemiologic facts suggest that wrestlers ultimately acquire their ringworm from other wrestlers' tinea capitis. One study cultured fungus in 29% of wrestlers' scalps even though the athletes had no symptoms of infection [36]. This asymptomatic spread could, in part, account for the epidemics noticed in wrestlers.

Infected athletes often do not possess the prototypical annular morphology expected with ringworm; rather, lesions appear as red, round minimally scaling papules and plaques (Figure 78.12). The differential diagnosis includes early lesions of acne, dermatitis, lupus erythematous, impetigo, and herpes gladiatorum. Potassium hydroxide examination confirms the diagnosis [25]. An optimal therapeutic approach includes both oral and topical therapies, but controversy exists surrounding the optimal duration of administration.

Two trials support the use of oral prophylactic therapy (weekly fluconazole [100 mg] [34] and every other week itraconazole [400 mg] [33]) to further prevent tinea corporis gladiatorum. To further prevent epidemics and expedite a player's return to play, infected athletes should apply topical fungicidal cream, wash with selenium sulfide or ketoconazole shampoo, and cover their lesion with a biodressing or tape. After 72 h from the start of topical fungicidal creams, athletes can return to competition with minimal risk to other competitors [1].

FIGURE 78.12 (See color insert.) This wrestler's back and neck demonstrate the annular and round, red, scaling lesions of tinea corporis gladiatorum.

Tinea Versicolor

In hot and humid conditions, *Malassezia globosa* and *Malassezia furfur* may cause tinea versicolor in susceptible athletes. Clinically, such athletes develop round and oval, variably sized, hyperpigmented or hypopigmented, scaling macules and patches on the trunk and proximal upper extremities, predominantly (Figure 78.13). Occasionally, the scale from these lesions becomes obvious only after scraping the lesions. Unlike the potassium hydroxide examination of tinea pedis or tinea corporis, the hyphae from tinea versicolor scrapings appear short and occur along with small spheres that represent spores. Occasionally, tinea versicolor mimics the pattern and hyperpigmentation of confluent and reticulated papillomatosis of Gougerot and Carteaud (Figure 78.14) or the pattern and hypopigmentation of progressive macular hypomelanosis (Figure 78.15) [25]. Confluent and reticulated papillomatosis of Gougerot and Carteaud clears quickly upon institution of daily minocycline, while the therapy of progressive macular hypomelanosis remains more elusive. Phototherapy and topical antibiotics purportedly improve this condition [1].

Myriad regimens exist to clear tinea versicolor, but athletes need to understand that the discoloration may take months to recover its natural shade. Selenium sulfide 2.5% lotion or shampoo applied to the affected areas, left on for 15 min, and then rinsed off once per day for 7–10 days clears tinea versicolor. Ingestion of 400 mg of ketoconazole once, followed by another dose 1 week later, also effectively clears this fungal eruption. Weekly application of sulfide 2.5% lotion or shampoo may prevent future tinea versicolor outbreaks [1].

Viral

Herpes Simplex

Athletes develop herpes simplex virus-1 (HSV-1) infection as a result of reactivation of prior disease or due to transmission

FIGURE 78.13 (See color insert.) This athlete has the hyperpigmented variety of tinea versicolor on his trunk and upper arms.

FIGURE 78.14 (See color insert.) This football player's reticulated red-brown diffuse eruption represents confluent and reticulated papillomatosis of Gougerot and Carteaud.

FIGURE 78.15 (See color insert.) Progressive macular hypomelanosis frequently occurs on the lower aspect of the trunk.

from infected athletes. Outdoor athletes, with extensive UV exposure, risk reactivation of herpes labialis. Skiers and other winter athletes experience even greater UV exposure for two main reasons [37]. First, skiers participate at high altitudes on the mountain where less atmosphere exists to filter out harmful UV radiation [38]. Second, snow reflects nearly 100% of all solar radiation; as such, if athletes protect themselves even with broad-brimmed hats, the reflected sun from the ground still affects the athlete's skin and can reactivate herpes labialis.

Athletes will notice a burning or stinging sensation before the typical erythema or vesicle develops. Taking valacyclovir orally during this prodrome, athletes significantly decrease the duration of the eruption and can even, in many cases, abort the development of herpes labialis altogether. Studies on prophylactic use of sunscreen [39] or oral acyclovir [40] by skiers reveal a significant decrease in reactivation of herpes labialis.

Herpes Gladiatorum

Athletes can also acquire HSV-1 from skin-to-skin contact with other competitors; most of the research regarding sports-related herpes simplex virus infection in wrestlers. Herpes gladiatorum refers to herpes virus infection wrestlers while herpes rugbeiorum or "scrum pox" refers to herpes simplex virus infection among rugby players who also experience an extensive amount of skin-to-skin contact. Many reports document epidemics with a range of 7.6%–37% of the team infected [41]; the first reported epidemic of herpes gladiatorum occurred in 1964 when 5 of 30 (17%) wrestlers developed lesions [42]. Fomites do not appear to play as large a role in transmission as does skin-to-skin transmission. One study noted that wrestlers who sparred with an infected athlete contracted herpes gladiatorum 33% of the time [43].

Infected wrestlers will often experience a prodrome characterized by burning or stinging preceding the presence of an obvious skin lesion. Classic, mature lesions of herpes gladiatorum appear as grouped vesicles on an erythematous base located on the head, neck, and upper extremities (Figure 78.16). Nonspecific erythematous papules represent very early lesions of herpes gladiatorum, whereas crusted plaques may typify later-stage lesions; recognizing the impact of age on clinical morphology assists the clinician in making an accurate diagnosis. The differential diagnosis of

FIGURE 78.16 (See color insert.) Grouped vesicles upon an erythematous base typify herpes gladiatorum.

early lesions includes tinea corporis gladiatorum, impetigo, acne, and dermatitis [1,17]. Tzanck smear or culture confirms the diagnosis; however, cultures can take several days to produce results.

Herpes gladiatorum becomes noninfectious after 5 days of oral valacyclovir (2 g daily) therapy, and athletes at that time can safely return to competition [44]. Some special groups of athletes, especially highly competitive athletes preparing for championships and those athletes with frequently recurrent lesions, should take daily suppressive doses (1 g) of valacyclovir to prevent outbreaks.

Verruca

Human papilloma virus causes verruca (warts) in athletes as it does in nonathletes. Athletes, however, acquire these warts more frequently due to their exposure to areas that harbor the virus such as pool decks and weight rooms [25]. Additionally, calluses, inherent to many sporting activities, may help harbor warts. These verrucae appear frequently on the hands and feet and may hinder athletic activity. The thick and rough nature of the wart presents a distraction to the athlete by causing pain and by catching on equipment. Occasionally, warts may mimic calluses or corns; paring the hyperkeratotic portion of the lesion ultimately reveals the tiny, round, black dots characteristic of pericapillary hemorrhages in the case of verruca (Figure 78.17). The presence of normal skin markings or a central core confirms the diagnosis of callus or corn, respectively [1,25].

While destructive methods such as liquid nitrogen, topical cantharidin, and laser often work well to clear verruca, these surgical approaches frequently cause significant discomfort that may prevent athletic activity for several days. To minimize the disruption of an athlete's routine during their season, clinicians should attempt more conservative measures. Athletes can soak their verruca in water for 10 min and subsequently rub or pare the affected area with a pumice stone or sharp instrument (such as a #15 blade), respectively. Thereafter, they can apply topical salicylic acid and cover the wart with duct tape. Repeated nightly, this procedure will slowly decrease the size of the verruca and may eradicate the verruca altogether. Instead of salicylic acid, athletes may also try off-label prescription topical options such as imiquimod and 5-fluorouracil [1,25]. Athletes should always wear footwear in the showers, locker rooms, and pool decks. While using the weight room, athletes should use gloves to minimize cutaneous exposure to fomites. Meanwhile, athletes should clean or discard protective pads, helmets, and clothing.

Molluscum Contagiosum

Molluscum contagiosum, caused by the Pox virus, affects athletes who experience intense skin-to-skin contact and who contact certain environments, such as pool decks. As such, swimmers, wrestlers, and hockey, basketball, and rugby players most often contract molluscum contagiosum [1,25]. One study showed that swimmers experienced a relative risk of two to develop molluscum contagiosum [45].

Mature lesions of molluscum contagiosum appear as discrete, most often small (2–4 mm), white papules with a central umbilication (Figure 78.18). Very early and tiny lesions may not acquire this central indentation, and clinicians can easily confuse these papules for folliculitis. Clinicians rarely must perform biopsies to confirm this viral infection except in these aforementioned instances.

Surgical methods to rid the athlete of this virus include curettage and liquid nitrogen. Off-label use of topical tretinoin or imiquimod daily for 4–6 weeks often clears the lesions as well. The surgical methods cure the lesions instantaneously, while the topical agents take much longer to work. Occasionally, athletes will have all visible lesions treated and return to competition only to discover that extremely tiny, previously subclinical, lesions have enlarged. Athletes must minimize all exposed skin and wear footwear on the pool decks and locker room floors [1,25].

FIGURE 78.18 (See color insert.) A moderate, endogenous, eczematous reaction surrounds the white lesions of molluscum contagiosum.

ENVIRONMENTAL CONDITIONS

Organisms

Jellyfish Envenomations

Water sport enthusiasts occasionally encounter various types of *Cnidaria* in their athletic pursuits. Like other classes within the *Cnidaria* phylum, the true jellyfish possesses nematocysts that sting athletes. The characteristic linear pattern of erythema and vesicles corresponds to the dangling threads of tentacles (Figure 78.19). The symptoms often include pruritus and pain, but rarely, depending on the type of jellyfish involved, severe systemic reactions occur. Treatments include vinegar solution applied to the attached tentacles and physical removal of the tentacles [1]. Athletes should avoid applying fresh water to the tentacles as this substance may activate nematocysts. Swimmers should avoid areas infested with jellyfish or wear wet suits to cover all submerged surfaces.

Cold

Frostbite

Numerous reports exist of frostbite in athletes who compete in cold weather such as long-distance runners and athletes who compete on the snow and ice [46]. After the initial exposure to cold, athletes develop pain and erythema; continued exposure can lead to blisters and eventual necrosis. Rapid rewarming in 40°C–42°C water bath remains the treatment of choice for affected athletes [1,46]. Athletes should never rewarm the frostbitten area until they can ensure no future exposure to freezing. To prevent frostbite, athletes should minimize any exposed skin. Especially for high-risk areas such as acral areas, layered clothing traps warm air. In addition, commercially available chemical packets activated and placed in gloves or socks keep the skin warm [1,46].

FIGURE 78.19 (See color insert.) While playing in extremely hot and humid conditions, this tennis player developed the extremely fragile blisters of miliaria crystallina.

FIGURE 78.20 (See color insert.) Jellyfish stings created linearly arranged erythematous papules on this swimmer's lower legs.

Heat

Miliaria

Miliaria crystallina occurs occasionally in outdoor athletes who compete and practice in extremely hot and humid environments. The eccrine duct, very superficially, becomes obstructed and quite fragile vesicles form on the trunk (Figure 78.20). Acclimating to the environment and wearing clothes that keep one cool (i.e., synthetic, moisture-wicking, light-colored clothing [with added UPF]) help prevent future outbreaks.

Ultraviolet Radiation

Athletes experience greater exposure to UV radiation for several reasons. First, athletes practice and compete for innumerable hours in the sun. Second, during these activities, athletes expose their skin to harmful UV rays during the peak hours of UV radiation (10 a.m. to 4 p.m.). Third, sweating decreases the efficacy of sunblock, and athletes do not adequately reapply their sunscreen. Fourth, athletes' sweat actually increases the risk for sunburn. Studies have shown that the minimal erythematous dose decreases markedly (more than 40%) after the athlete sweats [47].

To prevent the acute and chronic damage of UV radiation, athletes need to apply waterproof and sweatproof sunscreen 30 min before athletic activity. Broad-brimmed hats also provide sun protection; dark-colored, tightly woven clothing blocks more UV radiation than loosely woven, light-colored clothing. New synthetic sports clothing wicks away moisture to keep the athlete cool even though dark fabric generally absorbs infrared radiation and can cause athletes to overheat [1].

CONCLUSION

Athletes represent a unique group of patients who acquire some skin lesions, for a variety of reasons, more frequently than nonathletes and rarely also develop particular cutaneous ailments. Clinicians must recognize the impact of a patient's participation in sporting activities to ensure precise diagnosis, minimize infectious epidemics, and optimize therapeutic and prevention plans.

INTRODUCTION

Skin care is an important element in total body health. Once the skin disease has been treated, skin care products are necessary for the maintenance of healthy skin. However, skin care products, if improperly chosen or improperly used, can also cause skin disease. For example, the overuse of cleansers can cause eczema, more readily experienced in those with dry skin. This necessitates proper cleanser selection as part of the skin treatment algorithm. However, patients with dry skin also need to supplement their inadequate or ineffective sebum production with a moisturizer. Many moisturizers are on the market, yet the patient must pick the proper product for optimal results. Not only should cleanser and moisturizer selection be customized for dry, normal, and oily skin, but it must also be customized based on sex, age, and ethnicity. Skin care product selection is not as simple as it might seem.

This chapter delves into the basics of skin care, to include cleansing and moisturizing, but also discusses some of the other important skin care categories such as antiperspirants/deodorants and sunless tanning products. It is hoped that the reader will have a greater appreciation for skin care and its nuisances after reading.

CLEANSERS AND SKIN CLEANSING

What is the perfect cleanser? What is the perfect method for cleansing the face and body? These are simple, yet complicated questions that cannot be easily answered. Just walk down the isle of any mass merchandiser and count the number of cleansing products for purpose. There are bars, liquids, creams, scrubs, meshes, and wipes all trying to achieve the optimal clean. There are foaming and nonfoaming cleansers customized to every body area. There are scented and unscented cleansers with some labeled as appropriate for sensitive skin. There are cleansers for women and separate formulations for men. Finally, there are treatment cleansers for acne and eczema. However, in reality, there are only several basic categories of cleansers upon which many variations have been manufactured.

Soap

Soap is a common term used by many as synonymous with cleanser. However, soap is a specific cleanser with a definite chemical composition. Soap is defined as a chemical reaction between a fat and an alkali resulting in a fatty acid salt with detergent properties.[1] The simplest soaps are manufactured in bar form. There are currently three different types of bar cleansers on the market all called "soap" by consumers, but with very different skin effects. There are the true soaps, which are composed of long-chain fatty acid alkali salts, with a pH between 9 and 10.[2] This is the original soap formulation developed that revolutionized health care in the United States. Perhaps soap, more than any other invention, has improved the quality of human life by preventing the spread of disease. This is the type of soap that grandma cooked in her backyard from ash and animal fat. The high pH of these cleansers is excellent at thoroughly removing sebum, but can also damage the intercellular lipids in diseased or sensitive skin. This formulation also experiences difficulty when used with hard water. The alkali chemically combines with calcium and other minerals in the water to form what is commonly termed "soap scum." Soap scum decreases the ability of the soap to rinse cleanly from the skin, causing irritant contact dermatitis in susceptible individuals. The only major brand of true soap left on the market today is Ivory soap manufactured by Procter & Gamble, Cincinnati, Ohio.

Following the development of true soaps came the invention of synthetic detergents. Synthetic detergents are known as syndets and contain less than 10% real "soap." Rather than possessing a highly alkaline pH, these products can be made with a pH adjusted to 5.5–7. This more neutral pH is similar to the normal acid mantle pH of the skin, causing less irritation. The tightness that is experienced following cleansing is actually the perception of altered skin pH. This is not a problem in normal-complected individuals, but can be a source of concern in persons with eczema or atopic dermatitis. Unfortunately, many associate the tight feeling with cleanliness, and it can be a challenge to convince a patient that the tight feeling is possibly an indicator of impending skin disease. Most syndet cleansers leave the skin with a smooth, sometimes slimy, feel that indicates that the intercellular lipids have not been removed and the skin barrier is intact. Syndet cleansers, sometimes known as beauty bars, are the most popular cleansers in use today. They offer milder, yet thorough, cleansing of all body areas.

The third form of cleanser is known as a combar, an abbreviation for combination bar. Combars combine true alkaline soaps with syndets to create a bar with greater cleansing abilities, but less intercellular lipid damage.[3] The majority of the bars in this category are also known as deodorant bars. They contain triclosan, a commonly used topical antibacterial, to decrease body odor caused by bacteria especially in the armpits and groin.

Selecting the proper type of "soap" may be tricky for the physician, but once the three categories of cleansers are identified, the task becomes much easier. In general, all beauty bars, mild cleansing bars, and sensitive skin bars are of the syndet variety (Oil of Olay, Dove, Cetaphil). Most deodorant bars or highly fragranced bars are of the combar variety (Dial, Coast, Irish Spring), and very few true soaps are currently on the market (Ivory).

Lipid-Free Cleansers

There are cleansers manufactured for each skin type based on the need to remove sebum balanced by preservation of the skin barrier. For persons with little sebum production, but the need to obtain adequate hygiene, lipid-free cleansers have been developed. Lipid-free cleansers are liquid products that clean without fats, which distinguishes them from the soap-type cleansers previously discussed. They are applied to dry or moistened skin, rubbed to produce minimal lather, and rinsed or wiped away (Cetaphil cleanser, Aquanil).

Lipid-free cleansers, also known as low-foaming cleansers because of their inability to foam copiously, may contain water, glycerin, cetyl alcohol, stearyl alcohol, sodium laurel sulfate, and occasionally propylene glycol. They leave behind a thin moisturizing film and can be used effectively in persons with excessively dry, sensitive, or dermatitic skin. They do not have strong antibacterial properties, however, and may not remove odor from the armpit or groin. They also are not good at removing excessive environmental dirt or sebum. Lipid-free cleansers are best used where minimal cleansing is desired, but can be used remove cosmetics of the face and eyes in persons with sensitive skin.

Cleansing Cream

Another variant of a mild cleanser is the cleansing cream, perhaps the first beauty cleanser invented. Cleansing creams

are popular among mature women who grew up in an era where cleansing cream offered the only alternative to the harsh alkaline soaps of the past. Cleansing creams are composed of water, mineral oil, petrolatum, and waxes.[4] The most common variant of cleansing cream, known as cold cream, is created by adding borax to mineral oil and beeswax (Pond's Cold Cream).[5] Cleansing creams can remove cosmetics and provide cleansing for patients with dry skin in one step. They are rubbed over a dry or wet face and then wiped away with a cloth. A residue is left behind on the skin. These products are making a comeback as eye cosmetic removal products for waterproof eyeliner and mascara in persons with sensitive eyes.

Abrasive Scrub

Other forms of cleansing combine removal of sebum from the skin surface with exfoliation, the removal of the desquamating corneocytes. With advancing age, the ability of the corneocytes to slough is decreased. The retained corneocytes give the skin a rough texture and yellowish appearance. Exfoliation removes the corneocytes, smoothes the skin surface, and restores a pinker skin color. Many antiaging cleansers are abrasive scrubs because the exfoliated skin may have a younger appearance. However, aggressive frequent use of an abrasive scrub can remove too much stratum corneum resulting in sensitive skin and can even provoke eczema.

Abrasive scrubs use a particulate material rubbed over the skin surface with the hands to mechanically remove the corneocytes. Abrasive scrubs incorporate polyethylene beads, aluminum oxide, ground fruit pits, or sodium tetraborate decahydrate granules to induce various degrees of exfoliation.[6] The most abrasive scrub is produced by aluminum oxide particles and ground fruit pits. In general, products containing these rough-edged particulates are not appropriate for sensitive skin patients. More mild facial scrubbing is produced by polyethylene beads, which are smooth and round (Clinique 7th Day Scrub). The least aggressive abrasion of the skin is found in products that contain sodium tetraborate decahydrate granules, which soften and dissolve during use. The main problem with abrasive scrub products for exfoliation is the tendency for overuse by the patient.

Woven Mesh Cleansing Implements

Cleansers have also been combined with implements to aid in applying the cleanser to the face and body or to offer an added benefit. The first cleansing implement introduced for facial cleansing was a woven mesh, also designed to deliver exfoliation benefits. The first product to enter the marketplace was composed of a nonwoven polyester fiber web sponge (Buf-Puf).[7] Originally, this product was designed to remove open comedones, but was ineffective due to the stiffness of the mesh. More modern softer versions have been introduced that are impregnated with a cleanser appropriate for various skin types. The mesh is more aggressive than an exfoliating scrub in removing corneocytes and must be used with care. More recently, the woven sponge technology has given way to the facial cleansing wipe.

Facial Cleansing Wipes

The desire for thorough, but less abrasive, cleansing led to the development of the disposable cleansing cloth, also known as the facial wipe. These wipes are composed of a combination of polyester, rayon, cotton, and cellulose fibers held together via heat through a technique known as thermobonding. Additional strength is imparted to the wipe by hydroentangling the fibers. This is achieved by entwining the individual rayon, polyester, and wood pulp fibers with high-pressure jets of water, which eliminates the need for adhesive binders, thereby creating a soft, strong cloth. Adhesives stiffen the cloth making it more injurious to the skin. The soft cloths also are more likely to traverse the skin dermatoglyphics providing better cleansing of the skin around the pores.

These cloths are packaged dry and wet. The dry cloths are impregnated with a cleanser that foams modestly when the cloth is moistened. A variety of cleansers can be used to create products for normal to dry and normal to oily skin. The cleanser can be placed on the cloth with other skin-conditioning ingredients. For example, the cleanser can be placed on one side of the cloth for washing and the cloth can be turned over during the rinse phase to leave behind skin-conditioning humectants and emollients. The antiaging cloths may also contain vitamins, such as vitamin E and vitamin B_5 (panthenol), to provide cosmeceutical benefits. Humectants and emollients can also be added to the cloth to decrease barrier damage with cleansing or to smooth the skin scale present in xerosis. In general, the cloths that are packaged dry and wetted prior to use are more gentle than those that come premoistened.

In addition to the cleansing and skin-conditioning ingredients applied during cloth manufacture, the weave of the cloth will also determine its cutaneous effect. There are two types of fiber weaves used in facial products: open weave and closed weave. Open weave cloths are so named because of the 2–3 mm windows in the cloth between the adjacent fiber bundles. These cloths are used in persons with dry and/or sensitive skin to increase the softness of the cloth and decrease the surface area contact between the cloth and the skin yielding a milder exfoliant effect. Closed weave cloths, on the hand, are designed with a much tighter weave and provide a more aggressive exfoliation. Ultimately, the degree of exfoliation achieved is dependent on the cloth weave, the pressure with which the cloth is stroked over the skin surface, and the length of time the cloth is applied. Cleansing cloths offer a versatile hygienic method for skin hygiene.

Summary

Cleansing of the face, hands, and body is probably the single most important event in maintaining hygiene and preventing the spread of disease. It is interesting to note that soap is the only substance that is not regulated by any type of

governmental document in the United States. This is because the government recognized the importance of soap to public health and felt that regulation would increase the cost of soap and make people less likely to use it. There can be no doubt that cleansing must be customized to the needs of the individual and used to maintain skin health.

MOISTURIZERS

Moisturizers have a significant impact on skin health. They can become indispensable in the treatment of xerotic skin conditions. Further, moisturizers form the vehicle for many skin preparations including topical corticosteroids, facial foundations, and antiaging creams. Perhaps 80% of skin care products, both prescription and over-the-counter (OTC), have a moisturizer as a vehicle. Moisturizers are based on occlusive substances, such as petrolatum and dimethicone, and humectant substances, such as glycerin, with a variety of sunscreens and botanicals for added functionality and marketing impact.[8] This section discusses dry skin, moisturization, and the key ingredients in moisturizer formulations.[9]

Dry Skin

Dry skin, medically known as xerosis, results from a decrease in the water content of the skin. The water is lost to the environment due to a damaged barrier that is no longer waterproof. The skin barrier is contained in the stratum corneum, which resembles a brick wall. The bricks are the corneocytes and the mortar is the intercellular lipids. If the stratum corneum is aggressively exfoliated, the corneocytes are prematurely removed and xerosis results. Alternatively, if aggressive cleansers are used, as described earlier in this chapter, the intercellular lipids are removed and xerosis also occurs. Cleansers cannot distinguish between the sebum lipids on the skin surface and the intercellular lipids between the corneocytes. Probably the most common cause of dry skin in the United States is overbathing, especially among mature individuals whose sebum production is limited.

For the skin to appear and feel normal, the water content of must be above 10%.[10] Some sources believe that the normal water content of the dermis should be around 30%, but this depends upon where and how the measurement is made.[11] Water is constantly lost to the environment through evaporation and must be replenished by water from the lower epidermal and dermal layers.[12] More water is lost under low-humidity conditions and less under high-humidity conditions. For equilibrium to occur between the skin and the environment, the ambient humidity must be at least 70%. Most conditioned living spaces control the humidity below 30% meaning that water is lost from the body through the skin on a regular basis. This water loss is known as transepidermal water loss (TEWL) and can be measured with a noninvasive equipment, such as an evaporimeter.

A healthy stratum corneum must have the ability to maintain hydration or the skin will feel rough, scaly, and dry. Dehydrated skin also tends to fissure and crack, as can be observed in calluses over the heel and ball of the foot. The dehydrated skin cracks because it becomes a brittle material in the absence of water, which functions as a plasticizer of the skin. Thus, it is the role of the intercellular lipids, composed of sphingolipids, free sterols, and free fatty acids,[13] to inhibit excessive water loss. The major lipid by weight found in the stratum corneum is ceramide, which becomes sphingolipid if glycosylated via the primary alcohol of sphingosine.[14] Ceramides possess the majority of the long-chain fatty acids and linoleic acid in the skin. Some moisturizers contain ingredients, such as ceramides, found in the intercellular lipids to stimulate barrier repair, but the signal for barrier repair is TEWL.[15,16]

Following barrier damage, the skin must be remoisturized in four steps: initiation of barrier repair, alteration of surface cutaneous moisture partition coefficient, onset of dermal–epidermal moisture diffusion, and synthesis of intercellular lipids.[17] Other disease states, such as psoriasis and atopic dermatitis, also demonstrate abnormal barrier function due to ceramide distribution.[18,19] Interestingly enough, xerosis tends to increase with age due to a lower inherent water content of the stratum corneum,[20] but this does not account for the scaliness of mature skin; probably an abnormal desquamatory process is also present.[21] The main treatment for dry skin in persons of all skin types, colors, and ages is the use of moisturizers.

Skin Moisturization

Three major mechanisms exist for rehydrating xerotic skin. Well-formulated moisturizers combine ingredients functioning in each category: occlusives, humectants, and hydrophilic matrices.[22] Occlusives are oily substances that retard TEWL, much like an oil slick placed on an open-air water reservoir to prevent evaporation. Basically, the skin is hydrated from within, not from the outside or from the environment. Placing water on the skin actually increases water loss rather than rehydrating the skin. The second method for rehydration is the use of humectants. These are substances that function like sponges to hold water in the skin. They draw water from the lower epidermis and dermis to the dehydrated outer skin, which is then trapped in place by occlusive ingredients. All good moisturizers must contain both types of ingredients. Finally, hydrophilic matrices are large-molecular-weight substances that further inhibit water loss.

Occlusive Moisturizing Ingredients

There are many different oily substances that are suitable for topical application to retard TEWL and function as occlusives. Occlusives can be divided into 20 different chemical classes with each ingredient imparting a different feel and thickness to the moisturizer (Table 79.1).[23] The first occlusives used in skin care products were hydrocarbon oils and waxes, such as petrolatum and mineral oil. Petrolatum remains one of the most popular occlusive moisturizers because it more closely resembles the natural intercellular lipids than any other substance. Petrolatum reduces TEWL by 99%, yet the 1% water loss is sufficient to allow repair to occur.[24]

TABLE 79.1
Families of Occlusive Moisturizing Ingredients

1. Hydrocarbon oils and waxes: petrolatum, mineral oil, paraffin, squalene
2. Silicone oils
3. Vegetable and animal fats
4. Fatty acids: lanolin acid, stearic acid
5. Fatty alcohol: lanolin alcohol, cetyl alcohol
6. Polyhydric alcohols: propylene glycol
7. Wax esters: lanolin, beeswax, stearyl stearate
8. Vegetable waxes: carnauba, candelilla
9. Phospholipids: lecithin
10. Sterols: cholesterol

Humectant Moisturizing Ingredients

Another concept in rehydrating the stratum corneum is the use of humectants. Humectants have been used in cosmetics for many years to increase shelf life by preventing product evaporation and subsequent thickening due to variations in temperature and humidity. For example, humectants are a necessary part of all oil-in-water creams to maintain their required water content. Substances that function as humectants are glycerin, honey, sodium lactate, urea, propylene glycol, sorbitol, pyrrolidone carboxylic acid, gelatin, hyaluronic acid, vitamins and some proteins.[23,25] Hyaluronic acid is one of the most popular humectants found in some moisturizers. It is used in facial fillers in an injectable form to absorb water and fill facial wrinkles, but can also be applied topical to draw water to the skin surface that is then trapped by an occlusive moisturizing ingredient.

Cosmetic chemists have theorized that humectants could be used to draw water from the environment, under conditions where the ambient humidity exceeds 70%, and more commonly from the deeper epidermal and dermal tissues to rehydrate the stratum corneum. Water that is applied to the skin in the absence of a humectant is rapidly lost to the atmosphere.[26] Humectants may also allow the skin to feel smoother by filling holes in the stratum corneum through swelling.[27] However, under low-humidity conditions, humectants, such as glycerin, will actually draw moisture from the skin and increase TEWL.[28] Therefore, a good moisturizer should combine both occlusive and humectant properties.

Hydrophilic Matrix Moisturizing Ingredients

Hydrophilic matrices are large-molecular-weight substances that physically impede water loss from the skin surface. They are similar to occlusives in their mechanism of action, except that they are not necessarily oily substances. One of the oldest and still medically applicable hydrophilic matrices is colloidal oatmeal, which is available in a variety of particle sizes. Large-particle-size colloidal oatmeal is used as a powder placed in the bath to prevent water loss from the skin across an osmotic gradient in bath water. Colloidal oatmeal baths have been used by dermatologists for years in persons with eczema and atopic dermatitis. Fine-particle colloidal oatmeal is used in powders and oatmeal-based moisturizers similarly to retard water evaporation.

Moisturizers and Skin Emollients

Moisturization is the most medically important aspect of lotion and cream application to the body, but consumer product preference is based more on a concept known as emolliency. Emolliency is the ability of a lotion or cream to make the skin feel smooth and soft. Emollients provide this positive sensory experience by filling the spaces between the desquamating skin scale with oil droplets,[29] but their effect is only temporary. Most moisturizers are emollients, but not all emollients are good moisturizers. Most consumers base their opinion of how well a moisturizer works on skin feel, while it is more medically relevant to base the value of a moisturizer on how well it hydrates the skin. Thus, a popular moisturizer must both rehydrate and improve skin feel to succeed in the marketplace.

Moisturizer Formulation

The ideal moisturizer has yet to be invented, accounting for the myriad of products available for purchase. It is surprising to note, however, that the biggest difference among moisturizer formulations has more to do with the aesthetic than the medical aspects of the product. Fragrance, color, and packaging are the most distinguishing characteristics of modern moisturizers, which are only of importance for consumer appeal. The basic moisturizer formulation consists of water, lipids, emulsifiers, preservatives, fragrance, color, and specialty additives. Interestingly enough, water accounts for 60%–80% of any moisturizer; however, externally applied water does not remoisturize the skin. In fact, the rate of water passage through the skin increases with increased hydration.[30] The water functions as a diluent and evaporates leaving the active agents behind.

The most popular moisturizer formulations are oil-in-water emulsions where water is the primary phase into which oil droplets are introduced as the secondary phase. Oil-in-water emulsions are popular because the water evaporates leaving a minimally greasy film behind. Water-in-oil emulsions, where oil is the primary phase, are heavier and have a greasy feeling on the skin with poor consumer-accepted aesthetics, even though they are generally superior moisturizers. Of all the ingredients in the moisturizer formulation, emulsifiers are the most problematic. They are amphiphilic materials that are detergents emulsifying the oil within the water in concentrations of 0.5% or less. Emulsifiers can cause skin problems as they can also emulsify the sebum on the skin surface.

Finally, the other important ingredient in all skin care products is the preservatives. Preservatives are necessary to prevent the oil in the moisturizer from going rancid and to protect from microbe contamination. There has been a movement lately to manufacture preservative-free skin care products. This has been driven by some popular press

indicating that preservatives can cause cancer. These studies showing preservative-induced cancer were conducted in rodents that were fed the preservative in doses difficult for humans to consume. Indeed, preservatives for skin care products should not be eaten. The most commonly used preservatives in skin care products are from the paraben family.[17] Parabens are minimally allergenic and provide excellent protection against both gram-positive and gram-negative organisms. Formulations that claim to be preservative-free usually contain a preservative that is not labeled as such on the packaging. For example, phenoxyethanol is a frequently used preservative, but it smells like roses. It may be listed as a fragrance, but it is really a preservative. Similarly, clove and turmeric extracts may be used as fragrance ingredients, but they too are fragrances. Clove and turmeric are spices used in cooking. Most spices are flavorings but also preservatives and can be used multifunctionally in skin care preparations, as well.

A successful moisturizer formulation must meet three consumer-driven criteria: it must increase the water content of the skin (moisturization), it must make the skin feel smooth and soft (emolliency), and it must protect injured or exposed skin from harmful or annoying stimuli such as itching, stinging, and burning (skin protectant). If a moisturizer can produce these skin benefits, it will be useful to the consumer and medically relevant.

Moisturizer Ingredients

Most moisturizers use the same basic ingredients as the backbone of the formulation to achieve efficacy. While a review of all the ingredients in a moisturizer is beyond the scope of this chapter, the most beneficial and popular ingredients are reviewed to include petrolatum, dimethicone, and glycerin.

Petrolatum

The most commonly used active agent in skin care products, after water, is petrolatum.

Petrolatum is a semisolid mixture of hydrocarbons obtained through the dewaxing of heavy mineral oils. Pure cosmetic-grade petrolatum is practically odorless and tasteless appearing in the U.S. Pharmacopeia in 1880. *It is interesting that it has never been duplicated synthetically.*

Petrolatum is the most effective moisturizing ingredient on the market today, reducing TEWL by 99%.[31] It functions as an occlusive to create an oily barrier through which water cannot pass. Thus, it maintains cutaneous water content until barrier repair can occur. Petrolatum is able to penetrate into the upper layers of the stratum corneum and aid in the restoration of the barrier, which is initiated through the production of intercellular lipids, such as sphingolipids, free sterols, and free fatty acids.[32] Products containing petrolatum increase the rapidity with which these lipids are synthesized.

Petrolatum impacts all phases of skin remoisturization, the first step toward barrier repair and wound healing. Petrolatum allows the water content of the skin to rise by decreasing evaporative losses, which creates the moist environment necessary for fibroblast migration leading to wound healing and eventual barrier restoration. Furthermore, it is hypoallergenic, noncomedogenic, and nonacnegenic.

Petrolatum also decreases the appearance of fine lines on the face and body due to dehydration. It functions to reduce itching and mild pain by creating a protective film over exposed lower epidermal and dermal nerve endings. It acts as an emollient by entering the space between the rough edges of desquamating corneocytes, restoring a smooth skin surface. It can also function as an exfoliant by loosening desquamating corneocytes, which are physically removed as the petrolatum is rubbed into the skin. Petrolatum is also an important component of many other cosmeceutical formulations that contain additional actives.

Dimethicone

The major drawback to pure petrolatum as a moisturizer is its greasiness, which most patients find unaesthetic. This can be minimized by lowering the petrolatum concentration and adding dimethicone, known as an astringent moisturizer, to improve product aesthetics. Dimethicone is the second most common active agent in moisturizers today because it too is hypoallergenic, noncomedogenic, and nonacnegenic.[33] Dimethicone is one of a family of silicones that form the basis of all oil-free moisturizers and facial foundations.

Silicone originates from silica, which is found in sand, quartz, and granite. It derives its properties from the alternating silica and oxygen bonds, known as siloxane bonds, which are exceedingly strong. These strong bonds account for the tremendous thermal and oxidizing stability of silicone. Silicone is resistant to decomposition from ultraviolet radiation, acids, alkalis, ozone, and electrical discharges. The silicone used in topical preparations is an odorless, colorless, nontoxic liquid. It is soluble in aromatic and halocarbon solvents, but poorly soluble in polar and aliphatic solutes. Because silicone is immiscible and insoluble in water, it is used as an active agent in products designed to be water resistant. To date, there is no report of toxicity from the use of topical silicone.

Dimethicone cannot replace petrolatum, however, as a moisturizer for decreasing fine facial lines of dehydration or for creating an environment optimal for healing skin.[34] While dimethicone is insoluble in water, it is permeable to water vapor. Thus, if the skin barrier is wounded, dimethicone will not reduce TEWL. However, this water vapor permeability is important in the manufacture of facial foundations and sunscreens, since perspiration must evaporate or the product will contribute to miliaria and leave the skin feeling warm and heavy.

Dimethicone can provide many other skin benefits as an active agent besides moisturization. It can function as an emollient, making the skin smooth and soft to the touch by filling in spaces between the desquamating corneocytes. It can also smooth skin scale from the use of drying acne medications, such as benzoyl peroxide or tretinoin, without creating a greasy shine undesirable in oily complected patients. Dimethicone also does not easily mix with facial sebum,

allowing other ingredients in the formulation to remain in place on the face. This is valuable in sunscreens and facial cosmetics.

Glycerin

Glycerin is a commonly used humectant in skin moisturizers. Humectants are substances that attract water from the dermis and viable epidermis into the dehydrated stratum corneum.[26] However, if the skin barrier is damaged, the water will immediately evaporate into the lower-humidity environment. For this reason, humectants are always combined with occlusive moisturizers that retard water loss, such as the previously discussed petrolatum and dimethicone. Glycerin, petrolatum, and dimethicone form the backbone of most skin care products to which other novel agents are added.

Glycerin offers some unique skin benefits. It is one of the few moisturizers, in addition to petrolatum, that is able to form a reservoir effect on the skin. In other words, the effect of glycerin appears to persist long after the glycerin is no longer present. Previously, this effect was thought to be due to glycerin affecting the intercellular lipids. It is now recognized that glycerin is capable of modulating water channels in the skin, known as aquaporins.

Aquaporins are highly conserved water channels present in plants, bacteria, and human skin composed of integral membrane proteins from a larger family of major intrinsic proteins.[35] The 2003 Nobel Prize in Chemistry was awarded to Peter Agre and Roderick MacKinnon for work on aquaporins and ion channels. These channels conduct water in and out of the cell while preventing the passage of ions and some solutes. They are composed of a six-transmembrane alpha helical structure arranged in a right-handed bundle. Aquaporins form tetramers in the cell membrane and control the transport of water, but also glycerin, carbon dioxide, ammonia, and urea. Different aquaporins contain different peptide sequences controlling the size of the molecules that are able to pass; however, aquaporins are impermeable to charged molecules, such as protons. Typically, molecules can only pass single file through the channel.

The primary aquaporin in the epidermis is aquaporin-3. It is found in the basal and suprabasal layers of the epidermis, but not in the stratum corneum. Aquaporin-3 expression is also increased in human skin diseases with elevated TEWL. Thus, glycerin is being rediscovered as a moisturizing ingredient with potential to dramatically affect skin water balance. Since facial lines of dehydration are the easiest sign of aging to rapidly correct, skin care products based on glycerin, petrolatum, and dimethicone are commonly used to rapidly hydrate the skin and improve appearance. However, petrolatum, dimethicone, and glycerin are also present in the vehicle of most facial skin care creams and lotions. The vehicle is responsible for improving skin condition, but also delivers other active agents to the skin surface.

Summary

Moisturization of the skin occurs through the use of ingredients that function as occlusives, humectants, and hydrophilic matrices. Proper cleanser selection is the best way to avoid the need for moisturization, but the habit of daily bathing is hard to break in many patients. Thus, there is a need to synthetically replace skin lipids and maintain the barrier. Moisturizers attempt to create an environment for repairing the damage done by skin cleansing. The challenge is to find the balance that results in superior skin health and ultimately beautiful skin.

ANTIPERSPIRANTS AND DEODORANTS

Antiperspirants and deodorants are important skin care products different than any we have previously discussed because they fall into the OTC drug category. Antiperspirants contain active agents that are disclosed on product packaging. Whenever an active ingredient disclosure is made, the product is considered an OTC drug. This means that the ingredients and concentration of ingredients in the formulation are controlled by a government monograph. This places restrictions on the product different from cosmetics. Yet controlling axillary perspiration is important both to the patient and to the physician.

Antiperspirants are available in a variety of formulations from stick to cream to gel to aerosol spray, but the active ingredient in all is an aluminum-containing compound. The health safety of antiperspirants has been debated for years. Most recently, antiperspirants have been linked to breast cancer in the media, but no medical relationship has been established. While no antiperspirants are to be worn during breast mammography examinations, this is not related to breast cancer. The FDA did express some concern in 1978 regarding the long-term inhalation risk of aerosol antiperspirants; however, these preparations remain on the market.

The first antiperspirant was introduced in 1916, which was composed of a 25% solution of aluminum chloride hexahydrate in distilled water. This highly effective formulation only required every other day application but was extremely irritating and the low pH damaged clothing. The need to develop an antiperspirant that controls sweat yet is skin compatible has led to all of the products that are currently marketed. This discussion focuses on the important issues of sweat control.

Antiperspirants versus Deodorants

The words antiperspirant and deodorant are sometimes used interchangeably in the common vernacular, but to the cosmetic chemist, these are two very different personal care products. Antiperspirants contain ingredients to decrease sweating, while deodorants are used solely to manage axillary odor. For this reason, all antiperspirants can be considered deodorants, but not all deodorants are antiperspirants. Table 79.2 lists the mechanisms for axillary odor control. Most products in the current marketplace are both antiperspirants and deodorants. The rest of our discussion will focus on antiperspirants.

TABLE 79.2
Mechanisms for Axillary Odor Reduction

1. Reduce apocrine gland secretions
2. Reduce eccrine gland secretions
3. Remove apocrine and eccrine gland secretions from the axilla
4. Decrease axillary bacterial colonization

Perspiration Reduction

Sweat can be divided into apocrine and eccrine perspiration. Eccrine sweat is a clear, odorless fluid of pH 4–6.8 composed of 98%–99% water, sodium chloride, lower fatty acids, lactic acid, citric acid, ascorbic acid, urea, and uric acid. Apocrine sweat is a turbid, viscous, odorless fluid of pH 6–7.5 that has high content water, in addition to protein, carbohydrate waste materials, and sodium chloride. The amount of eccrine perspiration is much greater than the amount of apocrine perspiration. An effective antiperspirant must reduce both types of perspiration.

The reduction of apocrine and eccrine perspiration on the body is a daunting task, and the mechanisms for sweat control are summarized in Table 79.2. In the axilla, there are some 25,000 eccrine glands capable of producing large quantities of perspiration in response to heat and emotional stimuli. Antiperspirants work by coagulating the protein in the sweat duct. They contain metal salts that combine with intraductal keratin fibrils to cause eccrine duct closure and formation of a horny plug to obstruct sweat flow to the skin surface.[36]

The only two metal salts that are presently used in antiperspirants are aluminum and zirconium.[37] The original antiperspirant formulation was a 25% solution of aluminum chloride hexahydrate in distilled water, but it was extremely irritating.[38] More modern antiperspirant formulations contain aluminum chloride, aluminum chlorohydrate, aluminum zirconium chlorohydrate, and buffered aluminum sulfate.[39] These metals provide a better balance between efficacy and skin irritation.

Antiperspirant Efficacy

The FDA has established that an antiperspirant must reduce sweat by at least 20% to be marketed in the United States as an effective product. Antiperspirants that are labeled as highly effective must reduce sweat by at least 30%. Table 79.3 lists the efficacy of a variety of currently marketed formulations. Notice that the efficacy range is broad, but overall aerosols are the least effective and roll-ons are the most effective. This is due to the ability of the product to contact all of the sweat ducts in the axilla and deliver an optimal dose. For most patients, this amount of sweat reduction would be considered woefully inadequate. This is the main reason that not all antiperspirants provide sweat reduction in individuals with abundant perspiration. The ingredients were designed to perform at a 20%–30% reduction level.

TABLE 79.3
Antiperspirant Efficacy

Formulation	Percent Sweat Reduction
Aerosols	20–33
Creams	35–47
Roll-ons	14–70
Lotions	28–62
Liquids	15–54
Sticks	35–40

Efficacy is defined as the percentage reduction in the rate of sweating achieved after application of the antiperspirant product. The percentage sweating reduction can be determined gravimetrically.[40] This involves weighing an absorbent pad and then placing the pad in the armpit while the subject is induced to sweat in a hot room. The pad is then reweighed after a specified time in the hot room, and the increase in weight per time is converted into a sweating rate. The rate can be compared before and after the application of an antiperspirant.

Antiperspirant and Axillary Odor

Perspiration is the perfect medium for bacterial growth accounting for the odor associated with sweaty armpits. Axillary odor is caused by the action of bacteria on sterile eccrine and apocrine sweat. The apocrine sweat is responsible for a large part of the odor as it is rich in organic materials. Eccrine sweat, on the other hand, is more dilute and does not provide a high concentration of bacterial nutrients. However, eccrine sweat indirectly promotes odor by dispersing the apocrine sweat over a larger area and providing the moisture necessary for bacterial growth. Axillary hair also contributes to odor by acting as a collecting site for apocrine secretions and increasing the surface area suitable for bacterial proliferation.

Deodorants function either by masking the axillary odor with a perfume or by decreasing axillary bacteria. Therefore, many deodorants contain antibacterials, such as quaternary ammonium compounds (benzethonium chloride) and cationic compounds (chlorhexidine, triclosan).

Mechanism for Sweat Control

Antiperspirants reduce axillary moisture by employing aluminum salts to create a plug within the acrosyringium to occlude eccrine and apocrine ducts. Sometimes the aluminum is combined with zirconium to enhance efficacy. It takes about 10 days to create the plug, which physically blocks the transport of sweat from the gland on to the skin surface. Conversely, it takes 14 days for the plug to dissolve. It is for this reason that best results with antiperspirants are achieved with daily use to maintain the plug.

In order for the antiperspirant to work, it must physically contact every sweat duct. Even and thorough application to

entire axillary vault is necessary for optimal results. Some antiperspirants have a grid to encourage even application and metered dosing administered through turning a knob at the bottom of the stick container. Using the amount of antiperspirant recommended on the packaging is important.

Clinical Strength Antiperspirants

A new category of antiperspirants that have been introduced are labeled as "clinical strength" products. These products have a slightly higher concentration of active ingredients that must reduce sweat by 30% to substantiate the highly effective claim on package labeling, but are also recommended for twice-daily use. The twice-daily use is actually the key to their enhanced efficacy. The antiperspirant must remain in the axillary vault long enough to form or maintain the plug in the acrosyringium. If heavy sweating is occurring during application, the antiperspirant is washed away and ineffective. Since the armpit is generally at rest at night, bedtime application of antiperspirants allows the ingredients to contact the skin longer and create a better plug that translates into enhanced efficacy. Increased efficacy can be achieved with any antiperspirant that is used morning and evening.

The most effective antiperspirants create a deep plug in the acrosyringium. The more superficial the plug, the less sweat control obtained. Unfortunately, there is a direct connection between skin irritation and acrosyringial plug depth. Efficacious formulations must address both issues to create a skin-friendly product. Some manufacturers are including skin protectant ingredients, such as dimethicone, in antiperspirant formulations to increase efficacy while counteracting the inherent possibility of irritant contact dermatitis.

Improving Sweat Control

An effective antiperspirant must create a long-lasting plug in the sweat duct ostia quickly. This is best accomplished by evenly spreading the antiperspirant in the axillary vault. If the antiperspirant does not touch the sweat duct, it will not work. This is similar to botulinum toxin, which will work for sweat reduction only if it is injected over the entire area of moisture production. The ability to evenly distribute the antiperspirant accounts for the decreased efficacy of aerosol spray formulations that may easily miss sweat gland-containing areas.

The most effective antiperspirants are the sticks and lotions. These are vigorously rubbed in the axilla to remove the product from the specially designed applicator to distribute the chemical throughout the armpit. The active agent in the newer antiperspirants is aluminum–zirconium tetrachlorohydrex-gly complex. This complex can reduce axillary perspiration by 40%–60%. These aluminum salts have an acidic pH of 3.0–4.2.[41] Irritation is reduced by incorporating skin-conditioning agents, such as dimethicone or cyclomethicone, into the formulation. The silicone imparts skin soothing properties to the skin irritated by the antiperspirant ingredients.

The next most common reason for antiperspirant failure is the inability to get an even film that covers the entire armpit. The antiperspirant must be in contact with each and every eccrine and apocrine duct in the armpit to work. Thus, the applicator should be domed to fit into the axilla and dispense a thick even film of product. The film must be somewhat water resistant or it will be rinsed away by perspiration before the plug can be formed in the ducts. For this reason, the armpit should be dry when the product is applied. Many dermatologists recommend that patients apply an OTC or prescription antiperspirant and then occlude the armpit with plastic wrap. If the patient sweats profusely under the occlusion, the perspiration may wash away the active ingredients before a plug can be formed. Thus, the occlusion may decrease the efficacy of the antiperspirant rather than increase efficacy due to enhanced penetration.

Another possible cause for antiperspirant failure is inconsistent application. Compliance is important to achieve optimal results. It takes about 10 days of antiperspirant application for the complete plug to be formed in the sweat duct. If the patient decides after 3 days of application that the antiperspirant has not worked sufficiently, they have not given the product an adequate trial. Furthermore, the plug is completely gone 14 days after the last application. Continuous daily application is necessary to achieve and maintain the sweat reduction effect.

Another consideration is the depth of the plug within the sweat duct. Plugs that are more deeply placed in the sweat gland will provide better sweat reduction than those that are superficially situated. If the plug is very close to the surface, it is possible that it can be removed by the rubbing of clothing or shaving. Patients who complain that antiperspirants do not work may wish to wear loose fitting clothing around the armpits and use only light razor pressure when shaving the armpits. The deepest plugs are created by prescription aluminum chloride solutions, but these formulations must be used carefully as they can irritate skin and ruin natural fabrics, such as rayon, cotton, and silk. More superficial plugs are created by OTC antiperspirants containing aluminum chlorohydrate. Intermediate-depth plugs are created by OTC antiperspirants containing aluminum zirconium chlorohydrate.

Summary

Antiperspirants are a commonly used OTC drug. The creation of a deep plug within the sweat duct ostia is the key to excellent efficacy. This plug is best created by morning and nightly application of an even thin film of antiperspirant to the entire dry armpit. These simple tips may be helpful to the patient who is requiring treatment for hyperhidrosis.

SUNLESS TANNING PRODUCTS

Skin color has always been a source of preoccupation for the human race. There are reports of ancient man using burnt ashes to blacken the skin, Egyptians applying burnt ocher and beetle shells to adorn the face, and American Indians

decorating their bodies with vivid pigments. This concept of self-adornment still persists in the form of recreational tanning. The desirability of a tan was popularized by Coco Chanel, who was famous for her couture fashions. She conceived the idea of using tanned women in advertisements designed to promote her clothing and perfume. Prior to this time, women had shunned the sun, since tanned skin indicated that a woman performed manual labor outdoors. Society women, who dwelled indoors, used their fair skin color as a sign of class status. With the industrial revolution, more and more women were leaving their jobs in the fields to live in the city and work indoors in factories. These women had little time for recreational sunning. Thus, skin tanning became popular as a sign that northerners were able to vacation in a sunny locale.

Despite the known risks of premature aging and skin cancer associated with tanning, this remains a popular practice. Tanning from natural sun exposure or from artificial tanning booth light poses a health risk that is ignored by many. Since the societal desirability of tanned skin among Caucasians has not decreased, skin care manufacturers have searched for ways of achieving tanned skin without photodamage. Products designed to simulate a tan without sun exposure are known as sunless tanning creams or sunless tanning creams.

Sunless tanning creams utilize dihydroxyacetone (DHA) as the active agent.[42] This chemical was originally discovered in the 1920s as a possible substitute for sweetener in diabetic diets by Procter & Gamble, Cincinnati, OH. When the DHA was chewed in concentrated form as a candy, it was noted that the saliva turned the skin brown without staining clothing or the mouth. This side effect made the substance unsuitable as a glucose substitute, and DHA was not marketed until the 1950s when the first sunless tanning cream was introduced into the marketplace.

Sunless Tanning Cream Formulation

DHA is a three-carbon sugar that is manufactured as a white, crystalline hygroscopic powder. It interacts with amino acids, peptides, and proteins to form chromophobes known as melanoidins.[43] Melanoidins structurally have some similarities to skin melanin.[44] The browning reaction that occurs when DHA is exposed to keratin protein is known as the Maillard reaction.[45] DHA is technically categorized as a colorant or colorless dye.

DHA is usually added to a creamy base in concentrations of 3%–5%.[46] Lower concentrations of DHA produce mild tanning while higher concentrations produce greater darkening.[47] This allows sunless tanning creams to be formulated in light, medium, and dark shades. The depth of color produced by sunless tanning creams can be enhanced by increasing the protein content of the stratum corneum. This is accomplished by applying a sulfur-containing amino acid, such as methionine sulfoxide, to the skin just before applying the DHA.

As might be expected, skin areas with more protein stain a darker color. For example, keratotic growths such as seborrheic keratoses or actinic keratoses will hyperpigment. Protein-rich areas of the skin, such as the elbows, knees, palms, and soles, also stain more deeply. For this reason, it is advisable to remove all dead skin through exfoliation prior to sunless tanning cream application. DHA does not stain the mucous membranes, but will stain the hair and nails.

The chemical reaction is usually visible within 1 h after DHA application, but maximal darkening may take 8–24 h.[48] Many sunless tanning preparations contain a temporary dye to allow the user to note the sites of application and to promote even application, but this immediate color should not be confused with the Maillard reaction.

Sunless tanning creams have enjoyed a renewed popularity since their original introduction in the 1950s. The original self-tanners produced a somewhat unnatural orange skin color. This problem has been corrected through the use of more purified sources of DHA that yield a more natural golden color. Yet for persons with pink skin tones, the sunless tanning creams may still appear unnatural.

Sunless Tanning Safety

DHA is a nontoxic ingredient both for ingestion and for topical application. It has a proven safety record with only a few reported cases of allergic contact dermatitis.[49] Unfortunately, the browning reaction does not produce adequate photoprotection. At most, sunless tanning preparations may impart an SPF of 3–4 to the skin for up to 1 h after application.[50] The photoprotection does not last as long as the artificial tan. The brown color imparts limited photoprotection at the low end of the visible spectrum with overlap into the UVA portion of the spectrum.[51] DHA used to be approved as a sun-protective agent in combination with lawsone; however, the new sunscreen monograph has removed this ingredient largely due to its lack of popularity.

The staining reaction that occurs with DHA is limited strictly to the stratum corneum and can be readily removed with tape stripping and exfoliation. Thus, the product must be reapplied daily to maintain the optimal skin darkening. There are no known side effects, except for possible irritation, from frequent application. The DHA does have a distinct odor, which is difficult to mask with fragrances.

Summary

Sunless tanning creams are a safe, cost-effective, efficient manner to obtain temporary skin darkening. They should not be used in place of a sunscreen, however. A natural simulated tan can be achieved by applying the sunless tanning cream evenly to the desired areas. Care should be taken to apply less product to easily stained areas, such as the ankles, knees, elbows, and toes. The hands should be washed immediately following application to prevent unnatural staining of this skin surface. The product should not be applied to the hair or nails. Many times a more even application can be obtained by exfoliating large areas, such as the arms and legs, prior to application with a puff or scrubbing cream. Any loose skin scale will pigment more deeply than the surrounding skin.

Since a tan remains fashionable in our modern millennium society, sunless tanning creams should be used to stain the skin rather than risking sun exposure, which will ultimately result in premature skin aging and skin cancer.

SUMMARY

This chapter has summarized the major issues in skin care to include cleansers, moisturizers, antiperspirants/deodorants, and sunless tanning creams. These are all products that dramatically affect skin health, but are necessary for modern hygiene. An understanding of these products is important to the physician as patients frequently request advice on product use and selection. Further, some dermatologic problems may be related to improper product use. It is hoped that this chapter has provided a brief overview of skin care.

ST segment changes remain an essential tool to detect myocardial ischemia, but so much more clinical information can be derived from a stress test. Other components of the electrocardiogram (ECG) are just as useful, as well as an assessment of symptoms, hemodynamics, and exercise capacity. In this chapter, we discuss the importance of stress testing beyond the interpretation of the ST segment. We will review exercise protocols, nomograms, Bayes's theorem, diagnostic and prognostic considerations of stress testing, utility of cardiopulmonary stress testing, and pharmacologic stress testing with cardiac imaging for non-ambulatory patients. When relevant, we also denote gender differences.

EXERCISE STRESS TESTING

Exercise stress testing has traditionally been conducted as a diagnostic tool focused on ST depression and/or onset of angina symptoms as indications of underlying obstructive coronary artery disease (CAD). The stress test can be performed using a treadmill (common in the United States) or a cycle ergometer (common in Europe). From a diagnostic standpoint, greater exercise-induced ST depression and anginal symptoms have been reported for treadmill exercise versus cycle ergometer testing. Comparison of treadmill and cycle ergometry also reveals maximal oxygen uptake 10%–20% higher for the treadmill and maximal heart rate (HR) 5%–20% lower for the cycle ergometer.[1,2]

Many exercise laboratories in the United States have both the treadmill and cycle ergometer available, but the treadmill is the preferred modality for exercise testing in the United States. For motor-driven treadmills, the patient must work at the set speed and grade based on a chosen exercise protocol. Several treadmill exercise protocols exist, and no one protocol is optimal for all subjects. The patient's reported exercise tolerance and specific limitations to activity should be considered when selecting the appropriate protocol.

PROTOCOLS

The use of exercise to elicit anginal symptoms, associated ST depression, or both was documented as early as 1928.[3] However, it was not until the middle of the century that exercise protocols were standardized. The Bruce treadmill protocol was one of the first attempts to standardize progressive exercise testing to evaluate cardiac function. It is arguably the most commonly used exercise test protocol in medicine despite its significant limitations in a clinical population. The staged protocol starts at approximately five metabolic equivalents (METs) and progresses in two to three MET increments every 3 min. Although it is used extensively in clinical populations, the Bruce protocol is best suited for healthy, younger subjects since it starts at an intensity beyond the exercise capacity of many patients with cardiovascular disease and progresses in large work increments between stages. Consequently, patients often fail to attain a leveling off or plateauing of physiologic responses, and delineation of the precise MET level at the ischemic or anginal threshold is therefore difficult.

Several protocols have since been developed that have lower initial metabolic demands and stages that progress in constant, gradual, one to two MET increments. No one protocol is best for all subjects. The patient's reported exercise tolerance and specific limitations to activity (cardiac, orthopedic,

[b] Cleveland Clinic Chronotropic Assessment Exercise Protocol.

pulmonary, neuromuscular, as well as patient preference) should be considered when selecting the appropriate protocol. Protocols that are too aggressive provide limited data and may grossly overestimate functional capacity. In general, protocols that reach termination criteria between 8 and 12 min provide adequate and reliable data. See Table 80.1 for a comparison of common protocols for treadmill testing.

NOMOGRAMS

The clinical value of any test is dependent on the standardized application of test procedures, appropriately calibrated equipment, and objective interpretation of test data. For maximal/symptom-limited stress testing, the patient is a critical variable that modulates test results. If a test is prematurely terminated, key information may be missed and the predictive/prognostic value of the study will be negatively impacted.

Peak Heart Rate Nomograms

Nomograms that predict maximal HR are one tool that clinicians use to assess the quality of effort put forth by the patient. Maximal HR nomograms are also used to determine chronotropic incompetence and HR recovery abnormalities, both of which have significant prognostic significance with respect to mortality and morbidity.

The most common nomogram to determine peak HR has been the following equation:

$$\textit{Age-predicted Max Heart Rate} = 220 - \textit{Age in years}$$

Although widely accepted and applied, a review of the origins of this formula found no published scientific research supporting its development. The large standard deviation of this equation (approximately ±11 bpm) and the lack of documentation regarding its validity and reliability bring its utility into question.[4]

A meta-analysis of maximal HRs from 351 studies including 18,712 subjects was conducted to develop an age-predicted HR max equation. The equation was then cross validated in 514 healthy subjects. This robust study yielded the following equation[5]:

$$\textit{Age-predicted Max Heart Rate} = 208 - 0.7\,(\textit{age in years})$$

Despite the large sample size of the meta-analysis, the applicability to women remained a concern, since the majority of the subjects were men. A female-specific prediction equation was later developed using data from 5437 asymptomatic women who underwent symptom-limited exercise testing in the St. James Women Take Heart Project. When predicting maximal HR for women, the authors recommend use of the following equation[6]:

$$\textit{Age-predicted Maximal Heart Rate} = 206 - 0.88\ (\textit{age in years})\ (SD = 11.8)$$

Although greater attention has been paid to the validity and accuracy of maximal HR prediction equations, there is no one ideal equation. To best predict maximal HRs, the population-derived equation that best fits the individual being tested should be utilized.

It is also important to emphasize that the equations referenced earlier are based on generally healthy populations, free of medications and clinical conditions that could reduce the maximal HR. Application to clinical populations is limited. For all these reasons, termination of exercise testing at a set percentage of age-predicted maximal HR is inappropriate when attempting to assess functional capacity, chronotropic response, HR recovery, or even ST depression.

Functional Capacity Nomograms

Functional capacity is a powerful prognostic variable for all-cause and cardiovascular mortality.[7] Several equations to predict functional capacity, based on age, gender, and activity status, have been published.[8] Nomograms based on maximal exercise tests of healthy active as well as sedentary men have also been developed. These nomograms can be used to express a patient's exercise capacity as a percent of his expected age- and activity-matched group.[9]

One of the largest samples of normative data for maximal oxygen consumption (VO_2 max), a measurement of functional capacity, comes from the Cooper Institute with data from exercise tests on over 44,000 men and nearly 15,000 women. The data are presented in percentile by age and gender. A VO_2 max lower than the 20th percentile has been associated with a 3.44-fold increased risk of mortality in men and a 4.65-fold increased risk in women[10] (see Table 80.2).

PROGNOSTIC SIGNIFICANCE OF EXERCISE STRESS TESTING

Stress testing is widely used for the detection of CAD. Exercise electrocardiography is reported to have a sensitivity of 60%–75% and specificity of approximately 80%–85% using the criterion of ≥1 mm ST segment depression at 80 ms beyond the J point. However, the interpretation of these results is highly dependent on the prevalence of the disease in the population being evaluated.

Bayes's theorem: Bayes's theorem relates the probability of disease after the results of a test are known (posttest likelihood) to the pretest likelihood of disease as well as the characteristics of the test itself (sensitivity and specificity).[11] Thus a patient with a low likelihood of disease (5% pretest likelihood) who has an abnormal exercise test response has only a 17% likelihood of disease if a sensitivity of 60% and specificity of 85% are used in Bayes's analysis. Therefore, most positive tests in a low-risk population will be "false-positive" results. The power of an exercise test to detect underlying CAD is greatest when the pretest probability for CAD is moderate (i.e., 40%–60%).

Exercise capacity: In most epidemiologic studies that have employed exercise stress testing, functional capacity, expressed as mL/kg/min or METs, is a very strong predictor of subsequent cardiovascular mortality. In a study of 3400 consecutive adults referred for single-photon emission computed tomography (SPECT) testing, patients with fair or poor functional capacity had markedly higher all-cause mortality at 2 years of follow-up with 81% of deaths occurring in this group.[12] In another study involving 6213 men, exercise capacity was the strongest predictor of the risk of death after adjustment for age. For each one-MET increase in exercise capacity, there was a 12% improvement of survival.[7] Similarly, in a cohort of 5700 asymptomatic women who underwent peak or symptom-limited stress testing, there was a 17% decrease in mortality (after adjusting for age and Framingham Risk Score) for each one-MET increase in exercise capacity.[13] In general, subjects with an exercise capacity less than six METs had a poor prognosis in each of these studies.

Exercise-induced angina: Angina pectoris is a common symptom elicited during exercise stress testing among patients with significant CAD. The Duke group reported that either non-limiting or exercise-limiting angina was an important prognostic variable in their database of over 2000 patients (both inpatient and outpatient).[14] However, subsequent analyses of other databases have not shown an independent predictive value of exercise-induced angina. In the Coronary Artery Surgery Study, exercise-induced angina was not predictive of survival when catheterization variables, exercise time, and ST depression were included in the survival model.[15] Similarly, in a study involving elderly patients, exercise-induced angina was not predictive of survival (workload was the only variable predictive of death).[16]

Exercise-induced arrhythmias: A number of investigators have reported the prognostic significance of premature ventricular contractions (PVCs) during exercise. Jouven et al. postulated that PVCs would have no effect on long-term prognosis if PVCs during exercise were a "normal finding." They recorded ECGs during each stage of exercise and during recovery. Patients were defined as having frequent ectopy if they had greater than 10% PVCs at any recording. They followed 6101 men for a mean duration of 23 years. A small but significant number (2.3%) had frequent PVCs during exercise. This group had an increased risk of death during

follow-up (41.3% vs. 26.3% in the group with no PVCs).[17] Frolkis et al. used the criteria of greater than seven PVCs per minute to categorize frequent ectopy. Though exercise-induced ectopy was associated with increased all-cause mortality in the 29,000 patients in their cohort, increased PVCs during recovery were a better predictor of death (adjusted hazard ratio of 1.5, CI 1.1–1.9).[18]

Chronotropic incompetence: The HR increase during exercise is a result of withdrawal of parasympathetic inhibition (particularly in early exercise) and an increase in sympathetic tone. The inability to increase the HR adequately has been termed chronotropic incompetence. In one study, men whose resting HR did not increase as expected during daily activity or who had low peak HR response to exercise had a higher rate of sudden death than expected.[19] In another study involving heart failure patients, reduced peak HR was related to decreased sensitivity of the sinoatrial node to sympathetic stimulation.[20]

A number of approaches have been used to characterize the increase in HR with exercise. The classic method is using the regression formula of 220 minus age in years as the predicted maximum HR. The actual measured HR from the exercise test is reported as the percentage of the age-predicted maximum. This simple method unfortunately can be affected by testing modality, test termination criteria, medications, fitness level, and resting HR.

Chronotropic reserve has been used to overcome the problems with the percentage of age-related maximum. Chronotropic reserve is defined as the percentage of HR used (peak HR achieved on the exercise test – rest HR)/(220-age – rest HR) × 100. Using this definition, chronotropic incompetence has been defined as a value less than 80%. In one study involving 1877 men and 1076 women not taking β-blockers who were referred for treadmill thallium testing, a low chronotropic index was associated with an increased risk of death over a 2-year period after adjusting for age, sex, and thallium perfusion defects (adjusted risk 2.19; 95% CI 1.43–3.44).[21] In another study involving 2956 patients, a low percent HR reserve was a better predictor of cardiac death and all-cause mortality than failure to achieve 85% of the age-predicted maximal HR.[22]

Heart rate recovery: During the first few minutes after exercise, there is a significant decrease in HR, which is related to parasympathetic reactivation. Due to the known relationship of HR variability and cardiovascular mortality thought to be related to autonomic function (particularly parasympathetic function), it was hypothesized that a decrease in HR recovery would be related to cardiovascular mortality in a patient population referred for stress testing. In one study involving 2428 patients referred for a treadmill SPECT test, an abnormal value for 1 min HR recovery (less than 12 bpm drop) was strongly predictive of death, even after adjusting for confounding variables like age, sex, medications, thallium myocardial perfusion defects, known cardiac risk factors, resting HR, change in HR during exercise, and workload achieved (adjusted risk 2.0; CI 1.5 – 2.7).[23] In another study involving 5713 asymptomatic working men (ages 42–53) who underwent cycle ergometer exercise testing, there was an increased risk of sudden cardiac death in men who had a resting HR >75 bpm (relative risk 3.92), those who failed to increase their HR to 89 bpm (relative risk 6.18), and those who failed to decrease their HR by 25 bpm at 1 min postexercise (relative risk 2.20). This study emphasizes the differences of HR response to exercise and recovery during the cooldown period depending on the protocol used.[24]

Duke treadmill score: A number of studies have tried to incorporate many of the variables described earlier into a single risk score. The most widely accepted prognostic score is the Duke Treadmill Score, which incorporates exercise time (minutes), using the conventional Bruce Protocol, the magnitude of ST segment depression (mm), and anginal symptoms (0, none; 1, mild pain during test; 2, moderate-to-severe pain, which is the reason for termination of the test).

The Duke Treadmill Score = exercise time – (5 × ST displacement) – (4 × angina index). Investigators divided the patient cohort into three classes low risk (>5), moderate risk (–10 to +4), and high risk (–11 or lower). The score was derived on a population of 2842 consecutive inpatients who underwent an exercise stress test and cardiac catheterization and subsequently validated in outpatients. The high-risk group had a markedly worse 4-year survival (79% vs. 99% in low-risk group).[14] This score seems to be applicable to multiple populations; however, a subsequent study questioned its validity in the elderly (>75 years).[25]

CARDIOPULMONARY EXERCISE STRESS TESTING

Cardiopulmonary exercise stress testing (CPET) is the most objective and accurate way to assess exercise capacity while also distinguishing between cardiac and noncardiac causes of exercise intolerance or suboptimal effort. During CPET, progressive staged exercise is performed while analyzing breath-by-breath gas exchange using a mouthpiece or face mask connected to a non-rebreather valve to prevent mixing of inspired and expired air. Respiratory rate, tidal volume, and concentrations for expired oxygen and carbon dioxide are measured to determine oxygen uptake (VO_2), carbon dioxide production (VCO_2), and minute ventilation (VE) at rest and during exercise to assess exercise capacity. The oxygen and carbon dioxide gas analyzers are usually incorporated into a metabolic cart. The exercise protocols can be either with a cycle ergometer (more typical in Europe) or with a treadmill (more typical in the United States).[26–28] Exercise is ideally symptom limited but should be terminated if the patient develops significant ischemic ECG changes (>2 mm ST depression), hemodynamically unstable arrhythmias, second- or third-degree AV block, decline in systolic blood pressure >20 mmHg from the highest value, systolic blood pressure >250 mmHg or diastolic

blood pressure >120 mmHg, severe oxygen desaturation ≤80%, respiratory failure, or sudden pallor.[27]

Indications: CPET has been used to determine the cause of exertional shortness of breath, functional capacity, and candidacy for heart transplantation. The American College of Cardiology (ACC)/American Heart Association (AHA) guidelines for CPET are outlined below in the following.[29]

ACC/AHA GUIDELINES FOR CPET[29]

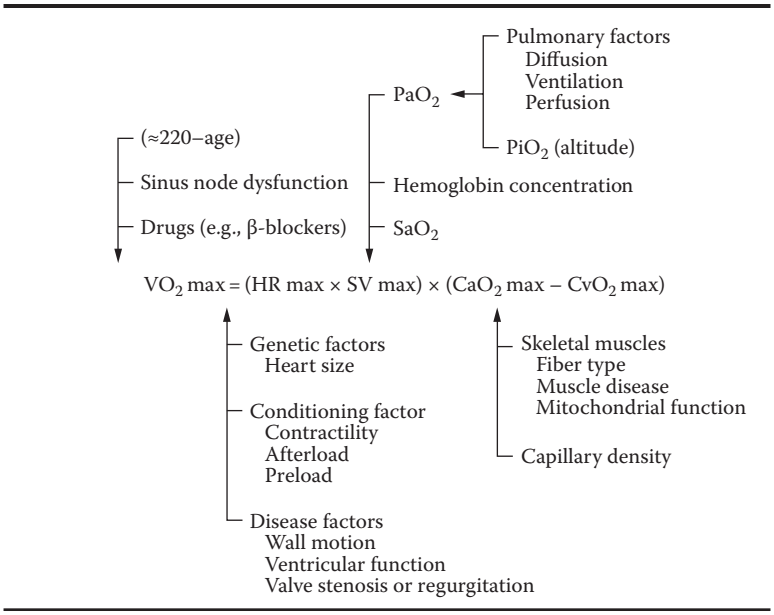
Class	Indication
Class I	1. Evaluation of exercise capacity and response to treatment in patients with heart failure who are being considered for heart transplantation 2. Assistance in the differentiation of cardiac versus pulmonary limitations as a cause of exercise-induced dyspnea or impaired exercise capacity when the cause is uncertain
Class IIa	Evaluation of exercise capacity when indicated for medical reasons in patients for whom the estimates of exercise capacity from exercise test time or work rate are unreliable
Class IIb	1. Evaluation of the patient's response to specific therapeutic interventions in which improvement of exercise tolerance is an important goal or endpoint 2. Determination of the intensity for exercise training as part of comprehensive cardiac rehabilitation
Class III	Routine use to evaluate exercise capacity

Measurement of exercise capacity: Exercise capacity (also called functional capacity) is defined as the maximum ability of the cardiovascular system to deliver oxygen to skeletal muscle and for the skeletal muscle during maximum exercise to extract oxygen from the blood.[28] During exercise stress testing, we can approximate work performed (functional capacity) by estimating the peak MET with regression formulas based on the workload attained, as well as the duration of exercise:

$$1\ \text{MET} = 3.5\ \text{mL/kg/min of oxygen consumed}^{26}$$

However, the usage of MET to approximate work may be inaccurate when exercise duration is impacted by inappropriate protocol selection, nonstandardized testing procedure (i.e., handrail holding), abnormal gait/balance, suboptimal effort, cardiovascular disease, as well as noncardiac factors such as lung disease. Therefore, methods that directly measure oxygen consumption are preferred. Exercise effort during CPET can also be established with the measures of carbon dioxide production (VCO_2) and VE, which can be used to determine relative effort (respiratory exchange quotient) and the anaerobic threshold.[27] These important cardiopulmonary measurements in addition to oxygen consumption are further defined in the following text:

Maximum oxygen consumption (*max* VO_2): In normal healthy people, oxygen consumption increases with exercise intensity/workload and then reaches a plateau despite increasing workload. This plateau in oxygen consumption is referred to as the maximum oxygen consumption. It represents the aerobic capacity and is further related to hemodynamics by the Fick equation:



$$VO_2\ \text{max} = (\text{SV max} \times \text{HR max}) \times (CaO_2\ \text{max} - CvO_2\ \text{max})$$

where
- max is maximum
- SV is stroke volume
- HR is heart rate
- SV × HR is cardiac output
- CaO_2 is arterial oxygen content
- CvO_2 is mixed venous oxygen content

Therefore, maximum oxygen consumption is achieved when further increments in work produce no additional increases in stroke volume, HR, or tissue O_2 extraction[27,28] (see Figure 80.1).

Peak oxygen consumption (*peak* VO_2): Peak oxygen consumption is the highest oxygen consumption achieved by an individual during progressive exercise to volitional fatigue or adverse signs/symptoms. It can be equal to the maximum oxygen consumption; however, this is rarely the case.[28] The main determinants of peak VO_2 are genetic factors, muscle mass, gender, age, habitual physical activity, and body size. Exercise training can further increase a patient's peak VO_2, and poor motivation during exercise testing can cause an "abnormally low" peak VO_2.[27]

Ventilatory threshold: It was previously referred to as anaerobic threshold. CO_2 levels drive ventilation. As exercise intensity increases, the metabolic demands reach a point where the demand exceeds the ability of the body to meet this predominately via aerobic metabolism and an increased reliance on anaerobic metabolism occurs. It is the point at which a nonlinear relationship between VE and VO_2 or VCO_2 and VO_2 is noted, secondary to the increased CO_2 production that buffers lactic acid produced by anaerobic metabolism. It is an indicator of submaximal exercise tolerance and, in general, occurs at 45%–65% of VO_2 max. The VT can be identified invasively or noninvasively. Invasively, the anaerobic threshold can be identified using serial blood samples with the rise in lactic acid or via the decline in bicarbonate levels. Noninvasively, which is the more common method, it is usually identified by two methods: (1) ventilatory equivalents method and (2) V-slope method using regression analysis (see Figure 80.2).[27,28] During progressive exercise, VE increases linearly with CO_2 production due to detection by chemoreceptors in the carotid body. In the early phase of exercise, the CO_2 production is aerobic and plasma lactic acid levels are low. In the later phase of exercise, the oxygen demand by

VO_2, oxygen (O_2) uptake; SV, stroke volume; HR, heart rate; PiO_2, partial pressure inspired; O_2, FiO_2 × Patmospheric; CaO_2, arterial oxygen content; CvO_2, mixed venous oxygen content.

(From UpToDate: Functional exercise testing: Ventilatory gas analysis, available at http://www.Uptodate.Com/contents/functional-exercise-testing-ventilatory-gas-analysis?Source=search_result&search=functional+exercise+testing&selectedtitle=1%7e33, last accessed on January 27, 2012. With permission.)

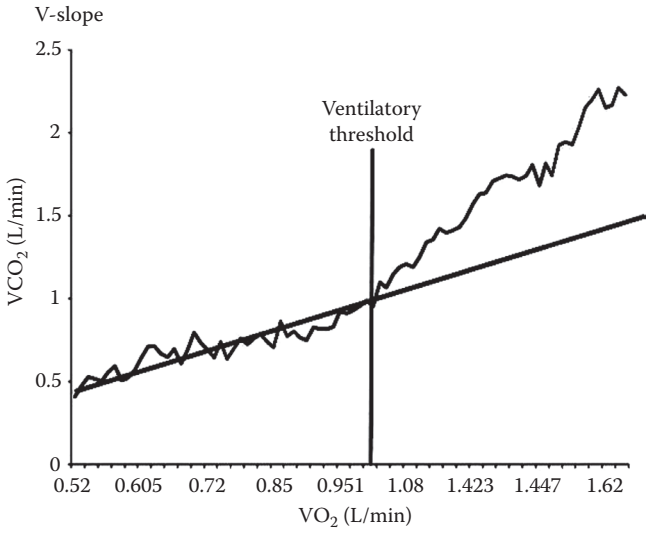


FIGURE 80.2 Determination of the ventilatory anaerobic threshold. (From Franco, V., *Curr. Heart. Fail. Rep.*, 8, 45, 2011. With permission.)

the muscle exceeds the metabolic supply and increasing reliance on anaerobic metabolism occurs, with the production of lactic acid. The lactic acid is buffered by sodium bicarbonate based on the carbonic anhydrase reaction:

$$HLa + NaHCO_3 \rightarrow NaLa + H_2CO_3 \rightarrow CO_2 + H_2O$$

The CO_2 produced during anaerobic metabolism is added to the aerobically produced CO_2 leading to disproportionate rise in VCO_2 and VE compared with VO_2.[26]

Respiratory exchange ratio: Respiratory exchange ratio (RER) is determined by the ratio of carbon dioxide production/oxygen uptake (VCO_2/VO_2). During rest and early exercise, VCO_2 production is slightly below oxygen consumption due to the reliance on aerobic metabolism and free fatty acids as the primary fuel source. As exercise intensity increases, there is a greater reliance on glucose as a fuel source and an increase in anaerobic metabolism for ATP production. Once the VT is reached, non-metabolic carbon dioxide is produced resulting in a disproportionate rise of VCO_2 relative to VO_2. RER values <1.0 reflect poor effort assuming that the patient is not limited by respiratory conditions, peripheral or myocardial ischemia, or neuromuscular disease. A RER between 1.0 and 1.1 indicates fair effort, 1.1–1.2 good effort, and >1.2 excellent effort, providing subsidiary evidence that a "true" max VO_2 has been attained.[26]

Differentiation of cardiac versus pulmonary symptoms: ACC/AHA guidelines recommend CPET to help evaluate shortness of breath and impaired exercise capacity when the cause remains unclear by history, physical examination, and laboratory tests.[29] CPET provides the unique opportunity to simultaneously assess physical effort, oxygen utilization, and exercise capacity. Impaired breathing reserve (BR) (<30%)

and desaturation during exercise suggest a pulmonary cause for symptoms.[30] BR is calculated by the following formula:

$$BR = 1 - \text{Peak minute ventilation following CPET/Maximum voluntary ventilation}$$

Maximum voluntary ventilation (MVV) is the maximum volume of air that can be inhaled and exhaled in 1 min.[31] MVV can be directly measured (ideal, especially if pulmonary limitation is suspected) or estimated using force expiratory volume in 1 s (FEV_1) × 40.[28] Arterial oxygen desaturation during peak exercise usually reflects underlying pulmonary disease or pulmonary hypertension but can also occur with congenital heart disease.[32]

Cardiac causes limiting exercise usually result in a low peak VO_2.[28] If the peak RER is adequate and VT and BR are normal, the cause is likely due to CAD or deconditioning. Heart failure often is identified by low peak VO_2, low absolute (high relative) VT, and normal BR (see Figure 80.3). However, these responses must be distinguished from poor effort, which will also be signified by a low RER. Low peak VO_2 and anaerobic threshold with low RER and low BR may also be seen with pulmonary disease, which may also represent a cause of exercise limitations.[28] Many patients are limited by both cardiac and pulmonary diseases, and a CPET algorithm can be used to help clarify the underlying causes (see Figure 80.3).

Prognostic significance in heart failure patients: ACC/AHA guidelines recommend CPET to determine optimal timing for heart transplantation in ambulatory patients with heart failure.[29] One of the most important predictors of mortality used to determine the need for transplantation is peak VO_2. According to ACC/AHA 2009 updated guidelines for management of heart failure, heart transplantation is indicated for the following:

ACC/AHA GUIDELINES FOR ORTHOTOPIC HEART TRANSPLANTATION (OHT)

Absolute OHT indication: Peak VO_2 < 10 mL/kg/min with achievement of anaerobic metabolism

Relative OHT indication: Peak VO_2 11–14 mL/kg/min (or <55% predicted) and major limitations in the performance of daily activities

Although these guidelines are not gender specific,[33] studies have shown that women often have a better prognosis than men for any given peak VO_2[34,35] (see Figure 80.4). Sex differences have also been noted in treadmill exercise time using a modified Naughton protocol, and the prognostic significance of treadmill exercise time may be similar to peak VO_2 based on one large single-center study.[36] Another important prognostic variable is the peak VE to carbon dioxide production slope (VE/VCO_2). In one study involving 470 heart failure patients, $VE/VCO_2 > 44.7$ was the strongest predictor of death and more important in predicting 18 month survival than a peak VO_2 < 14 mL/kg/min.[37] Others have reported poor outcomes with lower VE/VCO_2 slope including one study noting poor prognosis for heart failure patients with a VE/VCO_2 slope > 34.[38] Most of these studies have included heart failure patients with impaired systolic function; however, in a cohort of heart failure patients with both preserved and impaired systolic function, both peak VO_2 and VE/VCO_2 were powerful predictors of mortality.[39]

In summary, CPET is useful to determine the cause of exercise limitations and shortness of breath. Many variables measured during CPET have prognostic significance,

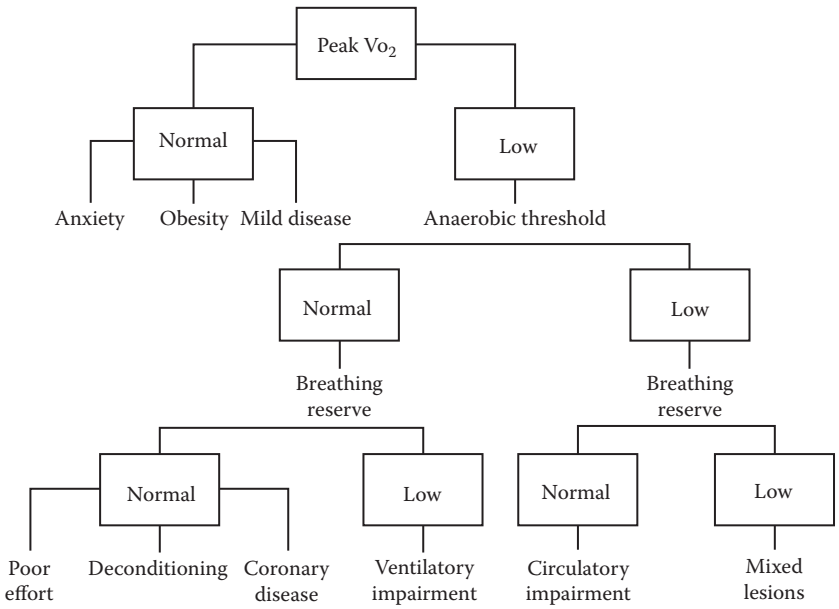

FIGURE 80.3 Evaluation of shortness of breath and fatigue with cardiopulmonary stress testing. (From Neuberg, G.W. et al., *Arch. Intern. Med*., 148, 2221, 1998. With permission.)

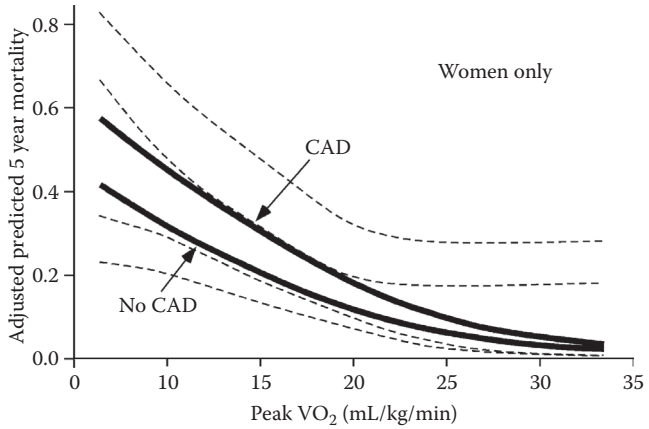

FIGURE 80.4 Adjusted predicted mortality in women with heart failure and impaired systolic function based on peak VO_2 and the presence or absence of CAD. (Adapted from Hsich, E. et al., *Am. J. Cardiol*., 100, 291, 2007. With permission.)

especially in heart failure patients. CPET is also useful in prescribing the intensity for exercise training as part of comprehensive cardiac rehabilitation.

PHARMACOLOGIC STRESS TESTING WITH IMAGING

The development of pharmacologic stress testing provides a noninvasive methodology to assess myocardial ischemia among patients who have contraindications or limitations in performing incremental exercise. The pharmacologic agents used are either vasodilators (dipyridamole, adenosine, regadenoson) or inotropes (dobutamine), and stress testing is usually performed with cardiac imaging (nuclear perfusion imaging or by echocardiography). Often the pharmacologic stress agent chosen is based on information regarding the patient, caffeine intake, concomitant medical therapy, and experience of the medical facility.

Vasodilators: Vasodilators used as pharmacologic agents for stress testing are drugs that cause coronary vasodilation mediated by A2A adenosine receptor stimulation. Relative differences in blood flow between stenotic versus normal coronary vessels during vasodilation help identify cardiac ischemia during stress testing. Vasodilator agents are often preferred for patients with left bundle branch block, hypertension, or aortic aneurysms. The drugs are contraindicated in patients with hypotension, high-degree AV block, sick sinus syndrome without a pacemaker present, dipyridamole usage, and significant reactive airway disease. Nonselective stimulation of adenosine receptors with these agents (more common with adenosine and dipyridamole) can lead to bronchospasm, which can be reversed with aminophylline. Caffeine and theophylline are adenosine receptor antagonists and should be discontinued 24 h prior to pharmacologic stress testing with these vasodilators. Nitrates are vasodilators that should also be discontinued prior to testing since they can alter the extent and the severity of perfusion defects.[40,41]

Dobutamine: Dobutamine is an inotrope used in pharmacologic stress testing for patients who are not candidates for vasodilators. The drug is given intravenously in increments to increase the HR to 85% of age- and gender-predicted maximum (starting with dobutamine 5 mcg/kg/min and increasing to a maximum of 40 mcg/kg/min). Atropine may be administered if goal HR is not achieved. Since dobutamine is a β-receptor agonist, it is less effective in patients who are using β-blockers. Side effects of dobutamine include arrhythmias, left ventricular cavity obliteration, and hypertension.[40,41]

Comparison of pharmacologic agents: A meta-analysis was performed involving 82 studies and over 10,000 patients to determine which pharmacologic agent best predicted significant CAD. The investigators compared adenosine, dipyridamole, and dobutamine stress testing, and all patients underwent cardiac catheterization. Adenosine and dipyridamole had similar sensitivities and specificities. Echocardiography increased the specificity of dipyridamole stress testing when compared with dipyridamole SPECT imaging but had a lower sensitivity. Dobutamine was the preferred agent in this meta-analysis with the highest sensitivity and specificity when combined with echocardiography (80% sensitivity, 84% specificity).[42] Although this analysis preceded the era of regadenoson, usage of this drug would be considered similar to the other vasodilators. Often, the decision to perform a given test is dependent on the experience of the center and additional factors regarding the patient.

CONCLUSION

This chapter reviewed the methodology and interpretation of stress testing beyond ST segment depression. The preferred stress test for most patients is an exercise stress test since this method can simultaneously assess functional capacity, concomitant ECG changes, symptoms, and hemodynamics during progressive activity. Cardiopulmonary stress testing is often utilized to help clarify the etiology of shortness of breath (cardiac vs. pulmonary) and, for heart failure patients, to aid in the optimal timing for cardiac transplantation. Pharmacologic stress testing should be reserved for patients who cannot achieve an adequate level of exercise stress or have ECG changes (e.g., left bundle branch block) that may limit the interpretation of results.

INTRODUCTION

Exercise professionals working with patients with coronary artery disease (CAD), both in (inpatient) and out of hospital (outpatient), must possess the knowledge to develop and modify exercise prescriptions for both cardiorespiratory (CR) endurance and musculoskeletal resistance training (RT). Exercise training prescriptions for CR-type exercise should include an individualized intensity, frequency, duration, mode, and rate of progression. This process involves more than target heart rate (HR) ranges and should emphasize the importance of total energy expenditure for the secondary prevention of CAD. This chapter will also address the issue of generating an exercise prescription in the absence of maximal exercise "stress" test data, a common occurrence in this era of cost containment. Prescribing RT for CAD patients requires careful consideration and will be discussed in this chapter. Finally, this chapter will conclude with a section that describes the special considerations and/or modifications of the exercise prescription for some of the more common conditions/comorbidities seen in CAD patients, including those with a history of (1) myocardial ischemia/infarction, (2) postcoronary revascularization, (3) implanted pacemakers and/or defibrillation, (4) heart failure, (5) diabetes, or (6) hypertension.

The optimal exercise prescription should be determined from an objective evaluation of an individual's responses to graded exercise and should take into account an individual's health status, chronic disease risk factors, behavioral readiness for change, personal goals, and exercise preferences. The purpose of an individualized exercise prescription is to (1) enhance some facet of physical fitness (e.g., CR endurance, muscular strength/endurance), (2) promote health by modification of chronic disease risk factors (e.g., decrease excess body fat, normalize blood lipids or blood pressure), and (3) ensure safety during exercise participation (i.e., decrease incidence of cardiovascular complications and/or musculoskeletal injuries) [1].

The American College of Sports Medicine (ACSM) [2], American Association of Cardiovascular and Pulmonary Rehabilitation (AACVPR) [3], and American Heart Association [4] have each published exercise prescription guidelines for CAD patients participating in rehabilitative

exercise programs. A review of these documents reveals that the basic principles related to exercise prescription are generally similar for primary and secondary prevention of CAD, yet some important differences exist. This chapter will describe and illustrate guidelines for prescribing CR and RT exercise programs and begins by looking at the current model of cardiac rehabilitation and discuss how the principles of exercise prescription are applied in this setting.

Beginning in the 1970s, cardiac rehabilitation programs were often divided into four sequential phases (I, II, III, and IV) based on the need for medical supervision and patient monitoring during exercise sessions [3]. Although most cardiac rehabilitation programs still contain the essential elements of these traditional phases, the time periods for the phases have become much less distinct in recent years, and for the most part, the terms *inpatient* and *outpatient rehabilitation* have replaced the Phase I–IV terminology. The combination of cost containment measures by medical insurance providers, along with the realization that many low-risk cardiac patients don't necessarily need the more costly elements of the rehabilitation program (i.e., direct medical supervision and continuous ECG monitoring), has led to a new paradigm for delivery of cardiac rehabilitation services [3]. The contemporary approach to the management of cardiac patients focuses more attention and resources on modification of CAD risk factors in an attempt to lower the patient's risk for disease progression and recurrent cardiac events [1]. Thus, the elements of the exercise prescription are designed to promote safety and to slow/reverse the progression of CAD. This chapter focuses on the exercise prescription guidelines for inpatient and outpatient cardiac rehabilitation programs. Other elements of a comprehensive rehabilitation program (patient education and counseling, risk factor intervention strategies, etc.) are discussed in other chapters.

INPATIENT CARDIAC REHABILITATION

The recommended physical activities and length of hospital stay for cardiac patients will vary depending on the nature of the clinical event precipitating hospitalization (i.e., MI, revascularization, etc.). Historically, Phase I typically lasted from 7 to 14 days and involved a gradual but systematic increase in activities of daily living (ADLs) and low-intensity exercise [3]. While ADLs and low-intensity exercise are still an important part of inpatient rehabilitation, the length of hospitalizations has shortened considerably in recent years, and in many cases, patients are in the hospital only for several days. Thus the amount of time available for inpatient rehabilitation is considerably shorter, and the goals for the program focus more on educating the patient about the disease process, offsetting the deleterious effects of prolonged best rest, assessing the patient's ability to complete ADLs safely prior to discharge, and perhaps most importantly, referral to the outpatient cardiac rehabilitation program. Extensive guidelines for *inpatient* physical activity can be found in the ACSM and AACVPR Guidelines [2,3] and should be reviewed thoroughly. Table 81.1 provides recommendations for the type, intensity, frequency, duration, and progression of physical activities during the inpatient phase [2]. Although structured, multistep inpatient exercise routines are available [2,3] and have been used within rehabilitation programs for years, many patients are now being discharged well before completing such routines. Before hospital discharge, patients should receive instructions outlining physical activities that are appropriate while they are at home, as well as any restrictions in physical activity based on their clinical status. They should also leave the hospital with an outline of physical activities including progressions for completion at home. Finally, all patients should be apprised of outpatient rehabilitation (Phase II) opportunities and encouraged to participate if at all possible. In order to enhance referrals, many hospitals now utilize an "automatic" referral to outpatient cardiac rehabilitation that is triggered when a patient enters the hospital with the appropriate diagnosis [5].

TABLE 81.1
Elements of the Exercise Prescription for Inpatient Cardiac Rehabilitation

Variable	Recommendation
Mode	Self-care activities, ROM, postural changes, walking (hallway or treadmill), stationary cycling, stair climbing
Intensity	Post-Ml: HR < 120 bpm or HR rest + 20 bpm (arbitrary upper limit)
	Postsurgery: HR rest + 30 bpm (arbitrary upper limit)
	RPE < 13 (Borg 6–20 scale)
	To tolerance if asymptomatic
Frequency	Early mobilization: three to four times per day (days 1–3)
	Later mobilization: two times per day (beginning on day 4)
Duration	Intermittent bouts lasting 3–5 min
	Rest periods at patient's discretion, last 1–2 min (shorter than exercise bout duration)
	Total duration of up to 20 min
Progression	Initially increase duration to 10–15 min, then increase intensity

HR, heart rate; ROM, range of motion; RPE, rating of perceived exertion.

OUTPATIENT CARDIAC REHABILITATION

Soon after hospital discharge, eligible cardiac patients should enter a structured outpatient cardiac rehabilitation exercise program designed to meet the following goals [3]:

- Optimal management of CAD risk factors to maximize secondary prevention
- Implementation of a safe and effective exercise program that is ultimately self-monitored
- Return to pre-event vocational and/or recreational activities with modifications when necessary

TABLE 81.2
Elements of the Aerobic Exercise Prescription

Variable	Recommendation
Mode	Aerobic: rhythmical and continuous in nature
Intensity	55/65 to 90% maximal HR
	40/50 to 85% maximal VO_2R or HR reserve
Frequency	Three to five sessions per week
Duration	20–60 min of continuous or intermittent aerobic activity
Progression	Individualized based on tolerance and adaptation
	Optimally. Maintenance programs should include energy expenditure threshold of >1500 kcal/week

HR, heart rate; VO_2R, oxygen uptake reserve.

An additional goal of the outpatient cardiac rehabilitation program is to provide appropriate medical surveillance for detection of a significant deterioration in the patient's clinical status, whereupon the program staff can alert the appropriate medical professional for assessment and treatment of the patient if necessary. Also patients entering cardiac rehabilitation programs should be "stratified" based on (1) their risk of "untoward events" during exercise training and (2) their risk of CAD progression. The AACVPR Guidelines [3] provide excellent approaches/models for this important aspect of the rehabilitative exercise program. General elements (mode, intensity, frequency, duration, progression) for prescribing CR exercise can be found in Table 81.2 and are discussed in the following text.

Cardiorespiratory Exercise Training

Mode of Cardiorespiratory Exercise

Cardiorespiratory (i.e., "cardio" or "aerobic")-type exercise includes a variety of physical activities that require the use of oxidative aerobic energy pathways and use large-muscle groups continuously and rhythmically. Traditionally, activities such as walking, jogging, cycling, swimming, cross-country skiing, and aerobic dancing are the primary modes for CR exercise training [2]. Moreover, a variety of indoor exercise machines such as stair climbers, recumbent leg cycles, and elliptical trainers, and the like are appropriate and quite popular in cardiac rehabilitation programs. Perhaps the most important consideration in choosing the mode of exercise for a given patient is their level of enjoyment and comfort. If a patient does not enjoy, or at least tolerate, a particular mode of exercise, it is unlikely that they will maintain sufficient compliance to this mode of exercise over time.

Intensity of Cardiorespiratory Exercise

Guidelines for defining an appropriate CR exercise training intensity for patients in secondary prevention programs vary based mainly on the clinical status of the patient (low, moderate, or high risk for exercise complications) [3]. While the general guidelines for prescribing exercise intensity apply to secondary prevention patients, the risks associated with exercise training are greater for those with a history of CAD [6]. For patients with normal responses to graded exercise, the appropriate CR exercise intensity can be based on a percentage of maximal heart rate reserve (MHRR) or percentage of maximal oxygen consumption reserve (VO_2R) [7,8]. For cardiac patients who have normal ECG and hemodynamic responses to graded exercise, the ACSM Guidelines [2] indicate that a minimal-intensity threshold lies between 40% and 50% of a patient's MHRR or VO_2R, with the upper end of the range set at approximately 85%. Once the relative intensity is defined (% VO_2R), a target VO_2 and/or HR range can be calculated (see Table 81.2).

However, for patients who have exercise-induced signs or symptoms (such as angina, hypotension, arrhythmia), the CR exercise training intensity needs to be set below the abnormal response in order to provide a safety buffer during training [2]. Table 81.3 provides a list of abnormal signs and symptoms for which an upper limit for exercise intensity should be set, regardless of the calculated MHRR or VO_2R. In such cases, the CR training intensity should be set at least 10 bpm below the exercise HR associated with any of the signs or symptoms listed in Table 81.3 [2]. In addition, careful monitoring of the patient's symptoms, HR, BP, and ECG is recommended to ensure that the intensity of exercise remains at a safe level.

Most of the medications used to control blood pressure and cardiac arrhythmias do not affect exercise tolerance and have minimal impact on HR and myocardial contractility. However, beta-blockers and some calcium channel blocker (i.e., Diltiazem and Verapamil) will likely decrease HR at rest and during exercise [8]. Consequently, HR ranges calculated to guide CR exercise intensity should be based on exercise test data obtained while patients are taking their standard regimen of medications. If the patient did not take his or her medication before the exercise test (commonly done for "diagnostic" stress tests) or when medication dosage changes, one option is to conduct an exercise "evaluation" (on a bike or treadmill) where patient exercises for several

TABLE 81.3
Signs and Symptoms for Which an Upper Limit for Exercise Intensity Should Be Set

Onset of angina or other symptoms of CV insufficiency
Plateau or decrease in SBP, SBP > 240 mmHg, or DBP > 110 mmHg
≥1 mm ST segment depression, horizontal or downsloping
Radionuclide evidence of LV dysfunction or onset of moderate to severe wall motion abnormalities during exertion
Increased frequency of ventricular arrhythmias
Other significant ECG disturbances (e.g., second- or third-degree AV block, atrial fibrillation supraventricular tachycardia, complex ventricular ectopy)
Other signs or symptoms or intolerance to exercise

minutes at approximately 40% and 80% of VO_{2peak}. HRs obtained at these intensity levels should provide the appropriate exercise intensity [1].

In addition to objective measures of HR and/or VO_2R, ratings of perceived exertion (RPEs) may be used as an adjunct to guide CR exercise intensity in cardiac patients [1–3]. The 15-point [6–20] RPE scale [9,10] is typically used for this purpose with RPE values of 11–13 being recommended for the early outpatient exercise sessions, whereas a range of 12–15 is recommended for the higher training intensities during subsequent exercise training sessions [2,3]. Use of such generalized RPE ranges for monitoring training intensity, such as those reflected earlier, is based on the assumption that a number on the RPE scale equates to a relative physiological intensity (% MHRR or VO_2R) [2]. However, within a given patient, specific RPE values do not always match with a given relative physiological intensity during exercise especially when attempting to transfer RPEs from exercise testing to the exercise training environment [11,12]. To use RPEs effectively for guiding the exercise intensity in cardiac rehabilitation programs, the following are recommended [11]:

- The RPE scale should be described providing explanations of the resting and maximal numbers (6–20, respectively) and reviewing the descriptors assigned to each number on the scale.
- Monitoring takes place in a discreet manner to avoid influence by ratings of other patients exercising in the same area.
- Once the patient reaches a steady-state level during exercise, have the individual rate his or her perceived exertion using the RPE scale. If over the course of several exercise sessions the patient reports a consistent RPE at the same physiological intensity, that RPE may be used, in conjunction with physiological markers, for monitoring the patient's training intensity.
- If the patient's RPEs vary considerably from day to day (at the same physiological intensity) after adequate acclimation, perceived exertion may not be an appropriate means for monitoring physiological intensity for this patient.

Prescribing Exercise Intensity without Exercise Test Data

The use of MHR and/or VO_2 to prescribe the intensity for CR exercise training intensity requires access to data obtained from an exercise "stress" test, preferably one with a "sign/symptom-limited" endpoint. However, a survey [12] of outpatient cardiac rehabilitation programs indicated that 60% do not require exercise stress test at entry to the program. Consequently, in lieu of "objective" exercise test data, the exercise prescription must be generated through other less objective methods. It has been well established that calculating exercise HR ranges based on age-predicting maximal HR formulae (i.e., 220-age) is inappropriate for CAD patients, particularly those on beta-blockers [13,14]. However, there are several "evidence-based" options [2,3] for prescribing exercise without exercise test data, including use of RPEs (as described earlier), resting HR plus an arbitrary value (generally 20 bpm for post-MI or post-CABG patients on beta-blockers or 30 bpm for non-beta-blocked patients), or data form the "talk test" [15,16] to regulate the CR exercise intensity in cardiac rehabilitation programs. Another approach is to perform a submaximal exercise assessment or conduct a 6 min walk test during one of the first outpatient exercise sessions and use HR and/MET levels derived from these tests as target intensities for early training sessions [1].

Joo and colleagues [17] evaluated the common practice of regulating CR exercise intensity using RPE as well as resting HR + 20 bpm in a group of patients entering an outpatient cardiac rehabilitation program. After two introductory/familiarity exercise sessions, patients wore a portable Cosmed ambulatory oxygen uptake analyzer while performing 10 min of continuous track walking at two different (and randomly ordered) exercise intensity levels: RPE levels of 11–13 and rest HR + 20 bpm (or for non-beta-blocked patients). The results demonstrated that prescribing CR exercise, in early outpatient cardiac rehabilitation participants, based on RPE and resting HR + 20/30 resulted in an average VO_2R of 42% and 71%, respectively (Figure 81.1). While the average exercise intensity from both techniques was at appropriate levels (Figure 81.1), using HR + 20/30 patients often exercised at a significantly lower (≤40% of VO_2R) intensity level whereas using RPE 11–12 patients commonly exercised at significantly higher (≥90% VO_2R) intensity levels. These findings suggest that prescribing CR endurance exercise using RPE and rest HR + 20/30 results in a significant amount of intersubject variability (Figure 81.1) and that caution should be used when guiding CR exercise intensity with either of these approaches. Brawner et al. [14] demonstrated that the exercise intensity calculated from resting HR + 20 corresponded with 45% and 31% of HR reserve of beta-blocked and non-beta-blocked CAD patients, respectively.

Pharmacologic stress tests are commonly conducted in patients whose inability to exercise adequately (due to

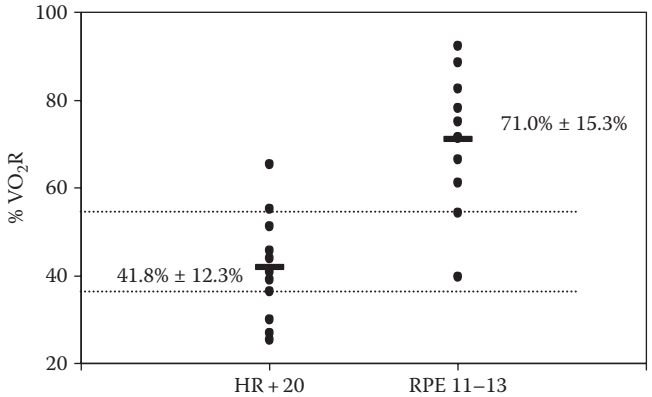

FIGURE 81.1 Average (41.8 ± 12.3% and 71.0 ± 15.3%, respectively) and individual % VO_2 of cardiac rehabilitation participants when exercising at HR + 20 or RPE 11–13.

neurological, vascular, or orthopedic) may compromise the predictive accuracy of the test [2]. Pharmacologic stress tests involve the infusion of medications that either increase myocardial demand (dobutamine) or reduce myocardial supply (dipyridamole or adenosine) by vasodilating non-occluded coronary arteries (e.g., coronary "steal") to induce myocardial ischemia with concomitant echocardiography or myocardial perfusion imaging, respectively. Although pharmacologic tests increase the sensitivity and specificity for myocardial ischemia, they do not provide an assessment of functional capacity, hemodynamic responses to progressive exercise, or an indication of the ischemic "threshold." Consequently, data from these tests are of little value in the determination of appropriate CR exercise training intensity. If the test was negative for ischemic abnormalities and symptoms, the highest HR obtained during the stress test can be used to guide the initial exercise training intensity. However, data obtained from a positive test will be more difficult to use since it will not be possible to determine the level of exertion where ischemic abnormalities begin to occur. Consequently, for patients with positive "non-exercise" stress tests, it will be necessary to use other complimentary methods (e.g., signs/symptoms and/or perceived exertion) to guide the exercise intensity in their initial exercise sessions.

One study [18] compared the rehabilitation outcomes of 229 post-MI and post-CABG that had undergone preliminary symptom-limited exercise testing with 271 matched patients who do not. All subjects underwent a 12-week exercise-based cardiac rehabilitation program (including ECG-telemetry monitoring for first 3–6 weeks). The group without a preliminary exercise test started at exercise levels of 2–3 Mets and progressed using HR and perceived exertion. Both groups showed similar physiologic improvement, and no complications were observed in either group. This study suggests that CAD patients, without preliminary exercise test data, can still participate safely and effectively in a cardiac rehabilitation program if proper monitoring of signs/symptoms and guidance on exercise training are provided.

Duration of Cardiorespiratory Exercise

The recommended CR exercise duration for CAD patients in outpatient cardiac rehabilitation programs is similar to that for apparently healthy participants in prevention programs [19]. Although 20–60 min of continuous CR exercise is the standard recommendation, recent guidelines [2] suggest that an accumulation of shorter exercise sessions throughout the day (i.e., three 10 min bouts) is comparable to a single, continuous session. Both of these approaches provide an increase in daily energy expenditure and can lead to improvements in functional capacity as well as other physiological benefits [20]. However, there is a need for more studies that directly compare the two training models (i.e., continuous vs. intermittent) in CAD patients before clear conclusions can be reached regarding comparable training adaptations. Finally, the exercise professional must recognize that CR exercise intensity and duration are generally inversely related; consequently, the standard recommendation is to have the patient start with a light to moderate exercise intensity and increase duration until the desired level (30–40+ min) is attained before increasing intensity [1,2].

Frequency of Cardiorespiratory Exercise

The recommendation for exercise training frequency for primary prevention programs [19]—3–5 days per week—is also appropriate for CAD patients in outpatient cardiac rehabilitation. Most outpatient programs offer two to three supervised exercise sessions per week and should also encourage their patients to be physically active—within prescribed limits—on most days of the week. The appropriate frequency for a given patient will depend on the individual's goals. Most CAD patients can achieve improvements in functional capacity (increased VO_2 max; decreased HR at given workload) with two to three sessions per week, provided that the intensity and duration of these sessions are adequate. However, patients in need of aggressive risk factor intervention (i.e., to decrease obesity or hypertension, normalize blood lipids, improve glucose tolerance, etc.) will likely benefit from a greater frequency of CR exercise [2]. Increasing the number of sessions per week (to four to five) will help to modify these risk factors over time; however, the exercise professional should be able to recognize that there is a direct relationship between the frequency of exercise and the risk of orthopedic injury [2]. Thus, patients must be instructed to slowly increase the frequency (and duration) of CR exercise and watch for signs of overuse injuries. Alternating modes of exercise may help reduce risk of overuse injuries [21].

Progression of Cardiorespiratory Exercise

As described, the general recommendation is to increase the CR exercise training duration and/or frequency before increasing the intensity. More specifically, patients should be able to achieve a duration of ≥20–30 min of continuous CR exercise before increasing the intensity [2]. Because many cardiac patients begin outpatient programs with a significantly lower functional capacity compared to their healthy counterparts, their rate of progression will likely be slower. In fact, as a consequence of extremely low functional capacity or limiting symptoms (i.e., claudication), some patients may need CR exercise to be intermittent during the early stages. The goal is to gradually work toward 15–20 min of continuous CR exercise at the target intensity. However, patients limited by symptoms will continue to need a more conservative rate of progression and may never reach the desired duration [2].

Prescribing Exercise Based on Total Energy Expenditure

Accumulating evidence suggests that specific health outcomes, including cardiovascular morbidity and mortality, are directly related to the total "volume" of physical activity, most accurately quantified in kcal/week [2]. Weekly energy expenditures exceeding 1000 kcal/week are more effective in modifying risk factors associated with obesity (hypertension, impaired glucose tolerance) and may also contribute to a slower progression of coronary disease. Hambrecht and colleagues [22] assessed the relationship between leisure-time

physical activity and coronary artery progression in 62 cardiac patients before and after a year of lifestyle intervention. Results showed an inverse dose–response relationship between the amount of physical activity and coronary disease progression. Patients who reported >2200 kcal of activity per week were found to be more likely to have regression of their CAD lesions. This amount of energy expenditure equated to approximately 5–6 h of physical activity per week. Patients who reported <1000 kcal/week were more likely to have progression of their lesions. The middle group of patients—those reporting an average of 1500 kcal/week—showed no progression (but no regression either) of CAD. It should be noted that the physical activity estimates in the study were derived from activity-recall instruments that rely on the patient's self-report of activity habits. Thus, there may be inaccuracies with these self-reported estimates (i.e., precise number of kilocalories expended per week). More studies on this issue are needed before the definitive dose of physical activity associated with the regression of coronary artery (if any) can be identified. Nevertheless, the results of Hambrecht et al. [22] study suggest that a threshold of approximately ≥1500 kcal/week can slow disease progression in cardiac patients. Consequently, cardiac rehabilitation professionals should encourage patients to achieve a volume of physical activity that will meet/exceed these caloric thresholds. Unfortunately, several studies [23–26] indicate that traditional cardiac rehabilitation exercise sessions usually result in <300 kcal/session. Thus, participating in three cardiac rehabilitation exercise sessions per week, without any additional lifestyle physical activity, will expend only 1000 kcal/week [27]. At this level of energy expenditure, CAD progression is likely to occur.

Prescribing Exercise for Weight Management in Cardiac Rehabilitation

Cardiac rehabilitation participants are certainly not immune to the "obesity epidemic," and >80% of patients entering cardiac rehabilitation are overweight and >40% are obese [28,29]. Accumulating evidence [30] indicates that the amount of exercise/physical activity required to sustain weight loss and prevent weight gain is considerably more than the general recommendation of 150 min/week. Overweight and obese individuals will benefit from progression to approximately 250–300 min/week (e.g., 50–60 min/week, 5–6 times/week) or ≥2000 kcal/week. For some individuals, progression to 60–90 min/day of exercise/physical activity may be necessary to promote and/or maintain weight loss. As discussed earlier, performing just three cardiac rehabilitation exercise sessions per week is unlikely to expend enough energy to reach these target levels. Thus, exercise/physical activity must be obtained outside of the center-based cardiac rehabilitation program if these target levels are to be achieved. Current research suggests that "bouts" of exercise/physical activity, as little as 10 min and distributed throughout the day, can be an effective strategy for weight loss as long as the total volume (or "dose") that is accumulated [31] achieve the levels described earlier. Thus, in addition to structured bouts of exercise, an increase in lifestyle physical activity should also be encouraged for overweight/obese patients with an overall goal of constructing a physical activity "pyramid" (Figure 81.2). The exercise professional must establish appropriate weight loss goals and convey to patients that a 5%–10% reduction of body weight during a 12-week cardiac rehabilitation program is considered successful and likely to produce significant health benefits [32].

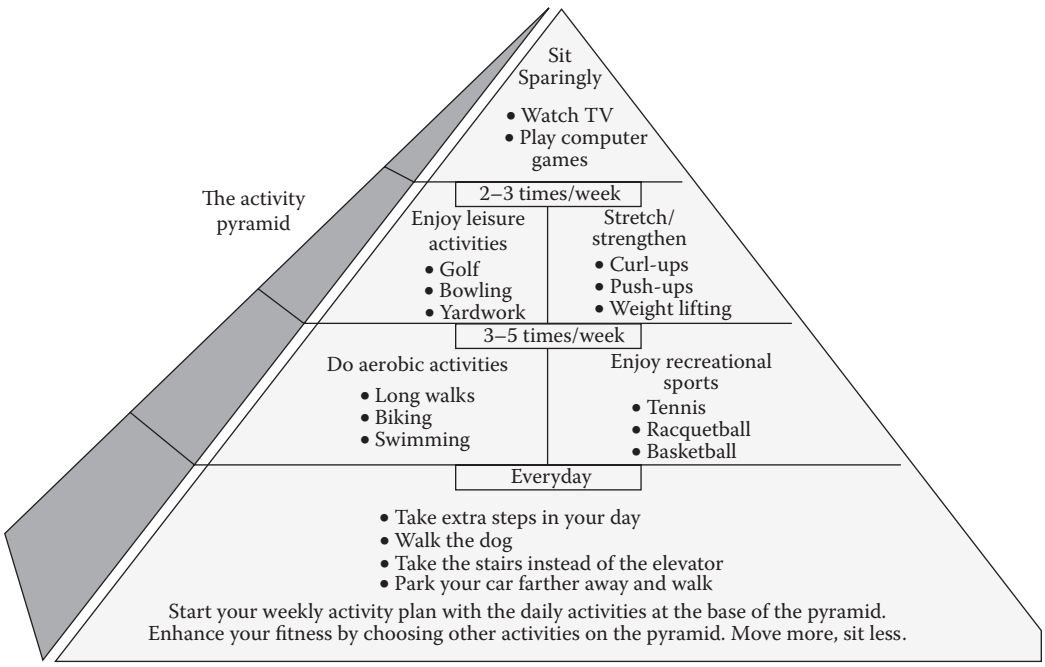

FIGURE 81.2 The Activity Pyramid, analogous to the USDA's Food Guide Pyramid, has been suggested as a model to facilitate public and patient education for the adoption of a progressively more active lifestyle. (Copyright 1997 Park Nicollet Health Source® Institute for Research and Education. Reprinted by permission.)

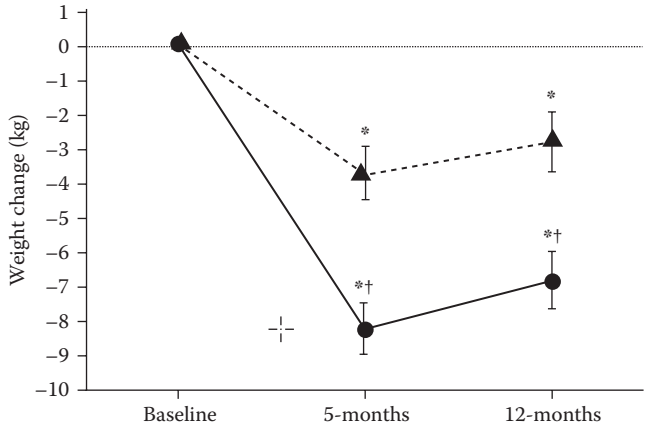

FIGURE 81.3 Demonstrates the change in bodyweight (kg) for cardiac rehabilitation (CR) patients in standard (triangles) and high-calorie-expenditure CR program after 5 and 12 months.

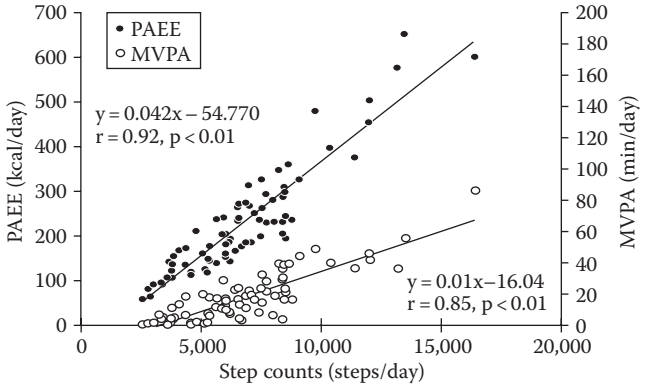

FIGURE 81.4 Demonstrates the relationship between levels of physical activity energy expenditure (PAEE in kcal/day) as well as minutes of moderate-vigorous physical activity (min/day) compared to steps/day.

Ades and colleagues [26] have recently demonstrated that a high-calorie-expenditure exercise (3,000–35,000 kcal/week of exercise-related energy expenditure) compared with standard cardiac rehabilitation exercise (>800 kcal/week) resulted in twice as much weight loss (Figure 81.3) and better cardiometabolic risk factor control, at 5 and 12 months, in overweight CAD patients. Furthermore, several studies have used physical activity monitors, such as pedometers and/or accelerometers, to help individuals achieve these higher volumes of physical activity [33,34] and successfully lose weight [35]. As shown in Figure 81.4, we recently demonstrated that accumulating 6500–8500 steps/day appears to be an appropriate target level of physical activity for cardiac rehabilitation participants as these levels are associated with approximately 1500–2200 kcal/week of energy expenditure [36]. As previously indicated, these levels of physical activity appear to be required for CAD stability/progression as well as weight loss in CAD patients.

Resistance Exercise Training

Since their inception in the 1970s, cardiac rehabilitation programs focused mainly on CR exercise training. Despite initial concerns regarding potential negative consequences on myocardial function, resistance exercise training (RT) has been shown to provide many important benefits for CAD patients in secondary prevention programs [3]. While the basic principles for prescribing RT apply to most stable CAD patients, the potential for complications should dictate who participates (i.e., patient eligibility) and when (i.e., time course following a cardiac event) as well as specific prescriptive guidelines [37].

Most CAD patients can participate in resistance exercise programs safely, as long as they receive instruction on appropriate lifting techniques and use loads appropriate for their capacity. In addition, CAD patients should be instructed to avoid the excessive isometric contraction associated with gripping too tightly and straining. A well-rounded RT program should include one to two sets of 10–15 exercises that work the major muscle groups, with a training frequency of 2–3 times/week. The decision to initiate an RT program should be made by the program staff in consultation with the medical director and/or surgeon. However, RT is generally contraindicated for CAD patients with the following clinical conditions [2]:

- Unstable angina
- Uncontrolled arrhythmias
- Left ventricular outflow obstruction
- Symptomatic heart failure
- Severe valvular disease
- Uncontrolled hypertension (i.e., systolic BP ≥ 160; diastolic BP ≥ 105 mmHg)

In addition to these clinical conditions, it is also advisable for CAD patients to have normal or only slightly reduced left ventricular function (EF > 35%) and a functional capacity >5 METs before starting a RT regimen.

As described earlier, range of motion (ROM) exercises are often initiated during the inpatient stage of rehabilitation. During the early outpatient stage (i.e., first few weeks), many cardiac rehabilitation programs incorporate very low-intensity RT using elastic bands, hand weights, etc. Most low-risk patients tolerate these activities without any problems. While these activities can be initiated at entry to outpatient cardiac rehabilitation, the ACSM and AACVPR guidelines [2,3] recommend the following for starting a traditional RT program (defined as lifting ≥50% of his or her 1-repetition [RM] maximum):

- Post-MI and postsurgical patients should defer traditional RT for at least 5 weeks after their event/surgery.
- Post-PCI (percutaneous coronary intervention = angioplasty, stent) patients should defer traditional RT for at least 2–3 weeks after the revascularization procedure.
- It is recommend that CAD patients complete a minimal period (i.e., 2 weeks for post-PCI and 4 weeks for post-MI/surgery) of supervised CR endurance training before starting a traditional RT.

SPECIAL CONSIDERATIONS FOR PRESCRIBING EXERCISE IN CORONARY ARTERY DISEASE PATIENTS

Myocardial Ischemia/Infarction

Although mode, duration, and frequency of the exercise prescription are similar to recommendations for other CAD patients, identifying the appropriate exercise intensity for ischemic or post-MI patients may be difficult when signs or symptoms arise. Myocardial ischemia is arrhythmogenic regardless of whether symptoms are present or not, thus the target HR for exercise should be set ≥10 bpm below the ischemic ECG or angina threshold [2]. The following are recommendations for prescribing exercise for the patient with myocardial ischemia [2,38]:

- Patients with angina should be instructed to recognize symptoms and avoid exercise interventions higher than level 2 (on 1–4 angina scale) during exercise, physical activity, or ADLs. Angina symptoms not relieved by cessation of exercise and/or the use of three sublingual nitroglycerin tablets (one every 5 min) require an emergent response.
- Exercise may be inappropriate for patients with angina and poor fitness levels or very low ischemic thresholds. However, non-weight-bearing exercise at very low levels may be appropriate to improve function.
- Exercise sessions should start with an extended warm-up and cooldown (10–20 min), which may decrease episodes of angina. The goal of the extended warm-up is to increase HRs ~10–15 bpm.
- Upper-body aerobic or RT may evoke early-onset angina, and caution should be used when RT programs are initiated. Patients also need to be advised that any physical activity in cold weather may also exacerbate symptoms of angina.

Surgical/Catheter-Based Revascularization

In 2007, more than 622,000 and 408,000 Americans underwent PCI and coronary artery bypass graft (CABG) surgery, respectively [39]. The majority of participants in cardiac rehabilitation programs have undergone surgical and/or percutaneous revascularization [40]. While the "standard" exercise prescription is generally appropriate for the postsurgical/PCI patient, the following are some specific modifications that should be made for these patients [2,41]:

- As there is often significant soft tissue and bone trauma to the thoracic cavity after CABG, ROM exercise should be undertaken in the early postsurgical period. ROM should be performed without feelings of pulling on the incision or mild pain.
- CABG patients that experience sternal movement or wound complications should not perform upper-body ergometry or RT until healing is complete. As described earlier, the CABG patient should perform 3–4 weeks of CR endurance exercise before initiating traditional RT.
- Asymptomatic PCI patients can begin RT after 2 weeks of CR endurance exercise training.
- Walking is a highly recommended and beneficial mode of exercise that can be initiated within a few days of the CABG or PCI procedure.

Implanted Pacemaker/Defibrillator

The number of patients receiving implanted pacemakers and/or defibrillator continues to increase as does the complexity of the devices. Exercise professionals working with these patients should consider a recent evidence-based review [42] and develop a solid understanding of these devices (including the four-letter code system used to describe the device functions) and their potential impact on exercise training programs. The following is a brief list of specific recommendation/considerations for these patients [2,43]:

- The device discharge thresholds must be known so that HR levels during exercise can be kept safely below this value (~10–20 bpm) to prevent inappropriate shocks.
- RPEs should be used in conjunction with HR to regulate exercise intensity.
- Upper-body/shoulder motion should be limited initially to prevent dislodging of the leads, and traditional RT should not be performed until 4–6 weeks postimplantation.

Diabetes (Type 1 and 2)

Diabetes leads to a number of pathological complications that result from chronically elevated blood glucose and/or insulin concentrations. Specifically, individuals with diabetes may develop conditions such as retinopathy, nephropathy, end-stage renal disease, and complications associated with neuropathy, which have the potential to impact the exercise prescription. While a comprehensive overview of exercise prescription for individuals with diabetes is provided by the ADA and ACSM [2,44,45], a summary of recommendations from these organizations for prescribing exercise for the patient with diabetes is listed in the following:

- In addition to traditional HR/BP monitoring, pre- and post-blood glucose monitoring is recommended during the initial weeks of the exercise program until glucose control has been established.
- The goal is to avoid postexercise hypoglycemia; thus, pre-exercise glucose levels should be ≥100 mg/dL. Low pre-exercise glucose levels should be increased with 20–30 g of carbohydrates before starting the exercise bout.
- Patient should not exercise if blood glucose levels are ≥300 mg/dL (or ≥250 with the presence of urinary ketones).

- The primary goal for individuals with type 1 diabetes is to develop a consistent "pattern" of exercise, carbohydrate intake, and insulin dosing.
- During exercise, autonomic neuropathy may cause chronotropic incompetence and/or a blunted blood pressure. Diabetics may also have difficulties with thermoregulation and dehydration and should avoid exercise in extreme hot/cold environments.
- Type 2 diabetics will benefit from participation in RT when contraindications such as retinopathy are not present. Emphasis must be placed on good technique to avoid straining and proper breathing to prevent the exaggerated BP responses associated with the Valsalva maneuver.
- Diabetics with peripheral neuropathy may need to avoid weight-bearing activity and regularly inspect their feet. Caution should be used for those with autonomic neuropathy while exercising in hot or cold environments.

Hypertension

The ACSM has published recommendations for exercise training of hypertensive individuals in a position stand [46] as well as within its Exercise Testing and Prescription Guidelines [2]. Hypertensive patients should be screened for contraindications to exercise and those with a resting BP $\geq$ 180/110 mmHg should be encouraged to see a physician for improved blood pressure control prior to beginning an exercise program. The following is a summary of the ACSM recommendations [2,46] regarding the prescription of exercise in hypertensive patients:

- Consistent monitoring of pre- and postexercise BP is important during the initial stages of the exercise program, and hypertensive patients should perform an active cooldown to avoid the risk of postexercise hypotension.
- CR exercise, performed at a lower intensity training (40%–60% of VO_2R), has been showed to effectively lower BP in hypertensive individuals [2]. The lower intensity training may also facilitate increased duration and total energy expenditure in patients that are overweight or obese.
- Do not exercise if resting blood pressure >200/110 mmHg. During exercise, blood pressure should remain $\leq$220/105 mmHg.
- Patients with hypertension should be advised to avoid isometric hand gripping during all RT exercises to avoid a disproportionate increase in SBP. Proper breathing techniques during RT should be encouraged to avoid the Valsalva maneuvers.

SUMMARY

This chapter presented the basics of exercise prescription principles pertaining to CR and RT programs in patients with CAD. While objective data from a GXT are preferred for developing the exercise prescription, often the exercise professional will have to rely on more "subjective" or arbitrary techniques. Consequently, prescribing exercise for CAD patients is often "more of an art than a science." This chapter also described the appropriate volume/dose of physical activity that is associated with CAD stability/regression and weight management in cardiac rehabilitation program participants. Finally, specific modifications to the standard exercise prescription were reviewed for some of the more common subgroups of CAD patients. Despite the potential for untoward events, there is considerable evidence to suggest that properly prescribed and monitored exercise therapy is not only safe but highly beneficial in patients with CAD.

MI	Myocardial infarction
NQF	National Quality Forum
PCI	Percutaneous coronary intervention

INTRODUCTION

For a number of reasons, cardiac rehabilitation/secondary prevention (CR/SP) services have experienced an important evolution over the past 30 years, similar in many ways to the evolution in health care services and policies that have generally occurred during that same time period. Once a service that was often an afterthought for most clinicians, a service focused on the rehabilitative episode of care during the hospitalization and subsequent 8–12 weeks following cardiac surgery or myocardial infarction, CR/SP has now transformed into a service that encompasses a multidisciplinary, evidence-based, and cost-effective approach for both short- and long-term care for a wide variety of patients with cardiovascular disorders. Current clinical practice guidelines for patients with coronary artery disease (CAD), percutaneous coronary intervention (PCI), or coronary artery bypass graft surgery (CABG) now rate the level of evidence for CR/SP at the highest rating possible (1A) [1–3].

Several important factors have prompted this transformation of CR/SP, including the following:

1. Changes in the science and practice of medicine
   a. Improved treatment options have been developed and implemented, leading to improved survival of patients who experience an acute cardiac event, such as MI, PCI, CABG, heart valve surgery, heart transplantation.
   b. Evolving treatment strategies that have increased the efficiency of inpatient management of patients with acute cardiac events, leading to a reduction in the hospitalization time and greater reliance on outpatient follow-up and management of patients with CVD.
   c. A widening array of evidence-based, lifestyle-based, and medication-based treatments have been developed that help to slow or reverse the effects of atherosclerotic CAD.
2. Changes in the science and practice of CR
   a. Growing evidence has emerged, over the past three decades, that multidisciplinary, short-term, and long-term approaches to CR/SP

and SP help improve both the quality and the quantity of life, for patients with a recent cardiac event.
   b. Technological innovations have opened new opportunities for CR/SP.
3. Changes in the types and complexity of patients in CR
   a. The number of patient groups eligible for CR/SP has expanded, now including six different groups: MI, PCI, CABG, heart valve surgery, heart transplantation, and chronic stable angina.
   b. The complexity of patients who participate in CR/SP and SP programs has increased (e.g., patients with concomitant heart failure, left-ventricular assist devices, those of older age, and those who are obese, have diabetes, or have musculoskeletal limitations).
4. Changes in expectations for health care quality and outcomes
   a. Health care policymakers have identified important gaps in the quality of health care that is delivered in the United States and have helped to increase societal awareness of potential and importance of reducing those gaps in care.
   b. Consumer advocacy groups, third-party payers, health care organizations, and governmental leaders have raised levels of expectations for the quality and outcomes of the care provided by health care professionals.
   c. Research has found that systematic approaches to health care delivery help to reduce inappropriate variability in health care services and increase the quality outcomes of those services.

These, and other factors, have paved the way for CR/SP services to transform and evolve, resulting in the contemporary model of CR/SP care that is practiced throughout the world today—a systematic approach to evidence-based, multidimensional, short-term, and long-term services that significantly improve both the quality and the outcomes of SP services for patients with CVD.

GUIDING PRINCIPLES FOR CONTEMPORARY CARDIAC REHABILITATION

Contemporary CR/SP programs fill an important role that is unique in health care systems—that of providing services that are aimed at optimizing a patient's short- and long-term health following a cardiac event. Research has shown that, for the most part, CR/SP programs have been very successful in filling that role, resulting in a reduction in the short- and long-term morbidity and mortality for patients who receive CR/SP services [4–15].

Several principles guide the way for effective CR services today. Those principles include the following.

Timing: Windows of Opportunity

CR services are effective at helping to improve patient outcomes primarily because they deliver important preventive services at key times in a patient's life (see Figure 82.1). These windows of opportunity result when a patient passes through a life-threatening and life-changing cardiac event, from which many emerge more committed to do whatever is necessary to improve health and well-being, and thereby reduce the risk of future cardiac events. These important times are sometimes referred to as "teachable moments" in which the patient becomes more open and more committed to adopt healthier lifestyle habits [16,17] as depicted in Figure 82.2.

These critical times of opportunity, in the case of the cardiac patient, usually occur at the time of the initial diagnosis of cardiovascular disease—usually a cardiac event—but can also occur soon after hospital discharge and at later times, such as during the transition from hospital to outpatient care, and from early outpatient care to long-term follow-up and treatment. During each of these times, patients find themselves in a particularly fragile and vulnerable point—both literally and figuratively. They have been diagnosed, for the first time in many cases, with a life-threatening medical condition, one that produces concerns about their current and future health, about their ability to participate in meaningful life activities,

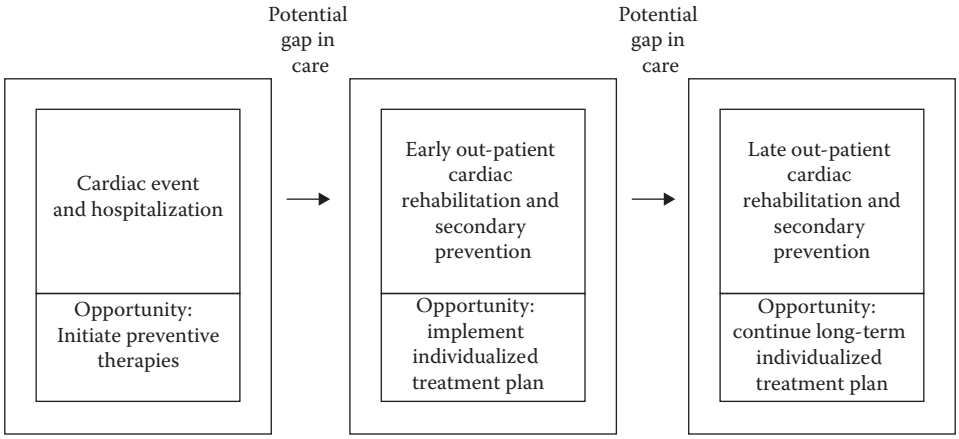

FIGURE 82.1 Windows of opportunity and potential gaps in care for cardiac rehabilitation and secondary prevention services.

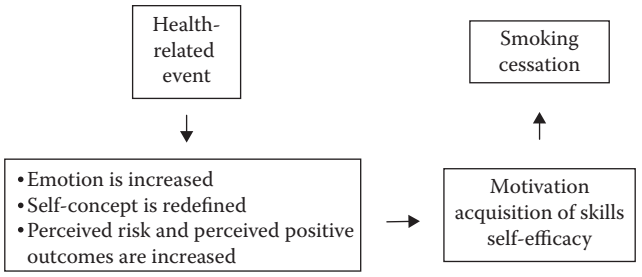

FIGURE 82.2 Conceptual model for the teachable moment for patient lifestyle change, using the example of smoking cessation. (From McBride, C.M. et al., *Health Educ. Res*., 18(2), 156, 2003.)

and about the financial and emotional challenges that are very likely to cross their path.

Just as there is an important therapeutic window of opportunity for the application of important lifesaving acute-care treatments (e.g., thrombolytic therapy and PCIs during acute coronary syndromes), research suggests that important therapeutic windows of opportunity exist for applying preventive therapies as well [18–22].

The Cardiovascular Hospitalization Atherosclerosis Management Program (CHAMP) study, for example, has shown that when hospitalized patients are treated using a standardized and systematic approach to SP, they are more likely to be started on appropriate preventive therapies during their initial hospitalization, are more likely to continue those therapies following hospital discharge, and are more likely to receive the health benefits associated with those therapies [19,20].

The CHAMP study was a landmark study that illustrated the impact of a systematic, evidence-based approach to help patients receive appropriate therapies during the window of opportunity that occurs in the hospital at the time of a myocardial infarction. Not only did the CHAMP investigators find that the CHAMP systematic processes of care helped to increase both the prescription of appropriate therapies during the patient's hospitalization and the adherence to those therapies after hospital discharge. Understandably, patients in the CHAMP system of care also were more likely to have favorable clinical outcomes, compared to patients who were managed prior to the initiation of the CHAMP system (see Tables 82.1 through 82.3).

Effective contemporary CR/SP programs take full advantage of the windows of opportunity for initiating and maintaining lifesaving preventive therapies—both in the hospital and in the outpatient setting.

TABLE 82.1
Percentage of Patients on Preventive Treatments at Hospital Discharge and 1 Year later, before, and after Initiating the CHAMP Inpatient System

	Pre-CHAMP (%)		Post-CHAMP (%)	
Therapy	At Hospital Discharge	1 Year Later	At Hospital Discharge	1 Year Later
Aspirin	78	68	92*	94*
β–blocker	12	18	61*	57*
Nitrates	62	42	34*	18*
Calcium blocker	68	58	12*	6*
ACE inhibitor	4	16	56*	48*
Statin	6	10	86*	91*

Coordination and Continuity: Bridging the Gaps in SP

A natural corollary to windows of opportunity is the concept of windows of *missed* opportunity, when patients don't receive the care they need at critical junctures and dangerous gaps occur in the delivery of SP care (see Figure 82.1). These gaps in care can occur even for health care providers with the best intentions or at the best health care centers and can occur for a number of reasons [23–26], including the following:

- *Provider barriers*: Health care providers are often unaware that CR/SP services provide numerous health benefits to participants, that CR/SP services are generally covered by most health care insurance companies, and that the process of enrolling a patient in a CR/SP program involves only a few relatively simple steps that start with an order from the patient's health care provider. In addition, providers are also often distracted at the "teachable moments" and at the "CR/SP referral moment" due to a large number of competing demands and a relatively short time with which the provider typically has to interact with the patient in the inpatient or outpatient setting.

TABLE 82.3
Clinical Events 1 Year Following Hospital Discharge for Patients in CHAMP Study, Comparing Results before and after Initiation of CHAMP System

	Pre-CHAMP 1992/1993 (n = 256)	Post-CHAMP 1994/1995 (n = 302)
Recurrent myocardial infarction	20 (7.8%)	10 (3.1%)*
Heart failure	12 (4.7%)	8 (2.6%)
Hospitalization	38 (14.8%)	23 (7.6%)*
Sudden death	3 (1.2%)	2 (0.6%)
Cardiac mortality	13 (5.1%)	6 (2.0%)*
Noncardiac mortality	2 (0.8%)	2 (0.6%)
Total mortality	18 (7.0%)	10 (3.3%)*

Source: Fonarow, G.C. et al., *Am. J. Cardiol*., 87(7), 819, 2001.
* $p < 0.05$.

- *Patient barriers*: Patient-oriented barriers contribute commonly to gaps in preventive care, including language and health literacy barriers, competing time and financial demands, and lack of understanding about the need for and benefits of CR/SP.
- *Health system barriers*: Health system barriers include lack of focus on SP policies and procedures, lack of appropriate inpatient staffing and resources to educate and refer patients to CR/SP, lack of CR/SP facilities in the vicinity of a patient's home, and lack of CR/SP resources for uninsured patients [24,26,27].

Standardized CR/SP processes of care, such as the CHAMP system described earlier, are the perfect remedy to the challenges listed earlier. A systematic approach that includes "automatic" and personalized processes of care helps reduce inappropriate variability in patient care and increases the appropriate use of preventive therapies for patients with CVD [21,22,28,29].

The American Heart Association's Get With The Guidelines (GWTG) is yet another example of an effective and systematic inpatient approach to SP care. The GWTG system includes materials, tools, and process steps that help hospital staff implement important preventive strategies for patients who are hospitalized with CVD. Studies involving GWTG hospitals have shown that appropriate SP therapies are provided to patients at much higher rates than that in non-GWTG hospitals [30,31]. For example, a study by Mazzini and colleagues evaluated patients who had been hospitalized with a cardiac event in a hospital that utilized the American Heart Association's GWTG system for standardized processes of care [31]. Among other things, the study found that patients in GWTG hospitals were more likely to be referred to outpatient CR/SP programs than patients who are in hospitals that did not use the GWTG system.

Unfortunately, however, there are occasional challenges to the full implementation and long-term impact of inpatient systems of care. The study by Mazzini and colleagues provides an excellent example of those challenges. When investigators evaluated the longer-term effectiveness of the GWTG system in the Boston area hospitals they studied, they found that the percentage of patients who actually enrolled in a CR program did not differ significantly between the two hospital groups (approximately 18% of all patients and approximately 33% of those who had been referred to CR). In other words, treatments initiated or recommended in the hospital may not necessarily translate into their application in the outpatient setting. Some patients—approximately 25% of those who did not enroll—reported that they did not remember being referred to a CR/SP program while they were in the hospital. Whether this is due to faulty patient memories or faulty referral processes in those hospitals is unclear, but it appears likely that inpatient systems aimed at improving the delivery of SP therapies must include steps that strengthen the link between inpatient recommendations and outpatient adherence to those recommendations. Simple "check box" processes of care may not be sufficient to bridge potential gaps between inpatient and outpatient preventive care.

Medication adherence is another important concern. An illustrative study by Shah and colleagues found that in insured, post-MI patients from Olmsted County, Minnesota, approximately 25% of patients did not even fill their prescription following hospitalization for their statin, ACE inhibitor, or beta-blocker medications [32]. Furthermore, only 45% of patients were taking these medications 3 years following their MI. Patients who were smokers were particularly at risk for non-adherence to their medications, while those who attended CR/SP were significantly more likely to remain adherent to their prescribed medications during the follow-up period.

This study is important because it highlights two important principles that argue for the important role of the multidisciplinary and long-term approach to contemporary CR/SP: (1) Patients, on their own, often fall into "prevention gaps," especially when attempting to start or continue with complex and expensive SP regimens, and (2) CR/SP services help improve patient outcomes, at least in part because they appear to help improve patient adherence to prevention-oriented therapies.

Delivering Evidence-Based SP Care

One of the major accomplishments in cardiovascular medicine over recent times has been the dramatic drop in cardiovascular mortality that has been observed in the United States over the past 50 years. A large percentage of this drop has been due to effective treatments aimed at controlling cardiovascular risk factors [33]. Unfortunately, however, the true impact of the wide array of efficacious preventive therapies has been dampened by the fact that these therapies are underutilized [34–38].

Contemporary CR/SP services are aimed at delivering evidence-based preventive therapies—lifestyle and medication therapies—that help to reduce the morbidity and mortality for patients with documented CVD. The core components and competencies of CR/SP, in fact, include a specific treatment plan that initiates, evaluates, and adjusts evidence-based treatments for participating patients [39,40]. It has been estimated, in fact, that at least half of the benefits that result from CR/SP are the likely result of improved cardiovascular risk factor control [14].

Evidence-based therapies that are delivered through CR/SP services include the following:

- Lifestyle modification counseling to initiate and maintain healthy lifestyle habits
- Initiate appropriate SP medications and help with adherence to those medications, in coordination with the patient's primary health care providers
- Identification, assessment, and management of comorbid conditions, such as diabetes, hypertension, depression, and musculoskeletal disorders
- Assessment of patient responses to lifestyle and medication therapies, assisting with adjustments to the patient's individualized treatment plan as needed

Accountability

Published research has clearly documented significant gaps in the quality of health care delivery—that the health care services we actually deliver are lacking for a large percentage of the population [36–38]. This evidence has led to the relatively slow realization by health care organizations, governmental organizations, and health care practitioners themselves that gaps in the quality of care do exist and that the health care providers and the health care systems are two of the major reasons for such gaps. However, lessons from the world of Total Quality Management have taught that problems with quality are not always due to "people problems" but are often the result of "process or system problems."

A good example of this fact comes from the work of W. Edwards Deming, a major force in the Total Quality Management movement. He related a classic case of a system problem involving a company that used a number of flammable materials in its production line [41]. To combat the numerous fires that were occurring in the production plant, the leaders of the company pushed the employees to set fewer fires while they were working. What the company perceived as a "people problem"—that their employees were setting too many fires—was, in fact, a situation or system problem. The production line used flammable materials!

Quality improvement efforts within the field of medicine have led to recent efforts to introduce new systems of accountability into the practice of medicine. Clinical practice guidelines have long been published in hopes of setting the basic standards for high-quality care. Such hopes have largely been unfulfilled, however, due to a number of shortcomings with clinical guidelines, including the lack of full and consistent implementation of clinical practice guidelines into clinical practice [42–44].

Following the example of quality improvement efforts in the field of business, health care organizations have in recent years begun to utilize quality improvement methods, including, among other things, quality of care indicators, scorecards, and performance measures to help improve clinician accountability for the quality of the care that they provide [45,46]. CR performance measures, jointly developed by AACVPR, ACCF, and AHA, were published originally in 2007 and updated in 2010. These performance measures are designed as quality of care indicators and hold clinicians and health care systems accountable for referring eligible patients to CR/SP programs and at the same time hold CR/SP programs and professionals accountable for the delivery of high-quality CR/SP services to the patients referred to them [47,48]. These measures have been endorsed by the National Quality Forum and are now in the process of being disseminated and implemented.

The Centers for Medicare and Medicaid Services (CMS) have announced their plans to begin abstracting the outpatient CR/SP referral performance measure as one of their reportable performance measures, starting in 2014. Plans for the inclusion of the inpatient CR/SP referral performance measure as a chart-abstracted performance measure are currently under review by CMS. Whether or not the CR/SP performance measures will be included in "pay for performance" strategies is yet to be seen. It is anticipated that the implementation of these performance measures will help reduce the gap in CR/SP referral and enrollment, much in the same way that gaps in the inpatient prescription of aspirin, beta-blocker, and statin therapy to MI patients improved when CMS and other organizations began assessing and reporting how well clinicians and health care systems were providing these medications to eligible MI patients [49,50].

Three national data registries include the CR/SP performance measures: (1) the American College of Cardiology's National Cardiovascular Data Registry, (2) the American Heart Association's Get With The Guidelines and The Guideline Advantage (the latter done in cooperation with the American Cancer Society, the American Diabetes Association, and the American Stroke Association), and (3) the American Association of Cardiovascular and Pulmonary Rehabilitation's National Cardiac Rehabilitation Data Registry (soon to be launched). These data registries, ideally, will continue to evolve and interface in ways that will help to connect inpatient and outpatient data with data from CR/SP programs. Such links will be important tools to clinicians, health care systems, and patients to help improve the coordination and continuity of preventive care provided to patients with CVD.

CR/SP programs will continue to be a key factor in helping clinicians and health care systems improve the quality of SP care that is provided to patients with CVD. The contemporary CR/SP program will capitalize on this opportunity—to

serve as an "accountability resource" to clinicians and health care system, assisting them by providing standardized, systematic, evidence-based, and collaborative model of coordinated care resulting in high-quality SP services and high levels of CMS-measured quality of care performance.

Putting It All Together: Cardiac Rehabilitation Programs as SP Centers

Contemporary CR/SP programs, when ideally organized and operational, are specialized centers of SP [51]. They are designed and operated in a variety of different ways, but generally, to be most effective, will include the following operational parts:

1. Inpatient CR/SP services
   a. *Window of opportunity*: Members of the CR/SP team take full advantage of the "window of opportunity" and "teachable moments" by assuring that patients who have a new cardiac event or diagnosis (MI, PCI, CABG, heart valve surgery, heart transplantation, or a new diagnosis of stable angina) are started immediately on the path of SP, initiating preventive medications and referring the patient to an outpatient CR/SP program.
   b. *Systematic and automatic process steps*: Effective process steps include the use of standing orders, clinical pathways, and automatic processes for CR/SP assessment and referral [25]. Liaisons, health care professionals who help guide and "coach" the new CR/SP patient as they initiate the new preventive therapies and transition to an outpatient CR/SP program, have been shown to help improve uptake of outpatient CR/SP services [52].
2. Early outpatient CR/SP services
   a. *Seamless transition from inpatient to outpatient setting*: Effective contemporary CR/SP programs have a system in place to smooth the transition time between the inpatient and outpatient settings. Effective methods start in the hospital, as noted earlier, as the hospital team completes the patient referral process by communicating the patient's information and referral order to the receiving CR/SP program.
   b. *Enrollment and adherence enhancement*: The receiving CR/SP program contacts the enrolling patient soon after hospital discharge—usually within the first week—to confirm their enrollment in the CR/SP program and to help them with the specific steps they will need to take to attend their first visit (appropriate clothing to wear, time to report, directions to the CR/SP program, parking locations, reporting location, etc.).
   c. *Core components and competencies*: The CR/SP program incorporates the core components [39] and core competencies [40] that are considered to be the standard of care for CR/SP programs.
   d. *Case management to provide full dose of CR/SP*: The CR/SP staff assigns a case manager or case management team to provide a personal assessment and individualized treatment plan for the patient to follow. The case management team encourages patient participation and completion of early outpatient CR/SP by using a number of potential tools, including phone calls when the patient misses a CR/SP visit or incentive programs that encourage patients to complete their prescribed course of early outpatient CR/SP (usually consisting of up to 36 sessions over a period of 12–36 weeks). Delivery of the "full dose" of early outpatient CR/SP is an important responsibility of the patient's case management team, since receiving the "full dose" is associated with improved patient outcomes, as shown in a study by Hammill and colleagues. Patients who attend all 36 sessions of early outpatient CR/SP had a 4-year mortality rate that was 14% lower than those who attended 24 sessions, 22% lower than those who attended 12 sessions, and a 47% lower than those who attend only one session [7].
   e. *Tracking of progress*: The CR/SP staff assesses the patient's progress in achieving treatment and prevention goals, and gives feedback to the patient and adjusts treatment plans if the goals are not met, or else encourages continuation of efforts if treatment goals are met.
   f. *Care coordination and transition*: Finally, the CR/SP staff helps to transition the patient from the early outpatient phase of CR/SP to the long-term follow-up phase by coordinating those plans with the primary care provider and with long-term case management services that may be available in their community.
3. Late outpatient CR/SP services
   a. *Long-term case management*: Long-term case management services for CR/SP are designed to continue with patients for the rest of their lives. Long-term case managers (nurses and other nonphysician providers) meet with and/or contact the patient at set intervals to help the patient maintain healthy lifestyle habits, continue to adhere to their preventive medications, and monitor symptoms, possible disease progression, and important comorbid conditions. The case manager helps to arrange for additional evaluation or treatment, if indicated, for new symptoms, abnormal findings, or other patient concerns. Such long-term systems of follow-up care have been found to help patients achieve excellent control of their cardiovascular risk over time and to optimize their cardiovascular health and survival [5,13,53].

CHALLENGES AND POTENTIAL SOLUTIONS

Adherence

Studies in the United States and in other countries have shown that a surprisingly low percentage of eligible patients actually receive CR/SP services. In the United States, there is considerable regional variation in CR/SP uptake by eligible patients, ranging from a low of 6.6% in Idaho to a high of 53.5% in Nebraska [54]. Participation rates for CR/SP appear to be even lower for women, the elderly, and for racial and ethnic minorities [55]. Clearly, important gaps in the delivery of CR/SP are taking place, which limit the significant potential of CR/SP to reduce morbidity and mortality for eligible patients.

Fortunately, a number of innovative investigators have helped to identify methods that can help improve the delivery of CR/SP care (as described earlier in this chapter). A systematic approach to starting CR/SP in the hospital is a critical component to improving the delivery of CR/SP services. This approach generally includes a standardized patient risk factor assessment, initiation of appropriate preventive medications, automatic referral to CR/SP, and predischarge assistance by a "liaison" or health care professional to help the patient with steps to begin and continue with their preventive medications, steps to begin and maintain healthy lifestyle changes, and steps to enroll in an outpatient CR/SP program [23,25,52,56,57]. A strong recommendation for CR/SP by the patient's physician has also been shown to be a very strong predictor of subsequent CR/SP participation [23].

Some barriers to CR/SP participation continue to be a challenge, including the fact that many patients do not have a CR/SP program close to where they live or have difficulty attending the CR/SP program during the hours of operation, due to work and/or family responsibilities. Potential solutions for these barriers include the use of alternative delivery models of care, such as home-based CR/SP [58–60] and Internet-based CR/SP [61,62]. In addition, CR/SP programs can help improve availability to patients by offering expanded hours of operation, to include early morning, evening, and weekend hours.

Unfortunately, the full implementation of new and innovative methods to delivery CR/SP, and thereby reach the "unreachable" patients who do not receive CR/SP services, is highly dependent upon health care policy that supports reimbursement for such programs. The MULTIFIT [58] and SCRIP [59] models are excellent examples of innovative CR/SP programs that could help expand the reach of traditional CR/SP programs and improve delivery of CR/SP services to patients who are currently not receiving those services, but are falling instead into the CR/SP "gap."

Health Care Policy and Reimbursement

While improvements in the systematic approach to inpatient, early outpatient, and long-term case management will increase the number of eligible patients who receive CR/SP services, these improvements alone will not be sufficient to provide CR/SP services to all eligible patients. As mentioned earlier, innovative models of CR/SP delivery will be essential in order to reach the "unreachable." And to make innovative models of care feasible, health care policy will need to change so that reimbursement for such models is provided to CR/SP professionals. As an example, CMS and most health care insurance companies currently do not provide consistent coverage for home-based CR/SP services, despite the fact that they have been shown to be effective in delivering CR/SP care, perhaps at an even more cost-effective level than that observed in the delivery of traditional "in-center" CR/SP services [60].

A major opportunity for health care policy makers and health care providers is the provision of CR/SP to patients *before* a cardiac event, when the patient is first diagnosed with atherosclerotic CVD. The COURAGE trial shed important light on this approach to CR/SP by comparing the use of optimal medical/lifestyle therapy alone with optimal medical/lifestyle therapy plus PCI in patients who had CAD with stable angina [53]. While angina control improved more quickly in the PCI group, the overall symptom control, morbidity, and mortality outcomes were similar in the two groups, over a 2-year follow-up. Similarly, a study from Germany has also suggested that lifestyle approaches to CR/SP may be superior to PCI with regard to patient outcomes in patients with stable CAD [63]. It is still unknown whether or not CMS and other health care insurance providers will set as a policy to provide or even require CR/SP services for patients with CAD before PCI or other more expensive and interventional approaches would be approved. A recent Presidential Advisory from the American Heart Association on the referral, enrollment, and delivery of CR/SP programs at clinical centers and beyond highlights the urgent need for CR/SP professional and health care policymakers to work together to take bold steps forward to expand the reach and impact of CR/SP services to all eligible patients [27].

Financial Viability of CR/SP Programs

There is an old adage that an ounce of prevention is worth a pound of cure, and health care policy for reimbursement has generally operated in the opposite direction—willing to pay high prices for the "cures" and yet not willing to cover prevention at a much lower cost.

CR/SP programs have been shown to reduce mortality as much as, or more than, other treatments of CVD [6,11,12,14,53,64] and at a cost that is equal to or better than most treatments for CVD [65].

While CMS has recently increased reimbursement for early outpatient CR/SP services, rates of reimbursement still fall well below operational costs for many programs. Some health care plans require high co-pays for CR/SP patients, in some regions charging patients high co-pays for *each CR/SP session*. Clearly, to help expand the reach of CR/SP services, health care policy will need to change to reduce disincentives for CR/SP participation, such as co-pays, and to increase the use of appropriate incentives to patients and health care professionals alike.

SUMMARY

Contemporary CR/SP services hold a unique and important role in health care today. Increasing evidence suggests that CR/SP services improve short- and long-term outcomes for patients with CVD by delivering evidence-based and cost-effective care during important "windows of opportunity" during and after a cardiac event. Systematic approaches to the delivery of CR/SP increase the percentage of eligible patients who receive evidence-based CR/SP services and their associated benefits. CR/SP programs, when ideally designed, can serve as important quality of care resource to health care providers and health care systems, an important fact during these times of increasing expectations and accountability for the provision of high-quality patient care and optimal patient outcomes.

The contemporary CR/SP program is an SP center that uses systematic approaches to patient care and outcome assessment that begin in the hospital, transition to the outpatient setting, and continue lifelong to help patients enjoy optimal cardiovascular health despite having CVD.

Efforts to expand CR/SP services in order to reach all eligible patients are taking place, but will have only moderate impact unless health care policymakers appropriately support and encourage new and innovative approaches to reach patients who do not currently receive CR/SP services. The full impact of CR/SP services will be seen as health care systems and CR/SP programs adopt methods that increase the uptake of CR/SP services, increase the quality of CR/SP services delivered, and track and report quality of care metrics through collaborative data management systems.

CR/SP programs have evolved significantly over the past 30 years and will continue to evolve as CR/SP services adapt to meet the ongoing challenges and opportunities that are sure to come as changes in technology, health care services, and health care policies continue to occur.

Cardiovascular mortality declined by ~31% over the last decade. Nevertheless, cardiovascular disease (CVD) still accounts for nearly one of every three deaths in the United States. In 2010, an estimated 785,000 Americans experienced a new coronary event, and 470,000 had a repeat acute myocardial infarction (AMI) [1]. With such an enormous burden of coronary heart disease (CHD), therapeutic strategies to reduce cardiovascular mortality are paramount for increasing life expectancy in the United States. Accordingly, for literally millions of previously affected adults, interventions that have been shown to reduce the risk of recurrent cardiovascular events, collectively referred to as secondary prevention (Figure 83.1) [2], are critically important.

Exercise training has been reported in numerous randomized controlled trials, "real-world" observational studies, and meta-analyses to reduce the overall morbidity and mortality associated with CHD [3–10]. Structured exercise after a coronary event is often prescribed as an integral component of a comprehensive secondary prevention program in outpatient cardiac rehabilitation (CR). This chapter details the benefits associated with regular exercise training and moderate-to-vigorous physical activity in patients with CHD, highlighting the underlying mechanisms and evidence for improvement in long-term cardiovascular outcomes. Additionally, we review the potential complications associated with exercise interventions, especially when concomitant chronic diseases or superimposed environmental stressors are involved, so as to enable physicians and allied health professionals to more accurately assess the risk–benefit ratio of exercise in the coronary patients they counsel.

The recently published American Heart Association/American College of Cardiology Foundation secondary prevention guidelines for patients with coronary or other atherosclerotic vascular disease list regular physical activity as a Class I indication for risk reduction. The guidelines recommend "30 to 60 minutes of moderate-intensity aerobic activity, such as brisk walking, at least 5 days and preferably 7 days per week, supplemented by an increase in daily lifestyle activities (e.g., walking breaks at work, gardening, household work) to improve cardiorespiratory fitness and move patients out of

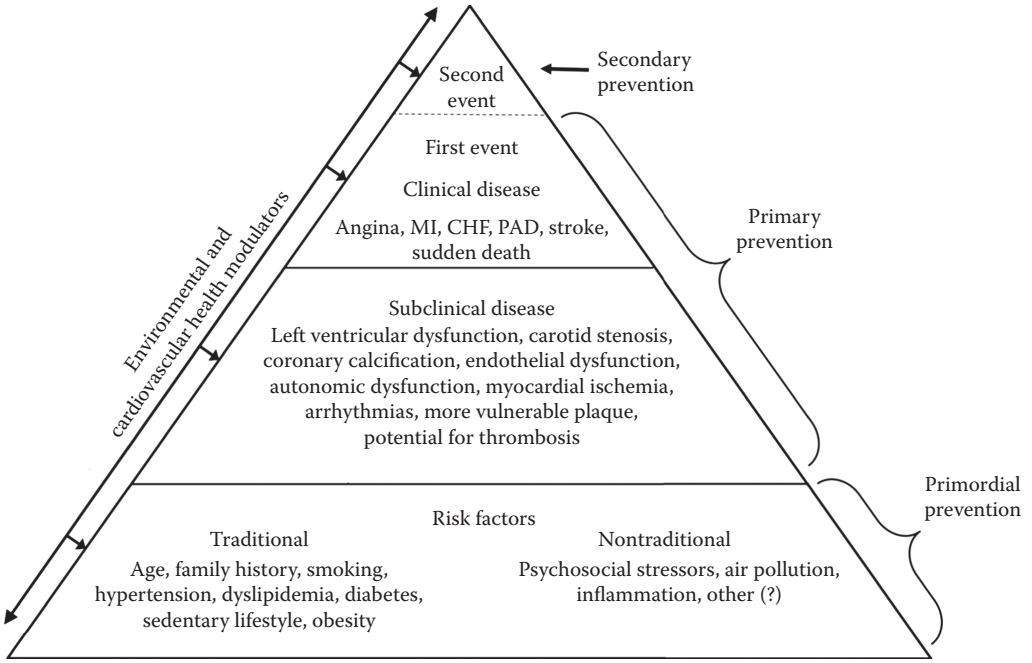

FIGURE 83.1 Multifactorial risk factor framework and the progression of CVD with corresponding primordial, primary, and secondary prevention. Environmental modulators include health care access, the built environment, advocacy/public policy initiatives, and potential intervention targets (e.g., personal, family, school, workplace). Cardiovascular health markers/interventions include smoking status, body mass index, physical activity, healthy diet score, total cholesterol, blood pressure, fasting plasma glucose, pharmacotherapies (e.g., aspirin, beta-blockers, statins, angiotensin-converting enzyme inhibitors), and coronary revascularization, when appropriate. MI, myocardial infarction; CHF, congestive heart failure; PAD, peripheral arterial disease. (From Franklin, B.A. and Cushman, M., *Circulation*, 123, 2274, 2011. With permission.)

the least fit, least active high-risk cohort (bottom 20%) [8]." Other contemporary guidelines recommend exercise training or exercise-based CR as a Class I indication after an AMI, percutaneous coronary intervention (PCI) [11], and coronary artery bypass graft surgery (CABG) [12].

In the most comprehensive and detailed meta-analysis of 47 studies that randomized 10,794 coronary patients (MI, PCI, CABG, angina pectoris, or angiographically documented coronary disease) to exercise-based CR or usual care, Heran et al. [6] reported a 13% relative reduction in all-cause mortality (RR 0.87, 95% CI 0.75–0.99) and a 26% relative reduction in cardiovascular mortality (RR 0.74, 95% CI 0.63–0.87) in patients with >12-month follow-up. In patients with short-term follow-up (≤12 months), a 31% relative reduction in hospital admissions (RR 0.69, 95% CI 0.51–0.93) was noted; however, no difference was observed in the risk of recurrent MI, PCI, or CABG between the exercise and usual-care groups. In another meta-analysis of secondary prevention programs including 63 randomized trials, a significant reduction in all-cause mortality and recurrent MIs was reported. Specifically, supervised exercise alone (17 trials, 2566 patients) was associated with a 28% reduction in all-cause mortality (RR 0.72, 95% CI 0.54–0.95) and a 26% reduction in recurrent MI (RR 0.74, 95% CI 0.57–1.01) [13].

The Exercise Training Intervention after Coronary Angioplasty trial randomized 118 patients who underwent PCI to exercise training versus usual care [14]. Exercise training was associated with a reduced incidence of subsequent cardiac events and/or revascularization procedures, including MI, PCI, and CABG (RR 0.71, 95% CI 0.60–0.91), and hospital readmissions (RR 0.69, 95% CI 0.55–0.93) at 33-month follow-up [14]. Recently, Goel et al. [4] reported that exercise-based CR was associated with significantly reduced all-cause mortality (RR 0.54, 95% CI 0.41–0.71) and cardiac mortality (RR 0.69, 95% CI 0.44–1.07) in a large community-based study of 2395 patients undergoing PCI. Studies in Medicare beneficiaries have also demonstrated a significant mortality reduction associated with participation in exercise-based CR [9]. More recently, the HF-ACTION randomized controlled trial in chronic heart failure patients with a left ventricular ejection fraction (LVEF) ≤35% found that exercise training reduced the incidence of combined all-cause mortality or hospitalization by 11% (HR 0.89, 95% CI 0.81–0.99), after adjusting for baseline prognostic variables [15]. Collectively, these data suggest that exercise training reduces all-cause mortality by up to 46% and decreases the risk of recurrent nonfatal MIs by ∼20% in patients with coronary disease. Several mechanisms have been suggested to explain the associated cardioprotective effects.

CARDIOPROTECTIVE EFFECTS OF STRUCTURED EXERCISE AND/OR LIFESTYLE PHYSICAL ACTIVITY

Longitudinal, observational, and experimental studies have now elucidated various biological and/or clinical mechanisms that may be responsible for the cardioprotective effects

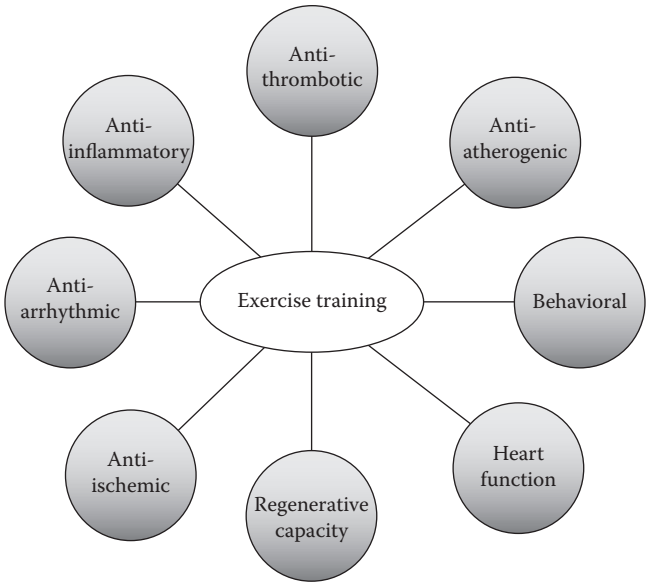

FIGURE 83.2 Potential cardioprotective effects of exercise training in coronary patients.

of exercise training. These are broadly summarized and outlined in Figure 83.2 and Table 83.1, respectively.

ANTI-ATHEROGENIC

Exercise training or regular physical activity has numerous anti-atherosclerotic effects that may reduce overall cardiovascular risk. In a meta-analysis of 48 trials including 8940 coronary patients, exercise-based CR was associated with significant mean reductions in total cholesterol (–14.3 mg/dL), triglycerides (–20.4 mg/dL), and systolic blood pressure (–3.2 mmHg) [16]. Similarly, another meta-analysis of 10 studies including 1260 patients with CVD who were randomized to aerobic exercise versus usual care for ≥4 weeks found that the exercise intervention was associated with significant increases and decreases in HDL cholesterol (9%) and triglycerides (–11%), respectively, with nonsignificant reductions in LDL and total cholesterol (–7.7 mg/dL and –8.8 mg/dL) [17]. Other studies, however, have reported significant reductions in LDL cholesterol with exercise training [18–20]. In addition, there is evidence that LDL heterogeneity may improve with regular aerobic exercise, transforming the more atherogenic small LDL particles into the larger less atherogenic form [21]. Physical conditioning also increases the resistance of LDL cholesterol to oxidation in previously sedentary subjects with CHD, highlighting the cardioprotective role of exercise in secondary prevention [22].

Previous studies and meta-analyses also report a modest, but significant reduction in systolic blood pressure with exercise training [16,23]. The underlying mechanisms may include a reduction in systemic vascular resistance, secondary to changes in sympathetic neural activity and/or the renin–angiotensin system [23]. Insulin resistance in coronary patients is associated with increased mortality [24]. Exercise training may have a beneficial impact on insulin sensitivity

and glucose metabolism [25]. The Diabetes Prevention Program Outcomes study showed that substantive lifestyle modification, including regular physical activity, reduced the incidence of new-onset diabetes, even at 10-year follow-up [26]. In contrast, another trial that randomized 55 cardiac patients to 12 weeks of exercise training versus usual care found insulin resistance unchanged in the absence of weight loss [27]. This suggests that adjunctive weight loss may be an essential component of some exercise training-induced adaptations, such as improved insulin sensitivity.

An "obesity paradox" has been reported in patients with CHD, wherein obese patients demonstrate a greater likelihood of survival as compared to their normal-weight counterparts [28–31]. Although a large body of evidence supports the obesity paradox when obesity is categorized using body mass index, central obesity as measured by waist–hip ratio or waist circumference has been shown to be directly associated with mortality [28]. Regardless of the adiposity indices employed, studies in coronary patients have shown that weight loss is associated with significant increases in HDL cholesterol [32] and brachial artery flow-mediated dilatation [33], and decreases in LDL cholesterol, triglycerides, C-reactive protein [32], major acute cardiovascular events, and total mortality [34]. Nevertheless, additional randomized controlled trials are needed to evaluate the short- and long-term effects of purposeful weight loss in secondary prevention programs.

ANTI-ISCHEMIC

Reduced myocardial oxygen demands and improvement in endothelial function are the epitome of anti-ischemic effects of exercise training in coronary patients. Exercise training decreases the heart rate and systolic blood pressure at a fixed level of submaximal exertion, reducing the rate-pressure product and associated myocardial oxygen demand. This allows selected patients to achieve greater workloads or metabolic equivalents (METs; 1 MET = 3.5 mL O_2/kg/min) before signs or symptoms of myocardial ischemia occur. The concept of "ischemic preconditioning" has also been described, primarily in animal models, and corresponds to increased tolerance of the myocardium to more prolonged periods of ischemic stress [35]. Physiological reduction in heart rate with regular physical activity allows for increased diastolic filling time, augmenting coronary perfusion during diastole. Finally, improvement in endothelial function with exercise training contributes significantly to the anti-ischemic effect. Hambrecht et al. [36] randomly assigned 19 patients with coronary endothelial dysfunction to exercise training or usual care. After 4 weeks, patients undergoing exercise training demonstrated significant improvement in endothelium-dependent vasodilatation in the epicardial coronary and resistance vessels, along with an increase in coronary blood flow reserve. Other studies have also reported that exercise training and/or habitual physical activity are directly associated with increased flow-mediated vasodilatation and exercise capacity [37,38]. Exercise training may also enhance coronary collateralization after an acute cardiac event [39].

ANTI-INFLAMMATORY

Subclinical inflammation measured by high-sensitivity C-reactive protein (hs-CRP) is associated with an increased risk of CVD and mortality [40]. Evidence also suggests that reduction of hs-CRP levels with cardioprotective medications (e.g., statins) has the potential to reduce long-term mortality [41]. Exercise-based CR programs have been shown to significantly reduce hs-CRP levels in patients with CHD [42]. Goldhammer et al. [43] reported that a 12-week aerobic exercise training program in coronary patients resulted in a significant reduction in the levels of CRP and pro-inflammatory cytokines, including IL-1, IL-6, and INF-γ, and significantly increased levels of the atheroprotective cytokine, IL-10. Walther et al. [44] randomized 101 men with moderately to severely obstructed coronary lesions to regular exercise training or PCI. At 2-year follow-up, exercise-trained patients demonstrated significantly reduced CRP levels and ischemic events as compared with patients who underwent PCI. Collectively, these findings suggest that exercise training and/or regular physical activity reduce chronic inflammation associated with coronary disease and that this adaptation may be responsible, at least in part, for the reduced long-term morbidity and mortality.

ANTI-THROMBOTIC

Exercise training produces intrinsic hemostatic effects that may reduce the plaque burden in coronary patients. The anti-thrombotic benefits of exercise training may include decreased fibrinogen levels, increased fibrinolysis, increased thrombolytic activity by increasing tissue plasminogen activator levels, decreased platelet aggregability, expansion of plasma volume, and reduction of blood viscosity [45–47]. A study of 23 nonsmoking coronary patients reported a significant reduction in the hematocrit standardized blood viscosity and plasma viscosity and an increase in red blood cell transport efficiency after a phase II exercise-based CR

program, thus improving blood rheology [48]. Short-term strenuous physical activity may be associated with increased platelet aggregation; however, this may be prevented with regular exercise [49]. Collectively, these data suggest that exercise training may reduce the incidence of recurrent cardiovascular events, possibly by attenuating the likelihood of plaque rupture and thrombus formation [14].

ANTI-ARRHYTHMIC

Threatening arrhythmias, including ventricular tachycardia and fibrillation, are directly associated with an increased incidence of sudden cardiac death (SCD), which is the most common cause of mortality in coronary patients. Exercise training may raise the threshold for ventricular fibrillation [50,51] by increasing vagal tone at rest while simultaneously decreasing the sympathetic drive [52,53]. Recently, Jolly et al. [54] found that CR participation was associated with improvement in heart rate recovery, which is considered to be reflective of vagal tone. In a classic experiment demonstrating the cardioprotective effect of exercise training in dogs, Hull et al. [52] reported heightened baroreflex sensitivity, a marker of the capability to reflexly augment vagal activity; increases in heart rate variability, an index of vagal tone; and increases in repetitive extrasystole threshold, an indicator of ventricular electrical stability. Subsequently, these adaptations were substantiated in patients with coronary disease [53,55]. In a randomized trial of 97 patients with CHD, a short-term residential exercise training program resulted in significant improvement in baroreflex sensitivity and heart rate variability [53]. In another randomized trial of post-MI and post-CABG patients, investigators reported that the observed increase in heart rate variability with exercise training persisted up to 1-year post-intervention [56]. These findings suggest that exercise-induced changes in cardiac autonomic control may create a myocardial milieu that is more resistant to the fostering of malignant ventricular arrhythmias.

REGENERATIVE CAPACITY

The number and morphology of endothelial progenitor cells (EPCs) in coronary patients are often low, more apoptotic, and functionally impaired [57,58]. One of the most important and emerging beneficial effects of exercise training may be the mobilization of progenitor cells from bone marrow. A randomized study of 37 patients with ST-segment elevation MI showed that regular exercise training was associated with a significant increase in the number and migratory capacity of the circulating progenitor cells [59]. Another investigation involving 19 stable coronary patients reported a significant increase in the number of EPCs and reduced apoptosis after 28 days of moderate-intensity exercise training [60]. Paul et al. [61] noted that participation in a 36-session CR program after a cardiac event led to a significant increase in the number of EPCs and EPC colony-forming units, and a significant reduction in the total number of apoptotic progenitor cells. Similar results have been replicated in experimental studies on exercise-trained mice [60]. These responses may serve to inhibit the progression of atherosclerosis in some patients by suturing the denuded endothelium, reducing neointima formation, promoting neoangiogenesis, and increasing re-endothelialization [60].

Mesenchymal stem cells are involved in the repair of myocardium via differentiation into cardiomyocytes, smooth muscle cells, and vascular endothelial cells, stimulating spontaneous cell fusion, endogenous repair, and local immunosuppressive properties [62]. Recent studies in patients with stable CHD have shown that brief bouts of high-intensity exercise (i.e., >90% peak heart rate) evoked a significant increase in mesenchymal stem cells [63]. Furthermore, growing evidence suggests that endurance exercise training may facilitate favorable cardiac remodeling by increasing the circulating and tissue-specific cardiac stem cells [64]. Experimental studies in mice have shown that exercise-induced hyperplasia may be due to the activation and differentiation of cardiac stem cells into cardiomyocytes [65].

HEART FUNCTION

Coronary artery disease is often associated with ischemic cardiomyopathy, systolic and/or diastolic dysfunction, and ultimately heart failure. Exercise training has the potential to enhance myocardial function with significant improvements in both systolic and diastolic functions. Oberman et al. [66] noted that high-intensity exercise training, as compared to low-intensity training, led to higher increments in rest–peak LVEF in sedentary men with coronary disease. Similarly, investigators recently reported a significant (31%) increase in LVEF after 12 weeks of exercise training in 42 cardiac patients [67]. Exercise training has also been consistently shown in numerous randomized controlled trials to improve indices of diastolic function in heart failure patients [68–70]. Wisløff et al. [70] randomized 27 patients with stable post-infarction heart failure to either high-intensity aerobic interval or moderate-intensity continuous endurance training and showed that the former intervention was more effective in promoting reverse left ventricular remodeling, reductions in left ventricular end-diastolic and systolic volumes, and increases in LVEF. Moreover, the Exercise Training in Diastolic Heart Failure pilot study showed that physical training improved exercise capacity, atrial remodeling, and indices of diastolic function in heart failure patients with preserved ejection fraction [68].

BEHAVIORAL

A high prevalence of psychosocial traits like anger, hostility, depression, and social isolation are often observed in patients who experience cardiovascular events. These behavioral characteristics are associated with a reduced quality of life and increased morbidity and mortality [47,71]. Recent data also show that positive recovery expectations at baseline are strongly associated with long-term survival and functioning in patients with angiographically documented

coronary artery disease [72]. Exercise training, especially in the form of comprehensive CR programs, has the potential to favorably modify psychosocial risk factors in patients with CHD. The Enhancing Recovery in Coronary Heart Disease Patients randomized trial showed that cognitive behavior therapy reduced depression and social isolation scores in 2481 post-MI patients; however, there was no difference in mortality between the intervention and usual-care control group [73]. Milani et al. [71] reported a 63% reduction in the prevalence of depressive symptoms following exercise-based CR as well as a significant reduction in long-term mortality. The Heart and Soul Study [74] raised the hypothesis that the increased risk of cardiovascular events associated with depression in stable coronary patients could be nullified by behavioral modification like regular physical activity, structured exercise, or both. To answer this question, the NIH-funded trial, Understanding Prognostic Benefits of Exercise and Antidepressant Therapy study, is under way, evaluating the effects of sertraline versus exercise on depressive symptoms and cardiovascular function in patients with CHD [75].

HEALTH RISKS OF PHYSICAL ACTIVITY AND/OR STRUCTURED EXERCISE

The risk of cardiovascular, pulmonary, musculoskeletal, and metabolic complications appears to increase transiently during strenuous physical activity compared with the risk at other times [76]. This seems particularly true when concomitant chronic diseases/medical conditions (e.g., diabetes, asthma, chronic obstructive pulmonary disease, coronary artery disease, orthopedic problems) are involved, especially among habitually sedentary, unfit individuals who were performing unaccustomed vigorous physical activity (i.e., 60%–89% of heart rate reserve or oxygen uptake [VO_2 reserve]) and/or ≥6.0 METs, where VO_2 reserve = percent intensity × (VO_2 peak − VO_2 rest) + VO_2 rest) [77–80].

This section reviews the pathophysiological basis for exercise-related untoward events, with specific reference to the absolute and relative risks for patients with known CHD, high-risk activities, identifying the "high-risk" patient, and recommendations to reduce the risk of activity-induced complications, including musculoskeletal injuries, cardiovascular events, adverse metabolic responses (e.g., hypoglycemia in diabetics), and/or the exacerbation of symptomatology related to asthma or chronic obstructive pulmonary disease.

PATHOPHYSIOLOGICAL BASIS FOR EXERCISE-RELATED CARDIOVASCULAR EVENTS

Pathophysiological evidence suggests that vigorous physical exertion may precipitate AMI or cardiac arrest in some persons with known or occult CVD [77–79]. Several hypotheses have been suggested as potential triggering mechanisms for plaque rupture (Figure 83.3) and acute coronary thrombosis, including abrupt increases in heart rate and systolic blood pressure, induced coronary artery spasm in diseased artery segments, or the twisting of epicardial coronary arteries [81,82]. An increase in platelet activation and hyperreactivity, which could contribute to (or even initiate) coronary thrombosis, has been reported in sedentary individuals who were engaged in sporadic high-intensity exercise, but not in physically trained individuals [83].

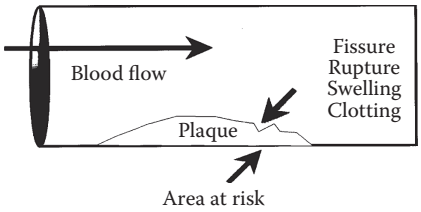

FIGURE 83.3 Atherosclerotic plaque can be either active and unstable or quiet and stable. If unstable, even mild-to-moderate blockages may fissure, rupture, or swell. Depending on the coagulative state of the blood, this cascade of events at vulnerable regions can induce thrombogenesis, triggering AMI. In some individuals, it appears that strenuous physical exertion can activate this sequence.

By increasing the rate-pressure product, a key index of myocardial oxygen consumption (r = 0.92) [84,85], and simultaneously shortening diastole and coronary perfusion time, exercise may evoke a temporary oxygen deficiency at the subendocardial level, which is exacerbated by abrupt cessation of exercise, arterial vasodilatation, or both. Because cardiac demands remain high in the immediate postexercise period, in the presence of known or occult coronary atherosclerosis, sudden decreases in venous return and coronary perfusion may increase the likelihood of myocardial ischemia, commonly manifested as significant ST-segment depression, angina pectoris, transient thallous (thallium) chloride-201 or technetium Tc99 m sestamibi (Cardiolite) perfusion defects, or combinations thereof. Ischemia can alter depolarization, repolarization, and conduction velocity (Figure 83.4), triggering threatening ventricular arrhythmias that, in extreme cases, may be harbingers of ventricular tachycardia or fibrillation. In addition, symptomatic or silent myocardial ischemia [86], sodium–potassium imbalance, increased catecholamine excretion, and circulating free fatty acids may heighten electrical instability.

EXERCISE-RELATED CARDIOVASCULAR EVENTS

For patients with known or occult CHD, the relative risk of experiencing cardiac arrest during vigorous exercise is estimated to be 6–164 times greater than that which might be expected to occur by chance alone [87]. Although isolated bouts of vigorous physical exertion may transiently increase the risk of cardiovascular events, the absolute risk associated with each episode of exercise remains extremely low. A large survey of cardiovascular events during rehabilitative exercise training in 142 U.S. CR programs (1980–1984) reported one cardiac arrest per 111,996 patient hours, one nonfatal MI per 293,990 patient hours, one major complication per

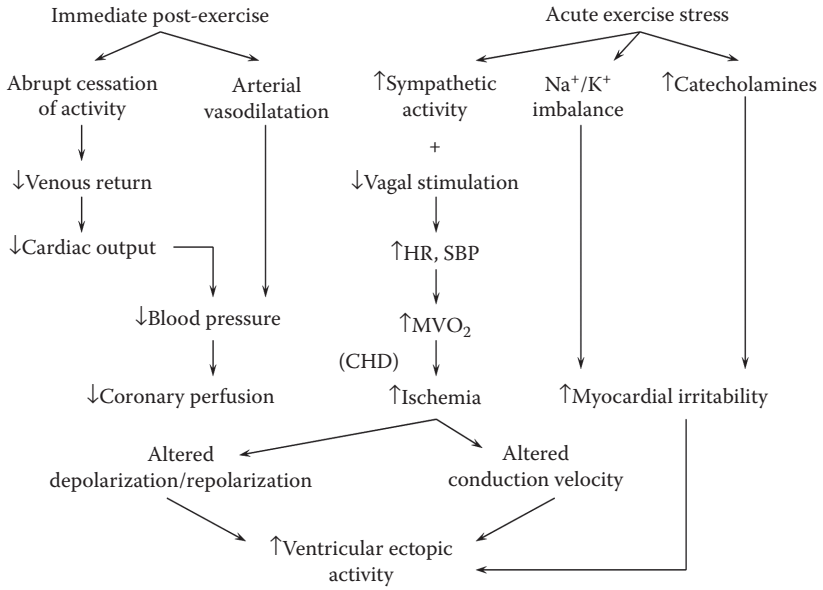

FIGURE 83.4 Physiological alterations accompanying acute exercise and recovery and their possible sequelae. HR, heart rate; SBP, systolic blood pressure; MVO_2, myocardial oxygen consumption; CHD, coronary heart disease.

81,101 patient hours, and one fatality per 783,972 patient hours of exercise [88]. However, these data antedate the current use of risk stratification procedures, emergent and elective coronary revascularization, newer cardioprotective pharmacotherapies, ablation techniques, ventricular assist devices, and antitachycardia pacemakers and implantable cardioverter defibrillators. Thus, these exercise-related complication rates may not necessarily apply to modern-day cardiac patients.

More recent studies suggest one major cardiovascular complication in every ~58,000 participant hours of outpatient cardiac exercise therapy, with no fatal events [89–91]. The French registry of complications during exercise-based CR reported a cardiac arrest rate of 1.3 per million patient hours of exercise [91]. It should be emphasized, however, that the absence of fatal cardiovascular events associated with CR applies only to medically supervised programs equipped with a defibrillator and appropriate emergency drugs. Numerous reports indicate that up to 90% of all patients with cardiac arrest occurring under such conditions are successfully resuscitated [88–91].

Morning versus Afternoon Exercise

During the early morning hours, a variety of pathophysiological mechanisms for AMI are more likely to be operative, including circadian surges in heart rate, blood pressure, catecholamines, and cortisol; platelet aggregability; coronary vascular tone; plasma viscosity; and fibrinolytic activity associated with awakening and assuming an upright posture [92]. Although it has been suggested that superimposed exercise training may accentuate these responses, and thus heighten the risk of activity-induced cardiovascular events, two studies of outpatient CR that compared morning-hour exercise with afternoon-hour exercise reported no difference in the overall cardiac complication rate [90,93].

Risk–Protection Paradox

Numerous independent studies have now shown that the relative risk of acute cardiovascular events is transiently increased by vigorous physical exertion, especially among habitually sedentary individuals with known or occult CHD and that the risk decreases with regular exercise participation [94]. To put these data into perspective, it is important to emphasize that the absolute risk associated with each bout of exercise is extremely low, the relative risk is inversely related to the habitual level of activity, and the long-term cardioprotective effect of regular physical activity and/or increased cardiorespiratory fitness is substantial. Two meta-analyses now suggest that regular exercise can reduce the long-term risk of cardiovascular events by up to 50% [95,96]. Moreover, recent studies in coronary patients have expressed exercise capacity in the context of survival benefit per MET [97]. These observations are noteworthy in that each 1-MET increase in exercise capacity appears to confer an 8%–55% reduction in mortality (Table 83.2) [15,98–103].

Based on data from the Onset study [104], the risk of AMI during each bout of physical activity is approximately doubled for an individual who participates in ≥5 vigorous 1-h exercise sessions per week. During the exercise bout, his or her risk will double and approximate the level that it would have been at all times if he or she were habitually sedentary. However, over the remaining 23 h of the day, his or her risk would be substantially lower, highlighting the clear net benefit of regular exercise and/or increased cardiorespiratory fitness, despite the modest, transient increased relative risk for a training-related cardiovascular event.

TABLE 83.2
Relation of Fitness or Exercise Tolerance to All-Cause or Cardiovascular Mortality in Secondary Prevention

Study	Population/Follow-Up Period	Fitness Measurement	Decrease in All-Cause or Cardiovascular Mortality
Vanhees et al. [98]	Male patients ≥4 weeks after MI (n = 312) or CABG (n = 215) for 6.1 years	Peak VO_2	71% per 1 L/min increase
Dorn et al. [99]	315 post-MI men randomized to a 6-month exercise program; patients followed over the course of 19 years	Peak METs	8%–14% per 1-MET increase
Kavanagh et al. [100]	12,169 men with CVD referred for exercise-based cardiac rehab; median follow-up was 7.9 years	Peak VO_2	9% per 1 mL/kg/min increase
Kavanagh et al. [101]	2,380 women with CVD referred for exercise-based cardiac rehab; average follow-up was 6.1 years	Peak VO_2	10% per 1 mL/kg/min increase
Kavanagh et al. [102]	6,956 men with CVD completing a 12-month walking-based training regimen; median follow-up was 9.0 years	Walking distance	20% per 1 mile improvement
O'Connor et al. [15]	2,331 medically stable outpatients with HF and reduced EF (≤35%), randomized to exercise training or usual care; median follow-up was 30 months	Peak VO_2	11% per 0.7 mL/kg/min increase
Feuerstadt et al. [103]	600 men and women with CVD who were referred to a 12-week exercise-based cardiac rehab program; mean follow-up was 4.4 years	Exit training MET level	34% per 1-MET increase 28% per 1-MET increase[a]

HIGH-RISK ACTIVITIES

Although the incidence of cardiovascular events during very light-to-moderate-intensity activities is similar to that expected by chance alone [45], vigorous physical exertion, especially when it is sudden, unaccustomed, or involving interspersed, near-maximal to maximal exercise bouts (≥90% VO_2 reserve), may increase the risk of AMI and SCD [77–79]. For example, jogging [45], racquet sports [105], skiing [106], marathon running [107], and strenuous sports (e.g., basketball) seem to be associated with a greater incidence of acute cardiovascular events than other activities. The excitement of competition may increase sympathetic activity and catecholamine levels, and lower the threshold to ventricular fibrillation [108]. Other recreational and domestic activities that are associated with a greater incidence of cardiovascular events include deer hunting [109] and snow removal [110], both of which may involve isometric and/or heavy upper extremity exertion and substantial increases in left ventricular afterload [111,112]. These responses, coupled with the body's normal thermoregulatory responses to cold, including increased platelet aggregability and plasma viscosity [113], coronary spasm or vasoconstriction [114], and superimposed emotional/hyperadrenergic responses [115], may present a hazardous milieu for cardiovascular events. During the winter months, an increased incidence of AMI and SCD has been reported in both the medical literature and lay press after hunting excursions [116] and heavy snowfalls [117–120].

RECOMMENDATIONS TO REDUCE THE RISK OF EXERCISE-RELATED CARDIOVASCULAR EVENTS

Recommendations to potentially reduce the risk of exercise-related cardiovascular events and their sequelae in coronary patients include the following: mandate medical clearance for participation and follow-up evaluations, which may involve serial peak or symptom-limited exercise testing; provide on-site medical supervision during and after exercise, until all patients have exited the shower and changing areas; establish an emergency plan, with provisions for cardiopulmonary resuscitation practice, regular emergency drills, and defibrillator and outdated drug checks; encourage sedentary patients to initially engage in regular walking so as to move them out of the least fit, least active, "high-risk" cohort (i.e., the bottom 20%) [46,121]; counsel inactive patients to avoid unaccustomed, vigorous physical activity (e.g., racquet sports, waterskiing, snow shoveling) [78,79];

advocate appropriate warm-up and cooldown procedures [122,123]; promote education of warning signs/symptoms (e.g., chest pain or pressure, light-headedness, heart palpitations/arrhythmias; unusual shortness of breath) [105,124]; emphasize strict adherence to prescribed training pulse rates, using perceived exertion as an adjunctive intensity modulator; use continuous or instantaneous electrocardiographic (ECG) monitoring in selected coronary exercisers, including suspected intensity violators [125]; minimize competition and modify recreational games to decrease the energy cost and heart rate response to play (e.g., doubles as opposed to singles tennis; allow 1 bounce of the ball per side during volleyball play); and adapt the exercise to the environment.

Cardiac patients can exercise safely in cold weather if proper precautions are taken. Nevertheless, inhalation of or exposure to cold air may evoke ischemic ST-segment depression, angina pectoris, or both. A cold-weather "jogging mask" may be helpful in this regard by attenuating signs or symptoms of myocardial ischemia in selected coronary exercisers [126]. Hyperthermic conditions may pose an even greater hazard than cold weather for cardiac patients who exercise. As the temperature increases at a given workload, heart rate response and myocardial demands may increase disproportionately [127]. Accordingly, patients may need to reduce their exercise intensity in hot and/or humid conditions. Because symptomatic or silent myocardial ischemia may be highly arrhythmogenic, the prescribed heart rate for endurance exercise training should be set at least 10 beats/min below the ischemic ECG or anginal threshold [128].

EXERCISE TESTING TO IDENTIFY PATIENTS "AT RISK"

It is difficult to identify cardiac patients who may be predisposed to cardiovascular events during exercise training; however, certain risk factors have been reported. For example, patients with previous MIs who have impaired LVEF (≤35%), rest- or exercise-induced signs and/or symptoms of myocardial ischemia (angina, marked ST-segment depression (≥2 mm)), high-grade left anterior descending lesions and/or significant multivessel atherosclerosis on angiography, inotropic impairment (exertional hypotension), a very low or relatively high exercise capacity, or threatening rest- and/or exercise-induced ventricular arrhythmias (especially in patients with impaired left ventricular function) appear to be at increased risk for an exercise-related cardiovascular complication [129]. Today, the latter cohort is increasingly treated with an implantable defibrillator to potentially reverse the catastrophic sequelae of SCD. Cardiac arrest victims are more likely to be chronic intensity violators (i.e., exceeding the prescribed training heart rate), disregard appropriate warm-up and cool-down procedures, or participate in sporadic high-intensity exercise. Low serum potassium has also been associated with electrical instability and worrisome ventricular arrhythmias. Nevertheless, it should be emphasized that coronary patients who have one or more of these widely varied characteristics may never experience an exercise-related cardiovascular event.

It is not necessary that all cardiac patients beginning a moderate-intensity and moderately progressive exercise program undergo a peak or symptom-limited exercise stress test, although this issue remains controversial since no data from controlled trials are available [25]. Exercise testing is recommended (i.e., Class I, Level of Evidence: B) for prognostic assessment, activity prescription, evaluation of medical therapy, and exercise-based CR after hospital discharge in patients with coronary and other atherosclerotic vascular diseases [8,130]. Cardiac patients who may be at increased risk for exercise-related cardiovascular events should also be considered for exercise testing before beginning a vigorous exercise training program [79]. On the other hand, empiric experience and previous studies have demonstrated the safety and effectiveness of early outpatient medically supervised exercise rehabilitation, using adjunctive intensity modulators (e.g., rating of perceived exertion and/or the patient's resting heart rate plus 20 beats/min) and continuous ECG monitoring, without a preliminary exercise stress test [131]. Joo et al. [132] reported that, on average, this methodology corresponded to ~42% VO_2 reserve among patients entering a phase II CR program, an intensity that approximates the minimum or threshold intensity for improving cardiorespiratory fitness in this patient subset [133].

Although exercise testing may be helpful in identifying threatening ventricular arrhythmias, a truly positive exercise test requires a hemodynamically significant coronary lesion (e.g., >75% stenosis; Figure 83.5), whereas most AMIs in previously asymptomatic persons occur at mild-to-moderate obstructions, due to vulnerable plaque disruption [134]. Consequently, an exercise stress test with or without concomitant myocardial perfusion imaging can be normal despite the presence of coronary plaque that may rupture. This requires that physicians and allied health professionals employ comprehensive risk stratification methodologies when advising patients on the feasibility of a vigorous exercise program.

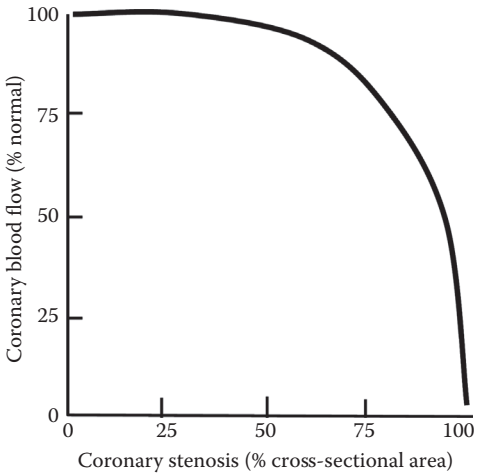

FIGURE 83.5 Relationship between coronary blood flow and coronary artery stenosis shows how perfusion is not significantly reduced until the obstruction exceeds 75% of the vessel's cross-sectional area.

OTHER EXERCISE RISKS

Although considerable epidemiologic evidence suggests that regular physical activity may help to protect against and treat aging-related chronic diseases, including CHD, cardiovascular, musculoskeletal, metabolic, and pulmonary complications appear to increase transiently during strenuous physical activity compared with the risk at other times. Accordingly, these risks must be considered when recommending the type and intensity of exercise for cardiac patients, especially those with concomitant orthopedic limitations, previous musculoskeletal injury, metabolic conditions, or pulmonary disease.

Musculoskeletal Injuries

Moderate-intensity physical activity, corresponding to between 40% and 59% of the heart rate reserve or VO_2 reserve, is associated with a relatively low risk of orthopedic complications [135]. On the other hand, the most common risk of vigorous physical activity is musculoskeletal injury, which can be as high as 55% among adults involved in jogging/running programs [136,137].

Jogging-related injury rates for novice exercisers are directly related to the intensity, frequency, and duration of exercise. Inordinate exercise demands, particularly during the initial weeks of a physical conditioning program, often result in muscle soreness, orthopedic injury, and attrition. An excessive frequency (≥5 days/week) and/or duration (≥45 min/session) of training offer the participant little additional gain in aerobic capacity (VO_2 max), whereas the incidence of orthopedic injury increases disproportionately (Figure 83.6) [138]. Similarly, near-maximal to maximal training intensities (≥90% of the heart rate reserve or VO_2 reserve) provide little additional improvement in cardiorespiratory fitness and are associated with an injury rate of ~50% [139]. Attention to warm-up, proper footwear, and terrain (avoiding hard and uneven surfaces) should aid in decreasing attrition due to injury.

Diabetes

For the diabetic who is adequately controlled or is only slightly hyperglycemic without ketosis, physical activity decreases blood glucose concentration, and a lower insulin dosage may be required. A lack of sufficient insulin before exercise may impair glucose transport into the muscles and lead to a cascade of potentially adverse metabolic responses, including ketosis and hyperglycemia. On the other hand, because exercise has an insulin-like effect, hypoglycemia is the most common problem experienced by exercising diabetics who take exogenous insulin or, to a lesser extent, oral hypoglycemic agents. Other precautions that should be taken include wearing proper footwear, practicing good foot hygiene, and recognizing that diabetic neuropathies can alter cardiovascular, skin blood flow, and sweating responses to exercise in hot/humid environments, increasing the risk of heat injury [128].

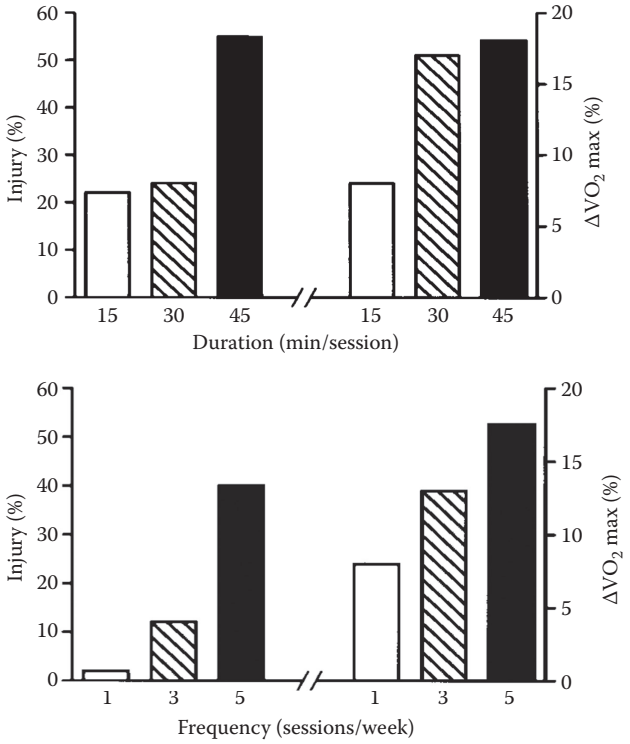

FIGURE 83.6 Relationships among exercise frequency and duration, improvement in maximal oxygen consumption (ΔVO_2 max), and the incidence of orthopedic injury in novice exercisers. Above an exercise duration of 30 min/session or a frequency of 3 sessions/week, additional improvement in VO_2 max is small, yet the injury rate increases disproportionately. (Adapted from Pollock, M.L. et al., *Med. Sci. Sports Exerc*., 9, 31, 1977.)

Selected recommendations and precautionary measures to reduce the likelihood of the previously referenced complications are outlined in Table 83.3.

Asthma or Chronic Obstructive Pulmonary Disease

Many coronary patients with moderate-to-severe asthma or chronic obstructive pulmonary disease may experience an exacerbation of pulmonary symptoms during exercise due to ventilatory limitations and/or oxygen desaturation. In patients in whom reactive airway disease is suspected or asthma has been documented, exercise-induced bronchoconstriction frequently occurs. Accordingly, such patients should be instructed in pursed-lip breathing during exercise, as well as the use of supplemental oxygen, especially those with a partial pressure of arterial oxygen of ≤55 mmHg, or a percent saturation of arterial oxygen of ≤88% while breathing room air [128]. Although there is no consensus as to the "optimal" intensity of exercise training for patients with cardiopulmonary disease, exercise at 50% of the peak VO_2 should improve exercise performance, and higher intensities may be periodically interspersed as tolerated by symptoms. Intermittent exercise, i.e., brief repetitive exercise–rest periods on alternate days, may be necessary for the initial training sessions until the patient can achieve 20–30 min of continuous exercise.

TABLE 83.3
Recommendations to Reduce the Risk of Exercise-Related Complications in Patients with Diabetes

- *Wear proper footwear and practice good foot hygiene*. Diabetics, especially those with impaired nerve conduction in their feet, should use cushioned shoes (gel or air soles) and avoid high-impact exercise. Because of their increased susceptibility to infection, diabetics should monitor their feet carefully for skin lesions, blisters, discoloration, or swelling and consult their physician if any of these appear
- Curtail outdoor exercise when the temperature is above 32°C (90°F), when the relative humidity is above 60%, or both, to decrease the likelihood of heat exhaustion or heat stroke
- *Monitor blood glucose before, during, and after physical activity when starting an exercise program*. Exercise at approximately the same time each day, ideally, 15–45 min after meals, when glucose levels are relatively high
- *Inject insulin in body areas that are not engaged by exercise*. For example, an inactive injection area like the abdomen should be used before walking, jogging, or stationary/outdoor bicycling
- *Avoid exercising during periods of peak insulin action*
- *Avoid exercise if the glucose level is below 100 mg/dL or above 300 mg/dL* (*or greater than 240 mg/dL with urinary ketone bodies*). Physical activity may be undertaken in insulin-dependent diabetics with low blood sugar, provided that 20–30 g of additional carbohydrate is ingested before exercise
- *Know the signs and symptoms of hypoglycemia*. These include heart palpitations, confusion, weakness, and visual disturbances, which, if left untreated, could lead to unconsciousness or convulsions. To reduce the likelihood of such adverse sequelae, diabetics should be instructed to always carry a form of fast-acting carbohydrate, e.g., juice, candy, glucose tablets, exercise with a partner, and wear a diabetic identification tag. Because the insulin-like effects of activity can persist for several hours after exercise, diabetics should also be counseled to eat more than usual or eat an extra carbohydrate-rich snack after working out
- *Monitor for symptoms of hyperglycemia, e.g., excessive thirst; frequent urination; blurred vision; itchy, dry skin; or a fruity odor or breath, which can lead to ketoacidosis, commonly called diabetic coma*

CONCLUSIONS

Although considerable epidemiologic and clinical evidence suggests that structured exercise, increased lifestyle activity, or both are cardioprotective, the absolute and relative risks of cardiovascular, musculoskeletal, metabolic, and pulmonary complications appear to increase transiently during vigorous physical activity. These risks should be considered when endorsing strenuous leisure-time or exercise interventions for cardiac patients. If the current mantra "exercise is medicine" is embraced, indications and contraindications require clarification, and under- and overdosing are possible. In some patients, prolonged, excessive, or vigorous-to-near-maximal physical exertion may elicit adverse signs, symptoms, and sequelae. Thus, exercise may have a typical dose–response curve with a plateau or even toxicity at more extreme levels [140].

In summary, there are numerous physiological and clinical benefits of regular exercise for cardiac patients (Figure 83.2; Table 83.1), and in the vast majority of patients, the benefits certainly outweigh the very low risk of untoward events. Accordingly, the medical community should adopt an evidence-based risk stratification approach, while avoiding hypermedicalization that may impede patient's decisions to become more physically active. Gill et al. [141] argued that any policy (e.g., the need for routine exercise testing and extensive safety monitoring procedures) that further deters a large number of older persons from participating in an exercise program may cause more harm than good. Perhaps Professor Per-Olof Åstrand [142] summed it up best when he said: "A medical examination is more urgent for those who plan to remain inactive than for those who intend to get into good physical shape!"

ACKNOWLEDGMENT

The authors express their appreciation and gratitude to Brenda White for her assistance in preparing this chapter.

Coronary heart disease (CHD) is the leading cause of death for American Indians and Alaska Natives, blacks, Hispanics, and whites. In 2004, 871,500 people died of heart disease, accounting for 36% of all U.S. deaths [1]. In 2005, CHD was projected to cost $393 billion, including health care services, medications, and lost productivity. We now know that the traditional risk factors, cigarette smoking, hyperlipidemia, diabetes, and hypertension, do not fully account for the timing and occurrence of CHD events, and it has been widely recognized that stress and negative emotions affect the development and course of CHD [2–4]. This chapter provides an update of our earlier chapter in which psychosocial risk factors associated with the development and clinical manifestations of CHD were reviewed, contextual factors that may moderate this risk were discussed, and potential mechanisms by which psychosocial factors increase the risk of adverse events in patients with CHD were presented. In addition, this revised chapter provides a more current review of interventions designed to modify psychosocial risk factors in patients with CHD.

PSYCHOSOCIAL RISK FACTORS

Type A Behavior Pattern and Hostility

Early observations by Friedman and Rosenman. [5] suggested that a large proportion of patients with CHD displayed a particular constellation of behaviors and personality traits, characterized by a hard-driving, competitive nature, a strong need for recognition and achievement, a sense of time urgency, and free-floating hostility. These attributes collectively were termed the *Type A behavior pattern* (TABP). Early retrospective studies supporting Friedman et al.'s initial observations found that patients with CHD were more likely to exhibit TABP than Type B behavior. A large prospective study known as the Western Collaborative Group Study (WCGS) found TABP to be predictive of CHD events in initially healthy individuals [6]. Based on a critical review of the literature, an expert panel of biomedical and behavioral scientists convened by the National Heart, Lung, and Blood Institute concluded that TABP contributed to CHD, conferring a twofold increased risk, which was of the same

order of magnitude as cigarette smoking, hypertension, and elevated serum cholesterol. Furthermore, this risk was independent of traditional risk factors [7].

In the 1980s, however, studies investigating the relationship between TABP and CHD provided inconsistent or negative findings. For example, a 22 year follow-up study of the WCGS did not support the earlier findings of a relationship between CHD and TABP [8]. Other studies also raised questions regarding the association between TABP and CHD, including the Multiple Risk Factor Intervention Trial [9] and the Aspirin Myocardial Infarction Study [10]. Subsequent reviews qualified the TABP-CHD relationship [4,11–13] and concluded that TABP is a multidimensional construct best represented by component measures [14] and that not all aspects of TABP are pathogenic.

Based on these considerations, investigators shifted their focus to examine *components* of Type A, with particular emphasis on anger and hostility [15]. Several cross-sectional studies found that ratings of hostility were associated with atherosclerosis [16,17]. Prospective studies also found that behavioral ratings of hostility predicted initial CHD events and progression of CHD [18], and Goodman et al. [19] found that patients undergoing percutaneous transluminal angioplasty (PTCA) with high hostility ratings were 2.5 times more likely to have subsequent restenosis compared to low-hostility patients. Although a follow-up of the WCGS failed to support the earlier findings of a relationship between global TABP and clinical events, analysis of these WCGS data indicated increased mortality rates among those highest in hostility [20], and further analysis of the 8½ year follow-up data showed hostility to be a significant risk factor for CHD events [21].

Self-report measures also have been used to investigate the relationship between hostility and CHD. In an early cross-sectional study of 424 patients undergoing diagnostic coronary arteriography, Williams et al. [22] found that hostility, as measured by the Cook–Medley Scale (CMHo), and TABP were both independently related to atherosclerosis. However, hostility scores were more strongly associated with atherosclerosis than was TABP. These findings have been confirmed by studies that have found similar results with other indicators of disease activity, such as frequency and severity of myocardial ischemia [23]. In addition, prospective studies also have shown CMHo scores to predict CHD morbidity and overall mortality in both medical students and law students at the University of North Carolina [24,25].

Reviews of the literature support the role of hostility in the development of CHD [26–29]. In a meta-analysis of prospective studies examining anger and hostility with future CHD events, Chida and Steptoe [29] found that higher levels of anger and hostility were associated with poorer outcomes in both healthy adults and cardiac populations. Among individuals healthy at study entry, higher levels of anger and hostility were associated with 19% greater risk of developing CHD (HR = 1.19). Cardiac patients with higher anger and hostility were also at greater risk, with greater anger and hostility associated with poor cardiac prognosis (HR = 1.24). It was suggested that anger and hostility may contribute to the development and progression of coronary atherosclerosis and also trigger acute CHD events.

Depression and Anxiety: The Role of Negative Affect

In addition to personality traits such as TABP and hostility that have been identified as risk factors for adverse cardiac events, it has been observed that myocardial infarction (MI) and sudden death may be preceded by excessive fatigue, lack of energy, hopelessness, and other symptoms of negative affect [30]. Depression in particular has been found to be a relatively common disorder among individuals with CHD and is now considered to be an important psychosocial risk factor for cardiac morbidity and mortality [31–34]. Carney et al. [33], for instance, found major depressive disorder (MDD) to be the best predictor of major cardiac events over a 12 month follow-up period of patients found to have CHD determined by cardiac catheterization. Furthermore, the relationship was independent of disease severity or smoking status.

Depression is particularly common among patients following an MI or cardiac surgery. Prevalence rates of MDD among patients with CHD have been estimated to be as high as 25%, with point prevalence rates estimated at up to 45% for patients with minor depression (mDD) or elevated depressive symptoms [31–36]. In a landmark study, Frasure-Smith et al. [31,32] found depression to be significantly related to cardiac mortality at 6 and 12 month follow-up and to be a significant predictor of mortality even after controlling for other important predictors, including previous MI, Killip class, and premature ventricular contractions of 10 or more per hour. In a meta-analysis of 20 prospective studies of CHD patients, depressive symptoms were associated with an odds ratio of 2.24 for mortality [36]. Importantly, even elevated depressive symptoms, without meeting formal DSM-IV criteria for MDD, have been shown to be associated with increased risk among CHD patients [37].

In addition to studies of post-MI patients, other studies also have shown that depression is associated with worse outcomes in other cardiac samples. Duke researchers [38], for example, found that among patients undergoing coronary artery bypass graft (CABG), moderate to severe depression before surgery and mild but persistent depression following surgery are associated with increased risk of death over extended follow-up periods. Similar findings have been reported among heart failure (HF) patients, with greater levels of depression predicting increased risk of mortality and rehospitalization [39,40]. Sherwood et al. at Duke demonstrated recently that depression was predictive of all-cause mortality and HF hospitalizations, and that persistent depression was a marker for increased mortality in HF patients [41].

Vital exhaustion is a related concept that resembles depression but occurs without feelings of sadness and other symptoms such as feelings of worthlessness or guilt. Several studies have shown that vital exhaustion is related to cardiac events and CHD severity [42–44]. Kop et al. [42] found vital exhaustion to predict new cardiac events in 127 post-PTCA

patients during 1.5 years of follow-up (odds ratio = 2.7). Multiple logistic regression showed the predictive value of vital exhaustion to be independent of traditional risk factors and initial disease severity.

Anxiety also has been studied as a possible risk factor for CHD events. In a meta-analytic review of 14 studies that investigated the relationship between anxiety and coronary disease, Friedman and Booth-Kewley [45] found anxiety to be a significant predictor of cardiac events, including both MI and angina. Subsequent studies have supported these findings and point to a relationship between anxiety and sudden cardiac death [46]. In one prospective study evaluating the association between symptoms of anxiety and risk of CHD using data from the Normative Aging Study, Kawachi et al. [47] found that, over 32 years of follow-up, the multivariate-adjusted odds ratio for men reporting two or more anxiety symptoms was 1.94 for fatal CHD and 4.46 for sudden cardiac death.

As with depression, prevalence rates of moderate to severe anxiety among MI patients in the hospital are relatively high, with estimates as high as 40% or more [51]. Moreover, about 15%–20% of patients still report anxiety 1 year after hospital discharge. Frasure-Smith [49] evaluated 461 post-MI men in the hospital and followed them for over 5 years. A high level of psychological distress in the hospital was found to confer a threefold increase in cardiac mortality over the 5 years of follow-up. In addition, highly stressed patients had 1.5 times the risk of recurrent MI over follow-up. In a related study, anxiety was associated with an adjusted odds ratio of 2.21 for a later cardiac event. Similar studies of post-MI patients also have found anxiety to have prognostic significance for future health problems, including the occurrence of cardiac arrhythmias [51].

Janszky et al. [52] recently examined the relationship between any diagnosis of anxiety and subsequent CHD events in a sample of 49,321 Swedish men, followed prospectively from age 18 to 20 over a 37 year follow-up period. Participants were initially diagnosed by a psychologist using a structured interview and the International Classification of Diseases—8th revision. Over the 37 year follow-up of the study, the presence of anxiety was associated with more than double the risk of CHD (HR = 2.17) and a similar risk for AMI (HR = 2.51). Interestingly, the authors did not find a significant association between depression and CVD outcomes in this study. In a meta-analysis of 20 studies, including 249,846 individuals followed for more than 11 years, Roest et al. [53] also found a relationship between anxiety and CHD. Anxious individuals had higher rates of CHD (HR = 1.26) and cardiac death (HR = 1.48) after controlling for other background factors and health behaviors.

There is also evidence that phobic anxiety may be associated with increased CHD risk and that this risk may be primarily for cardiac outpoints resulting from arrhythmias. Watkins et al. [54] found that the presence of phobic anxiety was associated with increased risk of CHD and sudden cardiac death, but only among women. Albert et al. [55] reported similar findings among women participating in the Nurses' Health Study. The authors prospectively followed 72,359 women for 12 years. They found that the presence of phobic anxiety, determined by self-reported symptoms on the Crisp–Crown Index, was associated with an increased risk of sudden cardiac death and fatal CHD, but not with nonfatal MI.

Although anxiety appears to be associated with increased risk of CHD, it is also often comorbid with depression. Several studies have therefore attempted to examine the unique and combined effects of these two psychosocial factors as they relate to CHD outcomes. In a study of 5073 middle-aged, healthy Dutch women, Denollet et al. [56] examined the relationship between anxiety and health outcomes while controlling for depression. At a 10 year follow-up assessment, they found that anxiety was associated with a 77% increased risk of mortality, a nearly threefold increased risk of CHD (HR = 2.77), and a tendency to be associated with an increased risk of breast cancer. Depression was not associated with increased risk of mortality or health outcomes in this study. Phillips et al. [57] found that individuals with generalized anxiety disorder and depression were at greater risk for CHD than individuals with either condition alone. Thus, there is a growing literature to suggest that both anxiety and depression are associated with increased risk and that the effects of anxiety and depression may be additive.

Acute and Chronic Stress

Acute stress has been implicated in the occurrence of cardiac events in CHD patients. For example, Kark et al. [58] examined the association between a life-threatening stressor, Iraqi missile attacks on Israel during the Gulf War in 1991, and subsequent mortality. The number of daily deaths during the 4 month period surrounding the war increased from December through January and subsequently declined through mid-March. There was an abrupt, significant increase in the number of deaths on January 18, the day of the first strike on Israeli cities, with a significant 58% increase in mortality risk on the first day of attacks. This increase was mainly due to CHD, other cardiovascular diseases, and a group of unknown causes, most probably representing sudden cardiac death.

In a naturalistic study of severe stress—a catastrophic natural disaster—Leor et al. [59] reviewed the county coroner records from the time surrounding the massive Los Angeles earthquake in January 1994. Results revealed that the number of sudden cardiac deaths rose sharply from a daily average of 4.6 in the preceding week to 24 on the day of the earthquake, only 3 of which could be attributed to physical exertion. Because the number of sudden cardiac deaths declined during the 6 days following the earthquake, to a daily average of only 2.7, the authors concluded that the earthquake itself was a significant trigger of sudden cardiac death and, based on the fact that sudden deaths due to cardiac causes declined in the week after the earthquake, that emotional stress precipitated cardiac events in predisposed individuals.

In addition to extreme emotional stress, everyday stressors have been shown to have potentially damaging health consequences. Mental stress, e.g., has been shown to provoke

myocardial ischemia in the laboratory in 50%–66% of cardiac patients with prior evidence of exercise (EX)-induced ischemia [60–63]. Moreover, stress during daily life has been associated with an increased incidence of ischemia measured by ambulatory monitoring [64–66]. Using a case-crossover design, Mittleman et al. [67] reported a relative risk of 2.3 for MI in the 2 h following an episode of anger, indicating that anger was a trigger that doubled the risk of MI.

Chronic stress also has been shown to be associated with CHD. The widely cited INTERHEART study [68,69] used a case–control design to study 15,152 individuals with their first MI and 14,820 age- and sex-matched healthy individuals without CHD. Psychosocial stress was assessed by four questions about stress at work, home, finances, and major life events. CHD patients reported higher levels of stress in all categories and also were more depressed. The composite stress index had an odds ratio of 2.67 adjusted for all other risk factors, which was comparable to the "traditional" risk factors. Taken together, data from prospective and cross-sectional studies have provided compelling evidence for the importance of stress as a risk factor, which provide the basis for developing interventions to reduce stress in vulnerable cardiac patients in order to modify the natural history of these clinical events.

CONTEXTUAL OR ENVIRONMENTAL FACTORS

Social Support

A lack of social support and social isolation have been implicated as risk factors for both cardiac morbidity and mortality. Prospective studies have found initially healthy individuals as well as post-MI patients who live alone or who lack adequate social support to be at increased risk of future cardiac events, independent of other known risk factors. Case et al. [70] observed a 6 month mortality of 15.8% among post-MI patients living alone (16.4% of total sample) versus only 8.8% among those living with others. In a follow-up study of patients with angiographically documented CAD, Williams et al. [71] observed a 5 year mortality rate of 50% among those who were most socially isolated (unmarried with no confidant) versus only 17% among those not isolated. Given the large sample size, strong effects, and ability to statistically control for known biomedical predictors, these studies provide strong evidence for the important contribution of social isolation to poor outcomes in patients with established CHD.

In a study of 194 elderly post-MI patients, Berkman et al. [72] reported that the presence of emotional support prior to the MI was the most powerful and significant predictor of survival after the MI. At 1 year follow-up, 55% of patients without support had died, compared to only 27% with two or more sources of support. In a detailed analysis of the Enhancing Recovery in Coronary Heart Disease (ENRICHD) study, Lett et al. found that social support buffered the effects of stress; among patients with lower levels of depression, patients who reported high social support had fewer adverse events compared to patients with low social support [73]. In all of these studies, the impact of low social support on prognosis was independent of left ventricular ejection fraction and other biomedical prognostic factors. In a comprehensive review of the literature on social support and CHD, Lett et al. [74] found that low social support was associated with a 1.5- to 2.0-fold increased risk of CHD in both health and cardiac populations and concluded that perceived functional support was a more important predictor of outcomes than structural support.

Low Socioeconomic Status

It has long been known that low socioeconomic status (SES) is a significant contributor to increased CHD risk in healthy persons and to poor prognosis in CHD patients [75]. The Whitehall study was one of the first studies to demonstrate that social gradients were associated with variations in cardiac outcomes. Marmot [76] found that gradients of SES within the British Civil Service were associated with variations in cardiac outcomes and that graded increases in SES were associated with a protective effect on CVD outcomes. Ruberman et al. [77] found low education level to be a potent predictor of mortality, although not independently of social isolation. Williams et al. [71] found that the 5 year mortality rate of CAD patients with incomes less than $10,000/year was 1.9 times higher than that among patients with incomes greater than $40,000/year. This effect was independent of social isolation and disease severity. Case et al. [70] also found SES, as documented by less than a 12th-grade education, to predict increased first recurrent events, independently of social isolation or physical risk factors.

Taken altogether, these findings make a convincing case that low SES does contribute to poor prognosis in established CHD. The evidence suggests that SES has an impact over and above that conveyed by social isolation, but it is plausible that some of the adverse effects of low SES are mediated by its associations with depression and social isolation. Depressive symptoms are inversely related to SES in the general population [78], so that SES may interact with psychosocial risk factors and potentially produce an additive effect.

Job Strain

Certain job characteristics, either by themselves or in combination, also have been implicated as psychosocial risk factors for coronary disease, in particular psychological workload and decision latitude [79]. Job strain, which involves a combination of these two factors, has been the subject of intensive research in recent years. The job strain model characterizes exposure to psychosocial job stressors along the two dimensions of *demand* (psychological workload) and *control* (decision latitude). In a prospective study of CAD risk among Swedish men, Karasek et al. [80] found that high job demands were associated with disease. Low decision latitude on the job, characterized by low intellectual discretion and low personal schedule freedom, was

associated with the development of cardiac symptoms, and the job strain combination of low personal control over schedules and high job demands was associated with a four-fold increase in risk of cardiovascular-related death. These relationships remained significant after controlling for age, education, and overweight. Subsequent research has supported this relationship between the combination of high job demand and low control and increased risk of both CHD [81] and risk factors for CHD including hypertension and increased left ventricular mass [82].

POTENTIAL MECHANISMS LINKING PSYCHOSOCIAL VARIABLES AND CHD

A number of hypotheses have been proposed regarding the mechanisms whereby psychosocial variables may increase the risk for the development of CAD and the occurrence of clinical CHD events. It is widely believed that the relationship between psychosocial variables and CHD is mediated by activity of the sympathetic-adrenomedullary system, as reflected by heightened cardiovascular and neuroendocrine responses to behavioral stimuli including mental stress.

Cardiovascular and Neuroendocrine Reactivity

Exaggerated cardiovascular and neuroendocrine responses to psychosocial stressors have been proposed as one mechanism for promoting the progression of atherosclerosis and onset of clinical CHD events. Animal studies have shown a relationship between enhanced cardiovascular responses and atherosclerosis [83]. In addition, heightened responses to behavioral challenges in humans have been associated with increased cardiac mortality [84] and with the occurrence of myocardial ischemia [60], as well as with risk factors for CHD, including hypertension and dyslipidemia [85,86].

The process by which recurrent activation of the sympathetic nervous system, involving exaggerated heart rate and blood pressure responses to stress, may contribute to atherosclerosis is likely through its contribution to endothelial injury. Among the possible causes of such injury are mechanical forces, such as turbulence and sheer stress. In addition, chronic neuroendocrine hyperreactivity producing increased levels of circulating catecholamines, corticosteroids, and reproductive hormones may promote endothelial dysfunction, as well as other physiological changes. Stress may also affect clotting factors and may acutely promote plaque rupture.

Not all individuals respond to stress in the same way, however, and psychophysiological studies of humans have shown significant variability in cardiovascular and neuroendocrine reactivity to laboratory stressors. Exaggerated responsivity to stress may be considered an individual difference characteristic, and investigators have sought to associate psychosocial variables, including personality traits (e.g., TABP), mood (e.g., anger), and contextual variables (e.g., harassment or competition), that distinguish high and low reactors [87].

Heart Rate Variability

In addition to the contribution of heightened sympathetic and neuroendocrine activity, the antagonism of the parasympathetic nervous system on sympathetic activity also may influence the pathogenesis of CHD. The balance between sympathetic and parasympathetic (vagal) activity can be assessed using the analysis of heart rate variability (HRV), in which decreased variability is an independent risk factor for mortality among CHD patients. Research has shown that laboratory challenges can disrupt the sympathovagal balance, such that sympathetic nervous system activity becomes dominant under stress [88], suggesting that chronic negative arousal may be associated with decreased HRV. Indeed, research has shown decreased HRV to be associated with TABP [89], as well as with anxiety [90] and depression [91]. Alternatively, the mechanism by which such psychological traits or states impact HRV also may be behavioral, e.g., through nonadherence to regimens that affect sympathovagal balance, including regular physical activity and use of cardiac medications.

Myocardial Ischemia

Recent research has examined the relationship between stress and myocardial ischemia. Laboratory studies [60] have shown that EX produces significant increases in heart rate and blood pressure and that the double product, an indicator of myocardial oxygen demand, is significantly elevated. Although mental stress is also associated with increases in blood pressure and heart rate, it generally does not produce as great an increase in heart rate as EX but may be associated with greater diastolic blood pressure responses. The double product associated with mental stress, therefore, is considerably less than the double product associated with EX. This suggests that increased myocardial oxygen demand is not the only determinant of mental stress-induced ischemia and that myocardial oxygen supply also may be restricted during mental stress ischemia.

The possibility that a reduction in myocardial oxygen supply may be at least partially responsible for mental stress ischemia has been investigated in studies of both animals [92] and humans [93]. Such research has indicated differential vasomotor responses in stenosed versus nonstenosed coronary arteries; whereas vasodilation occurs in normal segments of coronary arteries during mental stress, paradoxical vasoconstriction leading to myocardial ischemia occurs in atherosclerotic segments. Although the precise substances responsible for such vasoconstriction have not been identified, it is known that several neurohumoral substances, such as catecholamines, are released during mental stress and may be responsible for abnormal vasoconstriction.

Inflammation and Platelet Function

Inflammatory factors, such as C-reactive protein (CRP), have been shown to play an important role in the pathogenesis and progression of CHD [94]. Higher levels of inflammation,

including interleukin (IL)-6, tumor necrosis factor (TNF) α, and CRP, have been associated with various psychosocial risk factors including lower SES, chronic work stress, caregiver strain, early life adversity, hostility, and social isolation [95]. There is also evidence that depression is associated with elevated levels of inflammation [96]. In an analysis of data from 6914 men and women between the ages of 18 and 39 years from the National Health and Nutrition Examination Survey III, a history of MDD was strongly associated with elevated CRP [94]. In a recent meta-analytic study, Steptoe et al. examined the relationship between acute psychological stress and inflammatory markers [95]. They found that acute psychological stress was associated with increased IL-6, IL-1β, and a trend for an association with higher CRP. Howren et al. [97] examined this relationship by studying the relationship between depression and several inflammatory markers, including CRP, IL-1, and IL-6 and found a dose–response relationship between depression and greater levels of inflammation across both clinical and community samples. In addition, Howren et al. found evidence to suggest that depression may predispose to greater inflammation and that inflammation may increase depressive symptoms.

Increased platelet activation also has been shown to play an important role in the pathogenesis of CHD [98,99]. Although platelet activation has been most closely related to depression [100], recent evidence suggests that other "negative" psychosocial factors, such as anxiety and mental stress, are also associated with higher platelet levels. Zafar et al. [101] found that depressed adults with comorbid anxiety had the highest platelet levels compared with either condition alone. Aschbacher et al. [102] observed elevated platelet activity following acute public speaking tasks that responsivity was stable over time. Increased platelet activity has been associated with higher levels of depression among both healthy populations and individuals with CHD [103]. In addition, severity of depression has been shown to correlate with platelet levels, and reduced depressive symptoms have been shown to be associated with lower platelet levels [104].

INTERVENTIONS TO IMPROVE PSYCHOSOCIAL RISK FACTORS IN CARDIAC PATIENTS

Despite the considerable epidemiological evidence for a stress–CHD relationship, as reviewed earlier, the health benefits of reducing stress in cardiac patients are not well established because of limited data from randomized clinical trials (RCTs) and a lack of hard evidence that improving psychosocial risk factors improves clinical outcomes.

Intervention programs specifically targeting psychosocial factors shown to play a role in CHD have been implemented as part of more comprehensive and longer-term rehabilitation programs, both to improve quality of life during rehabilitation and potentially to reduce cardiac morbidity and mortality.

In one of the earliest psychosocial interventional studies, Adsett and Bruhn [105] observed that coronary patients lacking close family relationships and the support of friends had more difficulty adjusting after an MI. Their study assessed the efficacy of short-term group psychotherapy for six male post-MI patients having trouble adjusting to their situation, with treatment including their spouses. Results showed improved psychosocial adaptation for both patients and their spouses, although there was no control group. Trzcieniecka-Green and Steptoe [106] studied the effects of a 12 week relaxation-based stress management program on a variety of psychosocial variables in 78 patients following MI, CABG, or PTCA. After treatment and at follow-up, subjects showed significant improvements in anxiety, depression, general psychological well-being, activities or daily living, social activity, quality of interactions, and satisfaction with sexual relationships. Because there was no control group, however, conclusive statements about the results are not possible.

There have been a number of RCTs assessing improvements in psychosocial factors in CHD patients. These studies have used a variety of therapeutic techniques, from relaxation training and cognitive-behavioral treatment to group counseling. Stern et al. [107] evaluated the effects of group counseling versus EX therapy in 160 MI patients who exhibited a low functional capacity on treadmill testing, were anxious and/or depressed, or both. Subjects were randomly assigned to 12 weeks of an EX program, group counseling, or a control group. Both active groups showed improvements in psychological functioning as compared to the control group. Subjects who underwent group counseling substantially reduced their level of depression and interpersonal friction and increased their sense of friendliness, independence, and sociability, whereas the control group showed no changes.

Van Dixhoorn et al. [108] evaluated the impact of adding relaxation training to a traditional physical conditioning program in 69 MI patients who were randomly assigned to an EX and relaxation group or an EX-only control group. Patients in the relaxation training group showed significant improvements in well-being, whereas those in the EX-only group did not show psychological improvements. Additionally, patients displaying the TABP showed the greatest improvements resulting from relaxation training. Lewin et al. [109] implemented a home-based psychosocial self-help program for post-MI patients. They found that psychological adjustment, as assessed by the Hospital Anxiety and Depression Scale, was better in the treatment group compared to the control group. Moreover, those in the treatment group had significantly fewer hospital readmissions during the first 6 months, and they had significantly less contact with their doctors over the next year. As in many of these studies, the greatest improvements were seen in those patients who were clinically anxious or depressed at baseline.

A limited number of studies have used "hard" clinical endpoints such as cardiac morbidity and mortality as clinical outcomes. In a controlled trial of brief group psychotherapy for post-MI patients, Rahe et al. [110] randomly assigned 44 patients to either a control condition or a supportive, educational group therapy condition with a modest emphasis on modification of coronary-prone behaviors. All patients

were followed for 3 years. Patients in the treatment condition showed significantly less coronary morbidity, including arrhythmias, mild to moderate congestive HF, and angina pectoris, as well as lower mortality at follow-up compared to control patients, and this was not explained by changes in conventional coronary risk factors. Therapy patients, however, did show changes in certain coronary-prone behaviors. Because educational information presented in the therapy sessions was largely forgotten over follow-up, the authors concluded that it was primarily the general support provided by the therapy that explained the outcome differences.

In the Ischemic Heart Disease (IHD) Life Stress Monitoring program [111,112], 461 post-MI men patients were assigned to either a usual care (UC) condition or an experimental intervention in which a monitor would call once a month and administer Goldberg's General Health Questionnaire (GHQ). Whenever a patient's responses generated a GHQ score of 5 or more, the monitor informed the nurse assigned to that patient, who would then schedule a home visit to work with the patient until the patient's problems were resolved or he or she was able to deal with them alone and the GHQ score had returned to normal. Nurses were instructed to lower the stress levels of their patients using whatever strategies seemed appropriate for each patient. This intervention provided patients with social support, both instrumental in terms of dealing with problems and emotional in terms of providing a caring human being to listen to the patient describe his or her problems.

The monitoring group exhibited reduced mortality relative to the UC group after 4 months. By the end of the first 12 months of follow-up, the monitoring group experienced a 47% reduction in cardiac mortality relative to the UC group. Interestingly, of the patients on beta-blockers, 11% of the controls died compared to only 3% of the treated group, suggesting that stress management might further complement medical therapy. Long-term follow-up revealed that the group with high distress (GHQ $\geq$ 5) assigned to stress monitoring/nurse intervention experienced significant reductions in both recurrent MI and cardiac mortality over 5 years. Whether in UC or monitoring intervention groups, the low-distress group (GHQ < 5) experienced lower mortality than the high-distress group assigned to UC. Thus, it was only in those with high distress that the psychosocial intervention in this study led to improved prognosis.

More recently, Frasure-Smith et al. [113] attempted to replicate their earlier findings in a new sample of 1376 post-MI men and women. Patients completed a baseline interview that included assessment of anxiety and depression. Patients were then randomized to either an intervention condition or to a UC control group. As in the earlier study, patients randomly assigned to the intervention were telephoned 1 week after discharge and then every month for 1 year. If a patient scored 5 or more on the 20-item GHQ scale or he or she was readmitted to the hospital, the research assistant contacted the study nurse who then arranged for an initial 1 h visit at the patient's home or at another convenient location. The intervention had no overall survival impact (the overall odds ratios were 1.44 and 1.41 for cardiac and all-cause mortality, respectively). Moreover, there was a higher cardiac (9.4% vs. 5.0%) and all-cause mortality (10.3% vs. 5.4%) among women in the intervention group. There was no evidence of either benefit or harm among men. However, there was no evidence that the intervention successfully reduced the patients' distress levels. Because the intervention failed to significantly reduce distress, it is not surprising that the intervention had no beneficial impact on clinical outcomes.

In a large-scale study of post-MI patients, the Recurrent Coronary Prevention Project (RCPP) [114] randomized 1035 Type A men and women who had suffered an MI within the past 6 months to cardiologic counseling (n = 270) or to an intervention that included not only cardiac counseling but also a behavioral program designed to reduce their Type A behavior (n = 592). A third group, who refused randomization, formed an additional UC control group. The intervention consisted of weekly group meetings in which cognitive behavior therapy and behavior therapy principles were applied to train patients in skills and strategies to reduce Type A behavior, including both the time urgency and hostility components. Subjects were given "drills" to practice as homework between group meetings, and the results of their efforts were shared with other group members at the meetings. The intervention was successful in reducing both time urgency and hostility, using behavioral observation to assess these components. At 3 year follow-up, statistically significant reductions in Type A behaviors were observed in those assigned to the Type A counseling treatment group. In addition, CHD recurrence rates were significantly lower (7.2%) among the treatment group compared with the control group (13%). This pattern continued at the 4½ year assessment, marking the end of treatment, with 35.1% of treatment-group participants showing a marked reduction in Type A behaviors compared to 9.8% in the control group, and a cardiac recurrence rate of 12.9% in the treatment group versus 21.1% in the control group and 28.2% in the nonrandom comparison group.

Mendes de Leon et al. [115] reported specific behavioral and psychosocial changes that occurred as a result of the Type A treatment program in the RCCP. Patients in the treatment group showed significant reductions not only in global TABP but also in the components of hostility, time urgency, and impatience. Furthermore, they had reduced depression and anger and improvements in self-efficacy, social support, and well-being. As with the initial IHD life Stress Monitoring study, the RCPP enrolled mostly men and too few minority group members to evaluate its impact upon them. Another omission was the absence of any reports of process variables that might be mediators of the treatment benefits.

Ornish et al. [116] assigned 48 patients with angiographically documented CHD to UC (n = 20) or to a comprehensive lifestyle change program (n = 28) incorporating EX, low-fat vegetarian diet, stopping smoking, and stress management training (SMT), with twice-weekly group support meetings. Compared to the UC group, patients in the intervention group were more likely to show regression of angiographically

documented lesions after 1 year in the program. The patients who were most adherent to the overall program showed the most pronounced regression of their coronary stenoses.

Given the comprehensive and extensive nature of the intervention in this study, it is not possible to identify which aspects of the program were responsible for the regression of arterial lesions. Certainly social support was provided by the twice-weekly group meetings and may have played an important part, but in the absence of a controlled design that permits evaluation of the impact of the various components, it is possible to say only that the "package" was responsible for whatever benefits were observed. The observation that those most adherent to the overall program experienced the greatest decrease in arterial stenoses is useful in guiding future trials to assess adherence to the intervention regimen. The Ornish et al. study also obtained consent after patients were informed of their group assignment, so that strict randomization procedures were not followed. Moreover, the sample size was too small to determine if changes in the extent of CAD were associated with reductions in clinical CHD events.

Other clinical studies also have examined the effect of behavioral interventions on morbidity and mortality but lacked adequate power to detect group differences [117,118]. In one of the largest studies to date, Jones and West [119] failed to show significant benefits for the psychosocially treated group. In this large-scale clinical trial conducted in Great Britain, 2328 patients discharged from the hospital within 28 days from a confirmed MI participated in an RCT comparing UC to a comprehensive rehabilitation program comprising psychological therapy, counseling, relaxation training, and SMT over seven weekly group outpatient sessions for patients and their spouses. At 6 months' follow-up, there were no significant differences between rehabilitation patients and controls in reported anxiety and depression. At 12 months there were no differences in clinical complications, clinical sequelae, health service use, return to work, or mortality. It was concluded that rehabilitation programs offered little objective benefit to post-MI patients. However, the short duration of the intervention and the failure to document treatment effectiveness were major limitations of the study. Because the intervention failed to effectively modify those relevant psychosocial risk factors that are thought to affect clinical prognosis, it is not surprising that no effects on clinical outcomes were observed.

Several recent studies have targeted patients at increased risk of CHD events because of high levels of psychosocial stress. One of the largest trials to examine the effects of a psychosocial intervention on mortality and morbidity was the ENRICHD randomized trial [120]. In this study, post-MI patients who were depressed or who had low social support were randomized to receive either UC or a cognitive-behavioral therapy (CBT) intervention. CBT was initiated soon after hospital discharge for up to 6 months of individual CBT. When possible participants were offered group therapy, psychiatrists were encouraged to prescribe medication for participants with Hamilton Rating Scale for Depression scores >24 or with BDI scores with less than a 50% reduction at 5 weeks. After 3 years, results revealed that the special CBT intervention group achieved significant reductions in depression and improvements in social support. However, there were no differences between the special intervention and education controls in event-free survival [121].

Other trials have examined the effects of antidepressant pharmacotherapy on CHD outcomes among individuals with depression. The SADHART trial was a randomized, double-blind, placebo-controlled, 24 week trial of sertraline for MDD among patients hospitalized for acute MI [122]. Results showed improvement in depressive symptoms among participants with more severe depression who were treated with sertraline but not in the overall sample. Although the study was considered a safety and efficacy trial, and was not powered to examine clinical outcomes, clinical data suggested that the sertraline group tended to have fewer adverse events. A second study of HF patients with depression, known as SADHART-CHF, found that sertraline did not reduce depressive symptoms any better than placebo and that patients treated with sertraline had no better clinical outcomes compared to those receiving placebo [123].

The MIND-IT study of antidepressant therapy for MI [124] showed similar results. In this multicenter randomized trial, 320 post-MI patients were randomized to either antidepressant treatment with mirtazapine or placebo, or received treatment as usual. If participants refused or did not respond to initial treatment, citalopram was offered as a second-line intervention. Results showed no differences between intervention and control participants in either depressive symptoms or cardiac outcomes.

Lesperance et al. [125] compared the benefits of antidepressant medication and psychotherapy in the CREATE study. In this randomized 2 × 2 design, cardiac patients with MDD were randomized to receive either citalopram plus clinical management, interpersonal therapy plus clinical management, clinical management only, or placebo plus clinical management for 12 weeks. Results showed that depressive symptoms were reduced more in the citalopram group compared to placebo, whereas there were no differences between the interpersonal therapy and clinical management groups.

The COPES study [126] was a recent RCT in which 237 patients, including 157 persistently depressed patients, were randomized to a special intervention depending on patients' preferences (problem-solving therapy and/or antidepressant medication) or UC. At the end of the trial, 3 intervention patients and 10 UC patients experienced a major adverse cardiac event. While the results were very preliminary, and the study was obviously underpowered for "hard" clinical events, results were encouraging.

Several recent comprehensive reviews have summarized the value of psychosocial interventions in cardiac patients. Linden et al. [127,128] noted that patients who received psychosocial interventions were over 40% less likely to die and

were 65% less likely to have a recurrent coronary event than controls over a 2 year follow-up period. Van Dixhoorn and White [129] also conducted a meta-analytic review on the effects of relaxation therapy in cardiac patients and reported that relaxation therapy was associated with improvement in a wide range of physiological outcomes such as resting heart rate, HRV, EX tolerance, HDL cholesterol, angina, arrhythmias, and EX-induced ischemia. Moreover, subsequent cardiac events and cardiac death were reduced in patients undergoing relaxation training. Notably, relaxation remained superior when EX-based CR programs were directly compared. Finally, Rees et al. [130] aggregated findings from 18 studies in which 5242 patients were randomized. Although there was limited support for the benefits of stress management on total mortality in the 10 trials that reported death as an outcome (OR = 0.9; 95% CI = 0.7–1.2) and on cardiac mortality in four studies (OR = 0.6; 95% CI = 0.4–0.99), there was evidence of a significant reduction in nonfatal MI compared to controls (OR = 0.7; 95% CI = 0.5–0.9) in eight studies. Thus, there is encouraging evidence that stress management is associated with improved health outcomes, although key methodological elements of RCTs (e.g., blinding of assessors and lack of allocation concealment) detracted from the overall quality of the studies. Moreover, the RCTs described earlier focused on "hard" clinical endpoints such as death and MI.

Another approach that has been recently adopted is to study intermediate markers of risk in CHD patients. Examination of changes in intermediate endpoints can provide important insights into the mechanisms and potential value of psychosocial interventions and has a number of important advantages over "hard endpoints" in that (1) fewer patients are required to detect treatment effects; (2) changes in cardiac risk can be reliably and objectively measured over short follow-up intervals; and (3) these studies can be performed relatively inexpensively at a single site. Blumenthal et al. [131] at Duke University Medical Center conducted a study of patients with mental stress-induced myocardial ischemia in which CHD patients were randomly assigned to EX or SMT; a third group of participants who lived too far from Duke to participate in the trial served as a control group. Results revealed that patients who underwent 16 weeks of SMT exhibited a relative risk of further cardiac events of only 0.26 compared to UC controls. Although the Duke study was not fully randomized, the findings demonstrated that stress management was effective in reducing stress-induced ischemia and ambulatory ischemia. Moreover, the 74% reduction in clinical events including MI, death, and revascularization procedures because of progressive angina was highly significant. EX training also was associated with a 32% reduction in risk for cardiac events, although this reduction did not achieve statistical significance. Moreover, a follow-up of study participants revealed that the benefits of stress management were maintained over time, with participants who received SMT experiencing fewer cardiac events and having less medical expenditures compared to UC or EX over 5 years of follow-up [132].

In an attempt to address the methodological shortcoming of their initial study, a subsequent, fully randomized trial of 134 patients with stable CHD examined the impact of SMT on biomarkers of CHD [133]. Patients were fully randomized to SMT, EX, or UC. Patients in both active treatment groups exhibited reductions in depression (and distress compared to UC controls) and exhibited smaller reductions in left ventricular ejection fraction during mental stress testing. In addition, there was a reduction in ischemia following SMT in the subset of patients who presented with significant ischemia at baseline, and patients in both active treatment groups exhibited greater improvements in a variety of cardiovascular "biomarkers" including flow mediated dilation (FMD) and baroreflex sensitivity (BRS). Interestingly, SMT patients also exhibited greater improvements in HRV compared to exercisers and UC controls, suggesting the potential added value of combining SMT with EX training in CHD patients.

The intervention trials reviewed earlier have several features in common. All included some aspects—whether regular group meetings or nurse home visits—that *directly* provided patients with added social support, over and above whatever support systems they had access to on their own. This suggests that providing social support has considerable promise as an intervention that will improve prognosis in patients with established CHD. The Ornish et al. study [117], the RCPP [115], and the Duke studies [131–133] also included instruction in what can be broadly characterized as stress management techniques—relaxation skills, cognitive strategies to decrease anger and hurrying, communication and assertion skills, time management, and the like. In addition to whatever direct benefits these components of the intervention provided (e.g., decreased sympathetic activation caused by relaxation and anger management), they also have the potential to increase social support *indirectly* (i.e., if one is not hostile toward one's family and friends, they may be more likely to provide social support).

CONCLUSIONS

Psychosocial factors play an important role in the development and clinical manifestations of CHD and contribute to adjustment and quality of life in a variety of cardiac populations including post-MI, cardiac surgery, stable and unstable angina, and HF. Despite the strong epidemiologic evidence for stress as a risk factor for patients with CHD, evidence that reducing stress improves prognosis is limited [134]. Future research is needed to determine the value of stress reduction in improving clinical outcomes and to identify individuals who could potentially benefit most from such interventions. For example, the NIH-sponsored ENHANCED study is currently under way to determine the added value of stress management when included in a traditional EX-based cardiac rehabilitation program [135]. Additional multicenter trials are needed to evaluate the impact of stress reduction on clinical outcomes.

PERIPHERAL ARTERIAL DISEASE

Peripheral arterial disease (PAD) results from systemic atherosclerosis. The disease process that affects the blood vessels is the same for patients with coronary artery disease (CAD) and stroke, and the risk factors for these atherosclerotic conditions are essentially the same. Among cardiovascular disease risk factors, diabetes is perhaps the strongest risk factor for PAD. The clinical presentation of PAD varies widely. Some individuals with PAD may be asymptomatic or experience exertional leg discomfort. Some present with the classic symptom of intermittent claudication (IC), which is characterized as leg pain during walking. IC limits exercise tolerance and presents a unique challenge to care providers in that it will require modification to the rehabilitative process and exercise prescription that is typically used for many other health conditions. This chapter will be primarily focused on individuals with IC.

EVALUATION OF CLAUDICATION

Because leg discomfort is a common complaint, particularly among older patients, it is important to recognize the characteristics of claudication that differentiate it from other causes of leg pain. IC is pain or profound fatigue in a muscle brought on by exertion and relieved by a few minutes of rest. Most commonly, a patient with PAD will develop pain in the calf, thigh, or buttocks that is worsened by walking. The pain subsides after a variable period of rest and the patient may resume walking, often for the same distance. The distance to onset of claudication depends on the severity of the disease. Claudication pain is consistent and reproducible and should not be confused with severe sudden onset pain due to an acute occlusion or thrombosis of an artery in the lower extremity. An acute occlusion of an artery will more likely result in pain that is severe and constant, even at rest, and associated with other signs of obstructed blood flow such as a cold, pale, or bluish extremity and the absence of pulses below the area of obstruction. Patients with PAD may have some of these same signs, but they will occur progressively as the disease worsens over time.

Claudication should also be differentiated from leg aches and pains such as arthritis and chronic venous insufficiency. Arthritis causes pain in the joints, may vary from day to day or with changes in the weather, and may occur with or without activity. Chronic venous insufficiency in the lower extremities results in blood pooling in the extremities and is associated with leg or ankle edema. The symptom is aggravated

by standing or sitting for long periods. It is described as an ache or full sensation in the legs that becomes progressively worse during the day and is relieved by resting with the legs elevated.

Specific findings on physical assessment help confirm the diagnosis of PAD and claudication. Peripheral pulses are diminished or absent by palpation. Color changes include pallor of the extremity, especially if elevated above heart level, or dependent rubor, a bright reddish color occurring in the affected limb when it is placed in a dangling (dependent) position. Diminished blood flow results in a cooler extremity when compared to the unaffected leg. Mild to moderate claudication is not a limb-threatening condition. The goal of treatment is the relief of symptoms with exercise training and risk-factor modification.

When PAD becomes severe, it is referred to as critical limb ischemia, and patients may develop rest pain. The patient experiences this symptom as a burning pain in the toes, and it occurs most often when the patient is in bed or has the affected limb elevated. Patients may get some relief by hanging the foot over the side of the bed or by sitting up in a chair. Even narcotics provide only minimal relief. Ischemic pain may progress to paresthesia and paralysis of the toes and foot. Rest pain is a limb-threatening symptom and must be referred immediately for further evaluation and revascularization.

DIAGNOSING PERIPHERAL ARTERIAL DISEASE

Test Modalities

Lower extremity PAD can be diagnosed using the ankle brachial index (ABI), which is a ratio of systolic blood pressure measured in the ankle and brachial arteries. The ABI is measured using blood pressure cuffs and a pencil-size Doppler probe. A stethoscope is not used because the structure of the foot makes it difficult to place the head of the scope on a flat area to detect the pulse. Normal ABI values are between 0.91 and 1.30, mild impairment from 0.70 to 0.89, moderate impairment from 0.40 to 0.69, and severe impairment $\leq$0.40. This procedure is easy to perform and can be followed by other testing such as Doppler and duplex ultrasound imaging, computed tomographic angiography, magnetic resonance angiography, or angiography if additional testing is needed prior to intervention or treatment.

Postexercise ABIs, measured immediately after walking on the treadmill, can also be used to confirm the diagnosis. A common initial procedure after the diagnosis is established by the ABI in noninvasive Doppler arterial testing of the lower extremities. A complete study begins with segmental systolic arterial pressures. These are obtained using BP cuffs placed in four locations: the upper thigh, above the knee, below the knee, and at the ankle. A Doppler ultrasound stethoscope is used to measure systolic pressures at each level. Generally, these pressures should be equal to, or slightly higher than, the brachial systolic pressure. Leg pressures that are lower than brachial pressures by 20 mmHg or more indicate arterial insufficiency.

Evaluation of Functional Status

The evaluation of the PAD patient includes an assessment of the impact of claudication on activities of daily living. Improving the functional capacity of the patient is an essential goal of exercise training for PAD. An initial assessment of functional disability can then be used to measure progress during treatment. Disease-specific questionnaires, such as the Walking Impairment Questionnaire and the PAD Physical Activity Recall Questionnaire, are useful in documenting the functional status of patients before and after participation in an exercise program [1].

ASSESSING CARDIAC STATUS IN THE PAD PATIENT

Cardiovascular Risk

The risk of CVD is markedly increased in patients with PAD [2]. More than 95% of persons with PAD have one or more CVD risk factors [1]. Because claudication limits physical activity, many patients may not experience any cardiac symptoms. Before beginning any exercise program, these patients should undergo appropriate cardiac stress evaluation. A bicycle rather than a treadmill test may permit increased myocardial work before leg symptoms occur and therefore allow more accurate assessment of cardiac risk. Though pharmacological stress testing with cardiac imaging may be considered for the patient with claudication, an exercise study is preferred before starting an exercise program.

Walking Capacity

Once cardiac risk status has been determined, as per ACC/AHA guidelines, standardized treadmill testing should ideally be performed prior to initiating exercise training to establish the magnitude of the functional limitation due to claudication and to provide a baseline to measure the response to therapy [3]. Exercise testing may also reveal nonvascular factors contributing to the impaired walking ability such as degenerative joint disease and assist in individualizing the exercise prescription. Continuous ECG monitoring is useful, particularly given the high prevalence of concomitant CVD. A treadmill test can be used to determine the extent of claudication and to evaluate the effectiveness of subsequent treatment. The two graded protocols are widely used with claudication patients. The same speed, 2 mph, is used in both protocols. The Gardner–Skinner protocol increases the grade by 2% every 2 min [4]. The Hiatt protocol increases the grade by 3.5% every 3 min [5]. Both protocols have been proven effective and accurate in evaluating the onset of claudication and the maximum walking distance.

During the test, the patient is asked to walk on a treadmill until the claudication forces the test to be terminated. Data including the time of onset of claudication symptoms and the maximum walking time should be recorded. Immediately after stopping, ankle pressures are also recorded again. In the absence of PAD, ankle pressures will not decrease with exercise. A postexercise drop in ankle systolic pressure confirms the diagnosis of arterial disease. Subsequent ankle pressures are recorded at 1 min intervals for 10 min or until the return to baseline levels. In addition to estimating the location and severity of the disease, this testing provides baseline information for subsequent progress evaluations. Follow-up testing should be performed upon completion of an exercise training program and should include a resting ABI calculation, a treadmill walk at the same settings as the baseline evaluation, and postexercise ankle pressures with recovery time. Though the ABI may actually change very little in response to exercise training, improvement is noted by a delayed onset of claudication, increased maximum walking distance, and shorter recovery time of ankle pressures.

If formal exercise testing is not performed, a 6 min walk test may be used as an alternative to treadmill testing [3].

Cardiovascular Disease Risk Factors

As stated earlier, the same risk factors that contribute to CVD are also associated with PAD and should be treated aggressively. Overall, smoking is the most significant controllable risk factor for PAD. Aside from its contribution to the development and progression of atherosclerosis, cigarette smoking increases claudication pain severity, reduces peripheral circulation, and negatively affects cardiac and pulmonary responses to exercise [6], thereby further reducing exercise capacity. The benefits derived from participation in an exercise program will be attenuated if patients, particularly those who have undergone revascularization procedures, continue to smoke.

SKIN AND FOOT ASSESSMENT

Limited blood flow to the extremities contributes to poor skin perfusion, making skin more fragile and susceptible to injury and infection. Many patients with PAD also have diabetes and suffer from neuropathy, which decreases their ability to feel pain or irritations to the feet until damage is severe. Patients with PAD should be encouraged to see a podiatrist for evaluation to assure that proper shoes are used. When the skin is broken, and thus susceptible to infection, the arterial system is unable to meet the increased demands needed for healing. If healing is not progressing adequately, a referral for specialized wound care treatment or revascularization may be required. In more severe cases, if infections cannot be controlled, amputation may be required. If ulcers are present on the extremity, boots or casts that keep pressure off of the ulcer or alterations in the exercise regimen such arm exercise will be required until the ulcers are healed.

EXERCISE TRAINING

Evidence Base for Exercise Training

Supervised exercise training is considered a primary treatment for many individuals with PAD and IC. The American College of Cardiology/American Heart Association clinical practice guideline for treatment of PAD rated exercise therapy for IC as a Class I, level of evidence A, recommendation, which compares very favorably to similar or lower levels of recommendation for medications or revascularization procedures [7].

Because of the evidence-based efficacy of exercise training, the American College of Cardiology and American Heart Association Task Force on Performance Measures in 2010 recommended that health care providers either refer a patient to a program or discuss exercise training as a treatment option for appropriate patients with PAD [8].

A meta-analysis of both nonrandomized and randomized studies reported a 179% increase in pain-free walking distance and a 122% increase in maximum walking distance [9]. A Cochrane review of 22 randomized controlled trials for claudication reported an overall improvement in walking ability of approximately 50%–200% [10].

Most patients experience a near doubling of their pain-free and maximum walking distances with exercise training, with the most consistent results occurring in supervised programs versus home-based training. Another Cochrane review found a significant improvement in maximum treadmill walking distance in supervised compared to unsupervised programs, with a difference of approximately 150 m [11].

Only a few studies have compared exercise training to lower extremity revascularization for claudication. A prospective randomized trial compared supervised exercise to angioplasty and found that mean maximum walking distances progressively increased in the exercise group at 6, 9, and 12 months but did not increase in the angioplasty group despite an increase in ABIs with angioplasty [12]. In a follow-up at a median of 70 months, the functional outcome was the same between the exercise and angioplasty groups [13]. Among patients randomized to angioplasty or medical treatment [14] at 2 years, there were no group differences in treadmill walking distances or quality of life; the medical group was given “advice” to walk on their own but did not participate in a supervised program.

A randomized trial of 151 patients with claudication received either angioplasty with conditional stenting or 24 weeks of twice-weekly 30 min supervised exercise sessions [15]. Though revascularization provided more immediate clinical success, after 6 and 12 months, the treatment groups were equivalent for functional capacity and quality-of-life scores. The CLEVER (Claudication versus Endoluminal Revascularization) trial is an ongoing NIH/NHLBI-funded multicenter randomized clinical trial [16]. The treatment

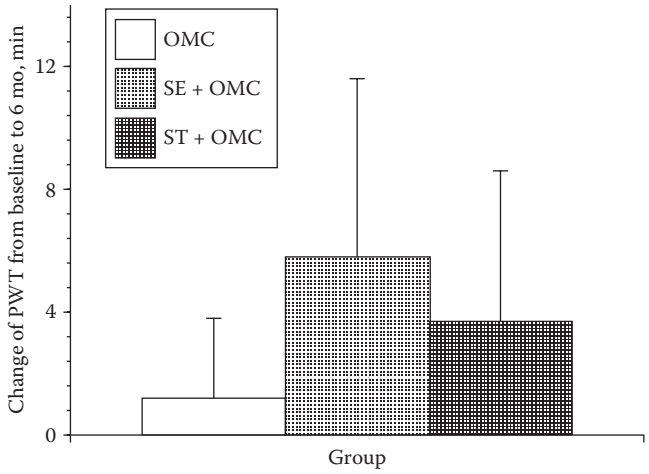

FIGURE 85.1 CLEVER 6 month change in peak walking time in superior treadmill walking performance compared with stent placement and medical care only, even for those with aortoiliac PAD.

arms are as follows: (1) medical care (claudication pharmacotherapy), (2) primary stent placement plus medical care, and (3) supervised exercise rehabilitation plus medical. The outcomes will be evaluated at 6 and 18 months [16]. The 6 month outcomes were recently reported [17], and as shown in Figure 85.1, supervised exercise resulted in superior treadmill walking compared with the stent and medical-care-only groups. Conversely, secondary measures of treatment efficacy favored primary stenting, with greater improvements in self-reported physical function. At the very least, these 6 month results suggest that supervised exercise is a reasonable option for patients compared with stenting and that efforts should be made to encourage exercise and to develop supervised programs that are available and affordable.

Disease-specific quality-of-life measures also improved with both exercise and stenting compared to medical care, with a trend toward greater improvements in self-reported physical function in the stent group. Nevertheless, the CLEVER 6 month results suggest that supervised exercise is a reasonable strategy compared with stenting and that efforts should be made to develop supervised exercise programs that are more readily available and affordable to patients.

Mechanisms for an Exercise Training Effect in Claudication

The specific mechanisms to explain why exercise reduces claudication symptoms is not known but is likely multifactorial. Initial theories proposed that exercise increases collateral vessels via angiogenesis or leads to increased blood flow, but subsequent data on these hypotheses are inconsistent [18–20]. Probable mechanisms for the benefit of exercise training include metabolic adaptations with improved oxygen extraction by the muscle, better walking efficiency from a biomechanical standpoint, and enhanced endothelial function [19–21]. Calf skeletal muscle may increase its oxidative capacity; improvements in exercise have correlated with changes in carnitine metabolism [18].

In addition, the benefits of exercise may not be fully explained by local effects on the lower extremities, as evidenced by a randomized trial in which patients with PAD were assigned to either upper-limb aerobic exercise, lower-limb aerobic exercise, or no exercise for 24 weeks [22]. Similar gains in claudication distance and maximum walking distance were seen in both exercise groups but not among controls, suggesting a systemic benefit of exercise. Furthermore, an increase in exercise pain tolerance was also observed in the exercise groups. A more recent study [23] randomized 41 patients with claudication to 12 weeks of 3 h/week of supervised training using arm ergometry, treadmill walking, or a combination, versus control. The results showed that arm exercise training improved walking capacity compared to controls, and improvement was not different from that seen in response to treadmill walking. Of interest, the combination of arm and treadmill exercise had similar improvements to either modality alone. These data also support a systemic benefit of exercise. Confirmation of these studies in larger studies is needed to provide support for the novel approach of arm exercise as a therapeutic option for PAD patients whose disease severity and claudication limit their ability to perform walking exercise, or who have an aversion to exercise-induced ischemic leg pain that occurs during treadmill exercise training.

Exercise may also attenuate inflammatory responses over the long term and has well-established beneficial effects on cardiovascular risk factors such as hypertension, diabetes, dyslipidemia, and obesity [19,20,24]. A 2009 nonrandomized trial from Japan showed that completion of a 12 week supervised exercise training program reduced both CV morbidity and mortality in patients with PAD [25] though the long-term impact of exercise on these outcomes in PAD patients needs further investigation.

Exercise Prescription

Based on current guidelines, for patients with PAD, supervised exercise is performed three times per week, generally in a cardiovascular rehabilitation or wellness program setting, usually for 12–24 weeks, for 1 h per session. The 60 min exercise session includes a 5 min warm-up and 5 min cooldown period. The initial exercise training intensity is established using a graded treadmill test or a functional evaluation during the initial exercise session and is defined as the treadmill grade (% inclination) that brings on the onset of claudication pain, with the initial speed set at 2.0 mph. The initial pain target should be set at level 2 of 5 on the claudication pain scale (Table 85.1). Some patients may not be able to walk at 2 mph and may need to start at a slower speed and progress as tolerated. Participants are asked to walk to a mild to moderate pain level (3–4 of on a scale of 5), stop and sit down and rest until the claudication pain has completely resolved, and then resume walking.

TABLE 85.1
Claudication Pain Scale

No pain	1
Onset of pain	2
Mild pain	3
Moderate pain	4
Severe pain	5

The initial goal of the early training sessions is to have the participants accumulate 15 min or more of total treadmill time, excluding warm-up and cooldown, with the eventual goal to progress the participant to a cumulative exercise session of 50 min of exercise including warm-up and cooldown periods of 5 min.

Participants walk at a constant work-speed throughout each session without change. The use of the claudication pain scale is an important tool for monitoring symptomatic improvements in exercise performance and resulting increases in exercise intensity. If the participant is able to walk at a workload for 8 min or more before experiencing moderate claudication pain (3–4/5), then the grade is increased by a 1%–2% increment for the following training session. Once a participant is able to walk at a 10% grade for 8 min or more, the speed is increased by 0.1–0.2 mph increments for the following session, up to 3.0 mph. If a participant is able to walk for 8 min or more at 3.0 mph/10% grade, the grade is once more increased by 1%–2% increments for the following training session up to 15% grade (i.e., last increase is 1% increment). This is followed by increases in speed by 0.1–0.2 mph increments for the following training session as tolerated.

It should be noted that in contrast to guidelines for people with coronary disease who experience angina, where cessation of exercise is recommended when pain occurs, patients with PAD should walk to the point of experiencing mild to moderate pain though severe pain should be avoided. Ischemic chest pain is not safe due to the risk of ischemic-induced cardiac arrhythmias whereas this is obviously not a concern when experiencing mild to moderate leg pain. For the IC patient, this level of pain serves as stimulus for the physiological adaptive responses that produces a beneficial training effect [19,20,26]. Table 85.2 shows several other key features of exercise rehabilitation for PAD versus CAD.

TABLE 85.2
PAD versus CAD Exercise Rehabilitation

PAD	CAD
Patients with PAD often remain at the same level of walking impairment for several years	There is often spontaneous recovery after a major cardiac event
Because symptoms remain stable, exercise goals are to relieve symptoms, improve functional capacity, and increase walking ability	Phase II (early) cardiac rehabilitation is more focused on recovery from an acute event and preventing deconditioning
Patients walk to leg pain to stimulate adaptive processes that lead to a training effect	Chest pain during exercise is a contraindication requiring the patient to slow down or stop, or use nitroglycerin

Alternative Modes of Exercise

Treadmill walking is the cornerstone of rehabilitation exercise for patients with IC. There is some evidence that other modalities of aerobic training may also be beneficial in improving symptoms. These modes of exercise may be useful if the patient cannot or will not tolerate walking. Additionally, because these exercises largely avoid leg pain, they may be useful to achieve higher exercise intensity in the presence of IC that markedly limits exercise capacity. These include pole striding [27], pain-free treadmill walking [28], and arm exercise [22,23,29,30]. However, the studies are relatively few and need further study with larger samples to warrant changes in PAD exercise rehabilitation guidelines. Though resistance training has been shown to provide some benefits in terms of functional capacity, the existing data are too limited to support a recommendation that resistance training be considered a primary mode of exercise rehabilitation for reducing claudication symptoms [21]. Thus, as tolerated, resistance training can be done as supplement but not as a substitute for walking minutes each for a total of 60 min per session.

POSTREVASCULARIZATION CONSIDERATIONS

The length of time after surgery until rehabilitation may begin will depend on the procedure and the overall condition of the patient. Generally, patients who have a minimally invasive procedure, such as peripheral angioplasty, will be ready for a rehabilitation program relatively quickly, within a week or 2. Conversely, abdominal aortic surgery carries a much longer recovery period (generally 6–8 weeks). Lower extremity bypass procedure patients may recover more quickly but are limited more by groin and knee incision soreness. Any graft placement that crosses the knee joint requires the avoidance of any prolonged, sharp flexion of the knee joint, which could cause a kink in the graft. The use of a cycle is usually permissible with proper seat height adjustment, but such patients should probably avoid rowing machines.

PROGRAM CONSIDERATIONS

In spite of the numerous studies demonstrating the efficacy of exercise training, several barriers prevent its widespread use. Most notably, supervised exercise rehabilitation is not generally a covered benefit under most health insurance plans including Centers for Medicare and Medicaid Services (CMS), though PAD rehabilitation has had a Current Procedural Terminology code (CPT 93668) since 2001. Of note, the lack of insurance coverage is not due to a lack of efficacy of the rehabilitation but because the exercise workout sessions are typically supervised by exercise physiologists or

nurses, who are not recognized providers by Medicare and other insurance carriers. Though these health care professionals may work directly under the supervision of a physician, Medicare has decided that there is not a sufficient amount of physician work involved to warrant payment. Other barriers to participation include a time commitment and lack of broad availability of PAD exercise rehabilitation centers.

Barriers also exist at the provider level as many clinicians hesitate to refer a high-risk patient with multiple comorbidities to an exercise program. However, that same patient may in fact derive the greatest benefit from exercise. Due to the systemic nature of PAD and the high prevalence of CVD in this population, in many cases, patients with PAD may qualify for cardiac rehabilitation by meeting one of the qualifying criteria for cardiac rehabilitation such as recent myocardial infarction, coronary revascularization, or angina [31]. The decision to refer a patient with PAD to an exercise training program should be individualized and may be affected by medical comorbidities that limit walking ability such as pulmonary or degenerative joint disease. Treadmill exercise is not recommended in patients with foot ulcers or critical limb ischemia.

To address some of the barriers to participation, there have been recent efforts for the development of dedicated exercise rehabilitation programs for PAD and the incorporation of PAD care within existing CR programs to accommodate the patient with both cardiac disease and PAD [32]. In 2010, the American Association of Cardiovascular and Pulmonary Rehabilitation in conjunction with the Vascular Disease Foundation published the P.A.D. Exercise Training Toolkit, A Guide for Health Care Professionals. This toolkit was developed to allow cardiovascular rehabilitation and other health care professionals to work within their communities to improve access to supervised exercise programs for people with IC. The toolkit includes information to implement appropriate and safe supervised exercise programs. It also includes practical tools such as sample brochures plus participant and staff education materials. This toolkit can be found at www.aacvpr.org or www.vdf.org. The toolkit is published in an electronic format (PDF) and will be updated regularly to incorporate the last clinical and scientific updates.

INTRODUCTION

Cardiovascular disease (CVD) is the leading cause of death in both men and women in the United States. According to the most recent Center For Disease Control and Prevention's National Vital Statistics Report, every year approximately 785,000 Americans experience their first myocardial infarct while 470,000 Americans who have already had their first cardiac event will suffer another episode.[1,2] The economic burden and predicted costs of CVD continue to increase with estimates of $444 billion in 2009 to greater than $500 billion in 2010.[2] However, recent trends show an overall decline in death due to CVD (between 1997 and 2007, death due to CVD among men and women ≥65 years of age decreased by 52% in men and 49% in women). This improvement in mortality, while at a significant cost, is due to both aggressive acute reperfusion strategies and intervention for primary and secondary prevention.

Patients who present with acute coronary syndromes (ACSs) face significant CVD risks (including death, heart failure, arrhythmia, stroke, or recurrent ACS) after hospital discharge. According to the Global Registry of Acute Coronary Events (GRACE) study, conducted between 1999 and 2002, those that experienced ST elevation myocardial infarction (STEMI), non-ST elevation myocardial infarction (NSTEMI), or unstable angina had 4.8%, 6.2%, and 3.6% ($p < 0.001$) risk of death, respectively, from discharge to 6 month follow-up, while up to 25% experienced a recurrent CVD event.[3] In this large multinational registry, an increase in 6 month post-discharge mortality was predicted by multiple factors[4] including age, history of heart failure, positive cardiac markers, elevated heart rate, systolic blood pressure, and ST depression at initial presentation. In addition, elevated serum creatinine and need for percutaneous intervention (PCI) during hospitalization were also risk factors for post-discharge mortality. Patients who presented with ACS continued to have an increased risk of mortality in subsequent years after initial ACS event with 14.8% dying at 1 year and 39.2% at 4 years.[5] Furthermore, those that presented with recurrent myocardial infarction (MI) experienced even higher rates of mortality or major CVD event at 1 year.[6] In addition, at age 40 or older, 5 year mortality for patients who have experienced an MI is 33% for men and 43% for women.[2]

Goals for secondary prevention include prevention of death, recurrent MI, revascularization, left-ventricular (LV) dysfunction, and anginal symptoms. The American Heart Association (AHA) and the American College of Cardiology (ACC) have recommended strategies for secondary prevention that target principles of lifestyle and behavior modifications, control of comorbid conditions, appropriate vaccinations, and evidence-based pharmacotherapy.[7] Over the last two decades, significant advances in lipid management, prevention of heart failure, myocardial remodeling, and sudden cardiac death (SCD) have significantly reduced mortality in patients following a CVD event. Blood pressure control, increase in physical activity, weight management, and smoking cessation are also important in secondary prevention.

Despite strong evidence and availability of reasonably priced pharmacologic intervention in secondary prevention, underprescribing and suboptimal adherence continue to be problematic.[8] In a study investigating long-term adherence of the use of medications for secondary prevention, only 71%, 46%, and 43% of patients consistently took aspirin, β-blockers, and lipid-lowering therapy, respectively, and only 21% of patients took the combination of the three drugs.[9] To bridge the gap between evidence-based practice guidelines and physician and patient behavior, the AHA along with other organizations initiated a campaign to address barriers to adherence.[10] Many hospitals have since emphasized quality control measures and guideline adherence in patients admitted for ACS and heart failure. In addition to the public health benefit of implementing such guidelines, economic benefits are also evident. The 2011 Post-Myocardial Infarction Free Rx Event and Economic Evaluation (MI FREEE) Trial found that enhanced prescription coverage improved medication adherence by 4%–6% compared to usual prescription coverage ($p < 0.001$) and decreased rates of first major vascular events (11.0 vs. 12.8; HR, 0.86; 95% CI, 0.74–0.99; $p = 0.03$).[11] Furthermore, enhanced prescription coverage decreased patient spending without increasing overall health care costs (relative spending, 0.74; 95% CI, 0.68–0.80; $p < 0.001$).

This chapter will focus on the impact of medical therapy on cardiovascular secondary prevention and corresponding supportive evidence. Antiplatelet and lipid therapies are highlighted. Appropriate use of β-blockers and angiotensin-converting enzyme (ACE) inhibitors are emphasized. Specific pharmacology and clinical indications are reviewed. Lastly, ineffective therapies are briefly covered.

PATHOPHYSIOLOGY OF ACUTE CORONARY SYNDROMES

ACS is composed of three clinical syndromes:

1. *Unstable angina*: Angina or an angina-equivalent lasting more than 30 min with no evidence of myocardial injury, onset of new angina, or change in stable angina pattern.
2. *NSTEMI*: Prolonged symptoms with no ST-segment elevation on an electrocardiogram in the setting of positive cardiac biomarkers.
3. *STEMI*: Prolonged symptoms with ST elevation ≥1 mm in two contiguous leads (≥2 mm in V_1–V_3 leads), or new left bundle branch block in the setting of positive cardiac biomarkers.

The majority of acute coronary events occur when the surface of an atherosclerotic plaque erodes or ruptures. The process leading up to plaque erosion or rupture begins years earlier with hypertension, hyperlipidemia, tobacco-related toxins, advanced glycosylated end-products, and inflammatory cytokines, all potential factors resulting in endothelial injury. Endothelial injury then permits atherosclerotic plaque formation due to subendothelial low-density lipoprotein accumulation, oxidation, and inflammatory cell accumulation. Atherosclerotic plaques that are vulnerable to rupture or erosion usually have thin fibrous caps and have a higher percentage of inflammatory cells such as monocytes, macrophages, and T-lymphocytes. Plaques that are prone to rupture also usually have a large lipid-rich necrotic core and are found more often in males. Plaques that are prone to erosion often have a missing endothelial cap lining, have less calcification and inflammation, and are more common in women.[12] Rupture or erosion of the fibrous cap then exposes subendothelial contents to the blood, causing a cascade that leads to platelet adherence, aggregation, fibrin deposition, and thrombus formation, with the potential for coronary artery luminal obstruction, resulting in myocardial ischemia or obstruction.

Secondary prevention emphasizes clinical risk stratification, atherothrombosis prevention, plaque stabilization with the potential for reversal, arrhythmia prevention, myocardial oxygen demand reduction, and prevention of adverse myocardial remodeling.

ANTIPLATELET AGENTS

Aspirin

Background

Coronary atherothrombosis occurs when a plaque is disrupted and circulating platelets are exposed to, and activated by, subendothelial plaque contents. Platelet activation then results in an intracellular process that releases thromboxane A_2, serotonin, and adenosine diphosphate (ADP),[13] which induces more platelet activation, aggregation, and thrombosis formation. By stimulating coronary atherothrombosis, platelets play a major role in the development of recurrent ACS. Therefore, preventing platelet activation and aggregation has been a mainstay in secondary CVD prevention, with several pathways in the activation cascade serving as targets.

Pharmacology

Aspirin (acetylsalicylic acid) was first isolated from the bark of the willow tree and has been used for many centuries for its analgesic, anti-inflammatory, and antipyretic effects. It was not until the latter half of the twentieth century that its anti-inflammatory and antiplatelet effects in coronary artery disease (CAD) were discovered. Aspirin works by irreversibly inhibiting cyclooxygenase-1 (COX-1), preventing thromboxane A_2 formation, and thereby reducing platelet activation and aggregation.

Indications for CVD

Aspirin has been shown to decrease CVD events and mortality in those with known CVD. In a randomized trial comparing aspirin to placebo, the administration of 324 mg of aspirin to 1266 men with unstable angina within 48 h of hospital admission reduced rates of death and MI by 51%.[13] A trial conducted in Canada in 555 men and women with unstable angina showed that treatment with 325 mg of aspirin four times daily markedly decreased cardiac death and nonfatal MI over a 2 year follow-up.[14] Another landmark trial comparing aspirin, heparin, or both in patients admitted with unstable angina showed that the use of 325 mg of aspirin twice daily significantly reduced the rate of fatal and nonfatal MI.[15] With increasing evidence in support of the use of aspirin for secondary CVD prevention, a meta-analysis of 16 randomized controlled trials in patients with previous MI, stroke, or transient ischemic attack comparing aspirin to placebo showed an 18% relative risk reduction (RRR) in both serious vascular events* ($p < 0.0001$) and coronary events† ($p < 0.0001$).[16]

Safety

In addition to inhibiting COX-1 intravascularly, aspirin also inhibits COX-1 production of gastric mucosal prostaglandins, increasing the risk of major gastrointestinal bleeding.[17] In a post hoc analysis of the Clopidogrel in Unstable angina to prevent Recurrent ischemic Events (CURE) trial, patients undergoing PCI taking low (≤100 mg), moderate (101–199 mg), and high (≥200 mg) doses of aspirin were followed and risk of major bleeding was evaluated.[18] Comparing the three dose categories, there were no differences in rates of CVD death, MI, or stroke. Risk of bleeding, however, was positively correlated with increasing doses of aspirin (1.9%, 2.8%, and 3.7%, respectively, $p = 0.0001$).[18] In the Clopidogrel and Aspirin Optimal Dose Usage to Reduce

* Myocardial infarction, stroke, or vascular death (coronary heart disease death, stroke death, death from pulmonary embolism and death from any hemorrhage).

† Myocardial infarction, coronary death or sudden death.

Recurrent Events-Seventh Organization to Assess Strategies in Ischemic Syndromes (CURRENT-OASIS 7) trial, patients who were randomized to either high-dose (300–325 mg) or low-dose (75–100 mg) aspirin also did not differ in the primary outcome of CVD death, MI, or stroke at 30 days.[19] Although there was no significant risk in major bleeding, minor bleeding was increased in the high-dose aspirin group.[19] Thus, in patients who have had ACS, low-dose aspirin is better tolerated than high-dose aspirin, with similar efficacy in preventing major CVD events.

Aspirin use can be associated with aspirin-exacerbated respiratory disease (AERD), a clinical syndrome that results in upper and/or lower respiratory reactions, such as rhinitis, laryngospasm, and bronchospasm.[20] COX-1 inhibition results in shunting arachidonic metabolism to leukotriene synthesis and subsequent release of histamine from mast cells.[21] AERD may occur in 0.3%–0.9% of the general population but up to 10%–20% of patients with asthma.[22] In those with adverse reaction to aspirin, monotherapy with a thienopyridine is an acceptable alternate therapy.

Summary

Due to strong evidence supporting the use of aspirin in secondary prevention, the ACC and AHA have placed a class I recommendation with level A evidence for daily use of aspirin to be continued indefinitely for patients with a history of ACS.[23] Higher-dose aspirin (>162 mg) has not been shown to be more efficacious than lower-dose aspirin in preventing recurrent CVD events and may be associated with increased risk of bleeding.

Thienopyridines

Background

Though aspirin is an effective antiplatelet drug, it is not sufficient to completely prevent all coronary atherothrombosis, as there are other pathways of platelet activation. Furthermore, it has been reported that aspirin "resistance," defined as the lack of an expected decrease in platelet activity with aspirin therapy, can be as high as 65% in the general population, and that 39% of these patients can experience a CVD event despite appropriate therapy.[24] Additional therapy with a thienopyridine (ticlopidine, clopidogrel, or prasugrel), a class of antiplatelet agents that inhibit ADP-mediated platelet activation, results in additional atherothrombosis prevention.

Pharmacology

ADP activates platelets via the P2Y12 receptors, inducing several intra-platelet pathways that increase glycoprotein IIb–IIIa complex and fibrinogen binding, amplifying platelet aggregation.[25] Thienopyridines such as ticlopidine, clopidogrel, and prasugrel irreversibly bind to the P2Y12 receptor, inhibiting ADP-related platelet activation.

Clopidogrel and prasugrel are prodrugs that require hepatic activation. Clopidogrel is initially hydrolyzed to an inactive form by esterases, leaving only 15% to undergo oxidative activation by a two-step cytochrome P-450 enzyme (CYP)-dependent processes using CYP3A4, CYP1A2, CYP2B6, and CYP2C19.[26] Prasugrel is activated in a single-step cytochrome P-450-dependent process, using CYP2B6 and CYP3A4, with less CYP2C19 involvement.[27,28] Prasugrel's simpler cytochrome P-450-dependent activation process results in more potent and predictable antiplatelet response with lower loading and maintenance doses required (60 mg loading dose vs. 300 or 600 mg of clopidogrel).[27] In one study, a prasugrel loading dose of 60 mg and maintenance dose of 10 mg caused greater platelet inhibition than a clopidogrel loading dose of 600 mg and maintenance dose of 150 mg.[29]

Indication in CVD

Clopidogrel as Monotherapy

In the Clopidogrel and Aspirin in Patients at Risk of Ischemic Events (CAPRIE) study, clopidogrel as monotherapy was found to be more effective than aspirin as monotherapy for secondary prevention in patients presenting with recent ischemic stroke or MI (RRR of 8.7%, $p = 0.043$).[30] It was also shown that severe bleeding, particularly gastrointestinal bleeding, was more common in patients treated with aspirin than in those taking clopidogrel, suggesting a safer bleeding profile for clopidogrel.[30]

Clopidogrel in ACS

While effective as monotherapy, clopidogrel's main role has been in combination with aspirin therapy, a strategy known as dual antiplatelet therapy (DAPT). In CURE trial, 12,562 patients who presented with non-STEMI or unstable angina were randomized to either clopidogrel or placebo, with all patients receiving aspirin.[31] The addition of clopidogrel to aspirin therapy was notable for a significant decrease in all endpoints (cardiovascular death, MI, stroke) as compared to aspirin alone.[31] The same decrease in major endpoints was found irrespective of whether patients with ACS were treated with PCI, coronary artery bypass grafting (CABG), or medical therapy alone.[32] The efficacy of clopidogrel was also confirmed in patients presenting with STEMI in the Clopidogrel as Adjunctive Reperfusion Therapy-Thrombolysis in Myocardial Infarction 28 (CLARITY-TIMI 28) study.[33] The addition of clopidogrel to aspirin in patients presenting with STEMI resulted in a 36% ($p = 0.03$) RRR in the odds of death or recurrent MI as compared to aspirin alone.[33] This strong evidence supports the premise that patients who present with ACS should be treated with DAPT as compared to aspirin alone. However, despite this strong evidence, DAPT is underused, particularly in those who receive medical therapy without PCI or surgical revascularization.[34]

Clopidogrel in Patients without ACS

While strong evidence for the benefit of DAPT has been shown in patients with ACS and in those undergoing percutaneous revascularization, the broader population of patients with stable CVD or who are at high risk for CVD (i.e., those with multiple CVD risk factors, such as diabetes (type I or II), diabetic nephropathy, ankle-brachial index <0.9,

asymptomatic carotid artery stenosis, age, tobacco use, hypertension, and hyperlipidemia) have not been shown to have the same benefit with the use of DAPT.[35] In the Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance (CHARISMA) trial, 15,603 patients with multiple CVD risk factors (asymptomatic) or established stable CVD (symptomatic) were enrolled and randomized to treatment with clopidogrel or placebo, in combination with aspirin. It was found that DAPT was not significantly more effective than aspirin alone in reducing the rate of MI, stroke, or death. In subgroup analysis, DAPT was found to possibly be associated with increased risk of mortality in patients who are "asymptomatic."[35] However, there was a slight but significant reduction in ischemic events in patients who were "symptomatic."[35]

Dosing and Length of Treatment with Clopidogrel

To achieve maximal platelet inhibition in patients with ACS without increasing the risk of bleeding, adequate dosing and optimal length of treatment are necessary. In CURRENT-OASIS 7, while there was no difference in the primary outcome of CVD death, MI, or stroke (4.2% in patients taking 150 mg vs. 4.4% in those taking 75 mg, HR, 0.94; CI, 0.83–1.06; p = 0.3), there was an increased risk of minor bleeding in the patients taking the higher dose (HR 1.13, p = 0.04).[19] Furthermore, the CURE trial, which showed benefit of DAPT in NSTE-ACS, evaluated up to a year of clopidogrel treatment. Therefore, current AHA/ACC recommendations are for continued DAPT with clopidogrel at doses of 75 mg daily for 1 year post-ACS. A more recent trial investigating a longer duration of DAPT in patients who had received drug-eluting stents, many for ACS, did not show any additional benefit to longer durations of clopidogrel plus aspirin versus aspirin alone.[36]

Clopidogrel and Proton Pump Inhibitors

Treatment with DAPT incurs a significant risk of gastrointestinal bleeding.[37] Clinical decision to continue antiplatelet agents is often difficult in patients who have CVD and an increased risk of gastrointestinal bleeding. In a small retrospective study, approximately 4.5% and 9.2% of patients on DAPT experienced a gastrointestinal bleeding complication in 1 and 2 years, respectively.[38] Therefore, prophylactic use of proton pump inhibitors (PPIs) has been used to prevent gastrointestinal bleeding. However, PPIs are prodrugs that also require cytochrome P450 metabolism, potentially causing competitive inhibition of clopidogrel activation.[39]

Omeprazole, one of the most commonly used PPIs, has been shown to have a higher degree of affinity for the CYP2C19 system.[39] A randomized trial, Omeprazole Clopidogrel and Aspirin (OCLA) Study, showed that patients undergoing PCI followed by treatment with DAPT plus omeprazole had significantly decreased platelet inhibition compared to those receiving DAPT plus placebo.[40] A post hoc analysis of a randomized controlled trial evaluation of different DAPT regimens demonstrated a lower inhibition of platelet aggregation in the group taking clopidogrel plus a PPI (predominantly omeprazole).[29] A large retrospective study of patients with ACS found that use of clopidogrel with a PPI (predominantly omeprazole) at discharge or at any time during a 3 year follow-up was associated with a higher risk of death or rehospitalization for ACS.[41] Therefore, these data suggested that, due to the biochemical pathway of omeprazole metabolism, its use can potentially attenuate clopidogrel antiplatelet activity, resulting in an increased risk of adverse ischemic clinical events.

However, the only randomized controlled trial comparing DAPT with and without omeprazole, the Clopidogrel and Optimization of Gastrointestinal Events (COGENT) trial, did not support these other findings. In COGENT, 3873 patients taking DAPT were randomized to omeprazole or placebo.[42] The rates of upper GI bleeding were less in subjects using PPI and DAPT (1.1% with omeprazole vs. 2.9% with placebo, $p < 0.001$) with no observed increase in CVD events. Furthermore, other PPIs may have different cytochrome P450 interaction profiles, with it being suggested that omeprazole is more likely associated with competitive and attenuating effects on clopidogrel metabolism as compared to pantoprazole or esomeprazole.[43] In a cross-sectional observational study, platelet activity was significantly higher in patients taking clopidogrel with omeprazole compared to patients taking clopidogrel with pantoprazole or esomeprazole.[43] In a head-to-head comparison of omeprazole and pantoprazole, the use of pantoprazole was associated with significantly better clopidogrel-induced platelet inhibition.[44] In another study, patients who were taking clopidogrel without PPIs had the same amount of platelet activity as those taking clopidogrel with pantoprazole or esomeprazole.[45] Therefore, concurrent use of a PPI, particularly one other than omeprazole, may be reasonable in patients taking clopidogrel when gastrointestinal bleeding risk is high or when PPIs are indicated for other conditions.

Genetic Polymorphisms and Clopidogrel Hyporesponsiveness

The genes encoding these cytochrome P450 enzymes have several polymorphisms, resulting in significant variability in enzyme activity.[46] CYP2C19 is one of these enzymes that has a relatively high prevalence of reduced-function alleles.[46] The presence of these reduced-function CYP2C19 variants in patients have been shown to result in slowed clopidogrel activation and more inactivation by esterases, reduced platelet inhibition in vivo, and an increase in the risk of CVD death, MI, stroke, and stent thrombosis.[47,48] In addition, platelet hyporesponsiveness to clopidogrel in general (whatever the cause) as measured by platelet function assays (such as light transmission aggregometry, vasodilator-stimulated phosphoprotein (VASP), and point-of-care assays such as VerifyNow and Plateletworks) have been shown to be associated with increased risk of adverse CVD events.

Unfortunately, effective strategies to overcome such clopidogrel hyporesponsiveness have not yet been demonstrated. In the Gauging Responsiveness with A VerifyNow

Assay—Impact on Thrombosis And Safety (GRAVITAS) trial, treatment with high-dose (150 mg) clopidogrel versus standard-dose (75 mg) therapy in patients with high on-treatment platelet reactivity did not show a significant difference in reduction in the rate of death, MI, or stent thrombosis.[49] Currently, other randomized trials using CYP2C19 genetic polymorphism assays and various platelet function assays to determine clopidogrel resistance are under way.[50]

Prasugrel

DAPT using clopidogrel has been established as the standard of care in ACS patients. Prasugrel was compared to clopidogrel in the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel-Thrombolysis in Myocardial Infarction 38 (TRITON-TIMI 38) study, in which 13,608 patients presenting with ACS and undergoing PCI on aspirin were randomized to prasugrel or clopidogrel. Those treated with prasugrel showed a 19% RRR in death from CVD causes, nonfatal MI, or nonfatal stroke (2.1% vs. 2.4%; HR, 0.81; CI, 0.73–0.9, $p < 0.001$) compared to patients treated with clopidogrel.[29] Similar clinical benefit was seen in urgent revascularization and stent thrombosis.[29] In addition, the use of prasugrel showed significant superior efficacy in certain subgroups, such as in those with diabetes and past MI.[29] However, patients taking prasugrel had a 32% relative risk increase in bleeding events compared with clopidogrel (2.4% vs. 1.8%; HR, 1.32; CI, 1.03–1.68; $p = 0.03$).[29] Post hoc analysis demonstrated that patients >75 years of age, patients weighing <60 kg, and those with a history of transient ischemic attack or stroke incurred particularly unfavorable risk versus benefit balances.[29] Though no difference in all-cause mortality was seen between prasugrel and clopidogrel treatment groups, this trial was not powered for mortality.

Currently, prasugrel is approved for use in patients presenting with ACS and undergoing PCI. However, the Targeted Platelet Inhibition to Clarify the Optimal Strategy to Medically Manage Acute Coronary Syndromes (TRILOGY-ACS) trial is currently evaluating the efficacy of DAPT with prasugrel in comparison to clopidogrel in patients undergoing medical management of their ACS.[51]

Non-Thienopyridine P2Y12 Receptor Antagonists (Ticagrelor)

Pharmacology

Like the thienopyridines, ticagrelor inhibits the P2Y12 platelet receptor. However, unlike the thienopyridines, ticagrelor does not require hepatic metabolism to be activated.[52] In addition, ticagrelor binds reversibly to P2Y12 receptors, allowing for possible faster reversal of platelet inhibition in patients at risk for bleeding complications.[52]

Indications in Coronary Artery Disease and ACS

In the Platelet Inhibition and Patient Outcomes (PLATO) trial, ticagrelor or clopidogrel in combination with aspirin was compared in 18,624 ACS patients. Ticagrelor use significantly decreased the relative risk of the primary endpoint, a composite of all-cause death from CVD causes, MI, and stroke, by 16% (9.8% vs. 11.7%; HR, 0.84; CI, 0.77–0.92; $p < 0.001$) and was associated with a decrease in other secondary endpoints, such as death from any cause, death from CVD cause, MI, and stent thrombosis.[53] Ticagrelor was not associated with higher risk of major bleeding, overall; however, it was associated with higher risk of non-procedure-related bleeding and some adverse reactions, such as dyspnea and asymptomatic ventricular pauses. With recent approval by the FDA, ticagrelor shows promise as an alternative reversible therapeutic option to the thienopyridines.

Summary

DAPT, using aspirin and a P2Y12 receptor antagonist for 1 year after ACS, is the standard of care for patients. Clopidogrel has been the most thoroughly studied of the P2Y12 receptor antagonists and has the most clinical experience behind it. The relatively recent introduction of other P2Y12 receptor antagonists (prasugrel and ticagrelor) with superior CVD event reduction and different risk and side effect profiles than clopidogrel has highlighted the need for careful consideration of their use in place of clopidogrel and continued investigation into the selection of the most appropriate agent.

LIPID-LOWERING THERAPY

HMG-CoA Reductase Inhibitors (Statins)

Background

Elevated serum cholesterol has been established as one of the most important risk factors for the development of coronary atherosclerosis and has become a crucial treatment target of both primary and secondary prevention of cardiovascular events.[54] Secondary prevention trials had demonstrated the importance of cholesterol lowering, even prior to the routine use of HMG-CoA reductase inhibitors.

Data from both the Framingham Heart Study and the cohort in The Multiple Risk Factor Intervention Trial (MRFIT) indicate a direct relationship between total cholesterol levels and rates of CAD, beginning with total serum cholesterol levels as low as 180 mg/dL and indicating a nearly fourfold increase in the top 10% versus the bottom 10% of observed values. The observations of the Framingham study and the Lipid Research Clinics Coronary Primary Prevention Trial (CPPT) indicate an approximate 2% reduction in coronary events for every 1% reduction in serum cholesterol.[54–56]

Pharmacology

The first statin, mevastatin (compactin), was isolated in 1972 from the bacterium *Penicillium citrinum,* along with other similar but less active compounds. Lovastatin was later isolated from *Aspergillus terreus*, representing the first statin to demonstrate reduction of LDL in human subjects.[57–59] Subsequently, multiple other agents with varying potencies

and pharmacokinetic/pharmacodynamic properties have been developed, including pravastatin, simvastatin, fluvastatin, atorvastatin, rosuvastatin, and pitavastatin.

HMG-CoA reductase inhibitors (statins) target the rate-limiting step of in vivo cholesterol synthesis, dependent on the enzyme HMG-CoA reductase, the majority of which takes place in the liver and to a lesser extent in the intestine. Statins reduce serum LDL by reducing hepatic LDL synthesis and increasing the expression of LDL receptors via promotion of mRNA formation.[59]

Conventional doses of statins reduce LDL by 18%–41%, varying widely with an individual's metabolic idiosyncrasies and variable CYP3A4-mediated first-pass metabolism of some agents. This feature of drug metabolism becomes important in considering drug interactions of various agents, notably simvastatin and lovastatin. Fluvastatin and pravastatin are not significantly metabolized by the CYP3A4 system, although fluvastatin undergoes extensive CYP2C9 biotransformation.[60] The dose–response curves of these agents are flat, and doubling doses of these medications has been reported to offer an additional reduction in LDL of approximately 6% over initial reductions.[61] A recent meta-analysis of 32,258 pooled subjects confirmed this magnitude of reduction with increasing doses, reporting an additional reduction of 4%–7% with doubling baseline doses of atorvastatin, simvastatin, or rosuvastatin. A majority of patients were able to meet NCEP goals for risk-based LDL cholesterol reduction when doses were escalated as indicated over a wide range of initial LDL levels.[62]

Indications for Secondary Prevention of Coronary Artery Disease

In addition to the establishment of LDL cholesterol as a marker of CAD, multiple large randomized controlled secondary prevention trials have demonstrated a reduction in cardiovascular events and total mortality with statins.

Reduction of Cardiovascular Events and Mortality

Several large trials have shown the benefit of HMG-CoA reductase inhibitors in secondary prevention during both long- and short-term follow-up. While most studies included patients less than 70 years of age, one study focused on patients 70–82 years of age, implicating the importance of HMG-CoA reductase inhibitors in all groups with CAD or significant risk factors (Table 86.1).

The Cholesterol and Recurrent Events Trial (CARE) enrolled 4159 subjects with acute myocardial infarction (AMI) in the previous 3–20 months, ages 21–75, plasma total cholesterol levels of <240 mg/dL, or LDL cholesterol levels of 115–174 mg/dL. Subjects were randomized to pravastatin 40 mg daily versus placebo with a median follow-up of 5.0 years. The pravastatin group experienced a 24% RRR in fatal coronary events or nonfatal MI, a 26% relative reduction in need for coronary artery bypass surgery, and 23% RRR in need for coronary angioplasty. The frequency of stroke was reduced by 31%. This study did not detect any significant difference in overall mortality or mortality from noncardiovascular causes. There was a greater decrease in the rate of coronary events among women compared to men, who comprised 13.8% of the study population, and individuals with the highest baseline LDL levels experienced the greatest benefit.[63]

In the Scandinavian Simvastatin Survival Study (4S), 4444 subjects (both male and female, ages 35–70) with a history of angina or AMI who were on a lipid-lowering diet were randomized to simvastatin versus placebo over a median 5.4 year follow-up period. Doses were initiated at 20 mg daily and titrated to achieve goal serum total cholesterol of 5.5–8.0 mmol/L over a range of 10–40 mg of simvastatin daily. In the simvastatin group, the relative risk of death was 0.7 ($p = 0.0003$), relative risk of coronary death was 0.58, and the relative risk of major cardiovascular events was 0.66. In addition, there was an observed 37% risk reduction in need for revascularization procedures. This benefit was shown consistently in subgroup analyses based on gender and age greater than 60.[64]

Another large double-blind randomized trial, the Long-Term Intervention with Pravastatin Ischaemic Disease (LIPID) Study, compared the effects of pravastatin 40 mg daily with placebo in 9014 individuals 31–75 years of age with a history of AMI or unstable angina and plasma total cholesterol of 155–271 mg/dL. All subjects were on lipid-lowering diets at baseline. During the 6.1 year follow-up period, there was a 24% RRR in death from coronary disease in the pravastatin group versus placebo (6.4% vs. 8.3% respectively, $p < 0.001$). A 22% reduction in overall mortality was observed in the pravastatin group versus placebo, as well as all other cardiovascular outcomes, including MI (29% RRR), stroke (19% RRR), and need for coronary revascularization (20% RRR).[65] These outcomes were consistent with the results of the 4S and CARE trials, confirming the long-term benefit of lipid reduction with HMG-CoA reductase inhibitors in the secondary prevention of coronary events.

The shorter term effects of HMG-CoA reductase inhibitors were investigated in the Lescol in Severe Atherosclerosis (LiSA) trial. In the trial, 365 subjects, ages 40–70 years, with stable, symptomatic CAD were enrolled with a follow-up period of 1 year. Subjects were randomized to receive fluvastatin 40 mg twice daily versus placebo. The fluvastatin group had a cardiac event rate of 1.6% vs. 5.6% in the placebo group, a statistically significant difference ($p < 0.05$). Subjects in the fluvastatin group also experienced improved exercise tolerance, greater reduction in the incidence of angina pectoris episodes (although not statistically significant), and decrease in exercise-ECG discontinuation due to angina pectoris and ST-segment depression (also not statistically significant). A subgroup of 76 patients with mean carotid intima–media thickness (CIMT) value of 0.73 mm remained unchanged over this 1 year study period.[66] The results of this study suggested that the HMG-CoA reductase inhibitors provide benefit soon after initiation with regard to altering the natural history of stable CAD.

Given the efficacy and tolerability demonstrated in the earlier studies in patients <70 years of age, the question

TABLE 86.1
Key Trials of HMG-CoA Reductase Inhibitors in Secondary Prevention of Cardiovascular Disease

Title	Study Drugs	Number of Subjects	Subjects' Characteristics	Follow-Up	Findings and Comments
Cholesterol and Recurrent Events (CARE)	Pravastatin 40 mg daily vs. placebo	4159	21–75 years of age AMI in prior 3–20 months TC <240 mg/dL LDL-C: 115–174 mg/dL	5.0 years	24% RRR in fatal coronary events or nonfatal myocardial infarction 26% RRR in need for coronary artery bypass 23% RRR in percutaneous coronary intervention 31% reduction in frequency of stroke
Scandinavian Simvastatin Survival Study (4S)	Simvastatin 10–40 mg vs. placebo	4444	35–70 years of age History of angina or AMI Lipid-lowering diet	5.4 years	RR of death was 0.7 (p = 0.0003) RR of coronary death was 0.58 RR of major cardiovascular events was 0.66 37% RRR in need for revascularization
Long Term Intervention with Pravastatin Ischaemic Disease (LIPID)	Pravastatin 40 mg daily vs. placebo	9014	31–75 years of age History of AMI or unstable angina TC: 155–271 mg/dL Lipid-lowering diet	6.1 years	24% RRR in death from CAD (p < 0.001) 22% RRR in overall Reduction in death from: myocardial infarction (29% RRR) Stroke (19% RRR) 20% RRR in need for coronary revascularization
Lescol in Severe Atherosclerosis (LiSA)	Fluvastatin 40 mg twice daily vs. placebo	365	Ages 40–70 years, with stable, symptomatic CAD	1.0 years	ARR in cardiac event rate of 4% (p < 0.05) Improved exercise tolerance
Pravastatin in elderly individuals at risk of vascular disease (PROSPER):	Pravastatin 40 mg daily vs. placebo	5804	70–82 years of age Smoking, hypertension, or diabetes mellitus	3.2 years	24% reduction in cardiovascular mortality No difference in adverse outcomes Statins safe and effective in elderly patients with CAD or significant risk factors
Intensive versus Moderate Lipid Lowering with Statins after Acute Coronary Syndromes (PROVE-IT)	Pravastatin 40 mg daily vs. Atorvastatin 80 mg daily	4162	AMI within the preceding 10 days	24 months	Greater magnitude of LDL-C reduction with intensive therapy 16% reduction in combined endpoint of all-cause mortality, AMI, unstable angina, revascularization, and stroke (p = 0.005) Benefit in intensive lipid-lowering therapy to a goal LDL of less than 70 mg/dL post-ACS
Effect of Very High-Intensity Statin Therapy on Regression of Coronary Atherosclerosis (ASTEROID)	Rosuvastatin 40 mg daily	507	Baseline IVUS performed	24 months	Statistically significant plaque reduction Limited by lack of control group High rate of drug discontinuation (63 subjects) due to adverse effects

ARR, absolute risk reduction; RRR, relative risk reduction; RR, relative risk.

of benefit and safety in older patients was examined in the pravastatin treatment in elderly individuals, 70–82 years of age, at risk of vascular disease (PROSPER trial). This study enrolled 5804 subjects, both male and female with CVD or risk factors, defined as the presence of smoking, hypertension, or diabetes mellitus, who were randomized to treatment with pravastatin 40 mg daily versus placebo. Over the 3.2 year follow-up period, there was a 24% reduction in cardiovascular mortality in the pravastatin group, consistent with reductions seen in previous trials with younger subjects. In addition, there was no difference between the pravastatin in adverse outcomes, including myalgia and rhabdomyolysis, indicative of both safety and efficacy in elderly patients with CAD or significant risk factors.[67]

The hypothesis that additional benefit is seen with more intensive reduction in LDL post-MI was evaluated in the PROVE-IT trial. A total of 4162 patients hospitalized with AMI within the preceding 10 days were randomized to standard treatment with pravastatin 40 mg daily or intensive treatment with atorvastatin 80 mg daily with a median follow-up of 24 months. The composite primary endpoint in this trial included death from any cause, MI, documented unstable angina requiring rehospitalization, revascularization (performed at least 30 days after randomization), and stroke. The median LDL cholesterol level was 95 mg/dL in the standard-dose pravastatin group and 62 mg/dL in the high-dose atorvastatin group ($p < 0.001$). Over the 18–36 month follow-up period, the rates of the primary endpoint at 2 years were 26.3% in the pravastatin group and 22.4% in the atorvastatin group, indicating a 16% reduction in the hazard ratio (HR) for the composite primary endpoint ($p = 0.005$; 95% CI, 5%–26%). These findings support intensive lipid-lowering therapy to a goal LDL of less than 70 mg/dL post-ACS. This is reflected in the most recent NCEP guideline update for lipid management.[181,82]

Regression of Atherosclerotic Plaque

Clinically, intensive reduction in serum cholesterol levels with HMG-CoA reductase inhibitors may promote regression of atherosclerosis as assessed by coronary intravascular ultrasound (IVUS). The Effect of Very High-Intensity Statin Therapy on Regression of Coronary Atherosclerosis (ASTEROID) Trial enrolled 507 patients who underwent baseline IVUS studies, 349 of which had evaluable follow-up studies performed at 24 months. All patients were treated with rosuvastatin 40 mg daily, although 63 patients withdrew during the study period due to adverse events. The majority of lesions assessed demonstrated statistically significant regression of percent atheroma volume (PAV) for the entire vessel of −0.98% (97.5% CI, −1.21% to −0.53%). The mean change in atheroma volume in the most diseased 10 mm subsegment of coronary arteries was −6.1 mm^3 (97.5% CI, −6.8 to −4.0 mm^3). The major limitation of this study was the lack of a placebo group due to the ethical concerns of assigning high-risk patients to placebo. However, knowing the pathophysiology and natural history of CAD, it is unlikely that spontaneous plaque regression would have occurred without intensive lipid-lowering therapy.[68]

Pleiotropic Effects

The observation that patients treated with statins have less cardiovascular events than placebo-controlled individuals with similar serum lipid levels, as well as the early benefit of these agents, raises the possibility of beneficial effects mediated via mechanisms other than lipid reduction.[63,69] These include inhibition of vascular smooth muscle proliferation, improvement of vascular endothelial function, and perhaps antioxidant and anti-inflammatory effects.[70–72]

A recent small study demonstrated improvement of endothelial function in 41 hypercholesterolemic subjects with LDL >130 mg/dL and mean age 52 years who were randomized to treatment with atorvastatin or cerivastatin. Endothelium-dependent vasodilatation was assessed by upper extremity plethysmography after infusion of acetylcholine at 3 and 14 days of treatment. There was an observed 46% improvement in endothelium-dependent vasodilatation after 3 days of statin treatment with no further benefit at 14 days. This was in contrast to reduction of LDL by 11.9% at 3 days and 29.6% at 14 days, indicating a mechanism of this observed improvement of vascular function independent of lipid-lowering effects.[73]

The anti-inflammatory effects of HMG-CoA reductase inhibitors have been evaluated in the Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin (JUPITER) trial of 17,802 healthy men and women with LDL less than 130 mg/dL and C-reactive protein (CRP) levels of 2 mg/L or higher. Patients were randomized to rosuvastatin 20 mg daily or placebo for a median 1.9 year follow-up (5 years maximum) and followed for the occurrence of the combined vascular endpoint inclusive of MI, stroke, arterial revascularization, hospitalization for unstable angina, or death from cardiovascular causes. The rosuvastatin group experienced a reduction in LDL cholesterol levels of 50% and CRP levels of 37%. The HR for the primary endpoint in the rosuvastatin group was 0.56 (95% CI, 0.46–0.69; $p < 0.00001$); 0.46 for acute MI (95% CI, 0.30–0.70; $p = 0.0002$); 0.52 for stroke (95% CI, 0.34–0.79; $p = 0.002$); 0.52 for revascularization or unstable angina (95% CI, 0.40–0.70; $p < 0.000010$); 0.53 for the combined endpoint of MI, stroke, or death from cardiovascular causes (95% CI, 0.40–0.69; $p < 0.00001$); and 0.80 for death from any cause (95% CI, 0.67–0.97; $p = 0.02$). Importantly, the rosuvastatin group did not have a significant increase in myopathy or cancer.[74]

Statin-Associated Myopathy and Management of Intolerant Patients

Consideration of the individual pharmacokinetic properties of various HMG-CoA reductase inhibitors are of importance when initiating, titrating, or otherwise altering therapy (Table 86.2). This is particularly true of CYP3A4-mediated interactions with other medications the patient may be concurrently receiving. Coadministration of commonly prescribed antibiotics including macrolides, cardiovascular drugs including diltiazem and verapamil, and azole antifungals among many others can significantly increase serum levels of HMG-CoA reductase inhibitors with resulting dose-related adverse effects, particularly myopathy (Table 86.2).[60]

When statins are used as monotherapy, the most significant limiting side effect is the development of myalgias. In most cases, this occurs in the absence of clinically detectable myositis or elevation in serum markers of muscle injury. Rhabdomyolysis, defined as serum CPK >10 times the upper limit of normal, is a rare but serious adverse event. The incidence of clinically significant myalgias has been reported to be as high as 10% in observational studies, although the incidence in clinical trials has been

exceedingly low, likely because of bias against enrollment of individuals with a history of myalgias in such trials. Subclinical myalgias remain a common reason for discontinuation of HMG-CoA reductase inhibitors in patients who may derive important benefit from their use. The mechanism of development of myopathy remains unclear, but proposed mechanisms include depletion of cellular cholesterol resulting in membrane instability, coenzyme Q10 (CoQ10) depletion, isoprenoid depletion, and mitochondrial dysfunction. However, none of these mechanisms have been consistently linked to development of myopathy in symptomatic or asymptomatic patients.[75] Coadministration of other drugs is another common reason for alterations in serum levels of statins that may increase the risk for statin-induced myopathy (Table 86.3).

Strategies for management of statin-intolerant patients remain a significant challenge in current practice, particularly since non-statin agents or combinations of non-statin agents have not shown comparable efficacy in reduction of serum lipid levels and corresponding cardiovascular events. Individual patients may tolerate some statins better than others for unclear reasons, and switching to another HMG-CoA reductase inhibitor is an appropriate initial step, particularly for patients who have no biochemical evidence of myositis.[76]

Alternate-day dosing of HMG-CoA reductase inhibitors has also demonstrated efficacy and tolerability in small studies, particularly with atorvastatin and rosuvastatin, although thus far available data have focused only on the effect on lipid levels and not on the incidence of cardiovascular outcomes.[77–79]

Summary

HMG-CoA reductase inhibitors are among the most important interventions in patients with known CVD regardless of age or gender. Benefits have been seen over a wide range of baseline serum lipids with cardiovascular and survival benefits related to LDL reduction. In addition, these agents may have vascular and systemic benefits that are distinct from their ability to reduce atherogenic serum lipid levels.

The AHA/ACC Guidelines recommend treatment of all post-ACS patients with LDL-C of 100 mg/dL or above (class I/LOE A) and LDL-C levels of less than 100 mg/dL or unknown lipid levels (class I/LOA B) with statins as primary agents for lipid therapy.[23] Treatment goals generally target LDL-C less than 100 mg/dL, but in patients with high cardiovascular risk, an LDL-C target of less than 70 mg/dL may be considered.[80,81]

Omega-3 PUFA

The Mediterranean region, along with Japan and Greenland, has a lower prevalence of atherosclerotic heart disease than other Western countries.[82,83] One proposed mechanism for this finding is the high intake of omega-3 polyunsaturated fatty acids (PUFAs) in these regions. There have been multiple epidemiologic studies showing a correlation between the intake of omega-3 PUFAs and the decreased incidence of CVD. The exact mechanism by which this occurs is unclear, but available evidence has demonstrated a reduction in risk of MI and SCD.

Pharmacology

The majority of studies involving omega-3 PUFA have focused on eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). These two types of omega-3 PUFA play different roles in improving the lipid profile and decreasing inflammation and oxidative stress.[84] Benefits seen in the incidence of SCD, arrhythmia, hypertension, and heart failure all likely involve very different mechanisms. These potential mechanisms include the following[85]:

1. Effects related to the metabolism of omega-3 PUFA on cellular mediators
2. Direct effects on ion channels
3. Effects on genetic expression of proteins important for lipid metabolism
4. Effects related to incorporation of omega-3 PUFA into cellular membranes

EPA has been shown to compete with arachidonic acid for COX-1 conversion to eicosanoids having anti-inflammatory, vasodilatory, and antiplatelet actions.[84] Alternatively, DHA is converted to cellular mediators that have known anti-inflammatory and antioxidant effects.[84,85] Omega-3 PUFAs also may have direct effects on ion channels in addition to being incorporated into cellular membranes of the heart, vessel walls, and the nervous system, which may modify responses to extracellular signaling.[85,86]

Indications in Optimizing Lipid Profile

Omega-3 PUFAs have been shown to decrease serum triglyceride levels through regulation of genetic expression of proteins controlling hepatic triglyceride metabolism.[87] High doses of at least 3 g and often greater than 6 g of DHA and EPA per day are necessary to achieve significant triglyceride-lowering effects. To date, there have been no large outcome-based randomized trials using omega-3 PUFA in patients with hypertriglyceridemia; therefore, it is not known whether using omega-3 PUFA in this manner has any benefit on clinical event reduction. While the triglyceride-lowering effects of omega-3 PUFA therapy can be potent, the effects on other lipid parameters are more modest with only a slight increase in both LDL-C and high-density cholesterol (HDL-C). There are both prescription and nonprescription omega-3 PUFAs available with the prescription formulation being the most highly concentrated.

Indications in CVD

The consumption of omega-3 PUFA has been shown in prospective and retrospective cohort and case–control studies to decrease major cardiovascular events, such as MI, SCD, atrial fibrillation, and death in individuals with chronic heart failure.[88–91] Several RCTs have demonstrated cardiovascular benefits with omega-3 PUFAs. In the Diet and Reinfarction Trial (DART), dietary advice to increase fatty fish demonstrated a 29% reduction in all-cause mortality over a 2 year follow-up, as well as a nonsignificant difference in nonfatal CVD events.[92] The GISSI Prevenzione trial was notable for a reduction in the risk of death, nonfatal MI, and nonfatal stroke by 15% (12.3% vs. 14.6%; RR, 0.85; 95% CI, 0.74–0.98; p = 0.023) in patients treated with 850 mg daily of omega-3 PUFA.[93] Significant reductions in CVD mortality, coronary mortality, and coronary events were also seen. The Japan EPA Lipid Intervention Study (JELIS) randomized patients with hyperlipidemia to receive either 1800 mg of EPA plus statin or statin alone. This trial demonstrated a significant 19% risk reduction of the cumulative rate of major CVD events, including SCD, fatal, and nonfatal MI compared to patients taking statin alone (2.8% vs. 3.5%; p = 0.011). There were also significant reductions in nonfatal events, such as unstable angina, angioplasty, or CABG.[94] In the GISSI-Prevenzione Heart Failure trial, there was a modest reduction in all-cause mortality in patients with heart failure who had been randomized to 1 g of omega-3 PUFA daily (HR, 0.9; CI, 0.833–0.998; p = 0.41) and CVD death (HR, 0.9; CI, 0.81–0.99; p = 0.045).[95] The exact mechanism for this benefit was unclear but is thought to be primarily due to reduction in arrhythmias as opposed to MI.

Although many trials have shown reduction in CVD risk with omega-3 PUFA use, not all have shown clinical benefit. In one large multicenter RCT, supplementing with 600 mg of EPA and DHA daily was not associated with any significant effects on major vascular events and all-cause mortality.[96] In another study designed to change dietary habits in 3114 male patients with stable angina, those advised to eat at least two portions of fatty fish a week or 3 g of fish oil supplement had no significant improvement in mortality and had a significantly higher mortality from cardiac and sudden death than those not advised.[97] EPA levels were measured in a portion of the patients studied, and a follow-up survey was issued to ensure compliance. Subgroup analysis of these patients showed a higher HR for mortality in the fish oil supplement group, which may be attributed to medication interactions and modification of risk-taking behavior. More recently, the Alpha Omega trial showed that supplementation with 400 mg of EPA and DHA daily did not significantly reduce the rate of major CVD events among patients who had recently experienced an MI.[88] Though this trial showed a nonsignificant reduction of 10% in ventricular arrhythmia-related events, patients with diabetes did have a significant decrease in fatal coronary events and arrhythmia-related events (HR, 0.51; CI, 0.27–0.97).[88] Another major RCT, the Omega trial, also reported negative results with the use of omega-3 PUFA in patients with CVD. It demonstrated that in patients with a history of acute MI, supplementation with highly purified 1 g a day of omega-3 PUFA did not show any differences in major vascular events and mortality from all causes in the background of standard therapy.[98]

Summary

Omega-3 PUFAs in high doses (3–4 g) have been shown to significantly decrease serum triglyceride levels. Although not all trials have demonstrated clinical benefit, overall there seems to be a modest protective effect of omega-3 PUFAs on CVD, such that the AHA has recommended daily use of 1 g of omega-3 PUFA in the form of DHA and EPA for secondary prevention of CVD.[99]

Niacin

Background

In contrast to LDL-C, HDL-C has an anti-atherosclerotic effect through a different mechanism called reverse cholesterol transport. HDL is involved in cholesterol uptake from atherosclerotic plaques (and excess cholesterol in peripheral cells) and its transportation to the liver for bile synthesis or free cholesterol hepatic excretion.[100] Additional studies have shown other beneficial effects of HDL-C, including antioxidant, anti-inflammatory, and anticoagulation effects.[101] HDL-C may also play a role in stimulating endothelial regeneration by promoting endothelial progenitor cell-mediated endothelial repair[102] and accepting hydroperoxidases.[101] In addition, HDL-C may protect against thrombosis by inhibiting procoagulant activity.[103,104] Thus, there has been great interest in finding ways to increase HDL-C in patients with known CAD.

As early as 1955, it was shown that the use of nicotinic acid reduced total cholesterol levels.[105] Subsequent clinical trials utilized niacin to lower total cholesterol levels.[106,107] The Coronary Drug Project was the first randomized trial to assess the effect of niacin on CVD events.[108] It was a secondary prevention trial that randomized 1119 patients with CVD to niacin or placebo. In the initial trial, there was a modest reduction in nonfatal MI, but no difference was seen in overall mortality. However, subsequent studies at a follow-up of 15 years, nearly 9 years after the trial termination, demonstrated an 11% reduction in mortality in the niacin group compared to placebo.[109]

Pharmacology

Niacin, more specifically nicotinic acid, inhibits the hepatic synthesis of VLDL and LDL by decreasing triglyceride synthesis[110] and inducing apolipoprotein B (main lipoprotein found on LDL) degradation in the hepatocytes.[111,112] Decreasing VLDL directly decreases LDL, a VLDL catabolic by-product. Niacin also plays a direct role in increasing HDL levels by decreasing its hepatic clearance.[112,113] In addition, niacin also acts to induce enzymes that facilitate cholesterol transfer from monocytes and macrophages to HDL, thereby reversing the atherosclerotic process.[114] Niacin may increase HDL by as much as 15%–35%, while lowering triglyceride level by 20%–35% and LDL by 5%–25%. In combination with statins, niacin has been shown to improve lipid profiles with potential regression of atherosclerotic disease.[115–117] It has also been suggested that niacin may have antioxidant and anti-inflammatory properties through its ability to increase intracellular nicotinamide adenine dinucleotide phosphate, subsequently reducing reactive oxygen species, LDL oxidation, and TNF-α release.[110]

Three types of niacin formulations are available: immediate release (IR), sustained release (SR), and extended release (ER). Niacin IR is absorbed and metabolized quickly, requiring three times daily dosing. Niacin SR has a slower absorption and metabolism rate, but this is highly variable (12–24 h). Niacin ER has an absorption and metabolism rate intermediate of IR and SR formulations (8–12 h) and thus has a more predictable rate of action with improved tolerability.[118] It is important to note that nicotinamide, which is the amide form of nicotinic acid, has no lipid-altering effects. This is important because many, if not all, of the "no-flush" niacin formulations contain nicotinamide (not nicotinic acid). If clinicians recommend over-the-counter niacin preparations, they must educate patients about this crucial difference.

Indications in CVD

Despite achieving an LDL-C goal with statins, patients with a history of a CVD often have residual cardiac risk that may be attributable to low HDL-C and elevated triglyceride levels. Niacin, with its known HDL-C-raising properties, could potentially reduce this residual risk. In the HDL-Atherosclerosis Treatment Study (HATS), patients

were randomized to receive simvastatin plus either niacin or placebo. It was shown that patients treated with simvastatin and niacin had regression of coronary artery stenosis ($p < 0.001$) compared to placebo as measured by quantitative coronary angiography.[115] Furthermore, there was a 90% RRR ($p = 0.03$) in the combined primary endpoint of death from CVD causes, MI, stroke, and revascularization in favor of simvastatin and niacin. Niacin also has been shown to have a more pronounced regression than ezetimibe in the CIMT, a surrogate measure for atherosclerosis. In the ARterial Biology for the Investigation of the Treatment Effects of Reducing cholesterol 6-HDL and LDL Treatment Strategies in Atherosclerosis (ARBITER 6-HALTS) trial, patients treated with statins randomly assigned to ER niacin had a significant amount of CIMT regression compared to ezetimibe.[119]

However, more recent evidence from the Atherothrombosis Intervention in Metabolic syndrome with low HDL/high triglycerides: impact on Global Health outcomes (AIM-HIGH) trial demonstrated no significant added benefit from niacin for patients with adequate LDL therapy but low HDL. This was the largest trial looking at niacin in the modern era and examined patients with a prior history of CVD and low HDL-C randomized to simvastatin or simvastatin plus niacin with the goal of having equivalent LDL-Cs in the groups. AIM-HIGH was terminated early because of a lack of benefit in the simvastatin plus niacin arm of the trial despite this group having an equivalent LDL-C and higher HDL-C. The reasons for the lack of benefit seen with niacin in this trial are unknown; however, it is important to note that these patients were very aggressively treated with LDL-C in both groups approaching 60 mg/dL and had received state-of-the-art modern CVD therapies. The study also may have been underpowered to demonstrate a statistical difference. Since the early termination of the AIM-HIGH trial, the role of niacin in the secondary prevention of CVD has become less clear. Future studies such as the Heart Protection Study 2: Treatment of HDL to reduce the Incidence of Vascular Events (HPS2-THRIVE) that are currently under way may further define the role niacin will play in the secondary prevention of CVD. Niacin may have a role in patients with CVD who cannot achieve target LDL-C goal with statin therapy alone.

Although niacin may have beneficial effects on LDL and HDL levels, many patients are not able to tolerate the side effect profile of niacin. Up to 88% of patients taking the ER formulation experience a vasocutaneous flushing reaction.[120] It has been proposed that niacin induces skin Langerhans cells to release prostaglandin chemokines responsible for flushing symptoms.[121] These symptoms are better tolerated in patients using niacin ER, and continued use over weeks may further decrease this reaction. Patients may also empirically take aspirin 1 h prior to taking niacin to decrease prostaglandin synthesis and attenuate the flushing reaction. In addition to vasocutaneous flushing, patients with diabetes may experience worsening of glycemic control with niacin when used in doses greater than 2000 mg/day.[122] This effect has been associated more with the niacin IR formulation and has been attributed to an increase in insulin resistance. Combination therapy of niacin and a statin may increase the risk of hepatotoxicity. This effect has been observed in patients taking the niacin SR formulation at higher doses (>1500 mg).[56] Monitoring liver enzymes in patients using this combination therapy is necessary to avoid potential hepatotoxic effects. Niacin may also cause hyperuricemia and induce gout flares in patients who are predisposed to gout. Milder side effects include gastric irritation, an eczema-like reaction, and worsening of acanthosis nigricans.[106]

Summary

Though niacin has been shown to significantly improve lipid parameters, its clinical benefit when added to comprehensive medical therapy with well-controlled LDL-C is less clear. Niacin continues to have a role in patients who cannot achieve target LDL-C goal with statin therapy alone or who have significantly elevated triglycerides despite lifestyle modification. Niacin ER is usually better tolerated with less risk for hepatotoxicity. Patients should be discouraged from taking over-the-counter "no-flush" preparations as they do not release nicotinic acid and have no known clinical benefit.

Fibrates

Background

Hypertriglyceridemia is a common lipid abnormality that has a strong epidemiologic association with CVD. However, this association is significantly attenuated when studies adjust for LDL-C and HDL-C. This has created a great deal of controversy over the independent effect of triglycerides on CVD risk with some arguing that these findings are merely associations and that elevated triglyceride levels are only a marker for other processes that may play a more causal role in CVD risk. Regardless of this controversy, elevated triglycerides are at the very least a marker of a patient at potentially high risk for the development of CVD events, necessitating careful assessment of their risk factors, and more specifically their lipid profile.

Pharmacology

Indirect metabolic pathways of triglyceride catabolism have been implicated in the pathogenesis of atherosclerosis. It has been proposed that elevation of triglycerides promotes elevation of triglyceride-rich VLDL particles and a sequential increase in LDL serum levels. In addition, some have proposed that chylomicrons containing high amounts of triglyceride particles are metabolized to remnants that directly invade the subendothelial space, depositing cholesterol and activating foam cell formation.

Fibrates are synthetic ligands for PPAR $\propto$ receptors that act intracellularly to induce genetic expression of lipoprotein lipase, decrease the production of apolipoprotein C in the liver, and regulate the catabolism of free fatty acids. Additionally, fibrates also increase HDL levels by inducing the expression apolipoprotein A through the same PPAR

genetic regulation. In summary, fibrates affect the lipid profile through various mechanisms:

1. Increases LPL concentration and activity
2. Induces liver fatty acid uptake and decreases liver triglyceride production
3. Decreases LDL levels by increasing LDL affinity for removal from circulation
4. Decreases lipid exchange between VLDL and HDL
5. Increases HDL production by increasing ApoA production in the liver

Indications in CVD

It has been shown that fibrates are effective in decreasing triglyceride level by 35%–50%, while increasing HDL by 20%. Although highly effective in decreasing triglycerides and increasing HDL levels, clinical trials have been inconsistent in demonstrating reduction in CVD risk and mortality. In the Bezafibrate Infarction Prevention (BIP) Study, the use of bezafibrate in 3090 patients with a previous MI or unstable angina increased HDL by 18% and decreased triglycerides by 21%.[123] Despite significant changes in the patients' lipid profile, the use of bezafibrate did not decrease the primary endpoint of MI or SCD. However, in a subgroup analysis of patients with triglyceride ≥200 mg/dL, treatment with bezafibrate significantly decreased the cumulative probability of the primary endpoint by 39.5% ($p = 0.02$).[123] This finding was consistent with the Veteran Affairs High Density Lipoprotein Intervention Trial (VA-HIT). This study reported that treatment with gemfibrozil in 2531 men with a history of CVD reduced CVD events by 11% for every 5 mg/dL increase in HDL ($p = 0.02$).[124] In patients with diabetes, there have been mixed findings on the effects of fibrate therapy and reduction in CVD events. In the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) study, 9795 type 2 diabetics not taking statins were randomized to fenofibrate or placebo.[125] Treatment with fenofibrate was associated with a nonsignificant 11% decrease (HR, 0.89; CI, 0.75–1.05; $p = 0.16$) in the primary endpoint of first MI or coronary heart disease death. However, this study did find a significant 11% reduction ($p = 0.035$) in total CVD events, which included a significant reduction in nonfatal MI (HR, 0.76; CI, 0.62–0.94; $p = 0.01$) and coronary revascularization (HR, 0.79; CI 0.68–0.93; $p = 0.003$). The Action to Control Cardiovascular Risk in Diabetes (ACCORD) lipid trial also evaluated the effects of fibrate therapy in patients with diabetes. In this large RCT, 5518 patients were randomized to fenofibrate and statin or statin alone. It was found that there was no significant reduction in the primary endpoint of first occurrence of MI, stroke, or death from CVD causes.[126] However, in subgroup analysis, patients with triglyceride levels ≥204 mg/dL and an HDL ≤34 mg/dL had a 31% risk reduction of the primary endpoint.[126] As observed in both BIP and ACCORD studies, fibrate therapy may play a greater role when targeting patients with higher baseline triglycerides (≥200 mg/dL).

Caution must be taken when using fibrates concomitantly with statins as there is an increased risk of myopathic adverse reactions (myopathy and rhabdomyolysis) and liver toxicity, particularly in elderly patients and those with diabetes. These adverse reactions may be less common with the use of fenofibrate compared to gemfibrozil. In addition, fibrates may interact with medications such as warfarin, and dose adjustment for these medications is necessary to avoid adverse events.

Summary

Hypertriglyceridemia is associated with increased CVD risk. It is less clear, however, that elevated triglycerides play a causal role in CVD. Patients with elevated triglycerides should have a thorough evaluation of their overall CVD risk, and consideration of medical therapy to help achieve target LDL-C and non-HDL-C goals should be undertaken. Fibrates are one of the most effective triglyceride-lowering agents, and although studies have been somewhat mixed in demonstrating clear benefits of fibrates, it must be noted that no large clinical trial has been performed in patients with significantly elevated triglycerides (≥200 mg/dL) and that subgroup analysis of the current trials has suggested benefits in those patients with very elevated triglyceride (≥180–200 mg/dL) and low HDL levels (≤32–34 mg/dL). Fibrates are also indicated in those patients who have not reached their LDL-C goal despite optimal statin therapy.

β-Blockers

Background

Robust evidence exists for the use of beta-adrenergic antagonists, both in the setting of AMI and long-term post-MI. There are several other indications for β-blocker therapy, many of which occur concomitantly with atherosclerotic coronary disease. These include anti-anginal therapy, cardiac dysrhythmias, systolic heart failure, glaucoma, hyperthyroidism, portal hypertension, and systemic arterial hypertension.

Over the past 30 years, beta-adrenergic antagonists have become a mainstay of treatment for secondary prevention of MI. As a class, these agents have been shown to reduce the rate of recurrent MI, the incidence of SCD from ventricular arrhythmias, and both cardiovascular and all-cause mortality in individuals with prior STEMI. Recently, beta-adrenergic antagonists have demonstrated benefits in slowing the progression of atherosclerosis as measured by IVUS and may help in the stabilization of potentially vulnerable coronary artery plaques.

Pharmacology

Pharmacologically relevant β-receptor subtypes include β_1-, β_2-, and β_3-adrenoreceptors. Currently available β-blockers possess a wide range of adrenoreceptor subtype selectivity, although most have very little β_3-affinity. These compounds exert variable actions at their target sites, including competitive antagonism, local membrane stabilizing/anesthetic properties, K^+-channel blockade, intrinsic sympathomimetic/partial agonist activity, and potential antioxidative effects.[127]

The administration of β-blockers leads to several net cardiovascular effects in humans, based on their actions at receptor subtypes. These include reduction in heart rate (negative chronotropy), reduction of velocity and force of contraction (negative inotropy), and reduction in blood pressure regulated a by decrease in renin release from the renal juxtaglomerular apparatus. In addition, some currently prescribed formulations (e.g., labetalol and carvedilol) have α_1-antagonist properties, which lower systemic arterial resistance primarily via reduction in splanchnic smooth muscle tone.

The effects of β-blockers both within the cardiovascular system and in other tissues often limit their use and maximally tolerated dosages. β-Blocker use is often limited by low blood pressure or bradycardia. Both sinus and associated nodal inhibition can cause heart block, which represents an extreme of intended treatment effects. In patients with acutely decompensated heart failure, administration of β-blockers has the potential for worsening pump failure due to negative inotropy. In bronchial tissue, β_2 stimulation leads to smooth muscle relaxation and bronchoconstriction. Administration of β-blockers to patients with active asthma or chronic bronchitis can worsen bronchospasm, although this effect is less clinically significant with the so-called cardioselective β-blockers.

Indications for Coronary Artery Disease

β-Blockers have proven beneficial in many aspects of secondary prevention of CAD. The goals of treatment include reduction in anginal symptoms with a resulting improvement in quality of life, prevention of LV dysfunction, prophylaxis of ventricular arrhythmias, slowing the progression of atherosclerosis, and reducing the risk of recurrent ACS, SCD, and all-cause mortality. β-Blockers are also useful in the management of comorbidities, including hypertension, dysrhythmias, and systolic heart failure.

Chronic Stable Angina and Exercise Tolerance

β-blockers were initially developed to reduce angina associated with myocardial oxygen deprivation and MI. At rest, myocardial oxygen extraction is substantial, approximately 70%–80% of precapillary levels. Exercise is the most important stimulus for increased coronary oxygen extraction, and a substantial portion (50%–70%) of this is due to increase in heart rate to augment cardiac output in response to systemic demands. Increases in myocardial oxygen demand in the face of exercise are consequently largely met by increases in blood flow mediated by reduction in coronary vascular tone, augmenting flow rates by three to five times baseline levels in proportion to increases in heart rate.[128]

This vasodilatation becomes impaired in atherosclerotic coronary disease due to luminal narrowing from plaque formation and endothelial dysfunction due to impaired cell signaling pathways involved in nitric oxide (NO)-mediated vasodilatation. The result is impaired myocardial oxygen delivery, particularly when demand is higher, clinically manifested as exertional angina. β-Blockers mitigate oxygen supply/demand mismatch by reducing heart rate, contractility, and ventricular wall tension (the major determinants of oxygen demand).[129] β-blockers thus reduce myocardial oxygen consumption in the face of dynamic or fixed flow limitation, reducing symptoms of chronic stable angina.

Initial studies of healthy subjects given the prototypical beta-adrenergic antagonist, propranolol, found an adverse effect on exercise tolerance.[130] In later years, two randomized placebo-controlled trials of 23 individuals each with chronic stable angina given timolol at 10–30 mg twice daily versus placebo demonstrated significant reduction in anginal frequency and increase in exercise capacity.[131,132] In a subsequent randomized controlled trial of 77 individuals post-MI who were given either metoprolol succinate (target dose 200 mg daily) or placebo, there was a significant increase in maximal exercise capacity.[133]

Although there is no proven mortality benefit in patients with isolated chronic stable angina, β-blockers are frequently used for this indication over other agents (if only one agent is to be chosen) because of their impact on mortality and recurrent MI in patients with previous MI or systolic heart failure.

Prevention of Recurrent Cardiac Events, Reduction in Mortality

The most compelling evidence for β-blocker therapy post-MI lies in the effect on the rate of recurrent cardiac events and both cardiovascular and overall mortality. In the acute MI setting, β-blockers have been shown to reduce in-hospital mortality as well as long-term risk of cardiovascular death. In the randomized, placebo-controlled, double-blind Goteborg Metoprolol Trial, 1395 subjects with suspected AMI were randomly assigned to metoprolol (15 mg i.v. + 200 mg/day) or placebo for 90 days. The metoprolol group experienced a mortality reduction of 36%. All individuals were assigned open treatment with metoprolol at 3 months, but the group treated with metoprolol in the first 3 months maintained this survival benefit at 1 year. There was a reduction of infarct size in the subset who received metoprolol in the first 12 h of presentation and a 35% reduction of both fatal and nonfatal infarction during the next 90 days.[134]

The BHAT study (β-Blocker Heart Attack Trial), a randomized controlled trial of 3837 individuals given either propranolol (a nonselective β-blocker) or placebo post-MI at a dose of 180–240 mg/day, demonstrated a reduction in cardiovascular death and a relative reduction in all-cause mortality of 26%. Additionally, the propranolol group demonstrated a 28% relative reduction in SCD versus placebo, an important subset of cardiovascular mortality. Owing largely to rapid introduction and titration, side effects such as hypotension and symptomatic heart failure were more common in the treatment arm.[135]

The Norwegian study of timolol (another nonselective β-blocker) demonstrated similar benefits. This was a randomized, placebo-controlled trial of 1884 AMI survivors who were given timolol 10 mg twice daily or placebo. The treatment group demonstrated a 39.3% relative reduction in all-cause mortality, a 44.6% reduction in cardiovascular

mortality, and a relative reduction of 28% in the rate of recurrent cardiovascular events. As with the BHAT trial, the rate of clinically decompensated heart failure was higher in the timolol group.[136]

Multiple smaller randomized controlled trials have been performed with various agents in post-MI subjects. A meta-analysis of 23 of these heterogeneous trials indicated a 20% reduction in the risk of death post-MI with long-term oral beta-blockade.[137] This was corroborated by more recent large randomized controlled trials, specifically in individuals with depressed left-ventricular ejection fraction (LVEF) in addition to recent MI.

In the CAPRICORN trial (Effect of carvedilol on outcome after myocardial infarction in patients with left-ventricular dysfunction), a multicenter, randomized, placebo-controlled trial of 1959 post-MI individuals with an LVEF of <40% who received carvedilol at a dose titrated to 25 mg twice daily or placebo, the carvedilol group demonstrated a 23% reduction in all-cause mortality versus placebo. There was no significant difference in the two groups in certain relevant secondary endpoints, including rates of subsequent hospitalization or sudden death.[138]

Another similar study, the MERIT-HF trial, investigated the effect of beta-adrenergic blockade in patients with known CAD post-MI. MERIT-HF was a double-blind, randomized trial of 1926 individuals with a history of hospitalization for AMI with New York Heart Association class II–IV systolic heart failure and an LVEF <40%. Subjects were treated with metoprolol succinate controlled release/extended release versus placebo. Administration of metoprolol succinate at a goal dose of 200 mg daily reduced total mortality by 40% and SCD by 50%. The combined endpoint of all-cause mortality/hospitalization for worsening congestive heart failure was reduced by 31% and cardiac death/nonfatal acute MI by 45%. A subsequent subgroup analysis of individuals with more severe heart failure, LVEF <20%, showed similar benefits.[139] In contrast to earlier studies indicating significant survival benefit in post-MI treated with β-blockers (Norwegian study of timolol and the BHAT trial of propranolol), the CAPRICORN and MERIT-HF trials indicate no increase and likely benefit in subsequent clinical heart failure and cardiovascular hospitalizations, respectively.

In addition, β-blockers have shown significant benefits in euvolemic patients with NYHA class III–IV symptoms and LVEF <25% whether due to ischemic or nonischemic cardiomyopathy. In the COPERNICUS trial, a randomized controlled trial of 2289 such individuals given oral carvedilol at a goal dose of 25 mg twice daily or placebo in addition to standard therapy, carvedilol reduced the combined risk of death or hospitalization for a cardiovascular reason by 27% and the combined risk of death or hospitalization for heart failure by 31%. In addition, the subjects given carvedilol spent 27% fewer days in the hospital for any reason and 40% fewer days in the hospital for heart failure. Importantly, these individuals were also less likely than those given placebo to experience worsening heart failure, SCD, cardiogenic shock, or ventricular tachycardia (VT).[140]

Ventricular Tachyarrhythmia Prophylaxis

Roughly 50% of all deaths after AMI are due to SCD. Sustained VT or ventricular fibrillation (VF) leading to SCD occurs in up to 7% of AMI survivors within 180 days, with the highest risk being within the first 30 days. The majority of these patients (83%) experience SCD after hospital discharge, underscoring the importance and challenge of effective prophylactic management of such devastating events.[141]

The VF threshold is pathologically reduced in ischemic myocardium, both acutely and long term. β-blockers have been shown, in animal models in which myocardial ischemia was induced, to increase VF threshold in a dose-dependent fashion, leading to myocardial electrochemical stabilization.[142] β-blockers attenuate the lowered VF threshold, increased metabolic demand, and ischemic supply/demand mismatch provoked by B1-adernergic stimulation. The most effective agents in reducing SCD have been metoprolol, timolol, carvedilol, and propranolol, all of which are also highly lipophilic agents.[143] This benefit is attributed to the ability of these agents to cross the blood–brain barrier and reduce central sympathetic outflow. In rabbit models, metoprolol was superior to the hydrophilic atenolol in the reduction of VF in subjects with pharmacologically induced hyperadrenergic states and coronary artery ligation despite having similar effects on the degree of myocardial ischemia.[182]

There is a survival benefit in AMI patients treated with β-blockers in both the immediate post-MI period and long term. The overall impact of the effect is a 30%–50% reduction in mortality,[134–140] much of which is due to a reduction in SCD. Despite this, β-blockers remain underprescribed, particularly acutely in AMI patients who develop sustained VT/VF in hospital. In data from the Valsartan in Acute Myocardial Infarction Trial (VALIANT) registry, 5391 patients were evaluated for the incidence of sustained VT/VF and treatment rate/outcomes with β-blocker administration. Sustained VT/VF occurred in 5.7% of patients, with an in-hospital mortality rate of 20.3%. Only 55.2% of individuals were administered beta-blockade within the first 24 h, but those patients had an absolute risk reduction of 5.8% for in-hospital death, indicating an important immediate treatment benefit. It should be noted that AMI patients with sustained VT/VF were significantly less likely to receive β-blocker therapy than those without.[144]

Summary

Given the cumulative benefits in patients with known CAD, the ACC/AHA guidelines recommend indefinite use of a beta-adrenergic antagonist in all patients (except low risk) without contraindications post-STEMI (class I/LOE A); they should be strongly considered in low-risk patients post-STEMI (class IIa/LOE A).[23]

The most commonly prescribed agents for the secondary prevention of CAD include metoprolol tartrate, metoprolol succinate (which has added benefit in patients with comorbid systolic heart failure), and carvedilol. The dosage of the β-blocker chosen should be adjusted to attempt to achieve a

resting heart rate of 55–60 beats/min.[145] This goal is sometimes unachievable due to hypotension that is often more pronounced in agents with significant α_1-antagonist properties. Administration should begin with low doses titrating upward with a goal of reaching the doses found efficacious in recent randomized controlled trials: 200 mg daily for metoprolol succinate,[134,139] and 25 mg twice daily for carvedilol.[138,140]

Angiotensin-Converting Enzyme Inhibitors

Background and Pharmacology

The renin–angiotensin–aldosterone system (RAAS) mediates several important short- and long-term physiologic processes. Renin is released by the renal juxtaglomerular apparatus (as well as extrarenal tissues) in response to low glomerular perfusion, sympathetic autonomic stimulus, or decreased tubular delivery of chloride at the level of the juxtaglomerular apparatus.[146] Renin cleaves angiotensinogen to yield angiotensin I, which is in turn converted to the active angiotensin II by ACE.

There are two components of the RAAS in humans: circulating and tissue. Physiologically, in the setting of hypotension or hypovolemia, the circulating RAAS acts to preserve organ perfusion and prevent hemodynamic collapse. RAAS activation causes peripheral vasoconstriction, release of aldosterone with resulting renal sodium and water conservation, and increase in sympathetic tone and release of vasopressin from the posterior pituitary resulting in further peripheral vasoconstriction and antidiuresis. These actions are mediated in vivo by angiotensin II stimulating AT1 receptors found in cardiovascular, adrenal, and renal tissues. In contrast, AT2 receptors are found in many other tissues, including fetal tissues, vascular endothelium, and interstitial fibroblasts of adult myocardium. The tissue component of the RAAS is chronically operative at the local tissue level, notably within myocardium.[147] The expression of myocardial AT2 receptors is up-regulated in the setting of atherosclerosis, ischemia, infarction, and heart failure.[148] Long-term stimulation of AT2 receptors may play a role in myocardial remodeling and fibrosis, as well as physiologic antagonism of AT1 receptors, impairing normal circulatory and hemodynamic physiology.[149]

ACE is also responsible for degradation of bradykinin, a product of the kallikrein–kinin system that causes vasodilatation through the synthesis of NO and vasodilatory prostaglandins. The inhibition of bradykinin degradation leads to the ACE inhibitor-associated cough seen in many patients who are prescribed these agents.

The development of ACE inhibitors followed the isolation of a family of peptides named bradykinin-potentiating factors from the venom of the Brazilian viper, *Bothrops jararaca*, by Ferreira and Green in 1970 after the observation that human plasma incubated with viper venom yielded a substance capable of producing hypotension.[150,151] The chemical structure and synthesis were published in 1971[152] when it was noted that these peptides also blocked conversion of angiotensin I to angiotensin II.[8] The first ACE inhibitor that is still in use today, captopril, entered clinical trials in 1977.[150]

As expected, inhibition of ACE leads to decreased systolic and diastolic blood pressures, reduction of preload and afterload, and decrease in bradykinin degradation. There is negligible effect on cardiac output if any. The effects of various agents within this class depend on their ability to distribute into extravascular tissues and various other pharmacokinetic properties. Some agents may demonstrate additional benefits such as plaque stabilization, potentiation of NO and prostaglandin-mediated vasodilatation, mitigation of LV hypertrophy and smooth muscle proliferation, decreased coronary vasoconstriction, and antimacrophage function.[147]

Indications for Secondary Prevention of Coronary Artery Disease

Post-MI with LV Dysfunction

There is a large body of evidence that underscores the benefit of ACE inhibitors in AMI, which is outside the scope of this discussion. Survivors of MI with signs of cardiac damage, particularly LV systolic dysfunction, comprise the other major subgroup of CAD patients who derive benefit from ACE inhibitor therapy in both short- and long-term studies.

The RAAS and sympathetic nervous system (SNS) are activated within hours of AMI,[136] leading to increased systemic vascular resistance, increased heart rate, myocardial wall stress, and coronary vasoconstriction. This is particularly true in patients with complicated clinical courses when compared to uncomplicated MI.[153] This can result in increased risk of ventricular dysrhythmia, infarct expansion, adverse LV remodeling, progressive LV dilatation, and increased risk for myocardial rupture in the immediate post-AMI period. In particular, LV dysfunction and persistent SNS and RAAS activation have been shown to be major determinants of mortality after AMI.[154–157] Small studies also suggest that RAAS blockade improves coronary flow reserve and ability to meet increased oxygen demand.[158]

Several small early trials showed benefit in the use of ACE inhibitors to target RAAS-mediated LV remodeling and dilatation in the hope of reducing heart failure and mortality in AMI survivors. These trials focused on echocardiographic and hemodynamic parameters of LV function, such as end systolic and diastolic volumes as well as ejection fraction. Benefit with early initiation of ACE inhibitors in survivors of MI was noted, particularly in patients with depressed ejection fraction.[159–161]

ACE inhibitor therapy in AMI survivors with LV dysfunction was studied longitudinally in the Survival and Ventricular Enlargement (SAVE) trial. In this double-blind, placebo-controlled study, 2231 subjects with prior AMI and LVEF <40% without clinical heart failure were randomly assigned to treatment with captopril titrated to target dose of 25 mg three times daily or placebo in addition to standard therapy. The average follow-up was 42 months. Individuals treated with captopril experienced a 19% relative reduction

in all-cause mortality (p = 0.019), as well as significant reductions in both fatal and nonfatal vascular events including recurrent MI (RRR, 25%; p = 0.015) and heart failure (RRR, 37%; p = <0.001).[162] These results indicated significant additional benefit in patients already on standard treatment, including β-blockers and aspirin. The Acute Infarction Ramipril Efficacy (AIRE) trial evaluated the effect of RAAS blockade with ACE inhibitors in 2006 individuals with a history of AMI and clinical heart failure (regardless of LVEF) followed for an average of 15 months. Subjects were randomly assigned ramipril with a goal dose of 5 mg twice daily or placebo in addition to standard therapy. Mortality from all causes was significantly reduced in the ramipril group with an RRR of 27% (p = 0.002). Secondary outcomes including MI, heart failure, and stroke were reduced by 19% (p = 0.008), further supporting the role of ACE inhibitor therapy in post-MI patients with either symptomatic heart failure or LV dysfunction.[20,163]

These studies were followed by much larger multicenter trials. The GISSI-3 trial evaluated the benefit of ACE inhibitor therapy added to standard therapy in 19,394 AMI survivors randomized to lisinopril alone, nitrates alone, lisinopril plus nitrates or placebo. At 6 weeks, there was an 11% relative reduction in mortality, as well as reduction in rates of LV dysfunction (defined as EF <35%) in the lisinopril group.[164] Similarly, the Fourth International Study of Infarct Survival (ISIS-4) followed 58,050 AMI survivors randomized to captopril at a goal dose of 50 mg three times daily, mononitrate therapy, or placebo initiated within 24 h of AMI and continued for 1 month. The captopril group not only demonstrated a 7% relative reduction in mortality at 5 weeks but also showed mortality benefit at 12 months despite cessation of therapy after 28 days.[164] These studies confirmed the benefit of early initiation of ACE inhibitor treatment in all AMI survivors, with particular benefit in high-risk patients, including those with prior history of MI or LV dysfunction.

Coronary Atherosclerosis with No History of AMI or LV Dysfunction

Given the clear benefit in AMI, LV dysfunction, and post-MI survival and morbidity, several subsequent trials sought to evaluate the role of ACE inhibitor therapy in patients with known coronary disease without a history of MI or LV dysfunction. The Heart Outcomes Prevention Evaluation Study (HOPE), European trial on Reduction Of cardiac events with Perindopril among patients with stable coronary Artery disease (EUROPA), and Prevention of Events with ACE inhibition (PEACE) trials examined the benefit of ACE inhibitors in patients with stable coronary disease or high risk for future cardiovascular events.[165–167] Although there were conflicting results with regard to cardiovascular benefit in these studies, a meta-analysis of the pooled 29,805 subjects indicated that ACE inhibitors significantly reduced all-cause mortality (7.8% vs. 8.9%, p = 0.0004), cardiovascular mortality (4.3% vs. 5.2%, p = 0.0002), nonfatal MI (5.3% vs. 6.4%, p = 0.0001), all stroke (2.2% vs. 2.8%, p = 0.0004), heart failure (2.1% vs. 2.7%, p = 0·0007), and need for coronary artery bypass surgery (6.0 vs. 6.9%, p = 0.0036), confirming their role in both the primary and the secondary prevention of CVD.[168]

Adverse Reactions

Possible adverse drug effects of ACE inhibitors include hypotension, hyperkalemia, increase in serum creatinine, and ACE inhibitor-associated cough, a common reason for discontinuation of therapy. The development of cough in association with ACE inhibitors occurs in 5%–20% of subjects, most commonly occurring within the first 6 months of treatment and recurring with rechallenge with any ACE inhibitor. Proposed mechanisms include inhibition of ACE-mediated bradykinin degradation and accumulation of substance P and prostaglandin E2. Bradykinin can cause bronchial irritation and histamine release from mast cells, although the variable incidence in patients, the lack of detectable rise in serum bradykinin levels, and preponderance in women cast some doubt on the feasibility of this mechanism.

Clinically, patients taking ACE inhibitors may have many potential causes of new-onset cough, but discontinuation of ACE inhibitors or change to an angiotensin receptor blocker (ARB) is an appropriate first step due to the frequency of this side effect and the usually prompt cessation of symptoms (usually 1–4 days, although as long as 4 weeks) to obviate the need for extensive diagnostic workup.[169]

Although uncommon, one of the most serious adverse reactions related to ACE inhibitor therapy is angioedema. Most commonly, this includes symmetric swelling of the tongue, lips, face, and/or proximal aerodigestive mucous membranes, but can sometimes present as isolated laryngeal or gastrointestinal edema. This phenomenon has been described in patients on long-term therapy with ACE inhibitors, although it more commonly occurs soon after treatment initiation. Patients with hereditary or other acquired forms of angioedema are more likely to develop this problem. Patients who develop angioedema while taking ACE inhibitors should not be rechallenged with other ACE inhibitors. The association between ARBs and angioedema has been described, and although infrequent, this risk should be taken into consideration when contemplating change to ARB therapy in patients with ACE inhibitor-associated angioedema.[170]

Summary

Inhibition of the RAAS in patients with coronary disease with ACE inhibitors has been shown to be effective in patients with atherosclerosis with or without MI, survivors of AMI regardless of LV function, and patients with echocardiographic or symptomatic LV dysfunction. In the secondary prevention of CAD, the ACC/AHA guidelines state that an ACE inhibitor should be prescribed at discharge for all patients without contraindications after STEMI (class 1/LOE A). ARBs are an acceptable alternative in patients intolerant of ACE inhibitors with either clinical or radiological signs of heart failure and LVEF <0.40. Valsartan and candesartan have established efficacy for this recommendation, but with less robust evidence (class I/Level of Evidence: B).[23]

INEFFECTIVE THERAPIES

B Vitamins

Homocysteine has been implicated in many observational studies as an independent risk factor for CVD.[171,172] Homocystenemia leads to production of abnormal proteoglycans in the elastic fibers of arterial walls and the deposition of lipid droplets. In addition, calcium ions and excess sulfate groups of proteoglycan molecules facilitate calcification on arterial walls.[173] Homocysteine is an essential amino acid that is metabolized and converted to either cysteine or methionine. B vitamins, such as folic acid, B_{12}, and B_6, are essential cofactors in these metabolic pathways. It was hypothesized that supplementing with B vitamins may enhance metabolism of homocysteine to cysteine or methionine, thereby decreasing serum homocysteine concentrations and cardiovascular risk. Intervention trials and subsequent meta-analysis did confirm that supplementing with folic acid and B_{12} was associated with significant homocysteine-level reduction of 25% and 5%, respectively, while B_6 did not.[174] However, RCTs have not demonstrated a decrease in MI, coronary revascularization, or CVD mortality, despite a decrease in homocysteine levels.[174,175]

Though B vitamin supplementation is well tolerated in low doses of 1 mg/day, larger doses of 5 mg/day or more can cause abdominal cramps. Doses of >15 mg/day can cause disturbed sleep patterns, irritability, confusion, nausea, flatulence, and increase in seizure frequency.[122] Some RCTs may even suggest an increase in cardiovascular events, incidence of prostate cancer, breast cancer in women, or mental decline in patients greater than 65 years of age.[122,176] The routine use of B vitamins for secondary prevention is currently not recommended.

Antioxidants

According to the "oxidative-modification theory" of atherosclerosis, a central mechanism in the development of atherosclerotic plaque involves oxidation of LDL and accumulation of modified LDL in the subendothelial space.[177] Furthermore, oxidized LDL causes a direct increase in chemotactic activity of endothelial cells by inducing the production of chemokines, attracting monocytes and macrophages. In addition, complete lipid peroxidation of LDL by monocytes and macrophages further induces scavenger receptors on macrophages to internalize LDL forming foam cells. Several vitamins, mainly vitamin E, C, and beta-carotene, have been reported to reduce LDL oxidation. However, supplementing with vitamin E, C, and beta-carotene has not reduced CVD morbidity and mortality in primary and secondary prevention and may increase all-cause mortality and CVD mortality in postmenopausal women.[178,179] Furthermore, combining antioxidant supplements with statin and niacin blunted the lipid-modifying benefits of statin–niacin.[115] Thus, routine use of antioxidant supplementation for CVD prevention is not recommended.

Estrogens

The use of estrogen in the prevention of CVD has changed over the last three decades with the emergence of data from large placebo-controlled clinical trials centering on its use. Practice guidelines in the early 1980s and 1990s relied largely on observational studies that noted reduced all-cause mortality[180] and CHD risk[181–183] in women that reported to have used estrogen hormone therapy. However, two landmark trials, the Women's Health Initiative (WHI)[184,185] and the Heart and Estrogen-Progestin Replacement Study (HERS)[186] were pivotal in reversing these guidelines.

The use of estrogens in the secondary prevention of CHD was addressed in HERS. It analyzed conjugated equine estrogen (CEE) (0.625 mg/day) combined with daily medroxyprogesterone acetate (MPA) (2.5 mg/day) versus placebo in 2763 women aged less than 80 years (mean age, 67 years) with an intact uterus and prior diagnosis of CHD. Results demonstrated no significant differences between groups in the primary outcome (MI or CHD death) (HR, 0.99; 95% CI, 0.80–1.22) or in any of the secondary cardiovascular outcomes. A 3 year extension of HERS showed no evidence of later protection (relative hazard after 6.8 years of follow-up 1.00; 95% CI, 0.77–1.29).[187] The Estrogen Replacement and Atherosclerosis (ERA) trial demonstrated no benefit of CEE (0.625 mg/day), alone or combined with 2.5 mg/day MPA, on angiographic progression of disease in 309 women with angiographically verified coronary disease (mean age 65.8 years).[188,189]

Based on results largely centered around WHI and HERS, the 2011 AHA update on the Effectiveness-Based Guidelines for the Prevention of Cardiovascular Disease in Women recommend that hormone therapy and selective estrogen-receptor modulators (SERMs) should not be used for the primary or secondary prevention of CVD (*class III, Level of Evidence A)*.[190]

CONCLUSION

The treatment of atherosclerotic CVD has long been focused on mechanical interventions (Table 86.4). These mechanical interventions began with the advent of coronary artery surgery in 1967 and the first coronary intervention in 1977. The past 40 or so years have been dominated by these two approaches to coronary revascularization. These techniques have been a major focus of treatment despite limited randomized clinical trial data to demonstrate their efficacy. Recently published studies such as the COURAGE and BARI 2-D trials have cast doubts on the ability of these techniques to significantly reduce mortality in most populations beyond optimal medical and lifestyle therapy. Importantly, pharmacologic therapy for clinically stable atherosclerotic coronary disease has significantly advanced. This chapter highlights a number of these medications including aspirin and other antiplatelet drugs, β-blockers, and a variety of non-statin lipid-lowering agents such as omega-3 fatty acids, niacin, and fibrates. No class of drugs, however, has had more

TABLE 86.4
Optimal Medical Therapy in Secondary Prevention of Cardiovascular Disease

ACC/AHA Goals for Secondary Prevention in Patients with CVD

	Target Goals and Level 1 Therapeutic Recommendations
Smoking	Complete cessation. No exposure to environmental tobacco smoke
Blood pressure	<140/90 or <130/80 if patient has diabetes or chronic kidney disease
Lipids	LDL-C < 100 mg/dL if TG ≥ 200 mg/dL; non-HDL-C should be <130 mg/dL
Physical activity	30 min, 7 days/week (minimum 5 days/week)
Weight	Body mass index: 18.5–24.9 kg/m^2; waist circumference: men < 40 in.; women < 35 in.
Diabetes	HbA1c < 7%
Antiplatelet agents	*Aspirin*: 75–162 mg/day and continue indefinitely in all patients unless contraindicated
	Clopidogrel or prasugrel or ticagrelor: in combination with aspirin for up to 12 months in patients with acute coronary syndrome or percutaneous stent placement
Anticoagulation	*Warfarin*: for paroxysmal or chronic atrial fibrillation or flutter, and in post-myocardial infarction when clinically indicated (e.g., atrial fibrillation, left ventricular thrombus)
Renin–angiotensin–aldosterone system blockers	*ACE inhibitors*: start and continue indefinitely for all patients with left ventricular ejection fraction ≤40% and in those with hypertension, diabetes, or chronic kidney disease, unless contraindicated
	Angiotensin receptor blockers: those intolerant to ACE inhibitors and who have heart failure or in those with previous myocardial infarct and left ventricular ejection fraction ≤40%
	Aldosterone blockade: use in post-myocardial infarction patients, without significant renal dysfunction[a] or hyperkalemia,[b] who are already receiving therapeutic doses of an ACE inhibitor and β-blocker, have a left ventricular ejection fraction ≤40%, and have either diabetes or heart failure
β-Blockers	Start and continue indefinitely in all patients who have had myocardial infarction, acute coronary syndrome, or left ventricular dysfunction with or without heart failure symptoms, unless contraindicated
Influenza vaccination	Patients with cardiovascular disease should have an influenza vaccination

Source: Adapted from Smith, S.C., Jr. et al., *Circulation*, 113(19), 2363, 2006.

[a] Creatinine should be 2.5 mg/dL in men and 2.0 mg/dL in women.

[b] Potassium should be 5.0 mEq/L.

dramatic an effect on the history of coronary disease than has statins. Unfortunately, these potentially lifesaving medications remain suboptimally prescribed and used. It is our hope that education of physicians and patients will achieve a more complete implementation of these life-prolonging pharmacologic therapies.[180,181]

Considerable data from both observational studies as well as randomized controlled trials (RCTs) have demonstrated the significant benefits of physical activity, exercise training (ET), and overall cardiorespiratory fitness (CRF) in both the primary and secondary prevention of coronary heart disease (CHD).[1,2] We and others have published on the marked benefits obtained from formal cardiac rehabilitation and ET (CRET) programs in patients with established CHD, especially after CHD events.[1–6] However, despite the very clear benefits of formal, supervised outpatient CRET programs, as well as intense efforts to improve referrals to these programs, current statistics continue to demonstrate poor overall referral and participation rates for eligible patients, with dismal participation in rural areas and in patients with lower socioeconomic status, limited levels of higher education, as well as females and elderly patients.[1,2,7]

In this chapter, we discuss the proven benefits of formal CRET programs in the secondary prevention of CHD, including the impact on various CHD risk factors, psychological benefits, as well as the effectiveness of this therapy in reducing major CHD events.

POTENTIAL BENEFITS OF CRET

A broad range of patients, with differing clinical characteristics, benefit from formal CRET programs, which are summarized in Table 87.1. Although occasionally CRET programs are altered due to the individual needs of patients, the majority of documented benefits are from programs that last for 12 weeks, consisting of 3 educational and exercise sessions weekly, for a total of 36 outpatient education and exercise sessions.[2,8] Although most of the attention in CRET programs is directed at the exercise, especially aerobic exercise, it must be emphasized that formal CRET programs also involve resistance training, which is important to maintain strength with aging and improve insulin sensitivity and quality of life,[8] as well as dietary therapy and other behavioral interventions directed at multiple CHD risk factors, thus enabling both the patient and their family members to exert more control over the disease process and its management.[2,8] Finally, considerable focus in CRET programs is also directed at psychological aspects of CHD.[9] Therefore, the benefits obtained from formal outpatient CRET programs is likely the result of the combined impact of all of these components of the program.

EXERCISE CAPACITY

Perhaps one of the most important benefits of formal CRET programs are improvements in aerobic exercise capacity and major parameters of CRF.[1–3] Although there is variability in the improvements in CRF following CRET, on average a 35% improvement in estimated aerobic exercise capacity (defined as estimated metabolic equivalents or METs) has been observed. Our studies, however, have noted a considerable discrepancy between estimated METs and CRF that is precisely and directly measured by cardiopulmonary gas exchange, including peak oxygen consumption (peak VO_2 or peak measured METs).[10–12] Since this terminology can be confusing, we prefer to define CRF as either estimated METs (when estimated based on incline and speed on the treadmill by validated equations) or measured peak VO_2. Typically, studies have demonstrated that estimated METs significantly overestimate true CRF both before but, particularly, after ET. Nevertheless, despite these discrepancies, both studies that have estimated METs as well as those precisely measuring peak VO_2 have demonstrated that

TABLE 87.1
Benefits of CRET Programs

- Improvement in exercise capacity
  - Estimated METs, +35%
  - Peak VO_2, +15%
  - Peak anaerobic threshold, +11%
- Improvement in lipids
  - Total cholesterol, −5%
  - Triglycerides, −15%
  - HDL-C, +6% (+13% to +16% increase in subgroups with low HDL-C levels)
  - LDL-C, −2%
  - LDL-C/HDL-C, −5% (higher in some subgroups)
- Reduction in inflammation (hs-CRP, 40%)
- Reduction in obesity indices
  - Body mass index, −1.5%
  - Percent fat, −5%
  - Metabolic syndrome, −37%
- Improvements in behavioral characteristics (depression, anxiety, somatization, and hostility)
- Improvement in autonomic tone
- Improvement in blood rheology and viscosity
- Reduction in homocysteine levels
- Improvements in overall quality of life and its components
- Reduction in hospitalization costs
- Reduction in psychological distress (total, depression, anxiety, and hostility)
- Reduction in overall morbidity and mortality after MI and PCI, as well as HF

measures of CRF potently predict major clinical prognosis and mortality.[1–3,12] In fact, in studies of CRET of nearly 15,000 men and women, every 1 mL $O_2 \cdot kg^{-1} \cdot min^{-1}$ increase in directly measured peak VO_2 was associated with a 10% reduction in major cardiovascular (CV) mortality.[13,14] In one major study, mortality fell by 2% for every 1% increase in peak VO_2 that occurred as a result of ET.[15] Numerous studies and meta-analyses have demonstrated a very powerful relationship between estimated exercise capacity and major CV events and all-cause mortality.[16] Although patients with low baseline exercise capacity generally obtain considerably greater improvement in exercise capacity following formal CRET programs, we have demonstrated that even patients with relatively high baseline exercise capacity still obtain marked improvements following CRET.[17]

LIPIDS AND INFLAMMATION

In order to obtain goal levels of low-density lipoprotein cholesterol (LDL-C), most current patients with CHD are taking statin medications,[18–20] and, therefore, improvements in LDL-C with CRET are fairly minimal. However, many CHD patients also do not have optimal levels of high-density lipoprotein cholesterol (HDL-C) and/or triglycerides (TGs) that can significantly improve with CRET. Although improvements may average +6% for HDL-C and −15% for TGs, respectively, after CRET, considerably greater improvements have been noted in subgroups of patients who have more abnormal baseline lipid values.[21–24] Many patients with CHD have "isolated" low levels of HDL-C with relatively normal or borderline-elevated LDL-C and/or TGs, and these patients are often thought to be relatively resistant to nonpharmacological and pharmacological regimens. In these patients, however, we have reported fairly marked improvements in HDL-C (+17%) and LDL-C/HDL-C (−11%) following formal CRET.[22]

Many studies have demonstrated the significance of systemic inflammation, especially assessed by levels of C-reactive protein (CRP).[25,26] We have recently reviewed the potential improvements of CRP in both primary and secondary CHD prevention, as well as the potential roles of physical activity, ET, and overall CRF on inflammation, especially levels of CRP.[27] In a study of 277 patients with CHD, evaluating 235 CRET completers and 42 "controls" with CHD, we demonstrated that CRET was associated with a nearly 40% reduction in CRP (Figure 87.1).[28] We also demonstrated that CHD patients with the metabolic syndrome (MS) had a nearly twofold higher level of CRP compared with CHD patients without MS, and both groups of patients had nearly a 40% reduction in CRP following CRET.[29] This reduction in CRP, however, was 43% following CRET in 73 obese patients with CHD, whereas there was a nonsignificant 19% reduction noted in 72 lean CHD patients, indicating an interaction between CRET-induced reductions in systemic inflammation and body habitus.[30] To further support this hypothesized interaction, in a more recent study of 529 patients with CHD who completed CRET, 393 overweight/obese subjects were assessed for the relationship between weight loss and change in CRP. In the 196 overweight/obese who had more than the

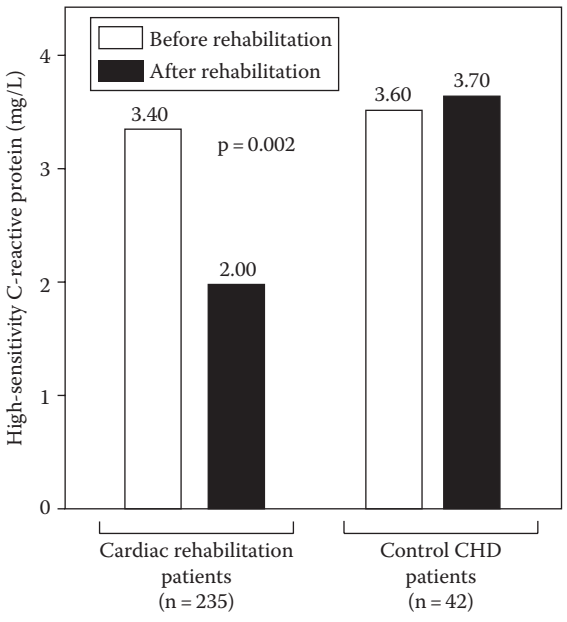

FIGURE 87.1 Median changes in high-sensitivity CRP in cardiac rehabilitation and in control patients with CHD. (From Milani, R.V. et al., *J. Am. Coll. Cardiol.*, 43, 1056, 2004. With permission.)

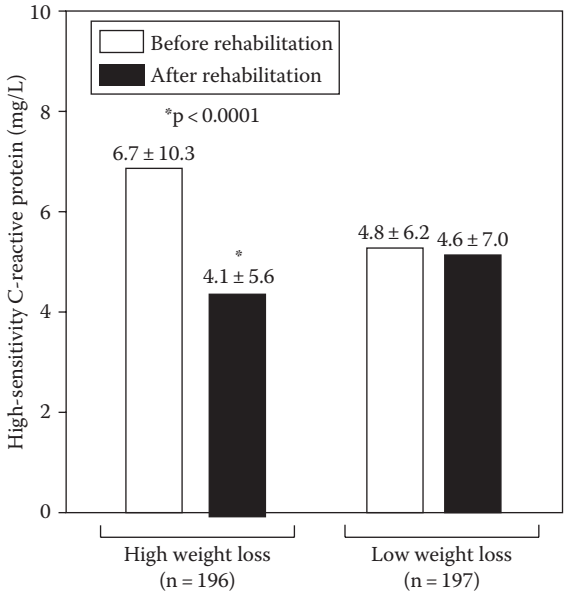

FIGURE 87.2 Mean levels of high-sensitivity CRP before and after CRET in 393 overweight and obese patients with CHD divided by median weight loss. (From Lavie, C.J. et al., *Am. J. Med.*, 122, 1106, 2009. With permission)

median weight loss (average reduction in weight 5%) during CRET, a 40% reduction in CRP was noted; on the other hand, the 197 overweight/obese without significant weight loss during CRET had only a nonsignificant 6% reduction in CRP (Figure 87.2).[31] Moreover, in a study by Caulin-Glaser et al.,[32] patients with CHD who participated in formal CRET programs have significant improvements in CRP that were independent of gender, age, or presence of MS. Ades et al.[33] also showed a significant 16% reduction in CRP in patients with CHD following CRET, but they failed to demonstrate any differences between high and lower exercise intensity and CRP reductions, despite the fact that higher intensity (or high-caloric-expenditure) exercise promoted greater weight loss. Collectively, these results suggest that CRET significantly reduces levels of CRP. Although generally CRP reductions appear to be more marked when accompanied by significant weight loss, there does not appear to be a significant direct impact on exercise intensity and reduction in overall inflammation.

OBESITY INDICES

Clearly, overweightness and obesity are increasing at alarming and epidemic proportions in the United States as well as most other Westernized/industrialized societies.[34] A potential benefit of formal CRET programs is the promotion of weight reduction in the large number of CHD patients who are overweight or obese, as well as those patients who meet criteria for MS. Despite the obesity paradox that our group has published extensively on,[31,34–45] we believe that many studies, including from our CRET programs, have established the efficacy and safety of purposeful weight reduction for patients with CHD.[46] In the large number of CHD patients who are at risk for MS, we have demonstrated that following formal CRET programs, there was a 37% reduction in the prevalence of definite MS.[29]

Several studies from cohorts of patients with CHD have supported the benefits of weight reduction in secondary prevention. In a small group of 45 obese patients from our CRET program who achieved 5% or greater weight loss during CRET (for an average of 10%), we noted greater improvements in exercise capacity and plasma lipids compared with 81 obese who did not lose weight.[47] In a more recent larger study from our CRET center, we noted that overweight/obese patients who lost weight showed significantly greater improvements in most of their CHD risk factors, including plasma lipids, fasting glucose, and inflammation (as discussed previously).[31] Although consistent with the obesity paradox, the overweight and obese CHD patients in secondary prevention have lower mortality compared to their lean counterparts; nevertheless, the lowest mortality appears to be present in the overweight/obese who successfully lose weight during CRET. A recent study of 377 consecutive CHD patients from the Mayo Clinic's CRET program demonstrated that weight reduction was associated with benefits on total mortality plus major CV events, even among those with a body mass index of less than 25 kg m^{-2}, as well as in those who are overweight or obese.[48] In a study by Ades et al.[33] of 74 overweight CHD patients enrolled in a high-intensity, high-caloric-expenditure ET program, as opposed to standard CRET, the authors demonstrated that those in the high-energy-expenditure group had twofold greater reductions in weight loss that was associated with reduced insulin resistance (including decreases in measures of insulin), improved lipids (increases in HDL-C and reductions in TGs and total cholesterol/HDL-C), as well as reduced blood pressure and plasminogen activator inhibitor I, which promotes systemic fibrinolysis.

Although collectively these studies and other recent reports,[31,34,46–49] support the efficacy and safety of purposeful weight loss in patients with CHD, there are limited data from large studies assessing weight loss in CHD. However, a study of over 1500 CHD patients demonstrated that intentional weight loss from a 6 month dietary program without specific ET produced a lower incidence of CHD events over a 3 year follow-up.[49]

PSYCHOLOGICAL RISK FACTORS

Although the lay public has generally been extremely interested in the impact of psychological stress (PS) on both general and, in particular, CV health, this topic has been greatly under-emphasized by clinicians, especially among those involved in the prevention and treatment of patients with CV diseases.[9,50] Clearly PS is an important risk factor for CHD and impacts prognosis following major CHD events.

Perhaps the most impressive data to date on the role of PS and CHD come from the INTERHEART study,[51] which evaluated CHD risk factors and PS among a diverse group of

over 11,000 MI patients and nearly 14,000 age and gender-matched controls from 52 countries in 262 centers. This landmark study demonstrated that among nine major modifiable CV disease risk factors, PS was ranked only below lipids and smoking in overall importance, accounting for almost one-third of the total attributable risk.

We have demonstrated a high prevalence of PS risk factor in CHD patients,[52–64] with marked benefits following CRET (Figure 87.3).[53] However, those patients who remained depressed following CRET had a fourfold higher mortality (20% vs. 5%; $p < 0.001$) during 3 year follow-up.[61] Among the group of patients with baseline depression who completed CRET, mortality was 73% lower (8% vs. 30%; $p < 0.001$) compared with a control group of depressed patients who did not participate in formal CRET. Perhaps more importantly, we demonstrated that patients who did not improve CRF, as determined by peak VO_2, after CRET have a high prevalence of depression and a high mortality risk, whereas those who either slightly improved CRF (<10% improvement in peak VO_2 following CRET) or who markedly improved CRF (≥10% improvement in peak VO_2 after CRET) had marked reductions in both depression and mortality during follow-up (Figure 87.4).[61] We believe that these results suggested only mild improvements in CRF are needed to reduce both depression and depression-related increased mortality. Although our results are obtained in CHD patients in CRET (secondary prevention), we believe that these results may also be applicable to the large number of patients with depression in primary prevention who also are at increased risk of major CV events.

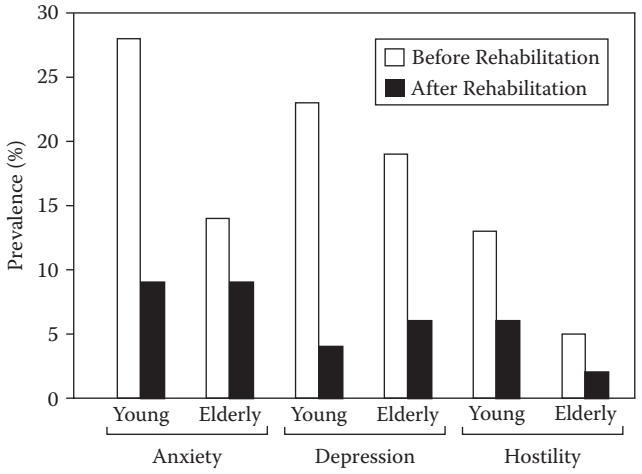

FIGURE 87.3 Impact of formal cardiac rehabilitation and ET programs on prevalence of adverse PS parameters (anxiety, depression and hostility) in older and younger patients with CHD. (Data adapted from Lavie, C.J. and Milani, R.V., *Arch. Intern. Med.*, 166, 1878, 2006.)

Very recently, we assessed the impact of ET and depression on survival in patients with CHD and significantly reduced left ventricular ejection fraction.[62] Similar to non-heart failure (HF) patients, depression symptoms fell by 40% after CRET. Among those HF patients who remained depressed following CRET, the mortality was fourfold higher (43% vs. 11%; $p < 0.001$) compared to those whose depression resolved with CRET. Depressed HF patients who completed CRET had nearly 60% lower mortality compared with depressed HF patients who did not complete CRET (18% vs. 44%; $p < 0.05$).

Our data have also demonstrated the benefits of formal CRET in patients with high levels of total PS.[63,64] Not only do CHD risk factors markedly improve following CRET in patients with high PS,[63] but there are also marked benefits on survival.[64] In fact, almost all of the mortality during follow-up in our CRET patients was noted in those with high PS who did not significantly improve CRF following CRET. Patients with low PS had lower mortality during 3 year follow-up, as did those with high PS who improved their level of CRF during CRET.[64]

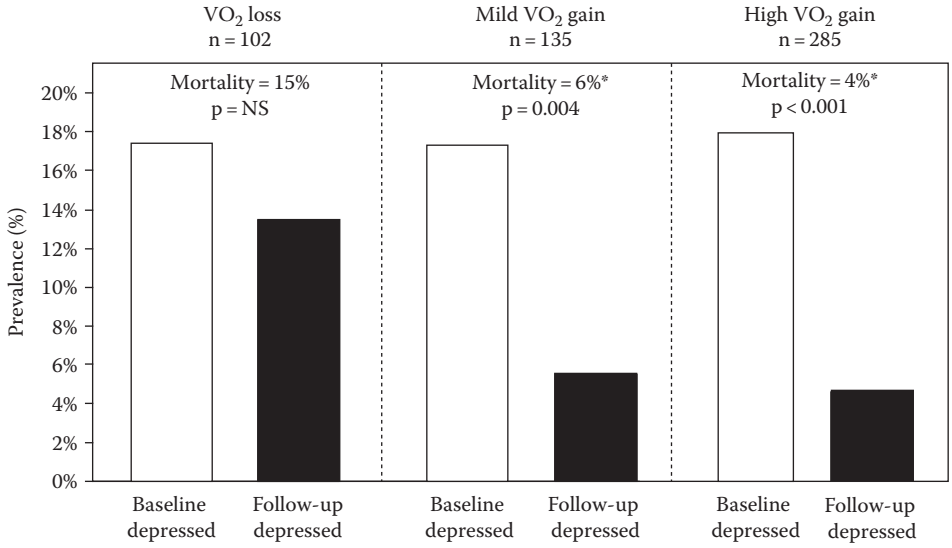

FIGURE 87.4 Prevalence of depression and subsequent mortality based on changes in peak VO_2 during cardiac rehabilitation and ET. *$p < 0.001$ compared with VO_2 loss. (From Milani, R.V. and Lavie, C.J., *Am. J. Med.*, 120, 799, 2007. With permission.)

MAJOR MORBIDITY AND MORTALITY

Perhaps one of the most important benefits of formal outpatient CRET programs is on major CV morbidity and mortality. Many individual trials of CRET have not been large enough or long enough to adequately determine major CV end-points, but several large meta-analyses have attempted to address these issues. O'Connor et al.[65] in 1989 performed a meta-analysis of 22 RCTs of CRET in 4554 post-MI patients followed for an average of 3 years following CRET. Compared with controls, those randomized to formal CRET programs had significant reductions in total mortality, CV mortality, and future MI of between 20% and 25%. Additionally, there was a statistically significant 37% reduction in the risk of sudden cardiac death after 1 year, with trends in favor of CRET at 2 and 3 years, which were not statistically significant. A more recent meta-analysis of 32 RCTs in 8440 participants demonstrated a 31% reduction in CV mortality in those randomized to CRET.[66] An analysis of 1821 post-MI patients from the Mayo Clinic Olmsted County, Minnesota, database demonstrated better 3 year survival (95% vs. 64%; $p < 0.001$) in those participating in formal CRET, even after adjusting for baseline variables.[67] Although one would expect that with the advances in other medical management, the benefits of CRET theoretically may be attenuated in more recent years, however, these Mayo Clinic investigators noted the benefits of CRET were actually more marked in 1998, when other medical interventions were more vigorous, than in 1982, when medical interventions and revascularization procedures were less aggressive.[67]

Suaya et al.[68] recently assessed the effects of CRET on survival in a large elderly cohort. Among those who attended CRET, there was a 34% reduction in 5 year mortality. Moreover, in those who attended 25 or more CRET sessions, (the average CRET program is 36 exercise and educational sessions), mortality was 19% lower ($p < 0.001$) than in those who attended fewer sessions. Hammill et al.[69] studied a natural 5% sample of Medicare beneficiaries and identified an elderly cohort (>30,000) attending at least one formal CRET session. They demonstrated a strong inverse relationship between CRET attendance and overall mortality. In fact, patients who attended all 36 CRET sessions had a 14% lower mortality risk and 12% lower risk of MI than those who attended just 24 sessions, a 22% lower mortality and 23% lower MI risk than those who attended 12 sessions, and a 47% lower mortality and 31% lower MI risk than those who attended just 1 session.

Although the benefits of CRET after MI have been noted for decades, the marked benefits have recently been noted after percutaneous coronary intervention (PCI). In a Mayo Clinic registry of 2395 consecutive patients who underwent PCI in Olmsted County, Minnesota, participation in CRET was associated with a 45% reduction ($p < 0.001$) in all-cause mortality during a 6 year follow-up.[70] Although a trend was noted for reduced overall CV mortality as well in CRET participants, there was no significant effect on subsequent MI or revascularizations. However, the association between CRET participation and reduced all-cause mortality was similar regardless of age, gender, and type of PCI (elective vs. urgent.)

BENEFITS OF CRET IN HF

For patients with stable, compensated chronic HF, numerous studies have established the potential benefits of ET for reducing symptoms, improving levels of CRF, reducing neurohormonal activation, improving overall health-related quality of life, and likely reducing major CV morbidity and mortality.[71] In fact, meta-analyses of ET and HF, where peak VO_2 typically increased by 15%–20%, reported 30%–35% mortality reductions.[72,73] However, a very large RCT of 2331 patients with HF, where patients were randomized to supervised ET versus usual care, had a suboptimal compliance with ET and demonstrated only a 5% improvement in peak VO_2.[74] Although this trial anticipated a 15% improvement in peak VO_2 and a 20%–25% reduction in major CV events and all-cause mortality, there was only a 7% reduction ($p = 0.13$) in the primary end-point (all-cause mortality or hospitalization). However, after preplanned adjustment for confounding factors (ejection fraction, baseline CRF, Beck Depression Inventory, and history of atrial fibrillation or flutter), there was a significant 11% reduction ($p < 0.03$) in the primary end-point in those randomized to ET. The unadjusted secondary end-point (CV mortality and HF hospitalization) was likewise only marginally reduced ($p = 0.06$) in the ET group, but after adjustment, the secondary end-point was reduced significantly ($p < 0.02$) in the ET group. Although this trial was less impressive than originally hoped, the constellation of findings support the use of ET and CRET in patients with HF, especially if peak VO_2 can be increased by at least 10% and preferably by 15% or greater with ET. Efforts are under way to obtain Medicare and insurance reimbursement for CRET in patients with a diagnosis of HF.

CONCLUSIONS

Substantial evidence demonstrates that formal CRET services improve major CHD risk factors, especially exercise capacity, lipids, inflammation, obesity indices, and psychological risk factors, and also reduces major CV morbidity and mortality. Despite these well-documented benefits, however, outpatient CRET referrals and participation rates remain disappointingly low. Therefore, a recent American Heart Association Science Advisory emphasizes the importance of efforts to reinforce the value of CRET programs among various health care systems, providers, and the general public, and thus hopefully increase referrals and participation rates.[7] With these and other efforts, hopefully the referral and participation in CRET programs will increase, thus leading to marked reductions in the prevention of recurrent CV events.

> Rehabilitation of the cardiac patient in the next millennium will likely differ substantially from that undertaken today owing to a number of different variables. Among these are changes in the demography of the population of the United States; changes in the demography of cardiovascular disease, and in particular changes in the clinical spectrum of coronary heart disease and of heart failure; a substantial expansion of the populations considered eligible for cardiac rehabilitative care; and an escalating emphasis on preventive interventions, with the boundaries of primary and secondary interventions tending to blur.[1]
>
> **(Nanette K. Wenger, MD, *Lifestyle Medicine*, James M. Rippe Ed., 1st edn., 1999)**

INTRODUCTION

Dr. Nanette Wenger accurately predicted important changes in health care needs and health care delivery for persons with coronary heart disease (CHD) in the first edition of *Lifestyle Medicine*. Over the past decade, our demographics have indeed dramatically changed. We are living longer lives but certainly not healthier lives. As the leading cause of death for both men and women in the United States, CHD continues to play an increasingly prominent role within today's health care framework. CHD affects more than 12 million people in the United States, 6.9% of the national population, and causes 40% of all deaths nationwide.[2] More than 2200 Americans die of CHD each day, averaging one death every 39 s. Nearly 33% of CHD-related deaths in the United States are in persons under 75 years of age. The direct and indirect cost of CHD for 2007 is estimated at $286.6 billion.[2]

In response to the epidemic of CHD, cardiac rehabilitation programs (CRPs) were developed to address both acute and chronic recovery. CRPs have evolved from exercise-based rehabilitation programs to centers for multifactor CHD risk reduction. Significant data exist to support this important evolution. In the 1990s, the Stanford Coronary Risk Intervention Program demonstrated angiographically that guideline-based systematic management of CHD risk factors resulted in reduction of atherosclerotic plaque, fewer deaths, and hospitalizations in persons with documented CHD.[3] More recently, the COURAGE Trial showed, in select persons with documented CHD, that intensive multifactor risk reduction alone was comparable to percutaneous interventions plus intensive multifactor risk reduction for CHD outcomes.[4] Thus, CRPs have an important role to play in supporting secondary prevention strategies in the twenty-first century.[5]

HISTORICAL PERSPECTIVE OF CARDIAC REHABILITATION

In the 1950s and 1960s, a heart attack was often seen as the end to a productive life. In 2012, with advances in medical therapies, surgical interventions, and CRPs, a major cardiovascular event has become an important turning point toward a healthier productive life. CRPs provide a safe and effective means of improving outcomes for patients with CHD. Improved outcomes include benefits for emotional as well as physical recovery. Over the past two decades, CRPs have grown to fully embrace exercise-based cardiac rehabilitation plus intensive secondary prevention. These programs, combining both exercise therapy and cardiovascular disease (CVD) risk reduction strategies, are now considered the standard of care. CRPs provide important resources necessary for a healthier life after a major cardiovascular event, optimizing the acute and chronic care of patients with CHD.[6]

Additional and important changes seen in many CRPs are moving the focus from "phases of care" to individualization of care. Historically, the structured phases of CRPs have included: Phase I, defined as the care provided during "early recovery" in the hospital, Phase II defined as the initial 6–12 weeks of recovery following discharge from the hospital, Phase III

TABLE 88.1
Guidelines Based Cardiac Rehabilition Services

Class 1 and IIa Recommendation for Cardiac Rehabilitation Services

Class I

1. All eligible patients with ACS or whose status is immediately post coronary artery bypass surgery or post-PCI should be referred to a comprehensive outpatient cardiovascular rehabilitation program either prior to hospital discharge or during the first follow-up office visit (*Level of Evidence: A*).
2. All eligible outpatients with the diagnosis of ACS, coronary artery bypass surgery or PCI (*Level of Evidence: A*), chronic angina *(Level of Evidence: B)*, and/or peripheral artery disease (*Level of Evidence: A*) within the past year should be referred to a comprehensive outpatient cardiovascular rehabilitation program.
3. A home-based cardiac rehabilitation program can be substituted for a supervised, center-based program for low-risk patients (*Level of Evidence: A*).

Class IIa

1. A comprehensive exercise-based outpatient cardiac rehabilitation program can be safe and beneficial for clinically stable outpatients with a history of heart failure (*Level of Evidence: B*).

Source: Smith, S.C. et al., *Circulation*, 124(22), 2458, 2011.

defined as recovery beyond the first 6–12 weeks, and Phase IV defined as the maintenance of healthy lifestyle including physical activity after 3 months of recovery. Phase II through IV CRPs can be hospital based, community or clinic based or home based.[7] Home-based programs can be supported through telemetry monitoring or other means of supervision by health care professionals. Ideally, all persons having an acute coronary event with acute myocardial infarction, bypass surgery, or percutaneous intervention, and those with chronic angina, heart failure, or peripheral arterial disease would participate in a CRP (see Table 88.1). Unfortunately, only a small percentage of patients with CHD are referred to CRPs. Additionally many persons with CHD do not have access to or do not attend "structured programs" due to lack of knowledge about CRPs, cost, distance, older or younger age, female gender, language or literacy barriers, depression, and lack of social support.[2,6,8–10]

BURDEN OF DISEASE

With the change in chronic disease worldwide and the growing need to individualize care, secondary prevention, a mainstay of cardiac rehabilitation, will continue to play a significant role for CRPs in the future. Secondary prevention of CVDs will remain at the forefront of CRP programs for both patients and family members.

Worldwide, chronic diseases are responsible for 70% of all deaths and 78% of health care costs.[11,12] Atherosclerotic vascular diseases include a variety of conditions that share common risk factors and treatments including guideline-based interventions that often overlap. These risk factors include dyslipidemia, hypertension, cigarette smoking, type II diabetes, physical inactivity, obesity, a diet high in saturated fat, and significant elevations in life stress. Outcomes from poorly controlled cardiac and vascular disease risk factors include heart attack, stroke, peripheral vascular disease, and renal disease.[2]

Our society and our health care system bear the burden of CVD prevalence and the accompanying expense of recovery and disability. While death rates from CHD have declined since 2007, the burden of disease remains remarkably high.[2] The number of disability-adjusted life years (DALYs) lost serves as an accurate measure of the total burden of a disease, as opposed to a measure of a disease's resulting deaths. In the United States, 18% of lost DALYs results from CHD, causing a projected 25% increase of national health care spending.[13] The epidemic of CVD is increasing locally and globally. The burden of CHD is projected to rise from around 47 million lost DALYs in 1990 to 82 million in 2020. Inarguably, the national and global burden of CHD is far-reaching and staggering.[14]

Prevention is key and action does work.[15] Approximately 78% of American adults aged 20–80 years alive today are candidates to participate in at least one prevention activity. If everyone participated in these activities, myocardial infarctions would be reduced by an estimated 63%.[14,16] Further studies indicate that, in the United States, for every 10 mmHg reduction of systolic blood pressure, there is a 30% decrease in risk of stroke for people aged 60–79 years.[17] Tobacco use is the most preventable cause of heart disease in the United States.[18] Contrary to public perception, smoking-related heart disease actually results in more deaths per year than smoking-related lung cancer. The CDC reports that cigarette smokers are two to four times more likely to develop CHD than nonsmokers and are twice the risk for stroke.[19] While the percentage of U.S. adults who use tobacco has declined since 1998, there has been no significant change in that reduction since 2005. Current smokers comprise highly addicted adults and new young smokers.[20] CRPs can reach out to these populations and family members of program participants through community health education and secondary prevention programs.[2,21]

Targeting hypertension and high cholesterol levels can dramatically reduce CVD incidence. Data from the National Health and Nutrition Examination Survey (NHANES) indicate that 33.5% of U.S. adults over 20 years of age have hypertension. Strikingly, this results in an estimated 76,400,000 American adults with hypertension, with only 48% of those aware that their hypertension is being medically controlled.[2] As blood cholesterol rises, so does risk of CHD. An estimated 10% decrease in total cholesterol levels population-wide would result in an estimated 30% reduction in national CHD incidence.[2]

Coupled with these risk factors, obesity also increases CHD-associated morbidity and mortality. In the United States, 67.3% of adults are estimated to be overweight or obese, amounting to approximately 150 million Americans. Obesity is associated not only with marked excess mortality

but also with increased incidence of diabetes mellitus and the development of CVD conditions (CHD, stroke, heart failure).[2] Health problems related to obesity cost the United States an estimated $117 billion a year. Despite prevention efforts, the prevalence of diabetes mellitus and obesity continue to dramatically increase.[2]

The reduction of morbidity and mortality from CHD rests in prevention, not cure. It is estimated that if just 10% of adults engaging in aerobic exercise, Americans would save billions of dollars in costs related to heart disease, with an accompanying reduction in the societal burden of disease.

BENEFITS OF CRPs

Participating in a CRP has many benefits including an opportunity to extend these benefits to other populations with chronic diseases not presently served through programs as they are structured today. Most notably, this includes patients with type 2 diabetes.[22] More recently evidence suggests that CVD risk reduction benefits persons with chronic renal disease.[23,24]

One obvious benefit to participation in CRPs is improved survival. Studies have shown that cardiac rehabilitation reduces the chance of death after a myocardial infarction by 20%–25% and reduces the risk of a repeat event by 28%.[25] This improvement is comparable to the effects of rigorous use of pharmacologic agents.[17] The implementation of a comprehensive secondary prevention program as an integral component of CRPs targets the assessment and modification of risk factors, creating a potent strategy to increase survival and quality of life.[18] CRPs support the improvement of health outcomes through nutritional counseling, lipid and hypertension management, tobacco cessation interventions, weight and diabetes management, exercise training, and support of psychosocial well-being—all actions contributing to the slowing, stabilization, or reversal of CHD progression. In addition, CRPs have been shown to improve adherence to lifesaving medications.[26]

Studies of efficacy and effectiveness of CRPs have not only documented significant morbidity and mortality reductions but shown improvements in a wide range of clinical and behavioral outcomes.[15] These benefits exist because of cardiac rehabilitation's comprehensive prevention strategy.

The future holds great promise. Intensive secondary prevention interventions for CHD have been shown to be as effective in preventing subsequent cardiovascular events compared to percutaneous coronary interventions plus intensive secondary interventions in appropriately selected patients.[27] This coupled with the knowledge that CRPs are positioned to provide such care further emphasizes the importance of cardiac rehabilitation services. Their challenge is to meet the needs of all cardiovascular patients and their families by expanding services and making them more cost effective and affordable. Reaching out to those who are underserved must become a goal of CRPs.

CHANGING PARADIGM OF HEALTH CARE DELIVERY

The national health care reform legislation marks a movement toward integrated service delivery models, changing the way our current health services are organized, distributed, and financed.[28] Accountable care organizations (ACOs) and patient-centered medical homes (PCMHs) are two notable health care delivery programs recently developed to address this integrated service model.

According to Centers for Medicare and Medicaid Services, an ACO is an organization of health care providers (i.e., hospitals, nurses, physicians) that agrees to be accountable for the quality, cost, and overall care of Medicare beneficiaries who are enrolled in traditional fee-for-service program. The goal is to provide seamless care, bringing together the different parties of health care delivery: primary care physicians, nurse practitioners, specialists, and nurse case managers.[28] CRPs would fit well into these models. CRPs are well positioned to extend the capacity to supervise and coordinate comprehensive CHD risk reduction therapies for numerous populations and those at risk of CHD.

PCMH are an alternative model to ACOs. The PCMH is a promising model for transforming the organization and delivery of primary care. According to the Agency for Healthcare Research and Quality, medical homes aim to create a patient-centered, comprehensive, coordinated, accessible and systems-based approach to care.[29] PCMH are based on care concepts including improved access to and continuity of care, identification and management of specific patient populations, the use of evidence-based guidelines for chronic and urgent care needs, provision of self-care management tools and resources, tracking, and coordination of referrals including lab testing, and ongoing evaluation and continuous quality improvement.[30] The concepts of this new model of care matches well with the concepts upon which CRPs are built.

PCMH, chronic disease management, case management, secondary prevention centers, telemedicine, patient directed self-care, and group care meeting—all new models of preventive health care that are consistent with the mission and goals of CRPs. However, these new models of care present CRPs with new and complex challenges. Can traditional CRPs fit into the rapidly evolving health care paradigm in the twenty-first century? Is the current model of cardiac rehabilitation able to adapt to the increasing demands for lifelong secondary preventive care? Can CPRs evolve to embrace the needs of all patients requiring secondary prevention for CHD including those without access to a formal program and the underserved?

Over the past 50 years, CRPs have been shown to provide safe and effective care. Care that is individualized, scientifically based, guideline directed, and associated with increased survival and quality of life. No doubt, over next 50 years, CRPs will more fully embrace changes in the way health care is structured and emerging technologies including the potential of "virtual" care to better serve all patients with CHD. The value of CRPs is found in the individuals, the families, and the communities they benefit.

Secondary prevention of cardiovascular disease (CVD) focuses on interventions designed to reduce the likelihood of CVD events and/or mortality in individuals who have established disease. Recent guidelines for secondary prevention include and encompass risk reduction therapies for individuals with coronary and other atherosclerotic disease. It is well established that CVD aggregates in families and those families have a critically important role in promoting adherence to therapeutic as well as preventive regimens. The purpose of this chapter is to review the evidence supporting family-based approaches to secondary prevention of CVD and provide suggestions for clinical and public health practice as well as future research.

SECONDARY PREVENTION

Evidence-based secondary prevention guidelines issued by the American Heart Association (AHA) and the American College of Cardiology Foundation (ACCF) reflect results of recent clinical trials in recommendations for targets for intervention, and in support of intensive risk-reduction therapies for patients with established and other atherosclerotic vascular disease (including peripheral artery disease, atherosclerotic aortic disease, and carotid artery disease) [1]. While details of these guidelines are beyond the scope of this chapter and discussed in chapter X, recommendations address the major risk factors for CVD including smoking, blood pressure control, lipid management, physical activity, weight management, and type 2 diabetes mellitus management. Other areas for intervention include recommendations for antiplatelet agents/anticoagulants, renin–angiotensin–aldosterone system blockers, influenza vaccination, depression, and cardiac rehabilitation [1]. The role of the family in promoting patient adherence to these recommendations and realizing treatment goals is not explicitly addressed in the 2011 update; however, reference to maintaining heart-healthy home environments (i.e., avoidance of environmental tobacco smoke) and, based on available evidence, recommendations for a home-based cardiac rehabilitation program for low-risk patients is also suggested. In addition, health care providers are encouraged not only to implement the therapies according to their class of recommendation but to assess and assist with patient compliance at each patient encounter. As discussed as follows, the family environment including patterns of family health behaviors as well as social support necessary for behavior change and adherence to prescribed therapies are central to optimizing secondary prevention.

RATIONALE FOR FAMILY-BASED APPROACHES: IMPORTANCE OF FAMILY HISTORY

Early in the twentieth century (1910), Sir William Osler first observed the occurrence of coronary heart disease (CHD) in successive generations of families [2]. Since then, numerous cross-sectional and longitudinal studies of diverse populations have documented intrafamilial clustering of CHD and other cardiovascular conditions [3–8]. Attributed to the interplay of genetic and shared common environmental and behavioral–lifestyle factors, familial aggregation of CVD is well documented, resulting in recognition and designation of family history as a major risk factor for CVD.

Results from several studies underscore the importance of family history in CVD risk prediction and disease prevention. Results from the Framingham Offspring Study, for

example, indicate that early onset parental CHD (prior to 55 years of age in males and 65 years of age in females) is an independent predictor of offspring cardiovascular events in middle-aged men and women (mean age, 44 years) [9]. After adjustment for other risk factors, premature CHD in at least one parent was associated with a significant doubling in risk for men and a 70% increase in risk for women over a period of 8 years. Of note, parental CHD was found to discriminate risk best among offspring with intermediate levels of cardiovascular risk as predicted by individual traditional risk factors and multivariable risk equations. Other studies of diverse population-based cohorts demonstrate associations of familial CHD with subclinical atherosclerosis including increased carotid intima-media thickness (CIMT) and coronary artery calcium (CAC), a surrogate measure of the presence and burden of atherosclerosis [10–13].

Of note and adding to the importance of sibling history of CVD are results of a cross-sectional study of 8549 asymptomatic individuals (69% men; mean age 52 ± 9 years) conducted by Nasir et al. indicating that sibling history of CHD may be more strongly associated with subclinical atherosclerosis than parental history of premature CHD [10]. Multivariate regression analyses indicated that the odds ratio (OR) (95% confidence interval) for the presence of CAC was 1.3 (1.1–1.6) among those with positive family history of premature CHD in parents only, 2.3 (1.7–3.1) and 2.5 (1.8–3.3) among those in siblings and a combined family history compared with those without family history of CHD in men, respectively. Among women, the corresponding ORs were 1.3 (1.0–1.8), 2.3 (1.7–3.6), and 1.9 (1.3–3.1), respectively. More recently, Nasir et al. assessed the strength of the association between a family history of premature CHD and CAC in 5347 asymptomatic individuals (47% men; 38% white; mean age 62 ± 10 years) drawn from the Multi-Ethnic Study of Atherosclerosis (MESA) [14]. The demographics-adjusted OR for CAC > 0 with vs. without a family history of premature CHD was 1.94 (95% confidence interval [CI], 1.64–2.29). On adjustment for CHD risk factors, the association was slightly attenuated to an OR of 1.84 (95% CI, 1.55–2.19). Of note, family history of premature CHD was significantly associated with CAC in all ethnic groups [14].

Taken together and placed in context of other clinical and epidemiological studies, the results support the importance of family history of premature disease in risk assessment and stratification and provided the impetus for the National Institutes of Health (NIH) Family History of Disease Initiative. This initiative encourages health care providers to include and emphasize multigenerational family history in assessment of risk for CVD and other chronic conditions [15].

RATIONALE FOR FAMILY-BASED APPROACHES: IMPORTANCE OF HEALTH BEHAVIORS

The associations of health behaviors, levels of established risk factors (i.e., low-density lipoprotein cholesterol [LDL-C]) and CVD endpoints have been investigated extensively. While the mechanisms through which these behaviors influence health outcomes remain to be fully explicated, accumulated data clearly indicate that patterns of dietary intake, physical activity, and smoking behaviors are important determinants of atherosclerotic and hypertensive processes [16]. Compelling evidence linking adverse health behaviors in children, adolescents, and adults with increased risk and progression of CVD processes has prompted inclusion of these health behaviors in primary [17,18] and secondary [1] prevention guidelines. The adoption and maintenance of healthy lifestyle behaviors and therapeutic lifestyle change remain as the cornerstone of primordial, primary, and secondary prevention [19].

Viewed within a social–ecological perspective and across cultures and operational definitions, families provide a critically important context for the development and maintenance of behaviors central to cardiovascular health [19]. Families also provide an important context in relation to initiation and maintenance of behavior change and adherence to therapeutic regimens. As discussed in the following, substantial data generated from clinical and epidemiological studies suggest intrafamilial associations of patterns of dietary intake, physical activity, and smoking behaviors.

Familial Associations of Dietary Intake

Early observations made in the population-based biracial Princeton School District Study of 6- to 19-year-old children and parents indicated significant parent–offspring associations of total energy intake ($r = 0.25$; $p < 0.001$) and selected macronutrients including carbohydrates, saturated, and polyunsaturated fatty acids [20]. In multiple regression analyses, parental nutrient intake explained a significant portion of the variance in children's intake with multiple R^2 ranging from 0.23 (cholesterol) for the total sample to 0.97 for total carbohydrates in Black fathers over age 40 and their children. In both correlational and regression analyses, parent–offspring associations in Black families exceeded those of their White counterparts. A report from the Framingham Children's Study, focused on White preschool children and their parents, is consistent with these results [21]. In the Framingham cohort, however, mother–child associations exceeded father–child associations for most nutrients. Other reports of White and Mexican American parent–child dyads provide additional evidence of familial aggregation of macro- and micronutrients relevant to CVD [22]. Of note, results from the Canadian Family Study, designed to quantify familial aggregation in daily energy intake in biological relatives and adoptees, reported that nontransmitted environmental factors, including home environmental effects, accounted for more than 50% of the variance observed in components of energy/dietary intake [23]. These results are consistent with a report from the Delaware Valley Twin Study (DVTS) [24]. In this cohort of school-age twins, significant monozygotic (MZ) ($r = 0.61–0.91$) and dizygotic (DZ) ($r = 0.39–0.84$) co-twin similarity of macro- and

micronutrients was observed; however, heritability analyses indicated negligible genetic influences.

Other studies of diverse populations of families are consistent with these results pointing to the family environment as an important and potentially modifiable context for developing and changing this important health behavior [25]. Less information is available regarding family-based dietary interventions in the setting of secondary prevention of CVD; however, results to date suggest the promise and potential of changing this health behavior in families with CVD [26].

Familial Associations of Physical Activity

Similar to dietary intake, familial resemblance of physical activity has been documented across the life course of families from diverse populations. Perusse et al. [27] quantified genetic and environmental determinants of physical activity (level of habitual activity and exercise participation) in n = 375 Canadian (Quebec) families using the BETA model of path analysis that allows the separation of the transmissible effect between generations (t^2) into genetic (h^2) and cultural (b^2) components. Transmission was significant but was accounted for by genetic factors for level of habitual physical activity ($t^2 = h^2 = 29\%$) and by cultural factors for exercise participation ($t^2 = b^2 = 12\%$). These results, supported by other research [28–31], indicate familial transmission of this health behavior, suggest the importance of both genetic and environmental influences, and indicate that nontransmissible environmental factors account for most of the variation in both indicators of physical activity in this population. Methodologic differences make cross study comparisons difficult to interpret; however, results from other studies are consistent in demonstrating parent–offspring and intrafamilial associations of this health behavior that is critically important to CVD prevention [28–31].

Familial Associations of Cigarette Smoking

Considerable multidisciplinary research attention has focused on the familial determinants and aggregation (including intra- and intergenerational familial transmission) of cigarette smoking. Data suggest that genetic and numerous environmental factors contribute to the initiation and persistence of cigarette smoking. Data also suggest that the relative contributions of genetic and environmental factors (including shared environments) vary by stage of smoking behavior (i.e., initiation, persistence), developmental phase, gender, and culture/ethnicity [16,32–34]. For example, in a population-based study of Dutch adolescents and young adults, Boomsma et al. [33] reported a heritability of smoking initiation of 31% with shared (family) environmental factors accounting for an additional 59%. A report from the National Academy of Science National Research Council (NAS-NRC) World War II twin panel indicated a heritability estimate of 59% with shared environmental effects accounting for an additional 21% of the variance [34]. For an Australian adult twin panel, heritability estimates of 28% for men and 77% for women were reported while shared environmental effects accounted for 43% and a nonsignificant 4% of the variance respectively [32].

While these results emphasize the population-specificity of such estimates, they also indicate the importance of both genetic and environmental factors in smoking initiation and persistence. Additional data, generated from studies of parent–offspring dyads and singletons, point to the importance of potentially modifiable familial and environmental influences and also suggest gender and ethnic differences in predictors of smoking initiation and persistence [35]. For example, data from Bogalusa and southern California suggest that parental smoking may be a more significant predictor of smoking initiation in White adolescents as compared with their Black counterparts [35].

Collectively, accumulated data suggest that patterns of dietary intake, physical activity, and cigarette smoking are influenced by both genetic and potentially modifiable environmental factors. Familial transmission and aggregation of these behaviors can be attributed to both shared genes and shared common family environments. Taken together, the results suggest the need and potential for family-focused behavioral–lifestyle interventions tailored to the individual family's developmental life course phase, structure, sociodemographics, and resources.

WHAT WORKS: MODELS FOR SECONDARY PREVENTION OF CVD

In the United States and globally, atherosclerotic cardiovascular conditions, particularly CHD and cerebrovascular disease, are leading causes of disability and premature death. CVD risk-reduction and evidence-based medical therapies play a critically important role in reducing the age-adjusted mortality due to CHD as exemplified in a report by Ford [36]. Specifically, Ford et al. applied an updated version of the IMPACT mortality model to data for the years 1980–2000 on the use and effectiveness of specific cardiac treatments and change in risk factors among U.S. adults, 25–84 years of age. The IMPACT model incorporates major potentially modifiable risk factors for CHD including smoking, high blood pressure, elevated total cholesterol, obesity, diabetes, and physical inactivity as well as standard evidence-based medical and surgical treatments for CHD. Results indicated that approximately half the decline in U.S. deaths from CHD in the period studied may be attributable to reductions in major risk factors while approximately half is due to evidence-based medical therapies [36]. These results are consistent with earlier U.S. and international studies and underscore the importance of potentially modifiable risk factors and behaviors in preventing mortality from CHD [19].

The evidence supporting the importance of multicomponent behavioral–lifestyle and pharmacological management in secondary prevention of CVD is compelling. As noted previously, over the past several decades, the AHA and ACCF

have issued evidence-based guidelines focused on secondary prevention/cardiac rehabilitation. The 2011 guidelines suggest a multifaceted and multidisciplinary approach to overall cardiovascular risk management [1]. With emphasis on behavioral–lifestyle modifications and patient adherence to individualized recommendations, the need for multidisciplinary team approaches and active involvement of the patient's family is imperative. The central and essential role of adherence to lifestyle modification and medication recommendations in preventing recurrent events in patients with documented CVD is well established [37]. Consistent with social–ecological models of health, optimal strategies for increasing adherence to preventive and therapeutic regimens consider and target individual (patient-level), provider, and health care system factors [39]. The role of the cardiovascular patient's family crosscuts each of these areas including providing social support and a shared family environment conducive to behavioral change/lifestyle modification, communicating with and clarifying treatment options with the patient's health care provider, and negotiating health care systems.

As discussed in the following, the efficacy and effectiveness of nurse-directed, multidisciplinary models for secondary prevention of CVD (and other chronic conditions) has been established. In addition, while less information is available on family-based approaches, results of studies conducted to date indicate the promise and potential of extending nurse-directed multidisciplinary models for secondary prevention to include and encompass the patient's family [38].

Lessons Learned: Essential elements of nurse-directed, multidisciplinary models of secondary prevention, including an often-cited meta-analysis [39] and recent systematic reviews conducted by Berra et al. [40,41], indicate that multidisciplinary, multicomponent secondary prevention programs are effective in reducing recurrent acute cardiovascular events and all-cause mortality and improving health-related quality of life and functional status in individuals with CVD. Of note, almost half (45%) of the 63 randomized trials included in Clark's meta-analysis were identified as nurse-led or nurse-managed [39]. Berra's systematic literature review focused on evaluating how nurse-based case management (NCM) according to recommended guidelines improves patient outcomes and enhances cardiovascular risk reduction [40]. Berra et al. also conducted a review of selected nurse-led case-management studies that were implemented in the United States and globally [41]. While the family was not the unit of intervention in the majority of studies included [26,42–45], observations made from these reviews combined with results of recent studies that included family subsystems (i.e., spouses/partners, parent–offspring dyads, siblings) apply to the effective implementation of family-focused CVD-prevention programs (see Table 89.1).

As illustrated in landmark and recent clinical and community-based trials, enhancing cardiovascular risk reduction and improving health outcomes in CVD patients from diverse racial, ethnic, and sociodemographic backgrounds is achievable but will require reforms in current systems of care. Key elements of successful secondary CVD-prevention programs identified in the research reviewed are consistent with the core components or pillars of the Chronic Care Model as defined by Wagner et al. [46] and Bodenheimer et al. [47]. These include self-management support, decision support (i.e., evidence-based clinical practice guidelines), computerized clinical information systems, community resources and policies (i.e., linkages between provider organizations and community-based resources), delivery system design (i.e., case-managed, multidisciplinary team approach), and health care organization (i.e., structure, goals, and values of provider organization that prioritize provision of care for chronic conditions). More specifically, as operationalized in effective CVD-prevention programs, essential elements include systems for coordination of services with multiple providers (nurse-directed, case-managed, multidisciplinary team approach), comprehensive lifestyle management programs that incorporate evidence-based principles of behavior change including self-management support and social support, clinical information systems (universal use of electronic health record that includes patient and family health behaviors, computerized participant management, tracking reports, and outcomes analysis systems), and efficient mechanisms for patient follow-up to monitor adherence, safety, and effectiveness of interventions. An essential component of effective nurse-led, case-managed programs is the use of evidence-based protocols and algorithms for management of patients with single and multiple risk factors [39–41].

Family-Focused Interventions for CVD Prevention

As noted previously, minimal research has focused on the family as a unit of intervention in the setting of secondary and/or primary prevention of CVD. Based on evidence that underscores the importance of family history of CVD, the family environment, and parental role-modeling of CVD-related health behaviors, guidelines for CVD prevention in children and adolescents have emphasized family-focused approaches to assessment and management of CVD risk factors and health behaviors [17,18]. Of note, the efficacy of family-focused interventions has been demonstrated in the management of childhood obesity [48]. For example, Epstein et al. conducted a prospective, randomized controlled study of obese 6- to 12-year-old children over a period of 10 years. The obese children and parents assigned to joint health behavior management sessions showed significantly greater weight loss after 5- and 10-year follow-ups than the families with child-centered behavior management [48]. More recent studies [49] reaffirmed the role of the family in the management of childhood obesity; the collective results have guided and informed weight management programs for obese children [50].

A recent study conducted by Mosca et al., FIT Heart: Family-Based Intervention Trial to Improve Heart Health, illustrates both the challenges and opportunities for family-focused interventions in the setting of secondary prevention of CVD [38]. Specifically, FIT, a randomized controlled trial, was conducted in healthy adult family members (n = 501;

TABLE 89.1
Selected Successful Nurse-Led Case Management Studies

Study, Mean Age (MA), % Male (% M)	Year	Country	Location	Patient Population	Number Randomized	Multifactorial Approach	Primary Outcomes
EUROACTION (hospital arm), MA 63 years, 63% M [26]	2008	Europe (United Kingdom, Sweden, France, Italy, Spain, Poland)	Hospital	Acute MI, unstable angina, stable angina	3088 (cluster randomization)	Smoking, diet, physical activity, weight, waist, BP, lipids and glucose, HRQoL, illness and risk perception	INT vs. UC: Hospitalized with CHD: reached goal for: BP (65% vs. 55%[a]); LDL-C (81% vs. 74%; NS); BMI (27% vs. 21%; NS); waist circumference (31% vs. 21%)
EUROACTION (general practice arm), MA 62 years, 53% M [26]	2008	Europe (United Kingdom, Denmark, the Netherlands, Poland, Italy, Spain)	General Practice	High multifactorial risk, on treatment for BP lowering, lipid modification, and diabetes	2317 (cluster randomization)	Smoking, diet, physical activity, weight, waist, BP, lipids and glucose, quality of life	GP high risk: Reached goal for BP (58% vs. 41%[a]); LDL-C (45% vs. 35%); BMI: (23% vs. 22%); waist circumference (23% vs. 15%; NS) significant improvements in diet[a] and physical activity[a] INT (both groups) vs. UC
ELMI (extensive lifestyle management intervention), MA 64 years, 83% M [42]	2006	Canada	Hospital	Patients with ischemic heart disease postcardiac rehabilitation	302	Smoking, diet, physical activity, weight, waist, BP, lipids, and glucose, quality of life	4.1 year of follow-up: significant reduction in global risk including TC, LDL-C, and BP
Campbell-Nurses primary care study, MA 66 years, 83% M [43]	1998	Scotland	General practice	Working diagnosis of CHD	1343	Smoking, diet, physical activity, BP and lipids	1 year: INT vs. UC improved use of aspirin (81.0% vs. 66.4%[b]); lipids (96.5% vs. 87.9%[b]); BP (96.5% vs. 87.9[b]); INY vs. UC overall OR,0.55[b]; 4.7 year: total mortality INT vs. UC (14.5% vs. 18.9%[a])
MULTIFIT MA 57 years, 79% M [44]	1994	United States	Hospital	Post-AMI	585	Smoking, diet, exercise, and lipids	INT vs. UC: improved: smoking cessation (70% vs. 53%[c]), functional capacity (9.3 vs. 8.4 METs[b]) LDL-C (107 vs. 132 mg/dL[b])
SCRIP (Stanford Coronary Risk Intervention Project), MA 56 years, 83% M [45]	1994	United States	Hospital	Angiographically defined coronary atherosclerosis	300	Smoking, diet, physical activity, weight, BP, lipids, glucose	47% less CAD progression by arteriography, INT vs. UC: (0.0024 vs. 0.045[a]); INT vs. UC: LDL-C –0.95 vs. –0.16 mmol/L,[b] TG –0.34 vs. –0.01[c]; increased in lipid lowering medications 80.7% vs. 24.4%[b]; fewer no. of primary cardiac events INT vs. UC (OR = 0.57[a])

66% female; 36% non-White; mean age, 48 years) of patients hospitalized with CVD and designed to evaluate a special intervention (SI) with personalized risk factor screening, therapeutic lifestyle-change counseling, and progress reports to physicians versus a control intervention (CIN) on the primary outcome, mean percent change in LDL-C, and other risk factors. At baseline and one year, validated dietary assessments and standardized risk factors were obtained. For 93% of the subjects at baseline, saturated fat comprised ≥7% of total caloric intake and 79% had nonoptimal LDL-C levels (50% were unaware). There was no difference in the SI versus the CIN with respect to the mean percent change in LDL-C (−1% vs. −2%, respectively; p = 0.64), owing to a similar significant reduction in LDL-C in both groups (−4.4 and −4.5 mg/dL, respectively). Diet score, however, significantly improved in the SI versus the CIN (p = 0.04). Further, cardioprotective high-density lipoprotein cholesterol (HDL-C) declined significantly in the CIN but not in the SI (–3.2% [95% CI, −5.1 to −1.3] vs. +0.3% [95% CI, −1.7tp +2.4]; p = 0.01). Relatedly, at 1 year, SI subjects were more likely than controls to exercise >3 days per week (p = 0.04).

While these results indicate that SI was not more effective than the CIN in reducing the primary end point, LDL-C, the screening process did identify many family members of hospitalized patients with CVD who were not aware of their risk factors. Relevant to implementation in "real-world" clinical practice settings, the special intervention included personalized risk factor screening and lifestyle counseling by certified health educators at regular intervals as well as progress reports to physicians. Participants in the CIN received a general prevention message at baseline. Of note, both groups significantly improved their intakes of saturated fat and cholesterol and the SI was more likely to exercise >3 days a week at 1 year. While these behavioral–lifestyle changes are modest, if sustained over time, it could be clinically important independent of lipid effects. As the investigators conclude, and supported by other data, physicians (and nurses and other health care providers) should ask about recent family cardiac events at each patient encounter and screen family members during this "motivational moment" [38].

While this study focused on adult family members, the design allows for extension to multigenerational family members of probands (individuals hospitalized for acute events or interventional procedures). Using age-appropriate, evidence-based guidelines for CVD prevention and implemented by a multidisciplinary, nurse-led, case-managed team approach, FIT could be adapted and implemented with multigenerational families. Essential to successful implementation of this family model of CVD prevention are elements of the chronic care model (discussed previously) and integrated systems of care.

SUMMARY

CVD aggregates in families and is attributable to the interplay of shared genes, and potentially modifiable environmental exposures, and health behaviors. The importance of health behaviors in the prevention and management of CVD across the life course is well established [19]. As reflected in current evidence-based guidelines, the adoption and maintenance of heart-healthy behavior patterns and therapeutic lifestyle change is the cornerstone of primary and secondary prevention of CVD [1,17,18]. The efficacy and effectiveness of multigenerational, nurse-based case-management in prevention of CVD (enhancing risk reduction and improving patient outcomes) has been demonstrated [39–41]. Accumulated data support the need for family-focused CVD prevention and the promise and potential of adapting multidisciplinary, nurse-based case-management models for implementation with multigenerational families. Research is needed to guide and inform optimal family-focused approaches designed to prevent and reduce the risk and burden of CVD in families from diverse populations [25,51,52].

The rationale for preventive medicine is based on the concept that human behavior is a strong determinant of one's health. How we eat, how much we exercise, how prudent we are in avoiding accidents, how we protect ourselves from risk of infections, how we restrict use of tobacco, alcohol, and drugs—they all act as primary determinants of health. Such influences can be immediate—wearing of seat belts, for example—while others contribute to long-term health, such as reduction in cancer rates with smoking cessation. By modifying certain behaviors, then, improvements in physical and mental health, translated into *well-being*, can be expected on both an individual and population-wide basis.

The implication here is that such a salutary effect is directly under the control of the individual. Individual choices in lifestyle truly matter; personal responsibility is central to effective preventive medicine interventions. Importantly, too, adopting a healthy lifestyle bears more than minor significance. The accumulated scientific evidence convincingly indicates that the list of diseases implicated as behavior-related includes the major causes of morbidity and mortality in the population.

Preventive medicine in children carries the same precepts, but with some important differences. First, lifestyle decisions—brushing teeth, nutritional choices, wearing bicycle safety helmets—are typically not under the control of the child him- or herself but rather fall to a parent or caretaker. Indeed, educating children as to the wisdom of proper health-related behaviors, and assuring they are carried out, are primary responsibilities of raising children. Obviously, autonomy in such decision making increases as the child grows. That means that preventive medicine strategies aimed for children need to be adjusted to the developmental stage of the child. Such considerations are important in educational initiatives as well as the means that evidence-based preventive medicine strategies are confirmed by scientific research. Structuring and evaluating the effectiveness of smoking cessation messages to teenagers, for example, can be expected to be very different from those presented to parents promoting early physical activity habits in preschoolers.

The other aspect that sets pediatric preventive medicine apart from that in adults is that of *time*. With an entire lifetime ahead of him, establishment of a healthy behavioral lifestyle in a 7-year-old boy is more likely to pay health dividends in the long run than if such habits are suddenly introduced at age 45 years. That's why interventions to establish patterns of healthy behavior in youth are often said to take advantage of a "window of opportunity" provided by an early start.

The kinds of lifestyle patterns in children that will offer protection from future health issues in the adult years are the topics of the chapters that follow. It is clear that behavioral influences in the growing years might affect salutary outcomes down the road by at least two possible mechanisms. First, by retarding the biological development of long-term disease processes that begin during the pediatric years (such as atherosclerosis and obesity), the risk clinical outcomes of these processes in the adult years (myocardial infarction, stroke)

might be reduced. And second, habits such as regular physical activity and good nutrition established during childhood may persist throughout the life span and provide long-term benefits.

The rationale for those aspects of pediatric preventive medicine whose goal is long-term health benefits rests on these two effects of behavioral conditioning during the growing years. While both are intuitively attractive, pediatric exercise scientists and health-exercise professionals face a number of challenges in providing evidence-based practices based on these premises. In the sections that follow, both perspectives will be reviewed. It will be obvious that while a number of significant obstacles need to be overcome, the potential benefit of appropriate behavioral initiatives in children offers to provide enormous benefit to the health and well-being of the population.

REDUCTION OF RISK FOR CHRONIC DISEASE

It is important to consider behavioral factors that might reduce or even interrupt chronic disease processes early in life, which would otherwise eventuate in disease in the adult years. Most attention here has been focused on physical activity and fitness in youth, and we can consider this as a strategic preventive health model. Certain facts are clear. Research data in the adult population have clearly documented what has been considered true since antiquity—exercise is good for your health. What's more, the list of diseases for which regular physical activity and fitness reduce risk includes those which are most responsible for morbidity and mortality in developed nations (myocardial infarction, hypertension, obesity, type 2 diabetes mellitus, osteoporosis, certain malignancies).

Important to recognize, though, is the fact that although adverse clinical outcomes from these diseases occur in adults, they often reflect the end-result of lifetime pathological processes that begin in the pediatric years. Early atherosclerotic vascular changes are commonly evident, for example, in teenagers. The majority of obese adolescents become obese adults. Youth who gain less bone density during the growing years carry a greater risk for osteoporosis and bone fractures when they are elderly.

By deductive reasoning, then, it makes sense that early institution of regular exercise habits during childhood and adolescence should be expected to retard the development of chronic disease processes over the course of a lifetime [1]. The result, goes this line of thinking, would be a reduction of disease risk later on in the older adult years. This is a solid concept that is intuitively attractive and which has served as a convincing rationale for promoting high levels of physical activity and fitness in children, sometimes as early as the preschool years [2].

The difficulty lies, though, in that scientific proof of the efficacy of this approach is elusive, since clinical outcomes of exercise interventions won't be obvious for another 30 or 40 years. Designing a long-term longitudinal study that would consider eventual adult health outcomes in active versus inactive children, while considering all the influencing variables, is a daunting proposition. Thus, specific proof of this rationale will probably therefore never be at hand.

As an alternative, then, researchers have focused on examining the influence of activity behavior in children on factors considered to reflect risk of future adverse health outcomes. The evidence, as will be addressed in the chapters that follow, has been mixed. Children who are more physically active generally have been found to exhibit superior bone density, supporting the idea that early accumulation of bone strength will limit the decline in bone density, which is the natural progression in the later adult years. So, here is a behavior—weight-bearing activity that places growth-stimulating stress on bones—which can be confidently supported in children as an effective preventive health initiative.

At the same time, studies examining the relationship in youth between levels of activity and fitness with risk factors for adult atherosclerotic coronary artery disease (abnormal serum lipids, blood pressure) have generally been disappointing [3]. Unlike research findings in adults, no associations have typically been observed. So, there may be differences in such effects between children and adults. However, when such risk factors are considered as clustered together in children, significant associations are observed with activity levels [4] (Chapter 96). And new ultrasound techniques for looking at the physical nature and reactivity of peripheral arterioles in children are showing unfavorable changes in those with other risk factors, particularly obesity [5] (Chapter 92). It is observed, too, that increases in level of physical activity and fitness in youth do appear to lower traditional coronary artery disease risk factors when such factors are abnormal to start with (i.e., in youth with obesity, or hypertension, or hyperlipidemia). It may be, then, that during the growing years, activity and fitness serve to *prevent* the development of cardiac risk factors [2].

Overall, a good deal of indirect information does support the concept, then, that behavioral change (in this case, improved activity habits) in youth can suppress long-term pathophysiologic processes and reduce risk of disease outcomes later in life. Improved noninvasive methods for assessing the development of such processes, as well as the extent that lifestyle changes in children might alter them, should provide better insights in the future.

The concept that behavioral interventions during childhood can result in improved adult health by retarding lifelong pathological processes is not without its challenges. There is currently no means by which the effect of various behavioral changes in the growing years on such disease processes can be directly assessed. The mechanisms by which behavioral interventions might influence pathologic processes is presumably different for the various disease outcomes (that is, one needs to restrict calories to prevent obesity but engage in weight-bearing activities to effect growth in bone strength). Also, establishing dose–effect relationships (how much activity is needed?) for each of these different relationships will be difficult.

CREATION OF HEALTH-PROMOTING HABITS

One of the linchpins of pediatric preventive medicine is the expectation that lifestyle behaviors adopted during the childhood years will persist through to the adult years. This idea serves as the basis for the strategy of introducing children to pleasurable physical activities that will become habit, for instance, rather than prescribing some specific threshold of amount of routine exercise (i.e., 1 h daily). So this is classic behavioral modification, attempts to alter behavior early on that will then hopefully "stick" through the course of a lifetime.

The argument for this approach is intuitively attractive. We expect that behaviors gained during the pediatric years will form the foundation for personal characteristics in adulthood. Such an approach has not, however, been met without criticism. Within the constraints offered by both biologic and external environmental influences, how possible is it to permanently alter lifestyle behaviors in youth? And if this can be accomplished, are there critical periods when attempts at behavior modifications are likely to be most successful? What types of interventions to alter behavior would be most successful?

Unfortunately, there exists a surprising dearth of research information on which to address these issues [6]. A number of studies have attempted to assess whether a physically active youth is more likely to be active as an adult. These have generally failed to show an impressive relationship, but such reports have been weakened by inadequate measures of activity, use of sports play instead of activity levels, and a focus on adolescents rather than young children [7]. Indeed, the key question, whether increasing a sedentary child's level of routine physical activity will result in long-term improvements in activity habits, has never been addressed.

Developmental psychologists have long been interested in what happens to children's behavior patterns over the course of time. Most of this literature has addressed the question of learning behavior, trying to tease out the answer to the question of whether early education will have an impact on future cognitive abilities. Also, much of the research information on acquisition of behavioral habits comes from studies in animals, in which the possible influence of cognitive mechanisms presumably can be disregarded.

In these reports, a number of possible means by which behavioral habits are acquired—and sustained—have been considered. Which, if any, truly reflect central mechanisms for habit formation remains controversial. But within these data might come some clues as to the influence of behavior modification in youth on health-related lifestyles in the adult years.

Conditioning

This is the well-known "Pavlovian reflex" whereby a certain behavior in response to an external cue (a bell ringing) is reinforced by a reward that supports the behavior. This approach has been a common one in efforts to establish intrinsic rewards to regular physical activity. Factors which might support this have included fun, lack of embarrassment or competition, peer acceptance, and charismatic exercise leaders. These have all been considered strong positive reinforcers for engaging in physical activity in youth, but the extent that they are successful in instilling exercise behaviors that persist long term is unknown.

Imitation

Behaviors in children are certainly to a great extent adopted in response to those they witness in family, peers, and what is viewed in the popular media. Development of language, musical tastes, and smoking habits are clear examples. When investigators have examined the importance of parent modeling of physical activities on their children, however, the results have been mixed. Too, the permanence of imitated behaviors might be suspected to change with time in respect to exposure to different social environments (i.e., college).

Imprinting

Studies in animals have convincingly demonstrated that persistent, permanent behavioral patterns can be established in young animals by stimuli presented at certain critical periods in development. These behaviors have generally been social in nature—mating activity, search-and-following behavior, and social attachments—that, interestingly, do not have any functional importance in immature animals and are formed without reinforcement by external rewards.

Whether or not permanent imprinting can occur in human children has been long debated by developmental psychologists, with no consensus of opinion. Moreover, if imprinting of social (or health-related) behaviors can be achieved in humans, the particular vulnerable periods in a child's life when this might occur are unknown.

Whether a child's health-related behaviors, particularly physical activity and nutrition, might be established early on for a lifetime by mechanisms such as conditioning, imitation, and/or imprinting remains an intriguing but unresolved question. Clearly, an impetus in developmental psychology research addressing this question might provide important dividends. The success of pediatric preventive medicine strategies designed to support future health of the child will depend on insights into just how youngsters can be motivated into sustained health-related behaviors.

BIOLOGICAL INFLUENCES ON HEALTH-RELATED BEHAVIORS

At the beginning of this chapter, the traditional concept was presented that behavior that influences one's health is under the willful control of the individual. This is based on the idea that self-determinism exists in making decisions regarding lifestyle and forms the foundation for preventive health efforts to encourage altering such behavior, both on an individual and population-wide basis. That is, when it comes to health lifestyles, one is free to choose.

In fact, however, recent data have indicated that certain biological factors may also influence not only lifestyle choices, such as how much one exercises, but also the extent that these decisions affect health risk factors. Some evidence suggests, too, that these intrinsic determinants might be more influential in the pediatric years. The extent that such biological factors might control the exercise-health link is not clear at present, but greater insights into such influences will be important in designing public health strategies and understanding outcomes of interventional strategies.

Central Control of Physical Activity Energy Expenditure

If one plots amount of daily physical activity observed in a child as he or she grows, and expresses this relative to body size, a progressive decline is observed [2]. The fall in activity with age is evident both in boys and girls and is consistently observed regardless of whether one uses measures of direct observation, activity monitors, or caloric expenditure. The drop-off in activity is more than minor, amounting to a decline of approximately 45% between the ages of 6 and 16 years. (This decrease in daily activity relative to body size actually continues throughout the life span, but with a less precipitous decline.)

Such a drop-off in regular activity has often been viewed by public health officials with alarm, being interpreted as a trend for adopting an increasingly sedentary lifestyle as the child grows. In fact, however, the persistent decrease in physical activity with age during childhood is a normal biological phenomenon. The best proof of this is that identical declines in daily energy expenditure are observed in all animals as well—from nematodes to chimpanzees. They all demonstrate dramatic decreases in body movement as they age [8].

What is the biological "meaning" of this decrease in energy expenditure as children grow? The clue to the answer to this question may lie in the observation that other major components of energy balance, caloric intake (appetite), and resting metabolic rate demonstrate parallel declines with age. The fall in daily energy expenditure via physical activity may represent, then, one means for the body to maintain a strict energy balance (and body composition) over time [9].

The obvious implication here is that, de facto, there must be an intrinsic, biological controller of daily motor activity that resides in the central nervous system. This conclusion is supported by other evidence, such as the recognized effects of certain pharmacological agents on daily activity as well as changes observed in motor activity after brain damage, either experimentally in animals or in humans with brain lesions [10].

When one considers the goals of strategies to improve physical activity in children, it is important to recognize this natural curve of activity with age. For instance, the significant drop-off in normal activity level indicated by this curve needs to be taken into account when attempting to establish recommended amounts of daily activity for health in children and adolescents of different ages. It is important, too, to realize that interventions to improve activity habits in children are actually attempting to "bend" upward a curve of normal decline in activity with age. The good news is that evidence exists that this biological curve of activity during childhood is, in fact, "plastic," that is, extrinsic factors can influence its shape [3]. Future research models might be best constructed with this concept in mind. Parallels to other health-related behaviors, such as caloric intake, are obvious. Preventive health interventions need to be conceived considering the natural developmental progression of the behavior during the growing years.

Gene–Environment Interaction

The role that genetic information might play in controlling how behaviors affect health risk is an intriguing issue that is just beginning to be investigated. To start with, the evidence is clear that factors such as one's body composition, physical activity habits, and serum lipid profiles are at least partially under genetic control [11]. The next questions, then, have drawn research interest: To what extent can purposeful behavioral modification modify this genetic expression? And what part might genes play in defining the interaction between modifiable risk factors?

As an example of new information, early studies in adults have suggested that an interaction might exist between physical activity and the ACE I/D genotype with blood pressure [12]. Limited studies in children, however, have failed to bear out such a genetic influence [13].

Genetic influences do, in fact, affect behaviors that bear on health and well-being. But the extent that these intrinsic factors control lifestyle "decisions" in contrast to those resulting from self-determined behavior, particularly in the pediatric years, remains uncertain. It does appear evident, however, that the potential biological influences on behavioral preventive health initiatives need to be appreciated when assessing outcomes of these interventions.

VENUES FOR BEHAVIORAL MODIFICATION IN YOUTH

Opportunities for altering health-related behaviors in children arise in a number of venues. Where such strategies might be best focused remains to be defined, though, since each possesses its own particular advantages and disadvantages.

Family

Since it is within the family structure that children first learn behaviors, striving to create a healthy lifestyle in the home setting has obvious appeal. The ways in which the family environment can influence factors such as physical activity and eating habits in youth, however, is complicated. In respect to physical activity, most studies have examined how

parents' role modeling (their own participation in physical activities) and support (verbal, providing exercise resources, or via transportation) are related to level of their child's activity. The results have not always been consistent, and in fact, are sometimes surprising.

Literature reviews have indicated that a significant positive relationship between children's overall daily physical activities and that of their parents (mostly by questionnaires) has been observed in only about one-third of studies. It is possible that this surprisingly weak association may be explained by inadequate measurement tools. In the few studies using more objective activity measures (i.e., accelerometers), positive relationships between parent and child activity levels have been observed. Too, a strong association has been reported between parents' role modeling and children's participation in organized sports.

Important relationships have been described between parent support and overall physical activity in youth. However, how this influence might differ with age and gender has not been consistent among different reports. Similar relationships in respect to age would appear to be obvious for factors such as eating habits, smoking, and sexual activity. More insights are needed on the forms of family-based activity interventions for health-related behaviors which might be most efficacious during different phases of the growing years.

School

The potential role of the school in educating youth regarding wise decision making in matters of healthy behavior would seem to be obvious. However, along with other subjects such as art and music that do not fit into a traditional academic curriculum, health education has often been relegated as a subsidiary and dispensable part of the school curriculum.

This has been particularly true in physical education, in which the school setting has been considered the optimal means of promoting exercise habits in youth. Participation is requisite, with supervision by knowledgeable instructors in a safe setting with proper facilities and equipment. It is particularly frustrating to health-exercise professionals, then, to witness the steady decline in physical education opportunities via its exclusion from the school curricula. Moreover, there appears to be no immediate sign that this trend will be reversed, indicating that efforts to enhance activity levels of youth will need to be expanded to other settings.

Even among the physical education leaders there exists some indecision regarding the particular role of PE classes in the schools for promoting activity. Should physical education class be a place where children actually expend their time in physical activity? Or should the focus be concentrated instead on not only teaching children motor skills but also teaching them why and how to develop a healthy lifestyle. That is, should "education" be the role of physical education?

Physicians' Offices

The advice of physicians carries considerable credibility, and exposure to young patients is high. Indeed, what doctors caring for youth typically do in their offices all day is practice different aspects of preventive medicine. But, in general, physicians have not played a major role in confronting specific issues of inadequate physical activity and poor nutritional choices in their patients. Since health care providers recognize that "exercise deficiency" carries medical risk, for example, one would expect they would. That this opportunity has not been widely embraced can be traced to several barriers: (1) there exists no evidence-based approach by which physicians can provide a specific exercise prescription for the sedentary child, (2) physicians have received little or no training regarding physical activity counseling or nutrition, (3) activity and nutrition counseling is hampered by the time constraints of a busy office, and (4) uncertainties exist regarding reimbursement for behavioral counseling.

COMING CHAPTERS

With the foregoing comments as a preamble, the chapters that follow will provide the reader with an update on some of the more exciting issues that are currently in the forefront of pediatric preventive medicine. It will be obvious, too, that a good number of topics are missing, a necessity given page restrictions and the very global nature of how behaviors in youth can influence lifelong health and well-being. It should be recognized that neglected subjects such as smoking, drug abuse, sexual behavior, sleep and time management, social relations, stress management, sports injury prevention are all pertinent to youth as well as adults.

Pediatric preventive medicine might be expected to encompass issues varying from those of the infant all the way up to maturity. But one of the most intriguing new ideas in this field is that prenatal exposures—even before the fetus confronts the external world—might have important bearing for future health. And, in conforming to the construct of preventive medicine, many of these intrauterine influences might be modifiable. In Chapter 96, Debbie Lawlor reviews current information regarding prenatal influences on future health. It's a new perspective, not entirely well understood, but one which offers the promise of unique insights into factors influencing chronic disease processes.

Elevated cholesterol levels are associated with risk for coronary artery disease in adults, and limited information suggests that hypercholesterolemia bears the same triggering effect early on in the atherosclerotic process during the pediatric years. But the management decisions regarding identification and treatment of youth with abnormal lipid levels have not always been clear and, indeed, have been open to some debate. For clinicians confronting such patients, however, a well-defined approach is necessary. Frank Greer and Steve Daniels provide an overview of this issue in Chapter 94.

One of the most exciting advances in the field of preventive medicine has been the development of the capability for

examining the health of peripheral vessels by high-resolution ultrasound techniques [5]. Based on such studies, one can evaluate early changes in wall thickness, compliance, and reactivity that are reflective of initial phases in the atherosclerotic process. As noted earlier, a major obstacle for pediatric exercise scientists is linking behavioral interventions, particularly physical activity, in children with long-term adverse clinical outcomes. How can one establish, for instance, if a program of 1 h of activity daily in a 10 year old will suppress the development of atherosclerosis and reduced risk of myocardial infarction at age 50? Or determine if disease states in a child, such as obesity or systemic hypertension, accelerate that risk? Early studies, reviewed by Bo Fernhall in Chapter 92, indicate that ultrasound examination of the peripheral vasculature may provide some direct answers to these questions. Evidence of the utility of this approach in answering questions of epidemiology, causality, and intervention success in the field of pediatric preventive medicine is just beginning to accumulate. Whether application of ultrasound techniques to assess vascular health might eventually become useful in the future as a clinical tool in patient management is a tantalizing but as yet untested possibility.

Of all the childhood risks for future health problems, the dramatic escalation in frequency of obesity and the associated metabolic syndrome in the pediatric population has raised greatest concern. A strong link is recognized between childhood and adult obesity, and a distinct relationship exists between obesity and hyperlipidemia, hypertension, glucose intolerance, and insulin resistance as well as orthopedic, gynecologic, oncological, and other chronic health issues. All this adds up to an expected tsunami of adverse disease outcomes as the increasingly obese pediatric population moves into the adult years. This disturbing pattern is examined by Scott Owens in Chapter 91.

The role of physical activity in reducing risk factors for adult cardiovascular disease is described by Lars Bo Andersen and Robert McMurray in Chapter 95. From the standpoint of understanding these relationships in youth, the most important recent findings tell us that amount of daily activity is linked to clustered risk factors. Moreover, such studies have been able to estimate the volume of physical activity that might be necessary to achieve such an association. This information provides hope that future interventional studies looking a clustered risk may be able to establish evidence-based thresholds for salutary activity levels in the childhood population.

Of all the behavior-health links proposed for youth, the impact of early optimization of bone density development on reducing future risks for osteoporosis and bone fractures in the elderly years is perhaps the most compelling. Saija Kontulainen and Don Bailey provide an update on evidence supporting this construct in Chapter 93. This information is particularly useful in indicating that a certain *type* of exercise—weight-bearing activities that put stress on bones—is efficacious for a particular health outcome.

SUMMARY

Behaviors adopted during the growing years (and maybe even in fetal life) bear promise to positively affect health and well-being in respect to lifelong outcomes. In fact, when one considers the potential impact of such health-related behaviors on the major chronic diseases of adults, the importance of pediatric preventive medicine efforts in improving the health of the population becomes quite convincing. The "window of opportunity" of suppressing the early course of development of pathologic processes such as atherosclerosis and obesity offered by early preventive interventions in youth can be expected to pay significant long-term health dividends.

The rationale for the strategy of early lifestyle modifications for their salutary effects on long-term health is compelling and intuitively strong. Nonetheless, in implementing initiatives based on this model, practitioners of preventive pediatric medicine face a number of significant obstacles. Absolute scientific proof of this concept will probably never be available. The lack of immediacy of health outcomes from altered behaviors during childhood creates a problem of motivation. How can one convince a child and his family to exercise a certain amount, or eat a certain way, when any possible benefits won't be evident until 40 years later down the road? Perhaps as a consequence, health practitioners, while recognizing the importance of regular exercise and good nutrition, have traditionally had little confidence in their ability to make such behavioral changes in their patients.

Physicians, health-exercise professionals, physical education teachers—all those involved in guiding youth in positive health-related behaviors—are in need of better methods for modifying behavior. Disillusionment with the ability to change a child's activity or eating behavior on the art of professionals is likely if the means of achieving such results have not been established by good scientific research. Indeed, much more needs to be known before such strategies of behavior modification in youth can be expected to be successful. What strategies are useful? What factors influence success? How do we recognize and manage children at particular risk? And we need to consider children's activity in their social setting. What are the determinants of health-related behaviors in families? The challenges facing pediatric preventive medicine are considerable, but the potential rewards in creating a healthier population are great.

The prevalence of childhood obesity and the metabolic syndrome (MetS) has increased dramatically in the United States and other industrialized nations during the past two decades. While the social and psychological burdens often encountered by obese children might seem like challenge enough, there is the additional issue of the short- and long-term medical consequences of their obesity. Since it is likely that primary care clinicians and other health care professionals will have increasingly frequent interactions with obese children, it is important to stay abreast of the latest research in the field.

This chapter will present an overview of the current state of knowledge regarding childhood obesity and the MetS. Childhood obesity will be discussed first, focusing on issues related to definition, prevalence, consequences, causes, prevention, and treatment. Presentation of similar issues related to childhood MetS will follow.

CHILDHOOD OBESITY

Defining Childhood Obesity

Defining childhood obesity is difficult and no single definition is universally employed [1]. Ideally, the definition should reflect adiposity, or the amount of body fat, and be related to morbidity and mortality outcomes. An ideal measure of body fat would be the following: (1) accurate in its measure of body fat; (2) precise, with a small measurement error; (3) accessible in terms of simplicity, cost, and ease of use; (4) acceptable to the subject; and (5) have published reference values [2]. Unfortunately, no current measure satisfies all these criteria, and there is no precise, widely accepted definition of obesity in children based on body fatness [3]. Due to its simplicity, cost, and published reference values, large-scale national surveys have tended to describe and assess childhood overweight and obesity utilizing body mass index (BMI), which is calculated as weight in kilograms divided by height in meters squared. To account for variability due to age and sex, BMI in children is compared to age- and sex-specific reference values. In the United States, the Centers for Disease Control and Prevention (CDC) year 2000 growth charts serve as reference values [3]. The National Center for Health Statistics (NCHS) and the CDC now use the term "overweight" for childhood BMI values between the 85th and 95th percentiles (formerly called "at risk for overweight") and the term "obesity" for childhood BMI values at or above the 95th percentile (formerly called "overweight") [3]. Recently, two alternative approaches to defining childhood obesity have become popular: waist circumference (or indices based on waist circumference such as waist to height ratio) and BMI values interpreted relative to the International

Obesity Task Force cut-points rather than national percentile cut-points [1]. However, a recent systematic review concluded there was no compelling evidence for use of waist circumference or International Obesity Task Force–based BMI values in preference to national BMI percentiles for the identification of children with excess fatness or adverse cardiometabolic risk profile [1]. Other commonly used thresholds for overweight and obesity in childhood are 110% or 120% of ideal weight-for-height and weight-for-height z-scores of higher than 1 or 2 [4].

Prevalence of Childhood Obesity

The prevalence of childhood overweight and obesity has more than tripled in the United States over the past three decades with rates high among most age, sex, racial/ethnic, and socioeconomic groups [5]. Data from the 2007 National Survey for Children's Health (ages 10–17) reported the prevalence of overweight (BMI ≥ 85th sex- and age-specific percentile) as 31.6% and the prevalence of obesity (BMI ≥ 95th sex- and age-specific percentile) as 16.4% [6]. Thus, nearly one in three U.S. children is either overweight or obese [7]. Ethnic differences are also apparent. After adjusting for socioeconomic and behavioral factors and for state of residence, Black and Hispanic children, respectively, had 71% and 76% higher odds of obesity than their White counterparts [5]. Nor is the obesity epidemic limited to the United States, with estimates for overweight and obesity of 38% for Europe, 40% for the eastern Mediterranean, 27% for the western Pacific, and 22% for Southeast Asia [8].

Causes of Childhood Obesity

At the fundamental level the cause of childhood obesity can be seen as a greater imbalance between energy intake and energy expenditure than expected for normal growth and development [9]. Still, an epidemiologic perspective informs us that the causes of childhood obesity are complex and multifaceted [10]. A risk factor perspective for childhood obesity as summarized by Kipping et al. [11] and Han et al. [4] is shown in Table 91.1. Concomitant with the risk factor perspective is the notion that childhood obesity has been fostered by the presence of an "obesogenic" culture that relentlessly exposes children to a food environment that promotes overconsumption of calorie-dense, nutrient-poor foods while supporting a physical activity environment that favors sedentary behavior [12]. Thus, a complicated interplay of risk factors, an obesogenic environment, and genetic susceptibility appear responsible for the current epidemic in childhood obesity.

TABLE 91.1
Risk Factors Associated with the Development of Childhood Obesity

Risk Factor	Comment (References)[a]
Single-gene defects	Obesity is the specific abnormality, e.g., those related to the leptin signaling pathway [14]
Genetic obesity syndromes	Obesity is a manifestation of Prader-Willi, Cohen, Alstrom's, and Bardet-Biedl syndromes [14]
Endocrine disease	Diseases include hypothyroidism, Cushing's disease, Cushing's syndrome, growth hormone deficiency, growth hormone resistance, pseudohypoparathyroidism [15]
CNS pathology	Can result in hypothalamic obesity syndrome [16]
Inheritance	Genome-wide association studies have identified genetic variants that are associated with obesity [17]; children with obese parents are at high risk for becoming obese [18]
Ethnicity	Hispanic children have an increased risk of obesity compared with White children [19]
Intrauterine exposure to gestational diabetes	In populations at high risk for obesity (such as Pima Indians), exposure to gestational diabetes is associated with increased risk of childhood obesity [20]
Birthweight	High birthweight is associated with increased fat and lean mass [21]; Small-for-gestational-age babies who show catch-up growth might be at increased risk for childhood obesity [22]
Diet	High energy intake and high consumption of sweetened drinks are prospectively associated with increased risk for childhood obesity. Evidence for other dietary habits is not strong [23]
Physical activity	Low levels of physical activity are associated with high childhood obesity risk [24]
Television viewing	High television viewing hours associated with increased childhood obesity risk [25]
Sleep	Short sleep duration is associated with increased risk for childhood obesity [26]
Socioeconomic status	In developed countries, children in lowest socioeconomic groups have increased risk for childhood obesity [27]
Urban vs. rural residence	Urban residence increases risk for childhood obesity [8]

[a] References are generally for recent systematic reviews of the various risk factors.

Consequences of Childhood Obesity

Overweight children are at risk for significant health problems both during their youth and as adults [9]. As shown in Table 91.2, adverse associations have been observed between childhood obesity and numerous organ systems. Not only are obese children more likely to become obese adults [13], but obesity during childhood carries risk for adult mortality and morbidity. Greater BMI in childhood was associated with increased adult mortality risk from cardiovascular disease [28], being overweight or obese between the ages of 14 and 19 was associated with increased mortality (from age 30 years) from various systemic diseases [29]. In addition to health risks, obesity influences children's quality of life, impacting their physical, social, and psychological functioning [30].

TABLE 91.2
Adverse Associations with Childhood Obesity by Organ System

Organ System	Adverse Associations (References)
Cardiovascular	Dyslipidemia [31]
	Elevated blood pressure [32]
	Atherosclerosis [33]
Pulmonary	Obstructive sleep apnea [4]
	Asthma [34]
Endocrine	Insulin resistance [35]
	Proinflammatory cytokines [36]
	Pubertal advancement [37]
	Metabolic syndrome [38]
Gastrointestinal/ nutritional	Low vitamin D concentrations [39]
	Iron deficiency [40]
	Nonalcoholic fatty liver disease [41]
Orthopedic	Lower-limb malalignment [42]

PREVENTION AND TREATMENT OF CHILDHOOD OBESITY

Prevention and treatment of childhood obesity have progressed along dual tracks, employing both the medical and public health models. According to Schwartz and Brownell [12], the medical model frames childhood obesity as a disease or illness that strikes individuals due to internal or external causes, while the public health model frames it as a disease that strikes a population as a consequence of individual vulnerability combined with exposure to environmental elements. Within the medical model, childhood obesity is an individual child's physical problem identified by a health professional requiring individual treatment. Researchers and clinicians have developed individual and family treatments that address the needs of individual cases. From a public health perspective, epidemiological questions related to childhood obesity are addressed, causal factors for the population are identified, and community, state, or national changes are proposed that appear feasible and likely to have an impact on prevalence. Aspects of both approaches are discussed in the following.

Prevention

Although prevention is universally viewed as the best approach to reverse the rising prevalence of childhood obesity [4], the evidence base for how best to prevent childhood obesity is still incomplete [43]. From a medical perspective, Murray and Battista [44] note that primary care clinicians are in a unique position relative to preventing childhood obesity; no other professional has access to the child and the family in the early critical period before the influences of the obesogenic lifestyle have become fully manifest. They argue that primary care clinicians need to be unambiguous and direct about what the family should and should not do relative to the obesity threat. As a starting point, they recommend the 10 core evidence-based messages and suggestions developed by the Expert Committee on the Prevention and Treatment of Childhood Obesity [45]. Those 10 recommendations are as follows:

- Support exclusive breast feeding for the first 6 months
- Limit sweetened drinks
- Limit TV to 2 h/day and no TV in the child's bedroom
- Do 60 min/day of moderate-to-vigorous physical activity
- Consume five to nine servings of fruits and vegetables per day
- Consume a nutrient-rich diet, high in calcium and fiber
- Eat dinner as a family five to six times per week
- Limit eating away from home, especially fast foods
- Limit portion sizes
- Consume a nutritious breakfast everyday

While primary care clinicians cannot curb the childhood obesity epidemic in isolation from other allied health professions, it is of paramount importance that they continually encourage families to establish daily habits that strengthen their children's nutrition and activity levels [44].

Outside the clinical setting, the majority of prevention programs for childhood obesity have been conducted in schools with targeted outcomes that include reducing weight status or weight gain, changing dietary patterns, and increasing physical activity. The popularity of school-based interventions is not surprising as there are several benefits to the school environment as a context for childhood obesity prevention efforts [43]. For one, nearly all children attend school; the percentage of U.S. children aged 10–14 years of age attending school is greater than 98% [46]. Schools also provide context for the eating and physical activity behaviors that influence body weight, and provide staff and resources (e.g., teachers, coaches, and nurses) that can support the dissemination of interventions [43]. Gonzalez-Suarez et al. [47] conducted a meta-analysis to evaluate the effectiveness of school-based programs in the prevention of childhood obesity. Both short-term (measured at the conclusion of the intervention) and long-term (measured at least 6 months after the intervention) outcomes and odds ratios (OR) were determined. The interventions were generally designed to decrease overweight by increasing physical activity, decreasing sedentary activities, and decreasing intake of foods high in fat and sugar content. A total of 19 studies met the authors' inclusion criteria and were included in the meta-analysis. The results showed that school-based obesity prevention interventions were more effective than the control arms in decreasing the number of children who became overweight or obese (OR = 0.74, 95% CI = 0.60–0.92). Interventions that were conducted for more than 1 year had a higher OR of decreasing the prevalence of

obesity than interventions of shorter duration. The authors concluded that school-based interventions can be effective, at least short term, in preventing childhood overweight and obesity.

The importance of the physical activity component in childhood obesity prevention deserves special mention. In a systematic review of 28 controlled intervention trials to prevent childhood overweight and obesity, Connelly et al. [48] found 11 interventions were effective and 17 were ineffective in reducing adiposity. The main factor distinguishing effective from ineffective trials was the provision of relatively compulsory, rather than voluntary, moderate-to-vigorous physical activity in the effective as compared to the ineffective interventions. Data also suggest that excess abdominal fat accumulation in children can be prevented by regular participation in vigorous physical activity [49]. Based on their review, Watts et al. [50] suggested that obesity prevention in children should emphasize increased physical activity rather than diet since physical activity can help preserve lean body mass normally lost during dietary energy restriction. De-emphasizing diet may also reduce the odds of a child developing disordered eating attitudes and behaviors. The effectiveness of reducing sedentary behavior as an intervention strategy for prevention of childhood obesity has also been investigated. Although the literature is not extensive, a review by DeMattia et al. [51] concluded that an emphasis on reducing sedentary behaviors is an effective intervention to decrease sedentary behaviors and control weight in children and adolescents.

Despite some evidence of success, school-based obesity prevention efforts have several important limitations. For one, they don't include the preschool population [43]. By the time children enter school, more than 20% of 2- to 5-year-olds are already overweight or at risk for overweight [52], suggesting a prime opportunity for preventing childhood obesity is being missed [43]. Unfortunately, programs focusing on infants are lacking [43] and only two of five prevention studies focusing on preschoolers reported significant reductions in weight status or body fat [53]. It should also be kept in mind that even for children attending school, most of a child's day is spent outside of school where opportunities for obesogenic behaviors are abound. The household or family, therefore, plays a key role. Randomized controlled trials focusing solely on household or family-based interventions to prevent childhood obesity are lacking [4].

Current opinion is that in order for childhood obesity prevention efforts to have a consistent, meaningful, and widespread impact prevention efforts must include the larger social environment in which children reside [12,30,54]. The first fully embedded, community-based initiative designed to change the environment to prevent obesity in early elementary school children appears to be the Shape Up Sommerville: Eat Smart, Play Hard project conducted in Somerville, MA [55]. In this intervention, which targeted children in grades 1–3, academics partnered with community members to conduct a controlled trial evaluating whether an environmental change intervention could prevent a rise in BMI z-scores in young children through enhanced access and availability of physical activity options and healthy food throughout their entire day [56]. Year-one results showed that BMI z-scores in the intervention community (n = 385) decreased by −0.1005 (p = 0.001, 95% CI = −0.1151 to −0.0859) compared with the children in the control communities (n = 793). The authors suggested that the effectiveness of a community-based model represents a step forward in society's approach to childhood obesity.

While some limited successes in preventing childhood obesity can be pointed to, it has been suggested that legislative and regulatory action will be needed if substantial progress is to be made [12]. Some states have already taken action. For example, 28 states and the District of Columbia have set nutritional standards for school lunches, breakfasts, and snacks that are stricter than current USDA requirements, 20 states have passed requirements for BMI screenings for children and adolescents or have passed legislation requiring other weight-related assessments in schools, 23 states and the District of Columbia have laws that establish programs linking local schools farms to schools, and 23 states impose a sales tax on soda [57]. In addition, the White House Task Force on Childhood Obesity was created in 2010 and included a national action plan, with all agencies of the federal government participating, that included the goal of reducing childhood obesity rates from 17% to 5% by 2030 [57]. The impact of these recent legislative actions awaits evaluation.

Treatment

For the foreseeable future, treatment of childhood obesity will be an important individual and national health challenge. The Expert Committee on the Prevention and Treatment of Childhood Obesity has developed a set of recommendations for primary care clinicians that are prescriptive and specific [45]. Murray and Battista [44] note the intent of the expert committee was to put the responsibility for initial counseling and follow-up on the primary care clinician and to anchor the problem with one health care provider who could sustain long-term follow-through. Development of a care plan might begin with one or two easily achievable goals selected from the expert committee's evidence-based 10 core messages (listed previously). The process of shared goal setting by clinician and family, with subsequent close follow-up and establishment of fresh goals, is the central strategy for obesity treatment.

Recent meta-analyses indicate that multicomponent, family-based obesity treatment interventions are associated with modest, but clinically important, short-term improvements in child obesity status compared to standard care or no treatment control conditions [58–61]. While Epstein et al. [29] also noted that family-based behavioral pediatric obesity treatment programs have demonstrated both short-term and long-term efficacy, they

add that there is likely to be an increase in the prevalence of very overweight youth who require more powerful interventions than those currently available. They suggest that traditional clinical treatments that focus on the child and family may need to be combined with public health approaches that focus on the school and community to change the environment that promotes unhealthy eating and sedentariness.

Although schools have not been regarded as the main site for treatment of childhood obesity (as opposed to prevention), promising results from a randomized trial of classroom-based weight reduction in obese Mexican American children appear relevant [4]. In this study [62], 60 children between the ages of 10 and 14 years at or above the 85th percentile for BMI were randomly assigned to a 6 month intensive intervention or self-help condition. Children in the 12 week intervention group received nutrition instruction 1 day/week and physical activity training 4 days/week during a standard school period lasting 35–40 min. In addition, their parents were invited to attend monthly meetings to teach them how to adapt family meals and activities to facilitate healthy changes. Children and parents in the self-help group were provided *Trim Kids*, a book to be used for weight management by children and their families. Children in the intervention condition significantly reduced their z-BMI when compared to the children in the self-help condition at both 3 and 6 months. The authors noted that further efforts are needed to evaluate the long-term lifestyle changes.

At the community level, results on the effectiveness of the *Mind, Exercise, Nutrition, Do It (MEND) Program*, a multicomponent, community-based childhood obesity intervention, appear promising [63]. In this study, conducted in the United Kingdom, 116 obese children (BMI > 98th percentile) were randomly assigned to intervention or waiting list control (6 month delayed intervention). Parents and children attended 18 two hour educational and physical activity sessions held twice weekly followed by receipt of a 12 week free family swimming pass. At 12 months, children in the intervention group had reduced their waist circumference and BMI z-scores by 0.47 ($p < 0.001$) and 0.23 ($p < 0.001$), respectively. High attendance rates suggested the families found this intensive, community-based intervention acceptable.

Schwartz and Brownell [12] note a prime challenge for the future is to discover which childhood obesity interventions, policies, or programs have the greatest impact. They argue this will require a major research effort, one that is much larger than currently funded by the government. It must involve sensitivity to global factors that affect diet and activity and take into account broad social forces such as economics and the influence of industry.

CHILDHOOD OBESITY: SUMMARY

The prevalence of childhood obesity has risen to unacceptable levels. Progress has been made regarding our understanding of the causes of this epidemic, its current and future health consequences, and potentially effective prevention and treatment interventions. Much work is yet to be done, including increasing our knowledge of childhood obesity and its relationship to the MetS.

CHILDHOOD METABOLIC SYNDROME

The notion of a MetS, that is, the clustering in an individual of a set of risk factors thought to put the individual at increased risk for cardiovascular disease and type 2 diabetes, was developed more than 20 years ago [64]. Originally and most commonly applied to adults, the utility of a MetS designation for children has generated considerable clinical and research interest, coincident with the rise in childhood obesity. Although divergent opinions exist regarding the diagnostic value of MetS in children [65], it has been argued that the presence of several cardiometabolic risk factors in one individual, even at subclinical levels, predict future progression to overt chronic disease and potentially make MetS a sentinel marker for highlighting the need for more aggressive intervention efforts beyond the traditional treatment options for overweight and obese youths [66].

Definition and Prevalence of Childhood Metabolic Syndrome

Despite many publications on MetS in children, there are no standard criteria for what constitutes a pediatric MetS [44]. A number of diagnostic criteria for childhood MetS have been utilized, typically based on risk factors identified for adults, but with modifications in the cutoff values [66]. Recent consensus conferences have differed as to what the cutoffs should be [67–69]. The only consensus about the use of an adult definition of MetS for pediatrics is that none of the adult definitions can be applied without problems [44,65]. Pediatric-specific cut-points that are sensitive to age, gender, and ethnicity have not been determined for the majority of the MetS components [44,65].

The differing cut-off values used with children, even when relatively small, have resulted in widely varying MetS prevalence rates. For example, Goodman et al. [70] studied 1098 students in an Ohio public school district and reported a MetS prevalence of 3.4% using criteria suggested by the American Heart Association (AHA) that included the presence of three or more of the following: glucose ≥100 mg/dL, triglycerides ≥150 mg/dL, HDL-C ≤ 40 mg/dL for boys and ≤ 50 mg/dL for girls, waist circumference ≥ 102 cm for boys and 88 cm for girls, or diastolic BP ≥85 mmHg, systolic BP ≥ 130 mmHg. The prevalence was 4.5% when using the criteria suggested by the International Diabetes Federation (IDF), whose criteria were the same as those of the AHA except for waist circumference (≥94 cm for boys and 80 cm for girls). When these two sets of criteria were applied to a subset of obese children (BMI ≥ 95th percentile or BMI ≥ 30), the MetS prevalence rates were 14.8% using the AHA criteria and 18.5% using the IDF criteria.

Cook et al. [71] applied several different MetS criteria to the 1999–2002 National Health and Nutrition Examination Survey (NHANES) data set and obtained MetS prevalence rates that ranged between 2.0% and 9.4% for a nationwide sample of 12- to 19-year-olds. In obese children, the different criteria yielded prevalence rates that varied from 12% to 44%. Although these results illustrate the variability of prevalence rates based on the particular MetS criteria employed, they also consistently show that obese children have a higher prevalence of MetS regardless of MetS criteria employed. Data also suggest the prevalence of childhood MetS is increasing [72], with the 4.2% prevalence in NHANES III rising to 6.4% in the 1999–2000 NHANES data [73], and increasing to 8.6% using the 2001–2006 NHANES database [65]. The 2001–2006 NAHANES data also revealed gender and ethnic differences. Prevalence of MetS was higher in males (10.8%) than in females (6.1%) and higher in Hispanic (11.2%) and White (8.9%) individuals than in Black individuals (4.0%) [65].

Predictors of Childhood Metabolic Syndrome

Several predictors of childhood MetS warrant mention. Hirschler et al. [74] determined MetS in 1009 elementary school children and reported an overall MetS prevalence of 5.8%, which increased to 16.4% in overweight/obese children, and to 32% in the severely obese children. Multiple regression showed that BMI and insulin resistance (assessed using HOMA-IR) predicted MetS after adjustment for gender and Tanner stage. The predictive power of insulin resistance for MetS harkens back to Reaven's original hypothesis that insulin resistance was the driver and pathophysiological link for the clustering of the metabolic components [44,63]. Although physical activity was not assessed by Hirschler et al., its association with childhood MetS has been observed by others. Kelishadi et al. [75] determined MetS and physical activity levels in 4811 children aged 6–18 years and reported that in both genders, before and after adjustment for BMI and age, low levels of physical activity significantly increased the risk of having MetS (in boys: OR = 1.8, 95% CI = 1.2–2.1; in girls: OR = 1.6, 95% CI = 1.1–1.9). In the European Youth Heart Study, MetS risk score was inversely related ($p = 0.008$) to objectively measured physical activity (3 days of accelerometry) among 589 Danish children participating [76]. Okosun et al. [77] examined the independent and joint association of BMI and leisure time physical activity with MetS risk score in 12- to 17-year-old children in the 2003–2004 NHANES database. There was a gradient of increasing MetS risk score by increasing BMI and a gradient of decreasing MetS risk score when progressing from sedentary to moderate-to-vigorous leisure time physical activity. The authors suggested that promoting leisure time physical activity at all levels of weight status may help to reverse the increasing trends of MetS in U.S. children. In a group of 212 healthy 7- to 12-year-old children, Casazza et al. [78] reported that diet composition was a significant predictor of several components of the MetS, with a greater intake of energy from carbohydrate being associated with a greater waist circumference and higher triglyceride and glucose concentrations.

Consequences of Childhood Metabolic Syndrome

Debate over whether the clustering of risks of the MetS is synergistic or additive is probably less important than the recognition that finding any or all of the components of MetS in a child indicates a negative prognosis [44]. For example, it has been estimated that the number of years of life lost due to type 2 diabetes for an individual diagnosed at age 10 ranges from 16 to 23 years, depending on gender and ethnicity [79]. At the same time, MetS in childhood has been reported to be a predictor of adult type 2 diabetes [80]. Obesity associated with MetS comorbidities markedly increases the risk for early adult cardiovascular disease [81]. Diagnosis of MetS in adolescence appears to be a good predictor for developing adult MetS within a short period of time [82]. The extremely high prevalence of MetS in obese children indicates that children of excess weight should be considered as targets of any future screening initiatives [83].

TREATMENT OF CHILDHOOD METABOLIC SYNDROME

The first line of treatment of MetS in adults is generally approached with diet and physical activity (in lieu of pharmacologic treatment) [77]. This approach has also been recommended for childhood MetS [84]. Although the research literature specifically targeting childhood MetS with diet and physical activity is not extensive, some encouraging data have emerged. Reinehr et al. [85] examined changes in MetS prevalence (using IDF criteria) in 476 obese children receiving or not receiving a 1 year outpatient lifestyle intervention. The intervention included physical activity, nutrition education, and behavior therapy. Prevalence of MetS for children in the intervention group decreased significantly from 19% at baseline to 9% at 1 year, whereas the nonintervention group experienced no significant change in MetS prevalence. Kelishadi et al. [86] conducted a 6 week diet and exercise intervention with 35 obese children aged 12–18 years. Participants performed supervised moderate-to-vigorous aerobic activity for 60 min, 3 days/week for 6 weeks and received dietary advice from a registered dietician. At the end of the study, the prevalence of children classified as having MetS (using National Cholesterol Education Program Adult Treatment Panel III criteria) decreased from 32.4% to 14.2% ($p = 0.02$). Coppen et al. [87] conducted a retrospective review of 135 children and adolescents (aged 6–19 years) who completed a 10 week, medically supervised, weight-loss program that focused on healthy eating and physical activity. Initially, 53 of the 135 participants (39%) were diagnosed with MetS. After the 10 week program, resolution of MetS was seen in 75.5% of the participants originally diagnosed with MetS. These studies indicate

that lifestyle interventions can reduce the prevalence of MetS in children. Questions about optimal "dose" to achieve results remain, as do issues related to long-term effectiveness and whether treating childhood MetS differs in some meaningful way from treating childhood obesity.

CONCLUSION

Childhood obesity and childhood MetS are likely to be common in many societies in the near- and possibly longer-term future. It should be the goal of the health care professional to make that future as short as possible. The enormity of the problem suggests that all components of the culture will need to be participants in working toward solutions.

Carotid IMT 1141
Endothelial Function 1143
Arterial Stiffness 1147
Conclusions 1149
References 1149

Cardiovascular disease (CVD) is the leading cause of death in the United States and the Western world, and it is growing fast in developing countries, to the point where CVD has been called a global epidemic [1]. It is now clear that atherosclerosis, the underlying disease process in CVD, is a lifelong disease, starting in early childhood [2]. The beginning of lipid accumulation in the intima of large arteries eventually creates fatty streaks, recognized as a beginning stage of the atherosclerotic process [2,3]. Fatty streaks are common in the aorta by 3 years of age, and continue to increase throughout childhood as shown by autopsy studies [4,5]. Actual atherosclerotic plaque may be present in the coronary arteries during adolescence and early adulthood [6]. These changes in the artery result in alterations in arterial structure and function, which can be measured relatively easily in children using noninvasive technology [7].

Traditional risk factors for CVD, such as hypertension, elevated LDL-cholesterol, low HDL-cholesterol, diabetes, and obesity, are associated with early manifestation of atherosclerosis [8]. The prevalence of risk factors among children has also been increasing, concomitant with the increase in the incidence of obesity [1,7]. This is disconcerting as traditional cardiovascular (CV) risk factors that are present in childhood can predict CVD risk in adulthood [8–10]. CVD risk factors present in childhood also predict pathological changes in the arterial tree in adulthood [11,12]. These data suggest that there may be an increase in the incidence of CVD in the future, as children and adolescents progress into adulthood [1].

The ability to evaluate the risk for CVD more directly than through risk factor analyses is desirable, especially in children, since the presence of overt symptomatic disease will usually not present until later in adult life. Being able to evaluate arterial structure and function prior to the development of angiographically measurable atherosclerotic plaque is an important aspect of early detection and risk classification in both adults and children [1,13–15]. Although this can be done very accurately using noninvasive technology such as electron beam CT, the radiation exposure of this technique makes it less appropriate in children [1]. Other noninvasive measures more appropriate for children include measurement of carotid intima–media thickness (IMT), endothelial function, and arterial compliance [16–21]. These variables may be particularly useful in children, given their noninvasive nature and relative ease of measurement.

Collectively, IMT, endothelial function, and arterial stiffness can be considered markers of subclinical atherosclerosis, and alterations in these subclinical markers are associated with coronary artery disease, stroke, and CV mortality in adults [22–25]. Decreased endothelial function and increased arterial stiffness may also affect the ability to exercise due to reduced peripheral blood flow, impaired myocardial performance, and decreased myocardial blood flow [15,26,27].

CAROTID IMT

Carotid IMT is the most commonly measured IMT due to its accessibility and because it is predictive of adverse CV events in adults [22,23,28]. The artery can be reliably imaged using high-resolution B-mode ultrasound. The leading edge of the lumen–intima interface to the media adventitia interface is measured. The far wall carotid IMT from the ultrasound image provides an accurate representation of IMT compared with data from histological exams [1,16]. The image is normally obtained of the common carotid artery, 1–2 cm proximal from the bifurcation. Using wall tracking software, a segment of the artery can be selected and the maximal and mean IMT can be selected from that entire segment, as shown in Figure 92.1. For accurate determination in children, it is essential that the image is obtained using a high-frequency probe. For more detail on recommended procedures of how to obtain valid and reliable measures of IMT in children, the reader is referred to Urbina et al. [1].

The developmental changes in IMT with age during childhood are unclear at this time. There is some evidence that carotid IMT increases with age in a linear manner, but the

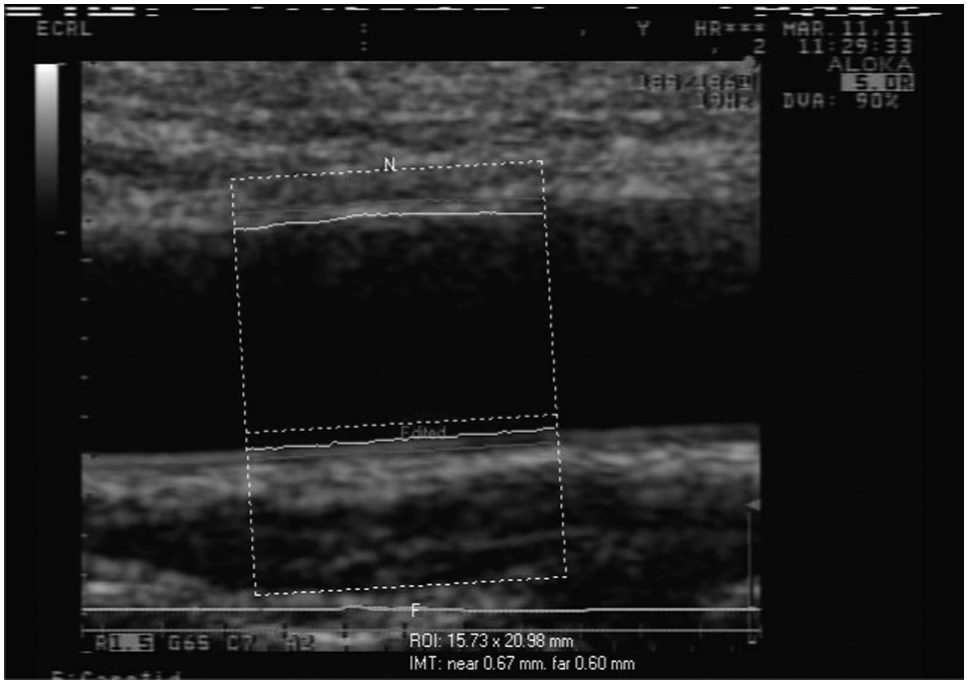

FIGURE 92.1 An example of a carotid artery image with automated detection of IMT, showing how a section of the common carotid is selected and IMT is evaluated over the entire section. This image also demonstrates the difference in image clarity between the near and far wall.

correlations are very low, usually 0.15 or less [29,30]. Others have found no correlations between age and IMT during the developmental stages of childhood [31,32]. This is likely a function of the small changes observed in IMT between 7 and 18 years of age. For instance, the median carotid IMT was shown to increase from 0.384 to 0.400 mm between 10 and 20 years of age [30]. This is only a 0.016 mm increase in 10 years and the clinical or functional significance of such a small change is unclear. These changes in carotid IMT are also accompanied by increases in arterial size [30,32], thus increases in carotid IMT may only be a reflection of an overall growth in vessel size. Nevertheless, since others have shown no change in carotid IMT with age in childhood, no clear conclusions can be made. It is also difficult to determine what would be a clinically "abnormal" IMT in children, since a child's IMT is usually considerably smaller than what is considered clinically significant in adults. However, mean carotid IMT in studies on normal children is rarely above 0.50 mm with 95% confidence intervals of ±0.07 mm. This would suggest that one could potentially consider a carotid IMT above 0.6 mm as "abnormal" in children regardless of age, but empirical and clinical support for this notion is lacking. However, it is likely that there are developmental changes in thickness and density of the media, as shown by postmortem studies of the aortas of children [33,34]. This suggests that even without developmental changes in carotid IMT, the arterial wall properties change, which will likely affect arterial function regardless of the absolute level of IMT [35].

Obesity is strongly associated with increased carotid IMT in children [36,37] although not all studies [38] have found increased IMT in obese children. Importantly, a recent large-scale study found not only increased carotid IMT in obese children, but the association between carotid IMT and body mass or adiposity was also present in children who were not overweight or obese [39]. Carotid IMT may be 25% higher and is directly correlated to body mass index (BMI) in obese children, but the increased IMT appears to be independent of vessel size. Furthermore, waist circumference was as strongly associated with carotid IMT as BMI, suggesting that abdominal obesity in particular may affect arterial structure [39]. This is important considering that obese children with metabolic syndrome have greater IMT and greater cross-sectional area of the intima–media complex compared to healthy control children [40]. Children with familial hypercholesterolemia [41–43] and type 1 diabetes [44–47] also exhibit increased carotid IMT. This suggests that the effect of obesity and other CVD risk factors on carotid IMT may be additive. However, it appears that obesity may have a greater effect on carotid IMT than other CVD risk factors. Mittelman et al. [39] found that the association between adiposity and carotid IMT remained after controlling for conventional risk factors such as blood lipids and blood pressure (BP). This is especially disconcerting since obesity in childhood is linearly related to carotid IMT in young adults, and those individuals with largest BMI who had been obese the longest exhibited the greatest IMT as young adults [48].

Recent studies have shown that both sex and race, and also possibly socioeconomic status affect IMT [39,49]. Mittelman et al. 2010 found boys to have greater IMT than girls, but this is not a uniform finding [30,32]. A more uniform finding is that African American children exhibit 4%–5% greater IMT values than Caucasian children [39,49].

The higher IMT values in African American children cannot be explained by traditional risk factors such as obesity, BP, or lipid profiles. However, since lower socioeconomic status is also related to higher IMT, it is possible that this contributes to the racial differences, since African Americans are overrepresented in the low socioeconomic strata [49]. The higher IMT in African Americans is consistent with data on adults, which also show higher IMT in this group [50,51].

Lifestyle interventions have not been found to affect carotid IMT in normal healthy children. However, lifestyle interventions may be effective in obese children. Longer-term interventions (6 months or more) may improve carotid IMT in overweight or obese youth [37,52,53]. For instance, carotid IMT decreased significantly in obese youth 11–16 years of age compared to age-matched controls following 6 months of exercise training [37]. Similar results were shown in 9- to 12-year-old children following 12 month programs of dieting alone or a combination of diet and exercise, although the diet and exercise program elicited greater benefits [52]. Interestingly, intervention-induced weight loss may be important to reduce carotid IMT, as a 12 month-long intervention in obese prepubescent children (the program included exercise training, nutrition education, and behavior therapy) reduced carotid IMT only in those children who experienced substantial weight loss [53]. In contrast, short-term lifestyle interventions have shown no effect on carotid IMT in children [52], suggesting that lifestyle interventions need to be sustained for a longer period of time to be effective. This notion is supported by data from a trial on pravastatin versus a placebo in children with familial hypercholesterolemia [54]. Following 2 years of therapy, carotid IMT was reduced in the statin group but not in the placebo group. Consequently, to have an effect on carotid IMT it appears that interventions need to be long term, suggesting that arterial structure is not easily modified in children.

The potential mechanisms for changes in IMT with lifestyle interventions are not currently known. It is possible that the detrimental effects of hypercholesterolemia on the arterial wall, which lead to increased expression of adhesion molecules, LDL infiltration and oxidation, and increased inflammation [2] are altered with lifestyle interventions. However, LDL-cholesterol has not always been associated with improvements in arterial structure [41,42,55], suggesting a more complex interactive process. Hypertension may also affect IMT and most lifestyle interventions lower BP, but there are no data in children linking changes in BP to changes in IMT [1]. The success of statin treatment in IMT in children, regardless of LDL-receptor genotype, suggest that other mechanisms such as the anti-inflammatory effect of statins may play a role; however, this remains to be elucidated.

ENDOTHELIAL FUNCTION

The endothelium controls the balance between vasodilatation and vasoconstriction and has a number of other functions related to vascular health, including control of coagulation and fibrinolysis, inflammation, and angiogenesis [56]. The vasoactive substance produced by the endothelium that has received the most attention is the production of nitric oxide (NO). NO is produced from L-arginine as endothelial nitric oxide synthase (eNOS) essentially cleaves NO from L-arginine. NO then produces vasodilatation through relaxation of the vascular smooth muscle [13,14,57–59].

Endothelial function can be evaluated using high-resolution ultrasound where the brachial artery is visualized and artery diameter is measured in response to various stimulators. This is commonly accomplished by the arterial response to infused vasoactive substances, such as acetylcholine, which increases NO production [58,59]. However, the invasive nature of this approach is probably not appropriate for use in healthy children. Thus, the more common approach is a noninvasive assessment using flow-mediated dilation (FMD). By inducing a hyperemic stimulus, the artery dilates as a result of NO release produced by shear stress. The amount of dilation can be accurately measured using high-resolution ultrasound, thus providing a measure of the ability of the artery to dilate in response to shear stress, a measure of endothelial function [13,14,58,60].

Endothelial function is usually evaluated in the brachial artery, as a measure of conduit artery function. With subjects in a supine position, the artery is visualized in the longitudinal plane above the antecubital fossa. The artery is imaged at rest with pulsed mid-artery Doppler measures of blood flow performed as well. In addition, a simultaneous ECG should be recorded, and the ultrasound images need to gated to the ECG, usually the R-wave, to ensure end-diastolic measurements. This is important because the size of the artery changes a great deal between diastole and systole. After the resting images, a BP cuff is typically placed on the forearm (but could be placed on the upper arm) and inflated to 250 mmHg, or to at least 50 mmHg above systolic pressure, for 4–5 min. It is important to standardize the time of inflation, as this will affect the outcome. Also, upper arm cuff placement generally produces greater vasodilatation but it is more challenging obtaining good images. Following release of cuff pressure, the artery is continually imaged for 2–5 min and evaluated for %maximal dilation, using automatic edge detection software [1,13,14,57,61]. This allows for a selected segment of the artery to be evaluated, resulting in more reliable measures [1,61]. An example of this is shown in Figure 92.2. The hyperemic response is also evaluated using pulsed Doppler, at least during the first 15–20 s, but ideally throughout the measurement period following cuff release [1,61]. The Doppler measurements are used to evaluate the hyperemic stimulus from the calculated shear rate. This is important, because the amount of vasodilatation needs to be standardized to the shear rate stimulus provided [61]. After the FMD measurement (and a 10 min rest period), the endothelium-independent vasodilatory response is often evaluated following administration on nitroglycerin. This is done without any cuff inflation, but otherwise using the same technique as described previously. The artery is visualized continuously for 4–5 min after nitroglycerin administration and the maximal amount arterial dilation is measured.

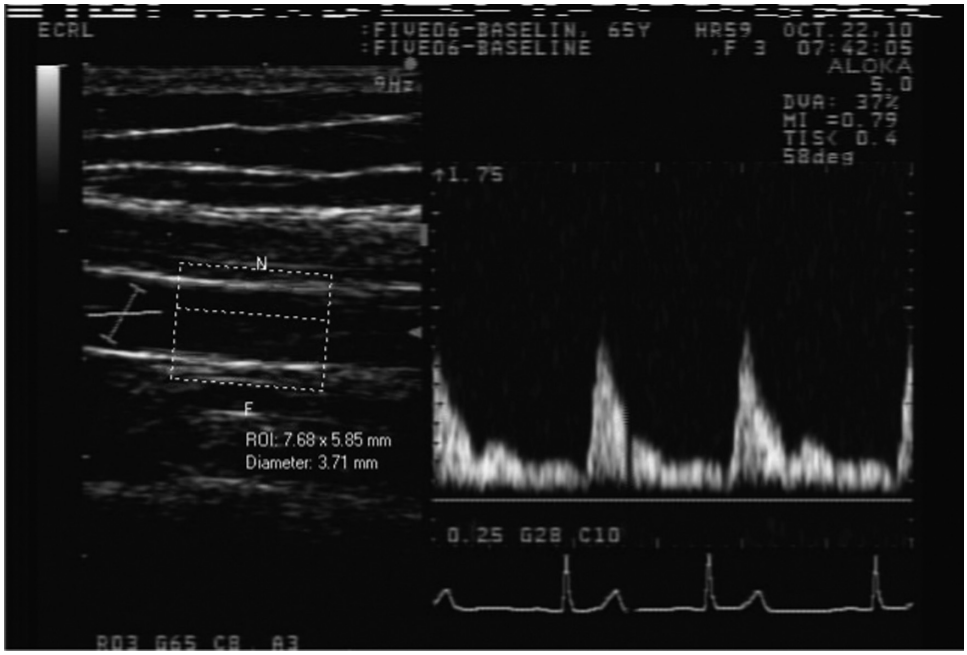

FIGURE 92.2 An example of a brachial artery image with automated wall detection and Doppler images as used for FMD.

The nitroglycerin-induced vasodilation is considered an index of smooth muscle function [14], which is not dependent on the function of the endothelium. It is also important to control for many other factors that affect endothelial function. This includes time of day of measurement, medication, caffeine, antioxidants, high-fat foods, smoking, alcohol, exercise, and menstrual status. (For a more complete description of the specific methodology, please consult the other following papers [1,13,14,61].)

Endothelial function does not appear to change throughout childhood in normal, healthy, nonobese children [37,38,52,62]. The mean FMD in healthy nonobese children is typically between 8% and 11% (Figure 92.3) [35], but values as low as 4% have been reported [63]. However, the range of a normal FMD response is very large, with the 95% confidence interval reportedly between 2% and 18% among healthy children [38,52,64]. This response is similar to that of healthy young and middle-aged adults [13,14], but also overlaps with values for populations with reduced endothelial function, making it difficult to address what a "normal" value for FMD is in healthy children [35]. It is also unclear if the large range of normal FMD values is due to normal biological variability or to measurement error, making comparisons of data between studies very difficult. However, FMD is reduced in both children and adults with CV risk factors [13,14,65,66] when compared with control groups. Although FMD has been shown to predict clinical outcome in adults [25,67], the clinical implications of low FMD in children are uncertain, even though children with standard CVD risk factors usually present with low FMD compared to controls [1,7,35].

Endothelial function is reduced in children with CVD risk factors compared to controls, and is also reduced in children with infectious diseases such as human immunodeficiency virus [1,7,35]. In addition, FMD is reduced in children with

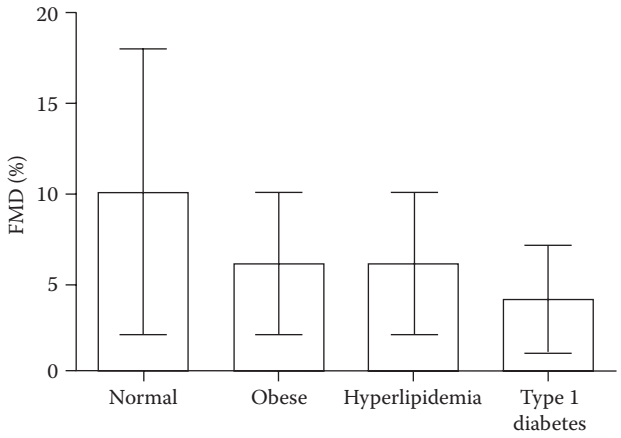

FIGURE 92.3 Common mean values with 95% confidence intervals of FMD for different groups of children demonstrating that children with CVD risk factors have reduced FMD, but the 95% confidence intervals are very large creating a great deal of overlap between all groups.

type 1 diabetes and in children with kidney disease, and this reduction does not appear to be related to other CVD risk factors [1,68,69]. This might suggest that other factors, such as inflammation and oxidative stress, have important influence on FMD in children, in addition to CVD risk factors, a phenomenon that is well accepted in adults [56]. A comparison of FMD between normal healthy children and children with CVD risk factors and/or other conditions is shown in Figure 92.3. It should be noted that even though the average FMD is higher in normal healthy children, the 95% confidence intervals are very large and, thus, there is a great amount of overlap between all groups.

Most studies have shown a decrease in endothelial function in obese or overweight children, with a mean FMD of

5%–6% in the obese cohorts compared to approximately 10% in normal-weight controls [35,38,70]. One study has also found smooth muscle function to be significantly lower in the severely obese children, but not in the middle-obese/overweight children, suggesting severe obesity may directly impact smooth muscle function [38]. Obesity may also present with a constellation of arterial deterioration as impaired endothelial function in children may coexist with hypertension, arterial stiffness, and impaired smooth muscle cell function [36,71–73]. Endothelial dysfunction may be due to increased inflammation, as obese children consistently exhibit higher levels of C-reactive protein (CRP) compared to nonobese children [37,40,74]. However, BMI alone contributes to endothelial dysfunction, even when controlling for CRP, suggesting an inflammation independent, but obesity-dependent factor [35]. Higher leptin levels in obese individuals may explain this, since there is a dose–response relationship between leptin and atherosclerosis [66,75]. Several other factors, including insulin resistance, increased blood lipids, and BP, may also have a role [37,38,40,74].

Endothelial dysfunction manifested as reduced FMD is often present in children with elevated blood lipids [13,65,76]. This may be related to detrimental effects of hypercholesterolemia on the arterial wall, leading to increased expression of adhesion molecules, LDL infiltration and oxidation, and increased inflammation [2]. This is probably a somewhat simplistic explanation though, because LDL-cholesterol may not be associated with decreased FMD [41,42,55]. Furthermore, children with a family history of CVD also display reduced FMD, even without familial hypercholesterolemia [77]. As shown in Figure 92.3, the FMD typically reported for children with hypercholesterolemia is similar to the FMD of obese children. It is likely that there is overlap between these conditions, both in terms of the phenotype and the potential mechanisms of the reduced FMD response.

It is well documented that children with type 1 diabetes have reduced FMD often in the magnitude of 50%–60% less than controls [44,47,69,78]. This is clearly illustrated in Figure 92.3 and is a larger reduction than what is observed in children with other CVD risk factors. However, it has been shown that the reduced FMD was only present if children with type 1 diabetes who had hypercholesterolemia [44] or with concurrent acute inflammation as a result of infection [79]. Others have also found that the reduced FMD was related to increased inflammatory status [80] or a combination of inflammation and expression of human leukocyte antigen, suggesting a genetic influence as well [35]. Folate status was also related to FMD in children with type 1 diabetes, suggesting a potential influence of homocysteine levels [78]. However, HbA1c levels do not appear to be related to FMD in children with type 1 diabetes, suggesting that glycemic control per se is not related to impaired FMD in these children [81]. Thus, the available data suggest that the reduction in FMD in children with type 1 diabetes may be associated with oxidative stress, leading to reduced NO bioavailability [1].

Various intervention strategies, such as physical activity, diet, and supplementation with antioxidants, may improve arterial function in children [37,38,53,76,77,82–85]. However, there are very limited data on normal healthy children, especially on the effect of exercise training. Cross-sectional data from Abbott et al. showed habitual physical activity levels measured with doubly labeled water independently predicted brachial FMD among 5- to 11-year-old children [86], with the most active children exhibiting significantly greater FMD compared to their least active peers. However, due to the cross-sectional nature of the study, they were unable to demonstrate that changing physical activity improves endothelial function in healthy children. More recent data, although also cross-sectional, showed that high-intensity physical activity measured using either accelerometry or questionnaire, was an independent predictor of FMD in children [87,88]. However, a subgroup analysis showed that only children in the low-FMD tertile benefited from high-intensity physical activity. Physical activity did not impact FMD in children in the highest FMD tertile [87]. This suggests that only children with substandard FMD, or those with endothelial dysfunction, will actually benefit from physical activity. Interestingly, Pahkala et al. showed that children with the highest leisure time physical activity also had higher FMD [88], but this was only true in boys. In girls there was no association between FMD and physical activity, suggesting a sex difference in this relationship. However, follow-up analysis showed that boys and girls with similar physical activity also exhibited similar FMD. Thus, the lack of a relationship between physical activity and FMD in girls was likely due to the lower physical activity levels in girls [88].

Cross-sectional research also suggests that CV fitness is associated with endothelial function in healthy children [70,87,89]. CV fitness may explain up to 23% of the variance in femoral FMD among children aged 11–14 years [70]. Although Hopkins et al. supported the overall relationship between CV fitness and FMD, they did not find an association between FMD and CV fitness within FMD tertiles [87]. Instead, only high-intensity physical activity was associated with FMD within tertiles, but only in the lowest FMD tertile. Consequently, although fitness may affect FMD to some extent, it appears that high-intensity physical activity is more important in normal healthy children. The seemingly favorable response of endothelial function in healthy children to physical activity and fitness is probably related to increased (or decreased in the low-FMD tertile) NO bioavailability. This is thought to result from the up- or downregulation of eNOS gene expression in response to vascular wall shear stress [56,90,91]. Thus, for children who are not physically active, the eNOS expression is presumably downregulated, resulting in reduced FMD. Conversely, in active children, eNOS is upregulated resulting in improved FMD.

There is a dearth of data on the longitudinal effect of exercise training on endothelial function in normal healthy children. One recent study showed that a randomized controlled school-based exercise program improved the number and migratory capacity of circulating endothelial progenitor cells [92]. The authors provided a daily exercise program to the intervention group, whereas the control group continued

the twice a week normal physical education program. The intervention group showed a significant increase in this marker of endothelial function whereas the control showed a nonsignificant decrease. Unfortunately, these positive results of exercise training have not been replicated using FMD as the outcome variable. There is however, strong evidence that a reduction in physical activity actually reduces FMD [93]. Hopkins et al. found that seasonal variations in physical activity, as measured objectively using accelerometry, affected FMD. More specifically, a reduction in high-intensity physical activity, comparing summer to late fall, was significantly correlated with a reduction in FMD [93]. Thus, these findings support the prior studies showing that high-intensity physical activity or exercise is an important contributor to FMD in normal healthy children.

Another lifestyle intervention, using an 11 year-long dietary intervention (low saturated fat) showed remarkably similar results to those of the cross-sectional studies on FMD and physical activity. The program had long-term beneficial effects on endothelial function in boys, but not in girls [94]. The intervention, which was initiated in infancy, improved brachial FMD in boys at age 11 compared to controls. Importantly though, this effect was nonsignificant after adjustment for cholesterol levels at age 3, suggesting that the relationship between endothelial function and diet was mediated by changes in cholesterol levels [35].

Many more studies are available on the effect of various interventions on the FMD in youth with comorbidities, such as obesity, type 1 diabetes, hypertension, and hyperlipidemia. This is likely because children with these conditions show disrupted endothelial function (Figure 92.3) [37,38,53,76,77,82–85]. Interestingly, several interventional strategies have shown endothelial function is nearly normalized following several types of interventions in various populations of children with risk factors [35].

FMD is improved among overweight and obese children and adolescents, following short-term lifestyle interventions, using either exercise training or dietary modification, or a combination of exercise and diet [52,95–98]. Exercise training alone improves and near-normalizes brachial FMD in obese children and adolescents [96–98]. Only 6–8 weeks of exercise training was needed to obtain these results. These programs were conducted three to four times per week and incorporating either 60 min of sport and play activities [98] or 30–50 min of progressively increased aerobic exercise at 50%–80% of the age-predicted maximum heart rate [96], or a combination of aerobic and resistance exercise training [97]. Interestingly, 6 weeks of inactivity reversed the exercise-induced improvement in FMD [97], suggesting that physical activity and exercise need to be adopted as part of a lifetime lifestyle to realize the benefits [52,97]. However, not all studies show improved FMD in obese children with exercise training. Recent findings from Farpour-Lambert et al. showed that FMD was unaltered following 3 months of exercise training in about 9-year-old obese children [72]. This lack of an effect was observed despite significant improvements in CV fitness and reductions in BP, BMI, and abdominal fat.

Dietary interventions, as short as 6 weeks, consisting of a well-balanced hypocaloric diet, can improve FMD in overweight and obese children [52]. Similar benefits have been obtained from combinations of dietary modification and exercise training [52,95]. The benefits of combining exercise and diet were greater than those of diet only, suggesting that this combination intervention may be the most effective in obese children [52].

Longer interventions also improve endothelial function of overweight or obese children [37,52,53]. Exercise training for 6 months improved FMD in 11–16 year-old obese children compared to age-matched controls [37]. Twelve month interventions of either dieting alone or diet and exercise in 9- to 12-year-old children also improved endothelial function [52]. In this study, the combination of diet and exercise also provided greater benefits than diet alone. However, another 12 month-long exercise training, nutrition education, and behavior therapy intervention in obese children, only showed improvements in brachial FMD in those children who experienced substantial weight loss [53]. This would suggest that weight loss is a determining factor for improving endothelial function in obese children. Unfortunately, only one of the three long-term studies included a control group. Although the results are promising, the lack of a control group makes it difficult to make conclusions regarding the effectiveness of these long-term lifestyle modifications in obese children [35].

Although the physiologic mechanisms responsible for the previous favorable outcomes in children with obesity remain speculative, they are likely multiple mechanisms given the multidimensional nature of interventions. Exercise-induced upregulation of eNOS is one possible mechanism for the improvements in the atherogenic risk profiles in youth with obesity. However, changes in proinflammatory markers may also contribute to this favorable effect [66]. Accordingly, increases in FMD following lifestyle interventions have been accompanied by reductions in proinflammatory markers [37,53,95]. These reductions in inflammation may be mediated by accompanying weight loss and/or decreases in abdominal fat [47].

Cross-sectional evidence shows that physical activity is related to FMD in children with type 1 diabetes [69]. Children with type 1 diabetes who were physically active for more than 60 min/day exhibited significantly higher levels of FMD compared to those children with less than 60 min of physical activity per day. Furthermore, the FMD in the active group of children with type 1 diabetes was similar to less active healthy children without type 1 diabetes [69], suggesting that physical activity can "normalize" endothelial function in children with type 1 diabetes. Nevertheless, the healthy children who were physically active for more than 60 min/day exhibited better endothelial function than any of the other groups, showing that type 1 diabetes has a negative effect on endothelial function even in active children. Only one study has evaluated the effect of exercise training on endothelial function in children with type 1 diabetes. In a small study (n = 7) without a control group, Seeger et al. showed a large improvement in FMD, from 7.5% to 12.4%,

following 18 weeks of exercise training [99]. Unfortunately, the small number of subjects and lack of a control group makes it difficult to evaluate the significance of the findings.

Other lifestyle or dietary practices may also improve endothelial function in children with type 1 diabetes. Folic acid or vitamin B6 supplementation, or a combination of the two, improved endothelium-dependent dilation of the brachial artery within 2 h compared to placebo [78,100]. This effect was also maintained during 8 weeks of supplementation [100]. The improved endothelial function following folic acid therapy is likely due to prevention of peroxynitrite-mediated BH_4 oxidation, leading to improved eNOS bioavailability [101]. Since children with type 1 diabetes also have inflammatory and blood lipid profiles that differ from children without type 1 diabetes, this may favor a positive response of endothelial function to folic acid. However, FMD was not improved by folic acid supplementation in obese children [102] even though they had higher levels of inflammation and blood lipids than children with type 1 diabetes [84]. Since the effect of folic acid supplementation in children with type 1 diabetes was reversed 8 weeks after cessation of supplementation, to gain benefit, continuous supplementation would likely be needed [78].

Various diets and supplementation regimens in children with familial hyperlipidemia have also been shown to improve endothelial function [77,82,83,103,104]. Following a diet using the National Cholesterol Education Program Step II recommendations coupled with supplementation with docosahexaenoic acid (DHA), an omega-3 fatty acid found in fish oil increased brachial artery in FMD [103]. This may have been related to possible improvements in eNOS upregulation induced by DHA [103]. Similar results were reported when the same diet was used in conjunction with antioxidant vitamin C and E supplementation [104]. However, short-term dieting alone does not appear to improve FMD [103,104]. Conversely, marked improvements in FMD were shown following 6 weeks of antioxidant therapy in children with hyperlipidemia compared to controls [77]. This is likely related to the effect of antioxidants on free oxygen radicals reducing inactivation of eNOS, thus increasing NO availability and improving endothelial function.

ARTERIAL STIFFNESS

Arterial stiffness has become an important aspect of evaluating subclinical arterial disease, as it is related to CVD outcomes in both clinical and healthy populations [15,24]. The current gold standard for evaluating arterial stiffness is pulse wave velocity (PWV), but other noninvasive methods, such as high-resolution ultrasound, are also common. Ultrasound measurements of the carotid artery or the aorta are common, but measures of peripheral arteries such as the brachial artery can also be made. Arterial distensibility (inverse of stiffness) and a measure of the elastic properties of the artery, and compliance, a measure of the capacity to respond to changes in blood volume, are common measures used [1]. These measures provide information on the amount of change in lumen size from diastole to systole, by evaluating the increase in lumen diameter during systole. Local distending pressure is an important determinant of compliance; thus the local artery BP needs to be measured. Carotid BP is usually measured in the contralateral carotid artery, using handheld applanation tonometry [65,105], but measuring the local BP in the aorta is more complicated. An estimation of aortic BP can be made from applanation tonometry-created pulse wave forms using a transfer function [15]. The beta (β) stiffness index, a measure of arterial stiffness shown to be somewhat independent of BP [106], and the incremental elastic modulus (Ep) are also often derived from the ultrasound measures. Ep is a measure of the intrinsic elastic properties of the arterial wall material, independent of vessel geometry [30].

PWV has emerged as the gold standard in adults studies, probably because of its widespread use in large clinical studies [1], and is a measure of the speed of the arterial pressure wave propagation [65,107]. A higher PWV indicates a stiffer artery. PWV is recorded using pressure sensitive transducers or Doppler ultrasound, and a simultaneously recorded electrocardiogram is often used as a timing marker. The PWV from the carotid to the femoral artery (central stiffness) or from the femoral to the dorsalis pedis artery (peripheral stiffness) are the most commonly used measures [35]. However, radial to dorsalis pedis artery measurements are also common (whole body compliance). The time delay of pulse wave propagation from the proximal to the peripheral artery is measured and then divided by the distance between the measurement sites to calculate the velocity [107]. Central (aortic) PWV is lower than peripheral PWV because the aorta is more compliant and less muscular than peripheral arteries. Since BP significantly influences PWV, it is important to measure PWV and BP simultaneously.

Although both aortic and carotid compliance change throughout childhood and adolescence, aortic compliance increases [108,109] whereas carotid compliance decreases with age [30,31]. This apparent difference is probably a function of the different measures of compliance used rather than a real difference between the aorta and the carotid artery. Both Senzaki et al. [109] and Ahimastos et al. [108] measured compliance as a change in flow volume for a given change in pressure. This measure is dependent on both mechanical properties of the artery wall and on vessel geometry, and better reflects arterial capacitance. Even though aortic compliance almost doubled between 5 and 20 years of age, this was primarily a function of increased arterial size, and the distensibility of the arterial wall actually decreased [108,109]. This is in support of the findings of carotid compliance [30,31], which was defined as the change in arterial diameter for a given change in distending pressure. There was a linear decrease in carotid compliance of 10%–28% over the same age range, coupled with an increase in Ep and β-stiffness of 9%–30% [35]. Thus, arterial wall stiffness increases during the developmental years in children; however, the amount of the increase in wall stiffness is highly variable between studies.

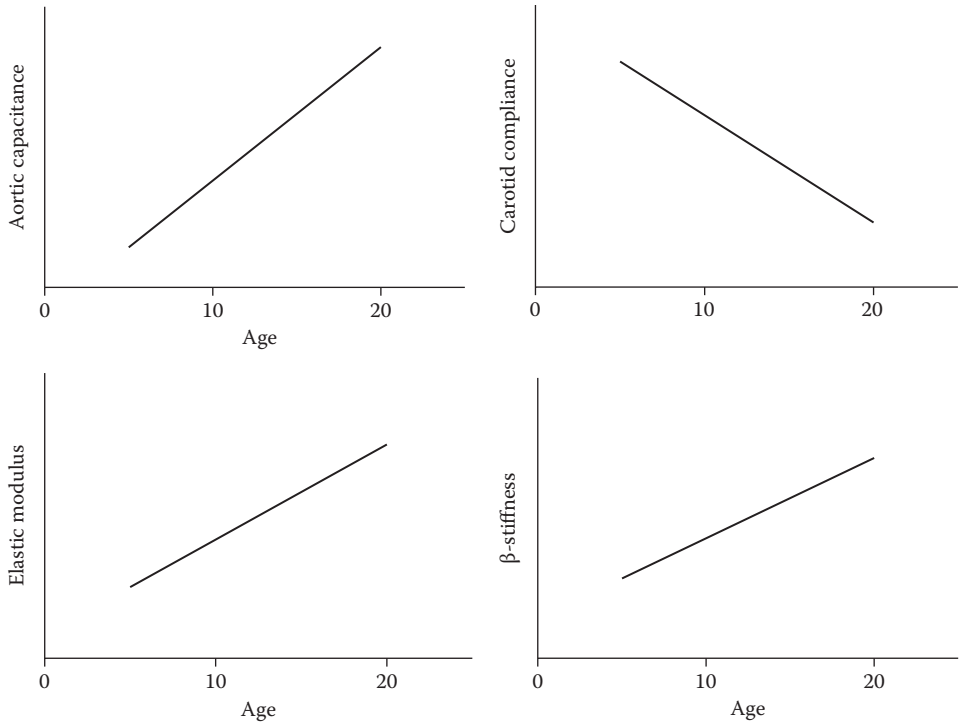

FIGURE 92.4 An example of how age affects various measures of central arterial stiffness in children. All measures of central arterial stiffness increase, whereas measures of central arterial compliance decrease as children grow older.

Figure 92.4 shows a schematic of the expected changes in arterial compliance, Ep and β-stiffness from 5 to 20 years of age. The increase in arterial wall buffering capacity is independent of changes in arterial wall elasticity in children, since both Ep and β-stiffness continually increase throughout childhood [109]. Thus, the increase in arterial size appears to offset the increase in wall stiffness. It is possible that this may prevent an increase in afterload, affecting ventricular performance [15,26,27]. This differs from the effect of adult aging. In older adults, arterial capacitance decreases concomitant with an increase in arterial wall stiffness [110,111].

Data on PWV support that arterial wall stiffness increases with age in children. Both aortic and peripheral PWV increases from childhood through puberty [110–114] as demonstrated in Figure 92.4. The increases in arterial stiffness are usually observed in both boys and girls [30,31,114] although at least one study has shown gender differences in the developmental changes in PWV and these changes were also influenced by puberty [108].

It is often assumed that developmental changes in elastin and collagen in the arterial wall are responsible for the changes in wall stiffness with age in children [115]. Since the atherosclerotic process begins in childhood, it is possible that decreases in elastin and increases in collagen is the start of arterial wall degeneration, indicative of the start of the atherosclerosis [114,115]. Considering that CVD risk factors including hypertension, BMI, physical inactivity, and high dietary fat intake are associated with arterial stiffness in healthy children, it appears plausible that arterial stiffness is indeed a marker of the atherosclerotic process in children [30,55].

Arterial stiffness in children also appears to be influenced by sex, race, socioeconomic status [49], and this is independent of CVD risk factors. African Americans have higher PWV than Caucasians [49,116] in both males and females, regardless of age, a finding that is consistent with data in young adults [117,118]. Boys have higher PWV than girls also consistent with data in adults [119]. Although more controversial, it also appears that low socioeconomic status is associated with higher PWV in children [49].

Obesity detrimentally affects arterial stiffness, as obese children have been consistently shown to exhibit higher arterial stiffness compared to normal-weight children [38,120,121]. This applies to multiple aspects of arterial stiffness and distensibility as obese children have been shown to have 38% higher aortic stiffness index, a 58% higher aortic elastic modulus [120], and 75% higher carotid Ep [38] compared to normal healthy children of similar age [35]. Even prepubertal children as young as about 8–9 years of age exhibited higher Ep than nonobese children, showing that obesity can detrimentally alter arterial stiffness at a very early age [71,72]. Metabolic syndrome appears to accentuate the effect on obesity alone, as Iannuzzi et al. [74] showed higher carotid artery stiffness in children with metabolic syndrome compared to obese children (with a similar BMI) without metabolic syndrome.

The mechanisms through which obesity impacts arterial stiffness are not completely understood at this time. Arterial stiffness may be related to increased low-level inflammation, and obese children have elevated levels of CRP [37,40,74]. Leptin levels may also be involved since leptin has been associated with arterial stiffness independent of inflammation

and insulin resistance [122]. However, other, more traditional CVD risk factors play a role, including insulin resistance, hyperlipidemia, and hypertension [37,38,40,74]. It is not surprising that BP contributes to arterial stiffness in children, since high BP is a substrate for development of arterial stiffness [15,35,123]. Consequently, it is no surprise that hypertensive children have higher arterial stiffness than normotensive children [124]. Insulin resistance and hyperinsulinemia have consistently been shown to be associated with increased arterial stiffness in both children and young adults [118,125]. It is also possible that autonomic dysfunction may contribute, as vagal tone is related to arterial stiffness following exercise [62,126]. Consequently, it appears clear that children with elevated CVD risk factors are likely to also exhibit higher arterial stiffness, consistent with early subclinical development of atherosclerosis.

There is some cross-sectional evidence that exercise and physical activity are associated with reduced arterial stiffness in healthy children. The amount of time spent in play or sport participation was inversely related to the arterial stiffness in 10-year-old children [55]. In contrast, others found no significant relationship between the total amount of physical activity, estimated with a 7 day questionnaire, and arterial compliance of 9- to 11-year-old children [89]. These disparate results probably reflect low accuracy in estimating physical activity levels, but no data exist with objectively measured physical activity levels in children. CV fitness has been shown to contribute to arterial compliance in healthy children [89]. Performance on a 20 m shuttle run contributed to large and small artery compliance (15% and 7%, respectively) [89]. Children with the highest performance score also had significantly higher arterial compliance than those in the lowest performance quartiles, providing evidence for a positive effect of CV fitness on arterial compliance.

In contrast, 12 year-old boys who had participated in 8–10 h/week for at least 4 years of swimming training exhibited higher upper limb PWV and lower distension index compared to age- and gender-matched nonswimmers [127]. More disturbingly, the child swimmers had similar PWV to adults. This may suggest that high-volume swim training has detrimental effects on upper limb arterial stiffness in children. Unfortunately, no data on central PWV were provided.

Longitudinal studies on the effect of exercise training on arterial function in healthy children are almost nonexistent. One study that did not include a control group [128] found decreased PWV after training 6 of 12 boys. The common characteristic among those who decreased PWV was that they also showed improvements in $\dot{V}O_{2max}$. Those children who did not improve $\dot{V}O_{2max}$ with training showed no improvement in PWV. Thus it is possible that arterial stiffness improves only with improvement in $\dot{V}O_{2max}$. However, physical growth during the training period often interacts with potential training-induced changes; thus, young children do not always improve $\dot{V}O_{2max}$ with training [129].

Very little information is available on the effect of exercise training using longitudinal study designs in children with CVD risk factors. Only one study in obese children has been conducted to date. Farpour-Lambert showed that 3 months of exercise training had no effect on arterial stiffness in obese children, despite a significant reduction in BP [72]. This suggests that arterial stiffness may be resistant to change through exercise training, or that a longer time period of training may have been needed. However, in adults, as little as 4 weeks of aerobic training significantly decreases both BP and PWV [130], suggesting that the response in children may differ from that in adults. Clearly, much more research is needed in this area.

CONCLUSIONS

Measures of subclinical atherosclerosis are becoming increasingly important in pediatric populations as they demonstrate early signs of arterial remodeling and functional changes related to the atherosclerotic process. Recently, the American Heart Association issued recommendations for testing of subclinical atherosclerosis in children [1], substantiating the increased focus on these measures. All measures of subclinical atherosclerosis are associated with both traditional and more novel CVD risk factors providing credence to their relationship with increased CVD risk. Furthermore, risk factors in childhood are associated with subclinical atherosclerosis in young adulthood. However, the effect of the development of subclinical atherosclerosis in childhood on the CVD risk in adulthood is currently unknown.

Both exercise training and various regimens of dietary supplementation and dietary interventions aimed at weight loss have been shown to improve some aspects of subclinical atherosclerosis in children. However, the long-term effect is unknown, and which interventions might be most effective is also not elucidated to date. There is very little information on the effect of lifestyle interventions on arterial stiffness in children. It is also unknown if reducing evidence of subclinical atherosclerosis in childhood through lifestyle intervention programs affects the risk of future CVD events in adulthood. Consequently, well-designed longitudinal studies are needed in the future.

Osteoporosis, through its association with age-related fractures, is one of the most common causes of longstanding pain, functional impairment, disability, and death in elderly populations [1]. The importance of optimal bone growth in childhood and adolescence has been recognized as one of the key strategies in osteoporotic fracture prevention [2]. Low birth size, poor childhood growth, and low peak bone mass at the cessation of growth have been linked to the later risk of osteoporosis and hip fracture [2,3]. Formerly, the focus was merely on maximizing bone mineral accrual since a high peak bone mineral mass may prevent the attainment of a critical "fracture threshold" associated with age-related bone loss and osteoporosis [4]. More recently, the focus has shifted away from bone mineral accrual—as measured by dual energy x-ray absorptiometry (DXA)—toward the optimization of bone strength. This is due in part to the advances in bone imaging that have enabled the estimation of bone strength beyond bone mass [5,6]. New imaging techniques, such as peripheral quantitative computed tomography (pQCT), can provide information on bone size, geometry, and tissue density within the imaged portion of the long bone and these parameters may be used to estimate bone strength. Moreover, pQCT can distinguish trabecular (spongy bone) and cortical (compact bone) bone compartments [7]. It should be noted that peripheral imaging techniques can measure long bones in the upper and lower extremity only, and thus the obtained information is limited to the assessment of long bone growth and development. We will first shortly describe the long bone growth and structural development in terms of alterations in length and size in addition to mineral mass and density. These considerations are important for our understanding of factors that contribute to the development of strong, healthy bones. Those factors will be summarized in the following sections.

BONE GROWTH PROCESSES

The human skeleton consists of two main types of bones: flat bones like the scapula and long bones like the femur. Flat bones are formed by a process called (intra)membranous ossification while long bones develop by a combination of membranous and endochondral bone formation [8]. Since it is the long bones that are most susceptible to fragility fractures, a brief discussion of long bone growth is warranted. During childhood and adolescence, bone structure is altered by growth in length and size (e.g., width or area) [9]. Bone growth in length occurs at the growth plate (also called the epiphyseal plate or physis), located just before the bone ends. At the growth plate, cartilage is replaced by bone and this process is known as endochondral ossification. A child's bone lengthens when bone formation proceeds outward from these growth plates. In order to maintain the structural stability of the growing long bone, the bone diameter needs to enlarge along the long bone shaft [9,10]. Growth in diameter occurs by apposition of new bone on the outer (periosteal) bone surface. Concurrently, resorption in the inner (endosteal) bone surface excavates the marrow cavity in the tubular long bone shaft. When periosteal apposition is greater than endocortical resorption, the cortical wall thickens or drifts further from bone center [11]. Growth in length and diameter are associated with increases in mass, density, and alterations in bone structure.

Changes in skeletal length and size are closely tied to changes in bone mass, with approximately one-quarter of adult total body bone mineral accrued during the 2 years around the adolescent growth spurt [12]. These structural and material changes are under mechanical regulation and influenced by the hormonal environment [6,8,13]. During growth, bones must continually adapt their structure and mass to withstand loads from increases in bone length (i.e., stature), muscle mass, and external forces [9]. However, the tempo, timing, and extent of such adaptations are also closely regulated by several systemic hormones. Changes in the bone mass, size, and structure are modified by three distinct processes: growth, modeling, and remodeling [14]. During the life span, a single process may dominate at certain times or the three processes may function concurrently at other times. In the immature skeleton, all three processes may be active simultaneously, with each having a different function.

Growth is the expression of the genetically programmed, hormonally mediated process of enlargement of the entire skeleton without regard to concurrent changes in shape that may be occurring regionally in response to local loading factors. In humans, skeletal growth is largely completed before the third decade of life.

Modeling takes place primarily during growth and is the main process altering the shape and mass of the skeleton [8]. Modeling represents a regional response to specific loading conditions whereby new bone is formed without prior resorption, resulting in a change in shape and size of bone. Since the young bone has a greater potential for adaptation to loading than the aging bone [15], the modeling process occurs primarily during growth and results in a net gain in bone over time [16].

Remodeling, although present in young individuals, is the predominant process modifying bone shape and mass in adults. It allows for the replacement of fatigue-damaged bone with new bone [17]. In addition to serving a preservation function, it provides a mechanism for the maintenance of calcium homeostasis. The remodeling cycle begins with an activation phase, followed in sequence by a resorption phase and a formation phase, which are coupled [8]. Since new bone never completely replaces the bone that has been resorbed, bone remodeling results in a net loss of bone over time, resulting in a decrease in bone mineral mass (i.e., bone mineral content, BMC) and alteration in bone structure that accompanies old age [18].

SKELETAL GROWTH AND BONE FRAGILITY

Total body bone mineral mass more than doubles between 8 and 15 years [12,19]. The peak gains in BMC at the lumbar spine, femoral neck, and total body occur at about age 13.0 for girls and 14.4 years for boys, which is explained by the earlier onset of sexual maturation in girls [12]. Longitudinal data from the Saskatchewan Pediatric Bone Mineral Accrual Study (PBMAS) indicated that in the 3 years around peak height velocity (i.e., growth spurt), about 30% of BMC in the total body and lumbar spine was laid down and about 20% of femoral neck BMC was accumulated [12,20]. These data are consistent with other studies showing that bone mineral accrual increases progressively in early childhood [21,22] and then accelerates during adolescence [19,22]. In a PBMAS cohort, both girls and boys achieved about 90% of their final adult height at the time of the peak height velocity, but had only achieved about 57% of their estimated adult total body BMC and lumbar spine and about 70% of the estimated femoral neck values [23]. For all sites, peak velocity in BMC occurred over a year later than PHV in both girls and boys [23]. This lag time between linear growth and bone mineral accumulation has clinical implications. Increased fracture incidence during adolescence is partly explained by this dissociation between rapid growth in bone length, size, and mineralization [24–27].

Growth during infancy, childhood, and adulthood is important for bone health later in life. Infant and early childhood growth predicts adult bone mass independently of adult lifestyle [2]. Both low birth size and poor childhood growth are directly linked to the later risk of hip fracture [28]. The evidence of mineral accrual during adolescence indicates that the population variance in bone mass, and also in structural traits, is probably largely established by the end of the second decade. Pubertal timing seems to determine some variance in development. Early or late maturation may be important for bone development and fracture risk in adolescents and young adulthood [29]. Cross-sectional evidence from a large cohort of young adult men indicated that maturational age negatively predicts both cortical and trabecular bone size and volumetric BMD and previous fractures [29]. In females, subjectively assessed maturational timing has been associated with adult BMD and osteoporosis [30]. The earlier maturing child may therefore have an advantage in their bone development over the late maturing child. Current literature, however, does not provide any retrospective evidence of maturational timing influences on adult bone structure, strength, or fracture risk in either of the sexes.

OPTIMIZING BONE MASS AND STRENGTH DEVELOPMENT DURING GROWTH

To optimize bone strength development, we need to identify those modifiable factors which can enhance or retard the attainment of bone mass, structure, and strength during growth. Bones adapt their strength according to the mechanical forces they experience. Studies with healthy children and adolescents highlight the potential of modifiable factors such as physical activity, lean mass, or muscle cross-sectional area in determining bone mass accrual, bone size, tissue density, and estimated strength. Key factors that determine and influence the development of bone mass, structure, and strength are listed in the following.

Non-Modifiable Factors: Genetics and Sex

Evidence from familial resemblance and twin studies indicates that genes control about 50%–85% of the variance in

bone mass or areal bone mineral density (aBMD) [31] but a much smaller (<20%) proportion of the variance in the rate of bone loss [32] or fractures [33–36]. Genetic influences on the skeleton are thought to contribute mainly to the acquisition of bone mass during childhood and adolescence [37,38], possibly by interacting with environmental factors such as physical activity and diet. The trait variance in the *population* is largely the result of diversity in genetic makeup rather than lifestyle [31,39]. However, at the *individual* level, environmental effects such as muscle paralysis [40] or exercise [15] have profound effects on bone structure and estimated strength.

As the heritability of bone mass is stronger than aBMD, some of the familial resemblance in aBMD may simply reflect the heritability of body size [41]. Only one study has reported the genetic influences on bone size, showing a heritability estimate of 27% for the cross-sectional area at the distal radius in young adults [41]. Heritability estimates for trabecular and cortical bone density have been shown to be higher: 40%–60% depending on the bone site [42]. These results are in accordance with a meta-analysis of genome-wide scans which concluded that genetic regulation of bone mass is sex and site specific [43]. Part of the collinearity between the heritability of body and bone size (or mass) may also be related to lean mass, muscle size, and their development [44–47]. An important aspect regarding bone fragility prevention is that these traits can be enhanced by a physically active lifestyle and healthy diet.

Fractures of the wrist and hip have strikingly different age- and sex-specific incidence patterns [48]. To optimize preventive efforts, we need to understand how bone strength develops and declines for both sexes. Small or nonexistent sex differences in bone mineral content (BMC), density, and structure at axial or appendicular skeletal sites have been reported in childhood and adolescence [10,23,49–57]. Observations appear specific to the measured site, used technology, and how body size and composition—especially lean mass or muscle size—were controlled for in the analysis. The most comprehensive evidence of sex differences in bone development during pubertal growth comes from longitudinal PBMAS data. After adjusting for differences in maturation, height, and body composition, BMC development in total body and femoral neck were noted to be slightly greater in boys than girls across puberty [23]. Structural analysis of hip bone scans from the same cohort indicated a greater estimated strength (section modulus) in the femoral neck across the pubertal growth in boys when compared to girls but a smaller increase in the femoral neck area after the growth spurt [53]. This evidence of a greater bone mineral gain (relative to muscle) in the female skeleton occurring later in the pubertal growth period is supported by cross-sectional comparisons between males and females [44,52,58–60]. It has been suggested that this "extra" bone mineral provides a calcium reservoir for reproductive purposes [18,61,62]. Observations of similar cortical thickness between sexes have indicated that girls have either endosteal apposition [63] or diminished resorption at the endosteal (inner) bone surface [10] in puberty. Since females may gain more endosteal than periosteal bone, their bones strengthen less than in males who tend to have more periosteal bone formation and thus greater increase in overall bone size during the growth. Absolute sex differences in adult BMC and bone size may also reflect greater overall body growth due to the longer pubertal growth period in males than females. In females, earlier completion of longitudinal growth with epiphyseal fusion and earlier inhibition of periosteal apposition likely result in smaller bone size and generally weaker bone when compared to that in males [10,63].

Modifiable Factors

Physical Activity and Muscle

It is important to note that modeling and remodeling described earlier in the chapter are essentially under the control of the mechanical strain environment (such as strain magnitude, rate, and frequency). This functional model of bone development is based on the mechanostat theory [18,64,65]. In this model, bone cell action is coordinated by the mechanical requirements of the bone [64,65]. If bone is not exposed to mechanical loading, the lack of stimulus (strain) results in increased remodeling with subsequent loss of bone mineral and likely alterations in bone structure. Mechanical loading that is familiar to bone will be sufficient to maintain bone mass and structure, thereby maintaining remodeling and modeling in a steady state. Loading that produces an unusual strain environment to bone tissue can initiate a remodeling and/or modeling response. Increased body and muscle mass during growth may, in part, increase the forces placed upon bones, leading to greater bone strain and adaptation [64]. For example, if a girl unaccustomed to gymnastics practices handsprings, her bones at the wrist are exposed to a new strain environment. Modeling response in these bones will adapt bone by increasing bone mineral mass, size, or altering mass distribution (i.e., bone structure). After adapting bone structure and mass, the bone is able to resist the strains better than prior to adaptation and strains will return to a steady state. Progressively increased training stimulus is needed for continuous bone adaptation, thereby avoiding acute and chronic injuries related to intensive training [66].

Observational studies have provided evidence of greater bone mineral mass not only in child and adolescent athletes involved in gymnastics or other high-impact activities but also in children and adolescents who simply had a more physically active lifestyle [12,67–69]. Exercise trials have supported this evidence by showing a 3%–6% greater bone mineral accrual in children randomized to exercise intervention when compared to the bone accrual in the control group [70–75]. However, less is known about bone structural and strength adaptation to exercise [76]. Further, it remains inconclusive if the bone mass benefit acquired during the growing years persists into adulthood. To date, studies examining the effects of physical activity during childhood and adolescence on adult bone mass have been limited to retrospective assessments of physical activity [77–79] or earlier measured youth physical activity [80,81] to adult bone mineral status. Follow-up data

of retired athletes have provided evidence of both sustained [82,83] and partially lost [84] bone benefit after reduced or ceased activity, whereas exercise-induced bone gain has been reported to persist 1–8 years after exercise intervention in pre- or early pubertal children [85–87].

Previous prospective observational data from Saskatchewan PBMAS cohort showed a 9%–17% greater bone mineral accrual in physically active children when compared to their less active peers [12]. These studies have lent credence to the concept that physical activity in pre- and early puberty provides a unique opportunity to enhance bone accrual and peak bone mass. However, even if exercise during the growing years affects bone accrual, the importance of these effects from a clinical perspective depends on their permanence. The long-term implications of these benefits on adult bone mass can only be established with prospective longitudinal studies that follow subjects from childhood to adulthood. The follow-up data of these same individuals in young adulthood suggest that these benefits in bone mass persist into early adult life [88].

Little is known about the influence of physical activities and loading on growing bone structure and strength [76]. Unilateral tennis studies that compared side-to-side differences between players who begin their career prior or after the growth spurt have provided the strongest observational evidence that the increased BMC is due to enlarged bone size, which leads to greater estimated strength in long bone [15]. Studies in young and retired gymnastics support these findings [89,90]. Intervention studies assessing structural changes in the tibia have shown modest effects only in prepubertal boys [91], whereas estimated strength in the proximal femur has increased in pre- and early pubertal girls only [92].

Pediatric bone studies have provided compelling evidence of the importance of lean mass [93–96] and muscle cross-sectional area [97–99] on bone mass accrual and strength development during childhood and adolescence. Lean mass and muscle size have been used as surrogate measures for forces from mechanical loading and these traits have been associated with enlarged bone mass, size, and strength [100,101]. These findings are in accordance with the mechanostat model which postulates that the growing skeleton adapts its mass, structure, and strength to keep loading-induced strains within an acceptable range [47,98,102,103]. The age of peak lean tissue velocity precedes the peaks in estimated size and strength at the proximal femur [104]. These observations support the theory that muscle development is an important factor in affecting bone strength. However, there are currently no comprehensive longitudinal investigations using novel bone structure and strength measurements to link bone strength development in growing years to bone structure and strength in adulthood.

Nutrition

In addition to physical activity, diet during the growing years has been associated with bone mineral accrual in childhood and adolescence [19,46,80,105,106]. Two important nutritional aspects related to bone mineral have been noted in the past years: (1) a shift in emphasis from calcium to vitamin D as the major dietary influence on bone [107] and (2) an interest in dietary patterns, in particular the importance of fruit and vegetable consumption on bone health [108,109]. The average calcium accretion is 92–210 mg/day in 9- to 18-year-old boys and girls [110] and bone calcium accretion can peak at 300–400 mg/day [19]. The current recommendation of 1300 mg calcium per day for 9- to 18-year-olds meets the needs for skeletal growth in practically all adolescents [111]. Calcium supplementations produce a small 1%–2% effect in the upper limb areal bone mineral density [112]. This small increase is probably not likely to result in a clinically significant decrease in fracture risk in the growing skeleton, and thus, current evidence does not support the use of calcium supplementation in healthy children as a public health intervention [112]. However, according to Institute of Medicine 2010 guidelines, adolescent girls continue to be a group at risk for low calcium intakes from food sources [111].

Recommended intake of vitamin D is 600 International Units (IU) per day for children and adolescents in North America [111]. Recommendations for vitamin D intakes from dietary sources are complicated because vitamin D is also synthesized in the skin through sunlight exposure, which varies from person to person. Minimal sun exposure was assumed when the current vitamin D recommendations were established [111]. Inconsistent vitamin D tests used in studies and variance in the description of normal and abnormal ranges for vitamin D (25OHD) serum levels in children further challenges vitamin D recommendations [113]. In northern latitudes, without assurance of adequate sun exposure, requirements and recommendations for vitamin D should probably be higher than those currently in place [107,114]. Estimated mean daily vitamin D intakes in PBMAS participants have been relatively constant: 200–240 IU for girls and 280–320 IU for boys. These are comparable to Canadian youth intakes [110] and lower than the recommended dietary allowance for vitamin D (600 IU/day) [111]. The evidence of dose, time, and form of vitamin D for bone strength development and maintenance requires further evidence, especially from children and adolescents with limited exposure to sunlight (e.g., northern latitude) and poor nutrition due to socioeconomic factors.

Some investigations have indicated a positive relationship between fruit and vegetable consumption and bone mineral accrual [108,109]. This evidence has provided some support to a theory that a low-fruit and low-vegetable diet may lead to chronic, low-grade metabolic acidosis which may have detrimental effects on long-term bone health [115–117]. On the other hand, vegetable and fruit consumption may reflect healthy dietary patterns. Further evidence is needed to better clarify the role of dietary patterns of fruit and vegetable consumption in determining bone development during growth.

Smoking

A few studies have shown a negative association between bone mineral and smoking during growth and adulthood

in young men [80,118] and women [119], while others have not demonstrated such a relationship [47]. Smoking during adolescence was negatively associated with areal bone mineral density only in men, but not in women [80]; therefore this relationship may be gender dependent or related to the amount of cigarette consumption [118]. In elderly smokers (both men and women), in whom the effect of smoking has accumulated over several years, areal bone mineral density has been reduced, bone resorption markers increased, and the fracture risk elevated. There is limited evidence of an association between smoking and bone size, structure, and volumetric density. In a cohort of young Swedish men, daily smoking was associated with lower cortical thickness [120], whereas no association was reported in older Spanish women [121].

RECOMMENDATIONS

There are still many questions remaining about the complicated mechanisms controlling bone mineral accretion and structural development during the growing years. Prospective studies and well-designed trials are needed to assess whether the bone benefits related to physical activity during growth are maintained into later years irrespective of adult activity levels. We need to know more about the threshold levels of physical activity and vitamin D intake required to elicit a significant bone mineral response. From a public health perspective, perhaps the greatest questions have to do with the development of strategies directed at relating a condition of the elderly to a largely disinterested teenage population that will not be at risk for 40 or 50 years. The ultimate target population for the prevention of osteoporosis may be the young and not the elderly [122]. Taking into account the fact that our knowledge of the complicated mechanisms controlling bone mass and structure is still incomplete, on the basis of what we do know it is possible to offer some sound and prudent lifestyle advice to young people.

With regard to exercise programs designed for skeletal health and bone mineral acquisition in the young, the following fundamentals should be kept in mind: (1) the skeletal response to exercise is greatest at the loaded site and (2) to cause an adaptive response, the training stimulus must be greater than that habitually encountered. On the basis of these fundamentals and the review of the pertinent literature, the following recommendations can safely be offered to the public at large:

1. An individual should make a lifelong commitment to physical activity at an early age. Growing bones respond to mechanical loading by the addition of new bone and/or a strengthened bone structure. The growing skeleton has better ability to adapt to mechanical loading than the mature skeleton.
2. Weight-bearing activities that provide impact loading like gymnastics, skipping, aerobics, squash, and basketball are better for the skeleton—especially for the lower extremity bones—than weight-supported activities such as swimming or cycling.
3. A variety of vigorous daily activities of short duration that provide a versatile strain distribution throughout the entire skeleton is better for bone health than a prolonged repetitive activity. Activities should be diverse and vigorous enough to ensure loading with odd and varied strain distribution and magnitude.
4. Progressive increased training allows musculoskeletal adaptation and prevents overloading and related injuries.
5. Activities that increase muscle size and strength should be encouraged as these can be osteogenic.
6. Inactivity and immobility should be avoided: when this is not possible because of sickness or injury, even brief periods of activity can help to conserve bone mineral.

The responsiveness of the growing skeleton to physical activity is dependent on the sensitivity of bone to circulating hormone levels and nutritional adequacy. This has important implications for exercise prescription in adolescents, which leads to the following important recommendations:

1. Children should have a diet of nutritious foods that will meet the recommended dietary intake for calcium and vitamin D, provide adequate but not excessive protein, and limit the intake of sodium and caffeinated beverages (soft drinks, coffee).
2. A well-balanced diet that is sufficient to meet the energy demands of growth and physical activity should be encouraged.
3. Cigarettes should be avoided: they may interfere with the attainment of an optimum level of bone mineral and structure following skeletal maturation.

INTRODUCTION

Cardiovascular disease (CVD) is the leading cause of death and morbidity in the United States [1]. Though most of the clinical burden occurs in adulthood, cumulative research over the last 40 years has provided strong evidence that the process of atherosclerotic cardiovascular disease begins early in life and is progressive throughout the life span. The number of children with dyslipidemia is increasing as the population of obese children with decreased insulin sensitivity continues to grow [2–5].

Cardiovascular risk factors in children are strongly correlated with body fatness. Therefore, it is not surprising that the most common dyslipidemia pattern seen in children today is the so-called combined dyslipidemia pattern associated with obesity. It consists of mild elevations of total cholesterol (TC) and low-density-lipoprotein cholesterol (LDL-C), moderate to severe elevation in triglycerides (TG), and low high-density-lipoprotein cholesterol (HDL-C). The combination of elevated TG and low HDL-C, which is often seen in the presence of obesity, has been called atherogenic dyslipidemia. In autopsy studies, early atherosclerosis is associated with both increased LDL-C and decreased HDL-C [6].

In 2008, the American Academy of Pediatrics (AAP) published its guidelines for lipid screening and cardiovascular health in childhood [7]. At this time, the AAP recommended targeted screening of children at risk for hyperlipidemia with a fasting lipid profile. It also recommended the use of statins for children with severe hyperlipidemia not responsive to dietary and lifestyle changes, which was not without controversy [8]. More recently, the NHLBI (The National Heart, Lung, and Blood Institute) published guidelines for lipid management of the pediatric patient which have been endorsed by the AAP and include recommendations for universal screening between the ages of 9 and 11 years with a non-fasting, non-HDL cholesterol determination [9]. It has also recommended the use of pharmacologic agents including statins for children and adolescents with severe hyperlipidemia. A review of these new guidelines is included in this chapter.

RELATIONSHIP BETWEEN DYSLIPIDEMIA IN CHILDREN AND ADULT CARDIOVASCULAR DISEASE

Postmortem studies in children and adolescents such as the Pathobiological Determinants of Atherosclerosis in Youth (PDAY) and the Bogalusa Heart Study have clearly demonstrated that the atherosclerotic process begins in childhood [6,10,11]. The PDAY study evaluated atherosclerosis at postmortem in adolescents and young adults between 15 and 34 years who died accidentally. The investigators determined

the indicators of CV risk status at the time of autopsy. These included cholesterol concentration and vascular pathologic features indicative of hypertension. The presence of increased coverage of the arterial intimal surface with fatty streaks and fibrous plaques was associated with elevation in cholesterol levels, elevated blood pressure, obesity, and cigarette smoking [10,11]. Using a risk score derived from this study, non-HDL cholesterol was shown to be a major correlate of coronary atherosclerosis in this age group, with a 30 mg/dL increase in non-HDL-C equivalent to 2 years of vascular aging [12,13]. The Bogalusa Heart Study found similar results to the PDAY study. In this study, the investigators identified a cohort of children whose risk-factor status for CVD was measured during a school examination [6]. As this population aged, some people died of accidental causes and were evaluated by autopsy for the extent of atherosclerotic lesions which again were associated with elevations of TC, LDL, and TG, but lower concentrations of HDL. Increased atherosclerotic lesions were also associated with dyslipidemia, high blood pressure, and obesity [6].

More recently, noninvasive methods of imaging (ultrasonography, computed tomography) have been used to study atherosclerosis development in children. These include the assessment of endothelial function by flow-mediated dilation (FMD) of the brachial artery, and the assessment of coronary artery calcium (CAC), and increased carotid intima-media thickness (CIMT), as precursors of atherosclerosis. Both the Muscatine study and the Cardiovascular Risk in Young Finns Study used carotid ultrasonography to evaluate CIMT [14,15]. In these studies, an association between childhood CVD risk factors and CIMT measurements made at or after 9 years of age was the best predictor of subclinical atherosclerosis in adulthood [16]. However, the American Heart Association (AHA) has recently concluded that improved noninvasive methods of assessing atherosclerotic risk in youth need to be developed and standardized before these methods can be adopted in clinical evaluation [17]. This includes longitudinal studies in low risk populations and collection of normative data across age, race, and sex.

Both the AAP and the NHLBI have concluded that the tracking of lipid and lipoprotein levels occurs and that elevated lipid levels from childhood and adolescence are predictive of future adult lipoprotein profiles [7,9]. The strongest statistical correlation occurs between the lipid levels measured in late childhood (prior to onset of puberty) and those found in the third and fourth decades of life. This has been rated as Grade B level of evidence, which indicates that "fair scientific evidence suggests that benefits substantially outweigh any potential risks" [9].

CHOLESTEROL CONCENTRATIONS IN CHILDREN AND ADOLESCENTS WITH A BRIEF OVERVIEW OF PEDIATRIC DYSLIPIDEMIAS

Data from the Lipid Research Clinics Prevalence study in children 0–19 years of age at multiple centers in the United States and Canada from 1970 to 1976 have shown that the concentration of serum lipids and lipoproteins are very low in cord blood at birth, increase during early childhood, and reach concentrations similar to those seen in young adults by approximately 2 years of age [18]. They remain stable until approximately 11 years of age. During puberty, paradoxically, the TC and LDL-C levels decrease with increasing age, before rising again in the late teens and again in the third decade of life. Thus, concentrations before 2 years of age and in the early adolescent years may not reflect values in older children or adults. In this survey [18], the mean TC level was 160 mg/dL and the mean LDL-C level was 100 mg/dL between 2 and 11 years. The 95th percentile for these two measures were 200 mg/dL for TC and 130 mg/dL for LDL-C [18,19]. Subsequent data collected 10 years later from the population-based National Health and Nutrition Examination Surveys (NHANES) have provided further information for the trends in lipids and lipoproteins during childhood and adolescence. Data from the 1988–1994 NHANES for ages 4–19 years showed that the mean total cholesterol concentration had increased to 165 mg/dL and the 95th percentile had increased to 216 mg/dL. Peak total cholesterol was 171 mg/dL between 9 and 11 years of age [20].

The NHANES 1988–1994 also demonstrated cholesterol concentration differences by gender [20]. Females had higher total cholesterol and LDL concentration than males. Females also tended to have higher HDL concentrations than did males after pubertal development had occurred. There are also differences in cholesterol and triglyceride concentrations according to ethnic group. In the 1988–1994 NHANES, black children had higher HDL-C and lower triglyceride concentrations than did non-Hispanic white children or children of Hispanic descent. On the other hand, in a second study of 8- to 10-year olds in North Carolina, black children had the highest prevalence of a total serum cholesterol concentration of >200 mg/dL: 18.7% compared to 11% in white children [21].

A substantial proportion of children and adolescents have elevated concentrations of lipids and lipoproteins. In the North Carolina study, in all ethnic groups, the overall prevalence of having a total cholesterol level of >200 mg/dL was 12.6% [21]. In the Children and Adolescent Trial for Cardiovascular Health, 13.3% of children in the fourth grade had a total cholesterol concentration of >200 mg/dL. The prevalence was 15.6% in girls and 11.1% in boys [22]. In the 1988–1994 NHANES, approximately 10% of adolescents had total cholesterol concentrations of >200 mg/dL [20].

There have also been trends over time in lipid and lipoprotein concentrations in children and adolescents as observed in adults. Comparing 1988–1994 and 1999–2000 NHANES, triglyceride concentrations decreased about 8.8 mg/dL in adolescents aged 12–17 years and total cholesterol, LDL, and HDL concentrations remained relatively stable [23]. The reasons for these changes or non-changes that have been seen in adults as well are unclear, but may be related to the increased efforts to alter diet and prevent CVD that have been in effect since the 1950s.

Dyslipidemias

Dyslipidemias are abnormalities in lipoprotein metabolism associated with any abnormal level of lipoproteins. There are a number of known genetic disorders of lipids in children. The most important ones are listed in Table 94.1. These include familial combined hyperlipidemia, familial hypercholesterolemia, and the familial and severe types of hypertriglyceridemia. The genetic disorders associated with dyslipidemias may be the result of a single-gene defect but usually are due to defects involving several genes that lead to abnormal lipoprotein metabolism [24].

The most common genetic disorder is familial combined hyperlipidemia with VLDL-C overproduction and associated elevations of TG and LDL-C and reduced HDL-C. Elevated non-HDL-C is also present in this phenotype. Twenty to thirty percent of obese children have evidence of this dyslipidemic pattern [25]. The presence of this cluster of findings in childhood predicts the development of type 2 diabetes, the metabolic syndrome, and premature clinical CVD in adulthood [26]. No single-gene defect is associated with this disorder and the expression of the several genes involved is exaggerated by obesity and other lifestyle factors. This dyslipidemic pattern in children has been shown to persist until adulthood [27], and a recent report from the longitudinal Young Finns study revealed that at 21 year follow-up, subjects with the combined dyslipidemia pattern beginning in childhood had significantly increased CIMT compared with normolipidemic controls [16].

Familial hypercholesterolemia is an autosomal dominant genetic disorder due to gene mutations in the LDL receptor with isolated LDL-C elevation. Homozygous familial hypercholesterolemia is very rare, but the heterozygous form affects 1:500 children in the United States. If untreated, both forms result in premature atherosclerosis and CVD events by 50 years of age [24].

Severe hypertriglyceridemia is rare in childhood and is a genetically based recessive metabolic defect. TG can be as high as 5,000–10,000 mg/dL and produces pancreatitis and eruptive xanthomas. However, it is not associated with premature atherosclerosis because the TG-enriched particles are too large to enter the vascular wall [24].

TABLE 94.1
Summary of the Most Important Lipid Disorders in Children and Adolescents

Lipid Disorder	Lipid/Lipoprotein Abnormality
Familial combined hyperlipidemia[a]	Type IIa: LDL-C Type IV: VLDL-C, TG Type IIb: LDL-C, VLDL-C, TG Types IIb and IV often with HDL-C
Familial hypercholesterolemia	Homozygous: LDL-C Heterozygous: LDL-C[a]
Familial hypertriglyceridemia (200–1000 mg/dL)	VLDL-C, TG
Severe hypertriglyceridemia (≥1000 mg/dL)	Chylomicrons, VLDL-C, TG

HDL-C, high-density-lipoprotein cholesterol; LDL-C, low-density-lipoprotein cholesterol; TC, total cholesterol; TG, triglyceride; VLDL-C, very-low-density lipoprotein cholesterol.

[a] These are the two lipid and lipoprotein disorders seen most frequently in childhood and adolescence; the familial combined hyperlipidemia is most often associated with obesity.

LIPID SCREENING IN CHILDREN

In 2008, the American Academy of Pediatrics reaffirmed using the 1992 National Cholesterol Education Program (NCEP) Pediatric Panel Guidelines for a targeted approach to cholesterol screening in children [7,28]. This approach recommends screening children with a family history of premature CVD or high blood concentrations of cholesterol (dyslipidemia). They also recommended screening pediatric patients with a fasting lipid profile for whom family history is not known or those who have risk factors for CVD such as obesity (BMI ≥ 95%), hypertension (BP ≥ 95%), cigarette smoking, and diabetes mellitus. This screening requires a 12 h fast and is often inconvenient for patients and families as it typically requires a return visit for phlebotomy after the fast.

However, in 2011, the AAP endorsed the NHLBI Expert Panel's new recommendations for *universal* screening in children between 9 and 11 years of age, or before the onset of puberty [9]. The report cites evidence that using family history of premature CVD or of cholesterol disorders as the primary factors in determining lipid screening for children overlooks many children with dyslipidemias. This is related to the fact that accurate and reliable measures of family history are frequently not available. The increasing prevalence of obesity [29] and the possibility that the prevalence of high blood pressure is also increasing [30] strengthened the argument for universal lipid screening in children. The Expert Panel report notes that there are advantages for identifying dyslipidemia and initiating treatment earlier in childhood, which may allow for some reversibility or slowing of the disease process. The report states that lifestyle changes and attention to risk are more readily accomplished in childhood than with older individuals [9]. In addition, the pediatric population generally has more regular contact with the health care system. There is also the potential for parental involvement in making lifestyle changes. However, it is not entirely clear that universal screening in children will impact on the future development of CVD as there have been no clinical trials demonstrating this [31].

The Expert Panel has also recommended using non-HDL cholesterol as a non-fasting screening test for evaluating dyslipidemia in children and adolescents [9]. This test has been shown to be a measure of atherogenic particles and is now used in evaluating adults, and is better than LDL cholesterol alone at predicting cardiovascular risk. Levels of LDL-C have been the primary focus of

TABLE 94.2
Cut Points for Total, LDL, and HDL Cholesterol Levels and Triglycerides in Children and Adolescents

Category	Acceptable (<75%)	Borderline (75–95%)	High (>95)
TC	<170	170–199	≥200
LDL-C	<110	110–129	≥130
Non-HDL-C	<120	120–144	≥145
TG	<75	75–95	≥95
0–9 years	<75	75–99	≥100
10–19 years	<90	90–129	≥130

Note: Values given are in mg/dL; to convert to SI units, divide the results for TC, LDL-C, HDL-C, and non-HDL-C by 38.6; for TG, divide by 88.6.

cholesterol screening until recently, though it is known that half of all heart attacks occur in subjects with normal LDL-C levels. To determine non-HDL-C, the HDL cholesterol is simply subtracted from the total cholesterol. The resulting value measures not only LDL cholesterol but also cholesterol contained in metabolic "remnants" of very low-density lipoproteins (VLDL), the main carriers of triglycerides. Like LDL-C, these remnants promote the buildup of plaque in arteries. Cut points for non-HDL-C in children are shown in Table 94.2 with acceptable levels being less than 120 mg/dL and unacceptable levels being equal to or greater than 145 mg/dL. 120–144 mg/dL is borderline high. Otherwise the cutoffs in Table 94.2 for TC, LDL-C, and TG are nearly identical to those recommended in the 2008 AAP report [7].

Others have noted that there may be very little differences in fasting and non-fasting TC, HDL, and LDL cholesterol in children after reviewing data from the 12,744 lipid profiles measured in children and adolescents in the NHANES 1999–2008 surveys [32]. The Expert Panel report [9] notes that in two large pediatric cohorts from the Bogalusa Heart Study, non-HDL-C was shown to be both sensitive and specific for identifying children who will have elevated LDL-C levels and other dyslipidemias as adults [33,34]. Those in the top quartile of non-HDL-C as children were approximately four times more likely to have dyslipidemia as adults. The top quartile also correlated with the top decile of CIMT as well as any other lipoprotein measure [34]. Thus, for children as in adults, non-HDL-C levels appear to be more predictive of dyslipidemia and atherosclerosis than TC, LDL-C, or HDL-C levels alone [33]. In a recent report of a nationally represented sample of children, unimportant differences in lipid panel results were found between children who had fasted and those who had not fasted before testing, supporting the recommendation that fasting before lipid screening in children may not be necessary in a screening situation [32]. However, in the follow up of LDL-C during treatment, fasting lipid profiles are recommended as they provide the most accurate and precise determination of LDL-C.

TREATMENT OF ABNORMALITIES IN LIPID AND LIPOPROTEIN CONCENTRATIONS IN CHILDREN

Non-Pharmacological Lifestyle Approach—Diet and Activity

The 1992 NCEP guidelines for children and adolescents, the AAP, and the recent NHLBI Expert Panel report all recommend diet and levels of physical activity that are appropriate for children and adolescents children greater than 24 months of age which follow the U.S. Dietary Guidelines [7,9,28,35]. These dietary guidelines include recommendations that children and adolescents generally should have a balanced caloric intake with sufficient physical activity to achieve an appropriate weight. They should also consume more fruits, vegetables, fish, whole grains, and low-fat dairy products. It is also recommended that the intake of fruit juices, sugar-sweetened beverages, and foods containing added sugar, saturated fat, trans fats, and sodium be reduced. In general, for healthy children over the age of 2 years, it is recommended that no more than 30% of the calories come from fat, less than 10% of the calories come from saturated fat, and cholesterol intake should be less than 300 mg/day. For all children, 1 h/day of moderate to vigorous physical activity with less than 2 h/day of sedentary screen time are recommended. The emphasis on a healthy lifestyle with a healthy diet is key in the prevention of the development of abnormal lipid and lipoprotein concentrations and has been shown to safely and effectively reduce the levels of total cholesterol and LDL-C in healthy children [7,9].

Given that a third of the pediatric/adolescent population is overweight or obese with or without family histories of early onset CVD and hyperlipidemia, there will be pediatric patients in the high-risk category in which the AAP, AHA, and NHLBI Panel have recommended even further dietary modifications for children over the age of 2 years [7,9,36]. This would include all children with LDL-C > 190 mg/dL and hereditary hypertriglyceridemia. For these high-risk groups, the recommendations are mostly the same as for the general population (25%–30% of calories from fat), but saturated fats are further restricted to less than 7% of total calories and dietary cholesterol to less than 200 mg/day. A trial of dietary modification is still warranted as there may be some lowering of the LDL-C concentration which will allow for lower doses of pharmacologic agents if needed. Implementation of this more aggressive diet will likely require involvement of a dietitian to help families make the appropriate changes without compromising overall adequate nutrition. Dietitians can also help families navigate the food environment outside the home including school, the homes of friends, and fast-food restaurants. Generally, a 6 month trial of lifestyle changes with appropriate dietary modification is recommended before pharmacological intervention is considered. According to the NHLBI Panel report, "A behavioral approach that engages the child and family when delivered by a registered dietitian, has been shown to be the most consistently effective approach for achieving dietary change" [9].

Dietary Adjuncts

Another non-pharmacological approach to treatment of dyslipidemia in children is the use of plant sterols or stanol esters (2 g/day) as dietary adjuncts, which lower the absorption of cholesterol. One of the few randomized controlled trials in children showed that a plant-stanol-enriched margarine supplying 1.5 g of plant stanol per day reduced LDL-C concentration by 8% [37]. Though long-term studies of stanol use in children have not been completed, the most significant safety concern is that they also result in decreased absorption of fat-soluble vitamins and beta carotene. Fiber has also been used as a dietary adjunct and is thought to bind with cholesterol in bile acids, removing it from enterohepatic circulation. Some studies have shown a reduction in cholesterol of up to 7% with dietary fiber, but others have shown no benefit [38].

Pharmacologic Intervention

The use of pharmacologic interventions for lipid abnormalities has increased since the 1992 NCEP report [28]. In 2007, the AHA recommended statins as a first-line agent for children who met certain criteria. The AAP Committee on Nutrition in 2008 recommended that pharmacologic treatment be considered after age 10 years, but acknowledged that, rarely, initiation of treatment with medications could be considered in FH patients 8 years or older [7]. Children younger than age 8 years with extreme elevation of LDL-C levels, above 500 mg/dL, as would be found in the homozygous form of familial hypercholesterolemia, also should be considered for pharmacologic therapy. The AAP also recommended that children with diabetes mellitus and LDL-C > 130 mg/dL be considered for therapy [7]. These recommendations have been controversial [8].

It is unlikely that randomized controlled clinical trials will ever be done to confirm that treatment of lipid abnormalities in children will reduce the risk of CVD when children become adults. Recent studies in children and adolescents have established the effectiveness and safety of available pharmacologic agents. However, it is not known whether there is an age at which development of the atherosclerotic process is accelerated, though pathologic studies have shown that the frequency of fibrous plaques increases with age [6,10,11]. Also, recent studies in children using noninvasive assessment of vascular markers have shown an increase in arterial abnormalities with an increasing number of risk factors for CVD [14–16]. It is also thought that early lesions are more effectively treated and reversed than more advanced lesions, making the case for initiating drug therapy in the pediatric age group with severely elevated LDL-C [7,9].

The new report from the NHLBI Expert Panel endorsed by the AAP has also recommended the use of drug therapy in children and adolescents with lipid disorders after 10 years of age when certain conditions are met [9]. It also advises that any decision for using medication be based on the average results from two fasting lipid profiles obtained at least 2 weeks but no more than 3 months apart, and only after a 6 month trial of lifestyle management change [9]. Recommendations for LDL concentrations for pharmacologic treatment of children and adolescents 10 years and older are given in Table 94.2. Several classes of medications are available for treatment of dyslipidemia in children and adolescents and will be summarized in the following.

Hydroxymethylglutaryl Coenzyme A Reductase Inhibitors (Statins)

There have been a number of well-designed short-term studies with statins in children and adolescents as noted in the AAP 2008 report [7,39–48]. Statins inhibit the rate-limiting enzyme 3-hydroxyl-3-methyl-glutarate coenzyme A reductase for endogenous synthesis of cholesterol in the liver. It then decreases the intracellular cholesterol pool, which results in the upregulation of the LDL receptors resulting in increased clearance of LDL-C from the circulation. Typically, the serum cholesterol is lowered by 20%–50% below baseline, depending on the baseline value and the statin dose prescribed. In adults, statins also decrease inflammation as indicated by decreased serum CRP measurements. Adverse effects of statins include myopathy and hepatic enzyme elevation. Asymptomatic hepatic enzyme elevation is common in adults on statin therapy, but is reversible and not clearly linked to liver disease. In a study of statin use in children, evidence of hepatic enzyme elevation did not differ between statin (n = 28) and placebo (n = 22) groups [47,48]. The bigger but rare cause for concern is the possibility of myopathy, myositis, and rhabdomyolysis. Patients on statin medications should be instructed to inform their health care provider if they are experiencing muscle pain, aches, cramps, or weakness that is disproportionate to activity. Finally, statins may be teratogenic and should not be used during pregnancy. When statins are used in adolescent females, the patient should be counseled regarding prevention of pregnancy.

The clinical trials in children with statins have shown them to be safe and effective in lowering cholesterol concentrations [39–48]. In at least some studies, statins have also been shown to improve endothelial function in children with high cholesterol levels. One of these studies in children with familial hypercholesterolemia demonstrated improvement in brachial artery flow-mediated dilatation after 28 weeks of statin therapy [47]. In a second study using ultrasound over a 2 year period, carotid intima-media thickness was shown to increase in children with familial hypercholesterolemia treated with a placebo, compared to a regression of carotid IMT in patients on statin therapy [48]. The latter study included prepubertal children as young as 8 years of age, and on the basis of these results and reassuring safety data, the U.S. Food and Drug Administration approved pravastatin for children with familial hypercholesterolemia who are 8 years and older, regardless of pubertal status [7]. The AAP has recommended the use of statins for patients 8 years or older with an LDL concentration ≥190 mg/dL (or ≥160 mg/dL with a family history of early heart disease or with ≥2 additional risk factors present or ≥130 mg/dL if diabetes mellitus is present) [7].

The NHLBI Expert Panel has made similar recommendations but recommended the use of statins only in children who are 10 years or older [9].

Bile Acid-Binding Resins (Cholestyramine)

Bile acid-binding resins work by binding cholesterol in bile salts in the intestinal lumen, thus preventing enterohepatic reuptake in the terminal ileum. This results in depletion of bile salts in the liver and is the signal for increased bile salt production and the potential for increasing the excretion of cholesterol. In children and adolescents with familial hypercholesterolemia, LDL-C levels are reduced 10%–20% [49,50]. Bile acid-binding resins do not have systemic effects and adverse effects are limited to gastrointestinal discomfort. This discomfort coupled with the difficulty in taking either the pill or powder form of the resins limits their usefulness in young patients. They may also be used for patients whose statin use fails to meet LDL-C target levels with either medication alone. The efficacy of the two drugs was found to be additive in one pediatric study [42].

Cholesterol Absorption Inhibitors (Ezetimibe)

The dietary cholesterol absorption inhibitors represent the newest class of cholesterol-lowering agents and have not been extensively studied in children. They inhibit dietary cholesterol absorption at the level of the intestinal villus. However, unlike the bile acid-binding resins, they are systemically absorbed. One study has been published in children using ezetimibe for treatment of familial hypercholesterolemia in combination with statins, which resulted in a significantly greater reduction in LDL-C levels than did statin alone [51]. In 2009, the U.S. Food and Drug administration released a safety alert about the potential adverse effects of ezetimibe in adults; hence, these drugs should not be used in children without consultation with a lipid specialist. More information about the long-term effectiveness of this drug in children as well as potential adverse outcomes is needed.

Other Pharmacologic Agents

There has been very limited experience with the use of niacin and fibrates in children for the treatment of dyslipidemia, both of which have potential significant side effects. Neither of these drugs is recommended for routine use in children or adolescents for treatment of dyslipidemias and should only be prescribed by a lipid specialist.

SUMMARY AND RECOMMENDATIONS

There is accumulating evidence that lipid and lipoprotein abnormalities contribute to the development of atherosclerosis and that this process begins in childhood and is progressive across the life span. There are both genetic/metabolic and environmental (mostly dietary) influences on cholesterol levels in children. The genetic dyslipidemias are associated with the highest levels of LDL-C and TG as well as the lowest levels of HDL-C. In fact, the heterozygous form of familial hypercholesterolemia occurs in 1/500 individuals, making it a relatively common problem associated with increased risk of accelerated atherosclerosis and cardiovascular disease.

These lines of evidence suggest the need for two strategies to improve risk. The first strategy is a population-based approach, which seeks to improve diet and lifestyle factors in all children. This approach could lower population levels of lipids and lipoproteins and broadly reduce risk. This diet approach is also similar to that recommended for the prevention of obesity and hypertension and could have an important impact across a variety of risk factors for cardiovascular disease.

The second approach has been labeled the high-risk approach. It focuses on identifying those individuals who are at the highest risk, usually as a result of a genetic form of dyslipidemia. Universal screening with a non-fasting non-HDL-C is now recommended for children aged 9–11 years [9]. When children are identified with an elevated non-HDL-C, they should have repeat testing with a fasting lipid profile. They should also be evaluated for the presence of additional cardiovascular disease risk factors. Because this is a genetic abnormality, other family members, including the parents, should also be tested.

For children and adolescents with lipid and lipoprotein abnormalities, the first line of treatment is to improve diet and physical activity. This intervention may be sufficient for many children. For those age 10 years and older with persistently elevated LDL-C, despite diet therapy, pharmacologic management should be considered.

If these approaches are systematically implemented in primary pediatric practices, the lifelong risk of cardiovascular disease could be dramatically reduced across the population. Future research to evaluate the impact of treatment in childhood on adult cardiovascular outcomes would be very useful.

INTRODUCTION

Atherosclerotic cardiovascular disease (CVD) and type 2 diabetes are associated with lifestyle and a number of biological risk factors such as hypertension, low high-density lipoprotein cholesterol (HDL-C), high triglyceride and low-density lipoprotein cholesterol (LDL-C) level, and insulin resistance in adults. These diseases are not usually manifested in children, but precursors of atherosclerosis such as fatty streaks in the arteries can be seen in children, and the degree of atherosclerotic precursors is related to the level of CVD risk factors [1,2]. However, type 2 diabetes, a disease which earlier typically was associated with adults, and its precursor insulin resistance, is becoming more common in children [3]. No studies have examined the progression of atherosclerosis from childhood until clinical manifestations in adults, and the exact importance of this early atherosclerosis is, therefore, not known.

Physical activity during childhood may protect against later CVD if certain assumptions are met. First of all, physical inactivity may exacerbate the atherosclerosis already present in childhood. This would be a problem if atherosclerosis progresses during the lifespan and tracks from childhood into adulthood. However, we have little knowledge about regression of atherosclerosis as a result of improved health behavior. There is some evidence of tracking of CVD risk factor profile and tracking of clustered CVD risk [4]. Second, physical activity and sports participation in childhood may influence physical activity levels in adulthood. Thus, changing to a more physically active lifestyle in later years may become increasingly difficult once an inactive pattern has been established. There is a rationale for primary prevention in children that can be summarized as follows: (1) a sedentary lifestyle causes increased levels in CVD risk factors, (2) a large percentage of children have a sedentary lifestyle to a degree that it may increase the risk of developing atherosclerosis, (3) CVD risk factors or sedentary behavior track during childhood and into adulthood, and (4) interventions including increased physical activity in children at risk are efficient in decreasing risk factor levels and changing behavior to a more physically active lifestyle.

Based on this rationale, this chapter focuses on (1) describing the association between physical activity/fitness and CVD risk factors, including clustered CVD risk in children; (2) key mechanisms, which link physical activity to the biological CVD risk factors including the atherosclerotic process; (3) tracking of physical activity, aerobic fitness, and CVD risk factors from childhood onward; and (4) the effect of interventions to promote physical activity and decrease CVD risk in children.

TRADITIONAL CVD RISK FACTORS AND EXERCISE

Numerous studies suggest a causal relationship between CVD and high levels in blood pressure (BP) and blood lipids in adults. Children are usually free of CVD, but BP, levels in cholesterol fractions, and triglyceride as risk factors of metabolic health track into adulthood [5]. Thus, these risk factors have been the focus of studies as they relate to exposures such as obesity, physical inactivity, and low aerobic fitness to health. Later, studies have added fasting insulin, glucose, and homeostasis model assessment for insulin resistance (HOMA-IR) to the list. Insulin resistance is probably the most important physiological factor in the development of metabolic syndrome, and some studies have, therefore, used a composite risk factor score based on the risk factors defined in metabolic syndrome. Finally, a new developing field in describing health status is inflammatory markers, such as C-reactive protein (CRP), tumor necrosis factor-alpha (TNF-α) and interleukin-6 (IL-6), and hormonelike substances such as leptin and adiponectin.

Physical activity is generally considered a behavior. One can choose to be active or inactive. Conversely, aerobic or cardiorespiratory fitness is considered a trait since there is a genetic component. However, participation in large amount of moderate and vigorous physical activity can result in improvements in aerobic fitness. Thus, the two concepts are somewhat interrelated. In the following paragraphs, we will summarize how physical activity or fitness is associated with these different health markers.

BLOOD PRESSURE

The association between BP and exercise is still controversial in children. Cross-sectional studies have found an inverse association between physical activity or cardiorespiratory fitness and BP but no association between self-reported sports participation and BP [6,7]. In contrast to self-reported activity, another large-scale study using accelerometer-measured physical activity observed graded associations [8]. Since accelerometers measure all physical activity and self-reported sports activity mainly assess high-intensity physical activity, this could support the importance of total amount of physical activity and not just high-intensity sports-related activity, as beneficial for BP. Furthermore, these population-based studies include primarily normotensive children, and the effect of physical activity is greater in hypertensive children [9,10]. With respect to aerobic fitness, there is an inverse association between aerobic fitness and BP, which was stronger in overweight than normal-weight children [7]. Associations between aerobic fitness and hypertension were moderate in magnitude with odds ratios for hypertension of 1.5–3.0. In the study of Nielsen and Andersen, risk was only elevated in the least fit (first quintile) [7]; but in the study of Andersen, an inverse, graded association between aerobic fitness and BP was observed from a fitness level below 50 and 45 mL/min/kg in boys and girls, respectively [6].

Experimental studies on exercise training have almost entirely focused on children with hypertension [11–14] or obesity [15–17], and most studies had small sample sizes ($N < 100$). Hansen et al. studied the effects of 8 months of exercise training in both normotensive and hypertensive overweight children. They observed a reduction in systolic and diastolic BPs in the training subgroups of 6.5 and 4.1 mmHg, respectively, for the normotensive group and 4.9 and 3.8 mmHg, respectively, for the hypertensive group. Bell et al. studied obese children with a mean systolic/diastolic BP of 109/87 mmHg before training, and they found reductions of 5 and 4 mmHg in systolic and diastolic BP, respectively [15]. Another study found a training effect of 17 mmHg in systolic BP in children with essential hypertension [12]. This study also found an effect of resistance training and BP returned to pretraining levels after cessation of training.

In conclusion, physical activity and exercise training, both aerobic and resistance training, have a beneficial effect on BP in children. The size of the effect depends on baseline levels of BP, fatness, and aerobic fitness. Higher effect is found with higher BP level, lower fitness, and higher fat content at baseline.

BLOOD LIPIDS

Research reviewed by Strong et al. [18] suggests weak associations between physical activity and total cholesterol, HDL-C, LDL-C, and triglyceride levels. Some cross-sectional studies have found negative associations between total cholesterol and physical activity or aerobic fitness level and no association between HDL and physical activity [8]. This is in contrast to most intervention studies, which usually find an effect of aerobic training on HDL-C but no effect on total cholesterol [18]. In 2009, Dobbins et al. published a Cochrane review including seven school-based randomized controlled trials [19]. This review identified seven studies [20–26], and two further studies have been published since this review [27,28]. Overall, studies including clinical or school-based trials (randomized and non-randomized) show a weak beneficial effect on HDL-C and triglyceride levels but no effect on total cholesterol or LDL-C levels [29–31]. Thus, the effect of physical activity on blood lipids is difficult to determine in growing children. Lipids change concomitantly with the hormonal changes occurring during puberty [32], physical activity levels tend to decline during adolescence, and aerobic power (VO_{2max}) increase in boys with increased maturity and the opposite happens in girls [33]. These confounders could be controlled in randomized trials, but trials usually have quite short duration, and changes in lipids may take longer time. Some of the school-based trials lasting more than a year have found larger effects in blood lipids. Kriemler et al. found a 17% increase in HDL-C and a 15% decrease in triglyceride in a cluster randomized trial including a population-based sample of children [28]. Similarly, Resaland et al. found a 12% decrease in triglyceride and 6% decrease in ratio of total cholesterol/HDL-C ratio [27]. These improvements are quite large in view of the fact that they

studied populations with healthy lipid levels. In a post hoc analysis, Resaland et al. examined the effect of intervention in children with a high composite risk factor score and a low score separately. Substantially larger effects of the intervention were found in high-risk children [27].

In conclusion, physical activity has a beneficial effect on blood lipids in children. It is uncertain if total cholesterol is affected or it is mainly an increase in HDL-C that occurs; but in all studies, the ratio of total cholesterol and HDL-C improves. It seems likely that both aerobic and resistance exercise improves blood lipids.

INSULIN RESISTANCE AND TYPE 2 DIABETES

The development of insulin resistance may be the most important of all the risk factors. Insulin resistance and type 2 diabetes mellitus have been linked to BP, blood lipids, and other cardiovascular risk factors [34]. Several cross-sectional studies have shown that there is an inverse relationship between physical activity levels and aerobic fitness in children [35–37]. Also, improved fitness reduces insulin resistance [38–40]. Thus, the consensus is that exercise improves insulin resistance and, possibly, type 2 diabetes. The improvement in insulin sensitivity is caused by increased glucose transport mechanism and an increased number of glucose transporters. In addition, increases in physical activity can also result in lowering body fat, which has also been shown to improve insulin sensitivity and glucose transport.

OTHER CARDIOVASCULAR VARIABLES

Hotamisligil et al. observed that adipose tissue from obese mice produced TNF-α, a proinflammatory marker, and this cytokine was linked to insulin resistance [41]. This observation changed our view on adipose tissue, and it is now apparent that obesity is linked to a state of chronic low-grade inflammation [42]. Several cytokines, IL-6, TNF-α, and CRP, have been associated with the adipocyte and the CVD risk factors. In addition, the adipokines (substances secreted from the adipose tissue), namely, adiponectin, resistin, and monocyte chemoattractant protein-1 (MCP-1) have also been linked to the risk factors.

Research is accruing that these cytokines and adipokines are influenced by exercise. Thomas and Williams recently conducted a comprehensive review of studies of the effect of exercise on CRP, IL-6, and fibrinogen [43]. CRP is an acute phase reactant that increases significantly in response to trauma and inflammation. CRP is a sensitive marker of inflammation, and there is evidence of its causal role in inflammation [44]. Age, sex, body mass index (BMI), adiposity, physical inactivity, aerobic fitness, and smoking are associated with CRP levels [45]. There is evidence to suggest that regular physical activity protects against disease associated with chronic low-grade systemic inflammation, and physical activity has a role in the lowering of CRP [46].

The mechanisms responsible for the association between reduced CRP and increased physical activity are unknown, partly because physical activity is related to several confounders that are independently associated with CRP concentration. However, the discussion of causal pathways may be of more academic interest because if physical *activity* causes a decrease in fat tissue, which produces the cytokines that affect CRP, physical *inactivity* is still the cause of the production. Studies reporting the association between physical activity and CRP concentration in young people are relatively scant, with much of the research concentrating on overweight and obese individuals [43]. Observational studies have shown associations between physical activity and CRP [47–50].

Some of this effect may be mediated through the changes physical activity cause on fat tissue. Other studies using self-reported physical activity have failed to find association with CRP [51–54]. When aerobic fitness is evaluated, studies find much stronger associations to CRP. For example, Andersen et al. found an association between cardiorespiratory fitness and CRP with a correlation coefficient of –0.49 in 9-year-old children. They further found an 11.3 times higher risk for CVD risk factors to cluster in the upper quartile of CRP compared with the lower quartile [55]. The reason why physical activity shows weaker associations with CRP than aerobic fitness could be that only high-intensity aerobic exercise may have an effect, but it could also be the fact that the measure of physical activity has a higher level of error than the measure of fitness.

Most intervention studies only include obese children, and many of the studies are quite small. Meyer et al. found a reduction in CRP in a 6 month intervention in obese adolescents [56]. Balagopal et al. also found a reduction in CRP during a 4 month intervention in obese adolescents, but the intervention included diet changes as well as aerobic activity [57]. However, the change in CRP was independent of weight. A similar decrease was found in a school-based intervention of Rosenbaum et al. [58]. Conversely, Nassis et al. did not find reduction in CRP in a study of obese girls even if aerobic fitness increased 18.8% [59]. Lack of effect on CRP was also found in two studies of obese children by Barbeau et al. [49] and Kelly et al. [60], but the latter study only included nine subjects, and the small sample size may have caused a statistical type 2 error. Also, because CRP is a general inflammatory marker and highly sensible to infection, small studies may be confounded by a few subjects having low-grade infections.

The role of other inflammatory markers in CVD risk factors is controversial. IL-6 has a proinflammatory influence and it is elevated in obesity. Originally, IL-6 has a negative effect on metabolism [61]; however, it is now proven that muscle cells also act as an endocrine organ and among other substances produce IL-6 during contraction [62]. Myokines may be involved in mediating the health-beneficial effects of exercise and play important roles in the protection against diseases associated with low-grade inflammation, insulin resistance, hyperlipidemia, and diseases such as CVDs, type 2 diabetes, and cancer. The muscle-produced myokine IL-6 enhances glucose uptake in the muscle cells, the glucose production from the liver, and the lipolysis in the adipose tissue. Training studies have shown reductions in

resting concentrations of IL-6. However, even if plasma-IL-6 appears to be downregulated by training, the muscular expression of the IL-6 receptor appears to be upregulated [63]. How these observations apply to children is not known. Further, it is difficult to evaluate the role of IL-6 in observational studies because the acute response to exercise recedes fast [55]. A decrease in IL-6 has been found in obese children after an exercise intervention [57], but it has also been seen in normal-weight children [58]. There is no consensus of the effect of physical activity on inflammation in children.

Adiponectin and leptin are produced in adipose tissue. Adiponectin is anti-inflammatory and hypoadiponectinemia is associated with insulin resistance [63,64] and is also associated with low aerobic fitness. Whether the latter association is caused by the effect physical activity has on fat tissue is not known, but Kynde et al. found that low plasma adiponectin was associated independently with insulin resistance [63]. Leptin affects appetite regulation negatively, but it doesn't seem to be associated with insulin resistance. However, it is negatively associated with aerobic fitness [64]. Steene-Johannessen et al. found an association of $r = 0.84$ between directly measured VO_{2max} and serum leptin. Concomitantly, leptin was strongly associated with a composite CVD risk factor score [65]. There are few studies looking at leptin in children, and because of the strong association between fat mass and leptin, it is difficult to judge the independent effect of physical activity and the importance for CVD risk factors. Recently, Hosick et al. found no association between fitness and leptin when accounting for body fat [66]. However, we know little about the relationship between physical activity and leptin in children. The role of resistin, another adipokine, in CVD risk factors and insulin resistance, as well as the influence of exercise on resistin, has yet to be determined [67].

KEY MECHANISMS LINKING PHYSICAL ACTIVITY TO THE CLUSTERING OF CVD RISK FACTORS

It is shown that CVD risk factors cluster in some children [68]. This means that each risk factor is not independently distributed and levels of all the risk factors are more likely to be increased in the same individual [68]. Even if the clustering of CVD risk factors did not exist in children, it is not too difficult to speculate that it is an undesirable condition. Further, low aerobic fitness is strongly associated with this condition [69]. It is, therefore, relevant to discuss some of the physiological mechanisms leading to clustering of CVD risk factors and to discuss the role of exercise in relation to this clustering. Benefits of physical activity can be separated into acute changes caused by the activity itself and more long-term physiological changes caused by the training effects of physical activity on the muscle and fat tissues, the heart, and the action of enzymes and hormones. Most of the biological CVD risk factors are linked to the metabolism, which are regulated by enzymes and hormones, mainly the oxidative enzymes, insulin, and noradrenalin/adrenalin (catecholamines). Clustering of CVD risk factors are closely linked to high levels of fasting insulin, and the upper quartile of HOMA score was found to have >25 times increased risk of having clustered CVD risk than the lower quartile even in a normal healthy, young population [70]. It is, therefore, important to understand the relationship between physical activity and insulin sensitivity and level, and how insulin affects CVD levels, but it is also important to understand that physical activity has beneficial effects through different independent physiological mechanisms, which all change risk factor levels in a positive direction.

Acute physical activity cause different physiological changes, which influence CVD risk factors. Some of these mechanisms are shared with adiposity, while others are unique for physical activity, but may affect fat accumulation. The most important physiological changes are probably insulin and catecholamine (adrenalin) sensitivity, and both of these hormones can double their action after a few weeks or months of exercise training. Training improves insulin sensitivity specifically in the trained muscle. One study, utilizing a single leg training protocol, found increased glucose clearance limited to the trained leg, with the same amount of insulin causing the glucose clearance to double in the trained leg [71].

Training increases adrenaline sensitivity and decreases its release, leading to increased glucose clearance since adrenaline blocks insulin-mediated glucose uptake at a given exercise intensity [72]. Besides this effect of training, glucose uptake occur independent of insulin [72]. Moderate-to-vigorous exercise appears to activate a second "pool" of transporters independent of insulin [73]. Thus, the same glucose uptake requires less insulin after exercise. This adaptation may affect lipid storage in the fat cells and indirectly appetite regulation. The contraction-mediated glucose uptake in the muscle cell is increased when the stored glycogen is used during prolonged exercise. Further, the contraction-mediated glucose uptake is not blocked by adrenaline [74]. Even during periods of stress, physical activity may help to maintain low levels of insulin. Other acute effects are a lowering of triglyceride level and increased HDL [75].

In contrast to these mechanisms located in the muscle cells, fat tissue releases cytokines such as TNF-α into the circulation, which can decrease insulin sensitivity systemically [40]. Most of the common CVD risk factors are worsened by the action of insulin, which affects both metabolic pathways (blood lipids) and sympathetic nervous system (BP). The insulin sensitivity of the muscle cells is, therefore, extremely important because 80%–90% of the glucose will enter the muscle cell mainly mediated by insulin under normal resting conditions.

Other mechanisms related to prolonged training are increased lipoprotein lipase (LPL) activity and increased oxidative enzymes in the trained muscles. LPL is situated on the inner wall of the capillaries, and the number of capillaries increases in proportion to the training state of the muscle [76]. LPL catalyzes triglyceride transported from LDL or very low density lipoprotein (VLDL) cholesterol into the muscle cell, where it is metabolized, thereby improving the ratio of total

cholesterol/HDL. Changes in oxidative enzymes related to training are substantial. In untrained young subjects, 8 weeks of exercise training caused key oxidative enzymes such as succinate dehydrogenase and hydroxyacyl dehydrogenase to increase by 30%–40% [77]. This change improves the metabolism of triglycerides, which in turn improves glucose uptake. Exercise training also increases superoxide dismutase, catalase, and glutathione peroxidase, which reduces damage from free radicals. Thus, increases in these oxidative enzymes have the potential to reduce free radical formation, which has been associated with atherosclerotic plaque formation. However, the effect of training on oxidative enzyme levels disappear as fast as it develops after the cessation of training.

CLUSTERING OF CVD RISK FACTORS AND ITS RELATION TO PHYSICAL ACTIVITY AND FITNESS

High levels in many CVD risk factors simultaneously have been observed in children not more than 9 years of age [68]. A major problem related to research on the health effects of physical activity in children has been weak associations between physical activity (or aerobic fitness) and CVD risk factors. The weak relationships could be related to the fact that the disease processes are just starting and have not had time to mature. Also, the weakness may be partly caused by methodological problems because both physical activity and most CVD risk factors fluctuate widely from day to day. This fluctuation is caused by both measurement error and true changes. Analyzing a composite score of many CVD risk factors can solve part of this problem. We have recently analyzed such clustering of risk factors in relation to objectively measured physical activity [8], aerobic fitness [69], and combinations of physical activity, fitness, and obesity [78]. We found approximately 13 times increased risk for clustering of CVD risk factors for the lower quartile of fitness compared with the upper quartile and around 10 times increased risk for the upper quartile of fatness compared with the lower. Physical activity exhibited a protective effect even after adjustment for both fitness and fatness in the European Youth Heart Study.

Recently, we analyzed clustering of CVD risk factors in preschool children 6–7 years of age, and unexpectedly, we did not find any sign of clustering [79]. It was surprising because children included individuals who were unfit, fat, and showed low insulin sensitivity [80]. Also, there was no association between fatness, or fitness, and CVD risk factors. The children were tracked until the age of 9 years, and at this time, clustering had developed in around 14% of the children. Further, we found that the lowest quartile of fitness had a 35 times increased risk of having clustering of risk factors compared with the upper quartile. It would seem that the clustering of risk factors, also known as the metabolic syndrome, develops after the children start school, suggesting that the decrease in physical activity that occurs when children are seated could be important. Further studies are needed before conclusions can be drawn.

TRACKING OF PHYSICAL ACTIVITY, FITNESS, AND CVD RISK FACTORS

Tracking is a measure of how well subjects keep rank order within a variable. It can be expressed as a correlation calculated over the whole distribution or as an odds ratio of staying at risk from one point of time to another. A correlation coefficient is a good way to express stability in a variable if risk increases linearly, which it does in many CVD risk factors, and there is no well-defined cutoff point in the risk factor above which risk increases. Odds ratio of staying at risk or staying above a defined level in a risk factor may be a better way to analyze relationships if they are not linear. A subject changing from the lower part of the distribution to the middle may be of less importance than a change from the middle to the top.

Most CVD risk factors are linearly associated to CVD. A high tracking coefficient gives a high predictive value of the risk factor measured later in life, but a low value does not necessarily mean the opposite because it may be caused by measurement error or short time fluctuations, i.e., total cholesterol is very precisely measured in a particular blood sample, but day-to-day fluctuations are great. A tracking coefficient can never be better than the error variation in the risk factor, and it is, therefore, difficult to compare tracking coefficient between risk factors. Assessment of physical activity is difficult and both accelerometer measurements and self-reported activity have a low reproducibility, so tracking coefficients are always low, which does not necessarily mean that the activity level in childhood is not a determinant of adult activity. Aerobic fitness is more stable and changes gradually if physical activity is changed, and a precise assessment is possible. The tracking coefficient normally decreases with increasing time span between the measurements.

Tracking of Physical Activity

Although low tracking coefficients are reported in studies of physical activity, some studies have found that childhood participation in sports, educational level, other life experiences, and aerobic fitness level are predictors of adult physical activity level [81]. One large population study measured physical activity with accelerometers [82]. When analyses were corrected for seasonal variation, within-week variation, activity registration during night time sleep, within instrumental measurement error, and day-to-day variation, moderate tracking in physical activity from childhood to adolescence was found (stability coefficients of 0.53 and 0.48 for boys and girls, respectively). The Danish Youth and Sport Study used self-report and followed subjects for 8 years from adolescence to young adulthood and found correlations of 0.31 for men ($p < 0.01$) and 0.20 for women ($p > 0.05$) [83]. The risk for a sedentary man to stay inactive was 2.2 times higher than expected, but for women, more sedentary women than expected from a random distribution became active. Similar results were found in the Young Finns Study [84] and in the Amsterdam Growth and Health Study [85].

Tracking of Physical Fitness

Physical fitness can be assessed as aerobic fitness, or as different measures of strength, flexibility, and motor coordination. When tracking of aerobic fitness is analyzed, the results depend on the assessment method because indirect methods, such as a field test or submaximal test, include more measurement error than direct assessment such as measurement of aerobic fitness (VO_{2max}) during a graded exercise test. Only few studies have used direct measurements of VO_{2max}. Aerobic fitness relative to body size tracks moderately with a correlation coefficient around 0.5 [85,86]. Somewhat higher coefficients are found when isometric strength is assessed ($r = 0.7$), but if strength is expressed relative to body size values similar to aerobic fitness are found. Even higher coefficients were found in the Leuven Longitudinal study [87]. Tracking coefficient after 1 year of observation was around 0.9 for both static and dynamic strength and decreased to about 0.6 after 5 years.

Tracking of CVD Risk Factors

A few studies have measured tracking of CVD risk factors from adolescence to young adulthood, and they found similar results [88]. Both blood lipids and BP track in children, but higher correlation coefficients are usually found in cholesterol fractions (0.5–0.7) compared with BP or circulating triglyceride (0.3–0.4). Tracking of BP was assessed in an American study, which followed 211 subjects from childhood (3–11 years) to adulthood (30 and 50 years of age) [89]. Correlations between BP as a juvenile and adult (age 30 years) were low and still lower for measurements at age 50 years. Tracking of systolic BP was higher than in diastolic BP. However, more hypertensive subjects dropped out of the study, which could influence tracking coefficients. Also, many subjects at the age of 50 years use drugs for hypertension, which is an additional bias. Tracking correlations for BP vary between 0.2 and 0.5 with higher coefficients for shorter time span. Associations between BPs measured with year's interval are weakened by large intrasubject variability from day to day and even within minutes. Part of this variation could be eliminated by more measurements before the follow-up and after the follow-up, but such data are not available.

Blood lipids and lipoproteins are more stable than physical activity or BP as one ages [90]. Most correlations are between 0.5 and 0.7 for total cholesterol and LDL cholesterol and somewhat lower for triglyceride and other lipoproteins. This is quite high because big fluctuations occur from day to day in total cholesterol. Subjects in the highest quintile of total cholesterol as children have a two- to threefold increased risk of being in the highest quintile after 8 years of follow-up [83] and a doubled risk after 15 years of follow-up [91].

Tracking of Clustered Risk

In the Danish Youth and Sport Study, a total or clustered risk score was calculated as the sum of scores in the single risk factors (ranked into 1–6) [88]. A high correlation coefficient was found from adolescence to adulthood in men ($r = 0.67$, $p < 0.001$) but not in women ($r = 0.33$, $p < 0.01$). Recently, a report analyzing tracking of clustered risk was published from this cohort, and those who had clustered risk as teenagers had a sixfold increased risk of having clustered risk as young adults [4].

In conclusion, CVD risk factors and physical fitness track from childhood into adulthood. BP, triglyceride, and physical activity only show weak tracking, which, in part, could be due to difficulties in assessing these variables, but clustered risk tracks strongly.

HOW CAN WE DECREASE RISK?

Increase in physical activity may be achieved in different ways, and the most effective way in a specific population may depend on the culture. Most children are quite active, but a key issue is how to reach sedentary children. Increasing physical activity in the most active children may reveal limited health gain, while an increase among the sedentary children may be much more important in the prevention of future disease. Some arenas where sedentary children could be targeted are schools and in interventions targeting everyday living such as active transport. In many countries, there are strong associations promoting organized sport. These organizations may have the resources, but the main goals in these organizations are to improve performance and develop elite athletes. They very often lack initiatives to include children who are not successful in sports.

In countries where physical education is compulsory, school-based interventions are a possible way to reach sedentary children. Dobbins et al. recently reviewed the effects of school-based intervention to increase physical activity and improve health [19]. Two other studies have been published since [27,28]. Studies showed positive effects of interventions on physical activity behavior and a number of CVD risk factors. It is possible to improve physical fitness and blood lipid profile, but most studies do not find any effect on BP, and only few found an effect on BMI. An interesting analysis was performed in the study of Resaland et al., who performed a 2 year intervention in a rural city in Norway [92]. They found a substantial increase of 9% in aerobic fitness in the intervention group compared to the control group. However, in a post hoc analysis, where they stratified subjects into quartiles according to their baseline fitness level, they found a 13% increase in the least-fit quartile and a 3% increase in the most-fit quartile compared with the corresponding quartiles in the control group. This is interesting from a health perspective because metabolic risk factors tend to cluster in the least-fit children [69]. In general, it is necessary that the intervention includes a substantial increase in physical activity if health gains are to be achieved. Small effect sizes have been found with an increase from two to four physical education lessons, but studies including 60 min of

physical activity every school day have shown substantial health effects. The 60 min need not be physical education lessons but can be arranged as play in the school yard as long as some intensity is achieved.

Another setting, which may be promising, is active transport to school. There are no randomized trials looking at the effect of walking or cycling to school in children, but some observational studies have shown that cycling to school may result in improved health. The European Youth Heart Study analyzed changes in fitness from the age of 9 to 15 years in children who did not cycle at baseline. Some of these children changed to cycling, while others were non-cyclists at the age of 15 years. Children who starting cycling had a 9% higher fitness at the age of 15 years than those who did not cycle [93]. Beside improved fitness, an improvement was found in metabolic risk factors [94].

Potentially, interventions can be targeted at the general population of children or at children at risk such as overweight and obese children. Intervention studies in obese youths show that favorable changes in insulin sensitivity, lipid profile, indices of inflammation, endothelial function, cardiac parasympathetic activity, and carotid intima-media thickness (IMT) are produced by moderate-to-vigorous physical activity doses of 150–180 min/week [56,57,95]. However, for nonobese youths, intervention studies suggest that such doses are not effective; higher moderate-vigorous physical activity doses of 300 min/week seem necessary [96].

CONCLUSIONS

A sedentary lifestyle in children is associated with increased levels in disease risk factors, which are known to increase risk of premature death later in life, and the prevalence of clustered cardiovascular risk is more common in sedentary children. Further, a large percentage of European and American children have a lifestyle sedentary to a degree that it may increase the risk of developing premature atherosclerosis and lifestyle diseases such as CVD and type 2 diabetes. It has also been verified that both risk factors and sedentary behavior track during childhood and into adulthood. In addition, a recent study has shown that lifestyle prevention may be more important than treatment [97]. Therefore, there is a strong rationale for early prevention starting already in childhood. Interventions aiming at increasing physical activity in children are efficient in changing behavior to a more physically active lifestyle and have resulted in decreased CVD risk factor levels. An important setting for this may be the school. Physical education lessons, activities in breaks, active commuting to the school, as well as afterschool sports have the possibility to reach all children and also children at risk through specific activity programs. However, physical education programs have been more successful when educated teachers have run the lessons [19], and there may be a major job to do before expert teachers are available in many countries.
